Since NZO mice originated from the same outbred stock that gave rise to the autoimmune-predisposed New Zealand Black (NZB) and New Zealand White (NZW) inbred strains, it is not surprising that NZO mice share with each of the latter two strains certain autoimmune proclivities. Indeed, the NZO is the only other inbred strain other than NZW known to express the recombinant H2^z MHC haplotype associated with lupus development in (NZB \times NZW) F1 mice. Other immune anomalies shared with (NZB \times NZW) F1 mice include development of autoantibodies to both native and denatured single-strand DNA, as well as deposition of IgG antibodies on the glomerular basement membrane (340,341). The NZO strain has an additional immune peculiarity-development of autoantibodies to the insulin receptor (342). While these autoantibodies may contribute to insulin resistance, they are not predictive of hyperglycemia in males (EHL, unpublished observation). Histologic analysis of pancreata of aging NZO/HI mice of both sexes reveal accumulations of leukocytes around pancreatic ducts and vasculature; since pancreatic islets also cluster around ducts and blood vessels, a periinsulitis forms around some of the islets. This periinsulitis differs from that observed in other strains of mice in that the content of CD19⁺ B lymphocytes is high relative to that of CD3⁺ T lymphocytes. Indeed, NZO/HILt mice share with NZB and NZW mice the presence of elevated numbers of CD5⁺ B lymphocytes in spleen (EHL, unpublished observations). These B1-B lymphocytes are thought to provide natural immunity and autoimmunity in contrast to the acquired immunity provided by B2-B lymphocytes (343). However, the humoral autoimmunity potentially generated in NZO mice by these cells against islet or other factors associated with glucose tolerance are likely to be secondary to and not causal for the diabetes syndrome, since levels of B1-B lymphocytes are higher in diabetes-resistant NZO/HILt females when compared with diabetic or nondiabetic NZO/HILt males (EHL, unpublished observations).

Complications. The principal complication described in NZO has been nephropathy characterized by an age-dependent increase in cellularity of glomerular tufts and mesangium, as well as mild thickening of the glomerular basement membrane due to the deposition of IgG (340,341). However, these changes probably are reflective of the generalized immune anomalies extant in NZO rather than to diabetes, since the changes are more pronounced in the diabetes-resistant females than in the more diabetes-prone males.

Potential research uses. Because type 2 diabetes in humans is polygenic in nature and associated with obesity in >80% of cases, the late-developing diabesity syndrome in NZO males makes this an excellent model for the human disease. Since the livers of NZO mice accumulate lipids as the mice age, this strain is exceptionally useful for screening insulin sensitizers, such as thiazolidinediones, for potential hepatotoxicity.

Husbandry Issues

NZO/Hl and NZO/HlLt mice are poor breeders and produce small litters when they do breed. Interestingly, hyperglycemia rarely develops in breeding males but frequently develops in group-caged virgin males, indicating an essential role for neuroendocrine factors in diabetogenesis. We have overcome the reproductive problems of NZO/HILt mice by supplementing the NIH-31 (4% fat) diet with 0.001% CL316,243, a β_3 -adrenergic receptor agonist known to suppress obesity development in genetically obese mice (344). NZO/HILt mice of both sexes maintained on a CL-supplemented diet for only a month from weaning to retard the rate of weight gain and then placed on standard NIH-31 (4% fat) diet mate almost immediately.

Availability

NZO/HILtJ mice are commercially available from The Jackson Laboratory (Bar Harbor, ME), and NZO/HIBom mice are available from Bomholtgard (Ry, Denmark). The recombinant congenic lines of NON/Lt mice carrying interval-specific segments of NZO genome producing various degrees of obesity and diabesity can be obtained from the author (EHL) at The Jackson Laboratory.

Rat Models of Type 2 Diabetes

BUREAU OF HOME ECONOMICS RATS

Strain Origin and Diabetic Phenotype

The Bureau of Home Economics (BHE/Cdb) is a subline of the parent BHE stock housed at the Genetic Resource Unit, National Center for Research Resources, National Institutes of Health. In 1975, the development of the BHE/Cdb strain began with selection criteria of hyperglycemia, hyperlipidemia, and the absence of obesity (345). After 36 generations, 75% of the rats showed fasting hyperglycemia and hyperlipidemia. Thereafter, all matings have been maintained along maternal lines and the diabetic phenotypes have strengthened to 95%. The IGT present in the BHE/Cdb is due primarily to a maternally inherited defect in glucose-stimulated insulin secretion (GSIS) (346–348). BHE/ \check{C} db rats have an average life span of 600 to 700 days if fed the stock diet (Purina Chow), with renal disease as the primary cause of death. If the animals are fed a purified diet having a composition similar to that consumed by humans, the impaired glucose tolerance appears at 100 days of age, and in this setting, 100% of the animals are intolerant. Various hepatic abnormalities in metabolic control have been observed before the development of glucose intolerance. Among these are a 200% increase in *de novo* fatty acid and cholesterol synthesis, a 40% increase in gluconeogenesis, and a 20% reduction in the efficiency of ATP synthesis (349-351).

Feeding BHE/Cdb rats purified diets containing sucrose as the carbohydrate source and coconut oil as the fat source resulted in a further increase in fatty acid synthesis, an increase in gluconeogenesis, and a further disruption in the coupling of mitochondrial respiration (352,353). Thyroxin, which has been shown to increase the synthesis of a variety of proteins in oxidative phosphorylation, was administered to "rescue" respiration (354–356). An increase in shuttle activity and Mg-ATPase activity were observed, but no increase in coupling efficiency was recorded; in fact, deterioration in coupling efficiency was observed (353). With all substrates, the mitochondria respired normally but the energy generated by the respiratory chain was not fully captured in the high-energy bond of ATP, implying an error in the ATPase. The observation that the Mg-ATPase was increased with thyroxin treatment showed that the F₁ portion of the ATP synthase was functioning normally. As a result of these observations, it appeared that the uncoupling occurred because the F_o, although increased in amount, was not fully functional.

Normal diurnal rhythms are lost as humans progress toward type 2 diabetes (357–359). These changes in rhythm are associ-

ated with losses in the rhythms of blood glucose, insulin sensitivity, growth hormone, and fatty acids, suggesting that prediabetic humans adjust their metabolic patterns in an effort to retain some control of glucose homeostasis. This phenotype of altered circadian rhythm is exhibited by the BHE/Cdb rat with a noticeable change in diurnal pattern at 200 days. Dietary stress that accelerates the onset of diabetes will also accelerate the onset of the perturbed diurnal pattern (360). In all cases, the alteration of the diurnal rhythm precedes the onset of type 2 diabetes.

Genetics

In genetic crosses of the BHE/Cdb with nondiabetic Sprague Dawley (SD) rats, reciprocal F1 males and females have shown that the type 2 diabetes phenotypes of the BHE/Cdb are maternally inherited (346,347). Because of the error in FoATPase function, the mitochondrial genes for the subunits ATP synthase 6 and 8 were sequenced from BHE/Cdb and SD rats at 50 and 300 days of age (361). Four single-base differences were detected when comparing BHE/Cdb to SD rats. The base sequences in the SD rats were identical to the Genbank sequence (362). Of the four differences, only the mutation at base pair 8,204 altered the amino acid sequence. At this position, the SD codes for a guanine while the BHE/Cdb cell codes for adenine. This substitution replaces an aspartic acid with asparagine in a critical portion polar pocket of the F_o molecule, through which the protons flow for the synthesis of ATP. This pocket spans the membrane and is surrounded by the membrane lipid. A polar amino acid instead of an acidic amino acid at this spot results in a reduction in the efficiency of ATP synthesis (363–365). When this occurs there is a reduction in the capture of the energy generated by the respiratory chain that is captured in the high-energy bond of the ATP. A reduction in the efficiency of ATP synthesis can be assessed indirectly through the determination of sensitivity to oligomycin. As has been shown in humans with a subunit 6 mutation somewhat similar to the one found in the BHE/Cdb rats, mitochondria from BHE/Cdb rats have a reduced sensitivity to oligomycin (366).

Potential Research Uses

The BHE/Cdb was the first animal model in which a defect in a mitochondrial gene was directly linked to a disease phenotype. This rat model not only has a diabetic phenotype but also shows heart defects and severe kidney disease. Therefore, this animal provides a unique opportunity for studying therapies for human mitochondrial diseases. As energy metabolism is an essential component in GSIS, the BHE also provides the opportunity to study therapies for increased mitochondrial function that would lead to improved insulin secretion. Because of the kidney disease, the BHE also serves as a model for the study of renal complications in the context of type 2 diabetes.

Availability

The BHE/Cdb is available without restriction from the NIH Animal Genetic Resource (Dr. Carl Hansen, Veterinary Resources Program, National Institutes of Health, Building 14F, Room 101, 14 Service Road South, MSC 5590, Bethesda, MD 20892-5590; Phone: (301) 402-3027: Fax: (301) 402-4258: E-mail: hansenc@ors.od.nih.gov). Control strains used in experiments with the BHE/Cdb have been the Wistar and SD rats.

E STILMANN SALGADO RATS

Strain Origin and Diabetic Phenotype

In 1978, spontaneous fasting hyperglycemia was detected in some males of a IIM albino rat line, resulting in the derivation by inbreeding of a diabetic line designated as the IIMe/Fm eSS (e Stilmann Salgado) (367). Type 2 diabetes in the eSS rat is char-

acterized by early onset of IGT that worsens with age in the absence of obesity. Males are far more severely affected than females. While biochemical and histopathologic manifestations are more severe in males than in females, orchidectomization does not effect the diabetic evolution. Conversely, ovariectomy appears to be a worsening factor (368). Early in life, male eSS rats exhibit normal plasma glucose levels in the fasted state, while impaired glucose tolerance persists after glucose load (369). Despite their IGT, male rats of the eSS strain demonstrate fasting hyperglycemia and glycosuria (370). An improvement in the metabolic disturbances was registered in diabetic eSS males under long-term food deprivation (371).

Histopathologic examination of the pancreas reveals marked changes. The pancreatic islet structure is disrupted, and islets became smaller and more scattered with advancing age (371). The volume and density of β -cells decreases with age. The diabetic rats show disruption of the islet structure and fibrosis in the stroma. Defects in pancreatic histology begin as early as 6 months of age and progressively deteriorate. The volume density of endocrine tissue is diminished, as is β -cell volume density and percentage. This decrease in the endocrine pancreas is accompanied by a concomitant increase in the volume density of exocrine pancreatic tissue and not β -islet cells. Pancreatic β cells showed an increase in the volume density of endoplasmic reticulum, immature secretory granules, and an apparent decrease in volume density of total secretory granules and microtubules of lysosomes (372,373).

eSS rats show diabetic lipid alterations at 5 months of age. Blood, liver, kidney, and testes all showed lipid alterations when compared with age- and sex-matched Wistar controls. Most noteworthy were the triglyceride and cholesterol profiles of the blood and liver (369,374). Feeding the eSS rats purified diets rich in lipids led to marked obesity and increased levels of circulating insulin, yet had no effect on the timing of onset of type 2 diabetes (370). A diet high in carbohydrates and fiber led to a leaner rat that was free of diabetes. High-protein diets appear to have the most detrimental effect on eSS rats. eSS rats fed this diet had the earliest onset of IGT; the highest levels of triglycerides, total cholesterol, and HDL-cholesterol; and the fewest islets of Langerhans at 23 months of age.

Complications

A diffuse glomerulosclerosis, interstitial lymphocyte infiltrates, and tubular nephrosis are present in kidneys (371). eSS rats as young as 6 months of age have increasing proteinuria and uremia as compared with Wistar controls (375). At 6 months of age, eSS rats exhibit areas of tubular dilatation with protein cylinders, and demonstrate increased capsular, glomerular, and Henle thin-loop diameters. At 18 months of age, glomeruli show diffuse hypertrophy of mesangial tissue and thickening of the basement membrane, with worsening proteinuria. Kidneys at this age are overtly damaged, with areas of markedly atrophic and dilated tubules containing acidophilic proteinaceous material.

Dietary manipulation of the eSS rat can markedly alter the onset of diabetic complications. While the feeding of a highprotein diet exacerbates the diabetic phenotype, this diet has extremely detrimental effects driving severe renal lesions and cataracts, which were total and bilateral in some cases. High-fat diets do not worsen the diabetic kidney abnormalities, but this diet does increase the incidence of cataracts.

Potential Research Uses

The eSS rat, while not genetically defined, could prove to be an exceptional model not only for the study of the pathogenesis of type 2 diabetes but also for the onset of complications. The slow progression through IGT toward overt hyperglycemia has pro-

duced a much more "human" model for the onset of type 2 diabetes. Much like the human with type 2 diabetes, the eSS rat loses β -cell function and mass with age, making this a nice tool for therapeutic interventions for the maintenance of the endocrine pancreas in the preclinical type 2 diabetes situation. While Wistar rats have been used in most of the studies with eSS rats, the lack of a genetic definition does not allow for the assumption of a more closely related nondiabetic control. Availability of dietary intervention to exacerbate or ameliorate the diabetic phenotype allows for either the more rapid progression of the diabetic phenotype or for a possible control. Because the female rats of this strain do not develop type 2 diabetes phenotypes, they could serve as controls. The possibilities of crosses between the eSS strain and rats of the spontaneously hypertensive SHR could lead to an excellent rat model for diabetic macrovascular complications.

Availability

The eSS rats are apparently not distributed.

GOTO-KAKIZAKI RATS

Strain Origin and Diabetic Phenotype

The Goto-Kakizaki (GK) inbred rat strain was derived from an outbred Wistar stock by selective breeding, with the highest blood glucose levels during an oral glucose tolerance test (376). Glucose intolerance was present in all rats after the sixth generation, and inbreeding was started at the ninth generation (377). The current stock of GK rats, available to the scientific community, is maintained at Charles River Japan and is in its 87th generation.

When compared with the control Wistar stock, GK rats of both sexes exhibit both mildly elevated blood glucose (GK: 154 ± 5 mg/dL female and 154 ± 4 male vs. Wistar: 120 ± 2 female and 122 ± 2 male) and plasma insulin (GK: 6.8 ± 0.3 ng/mL female and 6.3 ± 0.4 male vs. Wistar: 4.3 ± 0.4 female and 3.9 ± 0.2 male) levels at 8 weeks of age (378). While these pre-type 2 diabetes parameters are only mildly altered compared with those of the controls, as early as 4 days after birth, GK rats maintain a sharply reduced β -cell mass (35% of that of age-matched Wistar controls) and pancreatic insulin reserves that are only 31% of control values (379). By 4 months of age, the islets of GK rats maintain fewer β-cells, have a reduced islet insulin content, and exhibit abnormal islet morphology (380,381). A defect thought to be primary to the type 2 diabetes of the GK strain is decreased GSIS (rise in insulin levels of 42% in females and 17% in males of sex- and agematched Wistar controls). Results from perifusion mirror the in vivo data, with first- and second-phase insulin secretion severely decreased. Study of the biochemical mechanisms behind the aberrant GSIS has shown that GK islets are impaired in many of the pathways important for insulin secretion. Decreased adenylate cyclase activity in GK islets has been reported, and an increase in the adenylate cyclase activity by forskolin restored GSIS (382). Defects in energy and shuttle metabolism leading to reduced K⁺ ATP channel activity have been proposed as crucial to the type 2 diabetes of GK rats (383-386). SNAP-25 and syntaxin 1A, proteins essential for the process of membrane docking and fusion for exocytosis of insulin granules during insulin secretion, are reduced. Only the overexpression of SNAP-25 in GK islets restored GSIS to levels of control islets (387).

Genetics. GK rats have been extensively studied for the strain-specific genetic contributions to type 2 diabetes. Inheritance patterns of GK-derived type 2 diabetes phenotypes have been evaluated in crosses of the inbred GK strain with three nondiabetic control strains [Wistar, Fisher 344 (F344) and Brown Norway (BN).] GK × Wistar F1 hybrids were assessed for fasting blood glucose (oG), IGT, and GSIS. In all three instances,

male and female reciprocal F1 showed intermediate phenotypes (388). This would suggest a polygenic inheritance of the type 2 diabetes phenotypes.

For a more detailed genetic comparison, both the BN and F344 rat strains have been used in GK outcrosses. Genetic analysis reported the results of reciprocal F2 crosses with the BN. These F2 rats were analyzed for oG and fasting insulin (oI), as well as IGT, GSIS, arginine-stimulated insulin secretion (ASIS), body weight (BW), and adiposity index (AI). Two significant and five suggestive genetic linkages were reported for crosses with the BN strain. The strongest linkage for IGT (Nidd/gk1) was detected on Chr 1, under a broad, 64-cM peak. Statistical analysis also revealed that this peak held suggestive significance for the phenotypes of AI, oG, and ASIS. Further, a suggestive linkage for IGT was detected on Chr 5 (Nidd/gk4). In both instances, the GK contributed recessive susceptibility for IGT. On Chr 7, a significant linkage for body weight was detected and named *bw/gk1*. Again, this peak was quite broad, and the GK genome contributed in a recessive fashion to increased body weight. The AI phenotype also segregated suggestively in this region of Chr 7. The four other loci all held suggestive status but controlled two or more phenotypes. Nidd/gk2 (Chr 2) controlled oI and ASIS, Nidd/gk3 (Chr 4) affected GSIS and ASIS, Nidd/gk5 (Chr 8) had modest influence on GSIS and BW, and, last, Nidd/gk6 (Chr 17) modulated oG and BW.

Concurrent to the GK × BN genetic analysis, was a report assessing the genetic susceptibility to type 2 diabetes of GK in F2 crosses to the nondiabetic inbred F344. Genetic responsibilities for the type 2 diabetes phenotypes of IGT, oI, GSIS, and BW were determined (389). In accord with the GK × BN genetic analysis, a recessive locus controlling IGT was detected on Chr 1. In this case, however, because of the use of an increased number of F2 rats, the peak for statistical significance was shortened to a confidence region only 20 cM in length. This locus, termed *Niddm1*, was inherited in a recessive manner and was not contributory to any other diabetes-related phenotype. Further, two significant loci for IGT also were detected on Chr 2 (*Niddm2*) and 10 (*Niddm3*). The inheritance patterns of *Niddm2* and *Niddm3* are consistent with the action of the GK alleles in a recessive or additive manner to perturb glucose tolerance.

The genetic contributions of Niddm1 have been further analyzed by synthesizing F344 background recombinant congenic strains carrying Chr 1 segments from GK. Three RCS have been developed, a long congenic (*Niddm1a* carries a 52-cM region) and two smaller congenics that overlap Niddm1b (28 cM) and Niddm1i (22 cM), and assessed for IGT and GSIS (390). All three recombinant congenic strains are significantly less tolerant than the F344 parentals to glucose. Analysis of the subcongenic lines for GSIS differentiated these two chromosomal regions. Contained within the Niddm1b congenic interval are GK-derived genes that control increased oI, while rats of the Niddm1i recombinant congenic strain exhibit poor GSIS, yet maintain increased islet insulin reserves. Last, genetically delimiting the Niddm1b region has resulted in the mapping of this locus to a 1-cM interval. Testing of candidate genes in this region has led to the identification of a unique GK-derived allele for insulin-degrading enzyme (Ide), which maintains a single novel nucleotide difference (391). Analysis of this variant has shown that it maintains decreased insulin degradation activity, which is thought to contribute to the lack of insulin action on GK muscle cells.

Potential Research Uses

With alterations in multiple pathways essential for the maintenance of proper release of insulin by islets in response to glucose or other physiologic secretogogues, the GK rat provides a model for the study of islet growth and differentiation, of phar-

macologic agents to improve insulin secretion, and of the genetic factors contributing to type 2 diabetes. Genetic analyses of loci Niddm2-6 as well as of Bw/gk1 are of clear research significance. Pharmacologic agents for improved insulin secretion are of value in patients with type 2 diabetes as well as those with type 1 diabetes. Studies aimed at increasing β -cell cAMP or increasing the activity of guanosine triphospate (GTP)-binding proteins have shown that pharmacologic agents can reverse the impaired insulin secretory responses of the GK rat, and this model would be an excellent choice for investigation of new compounds that increase insulin secretion. Study of gene expression in GK rats also has led to an increase in the understanding of insulin secretory vesicle docking and fusion mechanisms. Knowledge of how to regulate docking and fusion proteins could lead to therapies not only for insulin secretion but also for GLUT4 translocation in peripheral insulin targets. GK rats have also been used for both nutritional and therapeutic interventions.

Availability

While the GK rat is an excellent choice for an array of research questions, this rat strain is difficult to obtain and the research can be restrained by the supplier. Currently, the GK strain may not be bred or crossed, therefore eliminating the ability to perform *any* genetic experiments. Control strains for research with the GK would include the Wistar stock. Wistar is used because the GK was selected and inbred from an outbred Wistar population. Use of Wistar for a control in metabolic or gene-expression experiments is common. The F344 and BN strains are inbred strains that have been crossed to the GK strain for analysis of the genetic susceptibility loci for type 2 diabetes. The knowledge of the major genetic components and the production of congenic lines of F344 carrying GK-derived *Niddm* loci make the F344 an important control as well.

OTSUKA LONG-EVANS TOKUSHIMA FATTY RATS

Strain Origin and Diabetic Phenotype

The Otsuka Long-Evans Tokushima fatty (OLETF) rat strain was derived from an outbred Long-Evans colony at Charles River Canada (St. Constant, Quebec, Canada) that had shown polyuria, polydipsia, and mild obesity (392,393). To establish the OLETF inbred strain, selection was based on the phenotype of spontaneous hyperglycemia. Since 1989, the OLETF has been maintained as an inbred strain at the Tokushima Research Institute, Otsuka Pharmaceutical Company (Tokushima, Japan) (392). After the first 20 generations of inbreeding, the incidence of spontaneous hyperglycemia has been approximately 50% at 24 weeks of age and more than 90% by 65 weeks of age. Type 2 diabetes in OLETF rats is sexually dimorphic, with females exhibiting a greatly reduced incidence and a much later onset compared with males (394). Orchidectomy reduces the incidence of hyperglycemia to 20%, whereas ovariectomy increases the incidence of type 2 diabetes to 30%. Furthermore, treatment of castrated males with testosterone restores the incidence to 89%. At the time of the selection of the OLETF, the control LETO (Long-Evans Tokushima Otsuka) strain was coselected as a nondiabetic control.

Phenotypes associated with high risk for developing type 2 diabetes begin to appear in OLETF males at 24 weeks. At this age, males show elevated circulating levels of glucose and insulin and have IGT. These phenotypes deteriorate with age, and by 65 weeks of age the incidence of hyperglycemia and hypoinsulinemia in males is higher than 90% (392,393). In females, phenotypes associated with type 2 diabetes are not present at 55 weeks of age, but approximately one third have

IGT 10 weeks later (395). When compared with the control LETO male and female, OLETF rats gain weight more rapidly with age and maintain an increased body weight (392). By 16 weeks of age, insulin-stimulated glucose transport is decreased in OLETF compared with that in LETO males, yet OLETF males have impaired GSIS throughout life. As early as 16 weeks of age, males hypersecrete insulin in response to glucose, but by 65 weeks the males fail to release insulin after a glucose challenge (392). These changes in the insulin secretory capacity are mirrored by the pancreatic islet morphology. There is an increase and deterioration in islet mass as the endocrine pancreas proceeds through three stages. The first or early stage (at less than 9 weeks of age) shows the presence of mild lymphocyte infiltration; at the second stage (10 to 40 weeks of age), β cells become hyperplastic, with increasing fibrosis in or around islets; and finally after 40 weeks, islets atrophy (393). Diabetic changes are seen at the peripheral levels as well. Although there was no difference in GLUT4 expression or level of GLUT4 protein, there were clear differences in adipocyte GLUT4 translocation compared with that in LETO controls at 7 weeks of age (396). Translocation of GLUT4 in muscle also is reduced in OLETF compared with the LETO controls, yet this abnormality begins at 30 weeks of age (396,397). One clear finding from work with the OLETF is that the insulin resistance precedes impairment of pancreatic β -cell function. Experiments have also shown that obesity is necessary for the development of type 2 diabetes in OLETF males and that insulin resistance may be closely related to fat deposition in the abdominal cavity (398,399).

Genetics

For the determination of the genetic susceptibility determinants of the OLETF, outcrosses were performed with three nondiabetic control strains, F344, LETO, and the Brown Norway (BN). Male progeny from F1, F2, and first backcross generations have been used for genetic analysis. F1 hybrids resulting from the cross of OLETF of any of the three strains did not become diabetic, suggesting that the inheritance pattern of the OLETF susceptibility allele(s) was recessive. Studies in which OLETF was crossed with F344 included very few F2 males in the analysis, yet the incidence was drastically different in the reciprocal groups (400). In the 161 (OLETF \times F344) F2 males used in the study, 5% progressed to type 2 diabetes, while an additional 7% had IGT. On the other hand, none of the 44 (F344 \times OLETF) F2 males became diabetic. In the BC1 generation created by crossing (F344 × OLETF) females with OLETF males, the incidence of type 2 diabetes was 67%, with an additional 11% proceeding only to IGT. In the genetic segregation analysis, a highly significant linkage was observed for postprandial hyperglycemia near the P-450ald locus on Chr 1 and for the marker D7Mit11 on Chr 7. These two markers were also statistically suggestive for the phenotypes of fasting glucose and body weight. Four other regions on Chr 1, 2, 5, and 17 were detected as influencing body weight, fasting glucose level, or postprandial hyperglycemia independently. This analysis, like that for type 2 diabetes of other murine models, suggests control by multiple genetic loci (401). A second group has repeated these studies with increased sample sizes for the F2 population, with very similar results (402).

Reciprocal F2 crosses of LETO with OLETF showed no difference, with an incidence of type 2 diabetes of approximately 12%. Of the BC1 [(OLETF × LETO) F1 × OLETF)], 44% of the males progressed to diabetes. The percentages of affected or diabetic animals, ~12% in an F2 and ~50% in a BC1, suggested that there was only a single locus controlling the type 2 diabetes phenotype of the OLETF when crossed with the LETO (400). Genetic linkage analysis confirmed a single major diabetes locus on the Chr X that segregates with type 2 diabetes. This locus has been named *Odb1*.

The third set of crosses to identify diabetogenic genes involved in the development of spontaneous type 2 diabetes in the OLETF rat was performed in F2 (OLETF \times BN) and BC1 [(OLETF \times BN) F1 \times OLETF] male offspring. In both the F2 and BC1 generations, diabetes was highly associated with the Hooded (*H*) coat color. The gene *H* is located on rat Chr 14 (403). In this cross, the marker that showed peak significance for the hyperglycemia phenotype was the gene for cholecystokinin type A receptor (Cckar). The maximum logarithm of the odds (LOD) score for this locus, designated Odb2, was 16.7 (404). Statistical tests have determined that the Odb2 locus accounts for 55% of the total variance, or is responsible for ~50 of the type 2 diabetes in the OLETF rats (404). Odb2 colocalizes with the gene encoding cholecystokinin A receptor (Cckar), which mediates the trophic effect of cholecystokinin on pancreas. Cckar is disrupted in the OLETF rat due to a 165-bp deletion in exon1 (405,406). Genetic segregation analysis has also showed that the Obd1 and Obd2 act in a synergistic fashion for type 2 diabetes in the OLETF rat (406). Both of these loci are required in homozygosity from OLETF to cause elevated plasma glucose levels.

Complications

While OLETF rats do weigh more than the nondiabetic control LETO rats for most of their life span, at 80 weeks of age, males generally lose weight and by 90 weeks of age they weigh less than the LETOs. This weight loss is most likely due to the diabetic condition. Levels of urinary protein of the OLETF begin to rise at 25 weeks of age and continue to do so for the remainder of life, reaching levels greater than 800 mg/dL late in life (396). Histologic changes are present and become worse with age. Fibrin caps are detected as early as 30 weeks. These deposits precede the thickening of the basement membrane, which thickens to the point of capillary occlusion (407). These lesions are called capsular drop and are present in human diabetic glomerulopathy (408). After the onset of diabetes, the OLETF rat displays hallmarks of macrovascular disease. Diabetic OLETF males are hypertensive, have thickening of artery walls, and show aberrant ventricular diastolic dynamics (409-412).

Potential Research Uses

Genetic predisposition for type 2 diabetes and obesity are major risk factors for the development of type 2 diabetes, and the interactions between these factors are likely to be important in the etiology of this disease. Further genetic dissection of *Odb1* is of clear research importance. The OLETF has been studied for dietary, exercise, and pharmaceutical interventions before and after the initiation of type 2 diabetes. As with many models of type 2 diabetes, caloric restriction can prevent type 2 diabetes and improve insulin sensitivity (413). This is most likely due to the key interactions of body fat or obesity and genetic susceptibility. Exercise training has also been shown to be effective in preventing the development of hyperglycemia (414-416). Exercise improved insulin sensitivity, yet there was no effect on islet morphology. The OLETF has also been used to test drug therapies for type 2 diabetes and the related complications. Troglitazone and metformin have both been successfully used to treat the type 2 diabetes phenotypes of OLETF. Troglitazone treatment reduced circulating glucose, insulin, cholesterol, and triglyceride levels to normal (417). Troglitazone treatment completely prevented or reversed histologic alterations such as fibrosis, fatty replacement, and inflammatory cell infiltration in the pancreas (417). Interestingly, sections of the liver from the untreated OLETF rats showed mild fatty changes in the central

zone of the hepatic lobule, whereas those from the troglitazonetreated OLETF rats appeared normal, with no fat deposition in the hepatocytes. Further, no significant influences on serum levels of markers of liver dysfunction [aspartate aminotransferase (AST) and alanine aminotransferase (ALT)] were detected. Troglitazone, as well as metformin, significantly decreased systolic blood pressure (418).

Availability

Control strains for experimentation with the OLETF include the co-selected nondiabetic, nonobese LETO. Obese controls could include the obese Zucker (*fa/fa*) rat. For metabolic experiments, a control could be the outbred Long-Evans or Sprague Dawley, but a better candidate would be an inbred rat strain such as the Brown Norway (BN), the F344, or Wistar. OLETF males can be obtained from Otsuka America Pharmaceutical, Maryland Research Laboratories, 9900 Medical Center Drive, Rockville, MD 20850. However, the following restrictions apply: Otsuka America Pharmaceutical only provides 4- to 6-week-old male rats without charge, but the investigator has to pay for the transportation fees. They also require that the investigator submit a research protocol and a letter of undertaking (forms are available from the company). Any investigators who are interested in this model should contact the above address for details.

ZUCKER DIABETIC FATTY RATS

Strain Origin and Diabetic Phenotype

The derivation of the Zucker rat began almost 40 years ago (419). Most published studies on Zucker rats are on the noninbred obese Zucker (ZF). The selection of the inbred Zucker diabetic fatty (ZDF) strain used Zucker (fa/fa) rats that had progressed to a diabetic phenotype. After two generations of brother–sister matings, a consistent reproducible diabetic phenotype was achieved in obese males fed Purina 5008 6% fat diet at Eli Lilly and Company (420). The characteristics listed in this chapter are for the commercially available ZDF/Gmi-fa/fa and are listed on the Genetic Models, Inc. (GMI) Web site (http:// www.criver.com/products/genetic_models/index.html).

In obese males fed Purina 5008 6% fat diet, hyperglycemia begins to develop after 7 weeks of age. All obese males (fa/fa) are diabetic after 10 weeks, with serum glucose levels greater than 500 mg/dL. Hyperinsulinemia precedes hyperglycemia, but by 19 weeks of age, insulin levels drop. At 6 week of age, insulinresistant ZDF and ZF rats are hyperinsulinemic compared with the Lean Zucker control (ZLC) (fa/+ or +/+) rat yet have normal plasma glucose levels (421). The diabetic state can be exacerbated with diets higher in fat or high in simple sugars. The development of diabetes between 7 and 12 weeks of age is associated with changes in islet morphology, and the islets of diabetic animals are markedly hypertrophic, with multiple irregular projections into the surrounding exocrine pancreas. In addition, multiple defects in the normal pattern of insulin secretion are present. The islets of prediabetic ZDF rats secrete significantly more insulin in response to glucose and show a leftward shift in the dose-response curve relating glucose concentration to insulin secretion (422). Islets of prediabetic animals also demonstrate defects in the normal oscillatory pattern of insulin secretion, indicating an impairment of the normal feedback control between glucose and insulin secretion (422). The islets from diabetic animals show further impairment in the ability to respond to a glucose stimulus (422).

By 12 weeks of age, hypersecretion of insulin at 5.0 mmol/L glucose was observed in perifused islets from both obese groups relative to that in the ZLC rat (421). Islets from ZDF rats failed to increase insulin secretion in response to increased glu-

cose concentration. Insulin secretion from ZF islets at 2.8 mmol/L glucose was two to four times greater than secretion from islets of lean ZDF littermate controls (ZLC) (423). Peak first- and second-phase insulin secretory responses of perifused ZDF islets to 20 mM glucose were also significantly greater (424–426). GLUT2, the high- K_m facilitative glucose transporter expressed by β -cells, is underexpressed in ZDF islets. Islets of diabetic rats exhibit a marked decrease in the volume of GLUT2-positive β -cells and a reduction in the number of GLUT2-immunoreactive sites per unit of β-cell plasma membrane. The deficiency of GLUT2 can neither be induced in ZDF β -cells by *in vivo* or *in vitro* exposure to high levels of glucose nor prevented in β -cells of prediabetic ZDF rats by elimination of hyperglycemia (427). ZDF islet glucokinase and hexokinase activity have been shown to be significantly increased compared with that of the ZLC (421). The glycolytic flux at 2.8 mmol/L glucose was significantly higher in ZDF islets versus ZLC islets and was suppressed by mannoheptulose inhibition of glycolysis. Inhibition of glycolysis or fatty acid oxidation also significantly inhibited basal insulin secretion in ZDF islets but not in ZLC islets. As in other animal models of type 2 diabetes, ZDF islets also show impairment in energy production pathways important for GSIS. The enzyme activities of mitochondrial glycerol phosphate dehydrogenase and pyruvate carboxylase were severely decreased compared with those of control Wistar rats and decreased with age and to a greater extent with diabetes onset (428).

In ZDF rats, severity of diabetes is highly correlated with increased GLUT2 in liver and decreased GLUT4 in adipose tissue, heart, and skeletal muscle (429). Further, an inverse correlation with hyperglycemia and proteins responsible for peripheral tissue GLUT4 vesicle mobilization and membrane docking and fusion has been documented. Cellubrevin, VAMP-2, and syntaxin-4 protein levels are elevated (2.8-, 3.7-, and 2.2-fold, respectively) in skeletal muscle from ZDF rats compared with lean controls. Restoration of normoglycemia and normoinsulinemia in ZDF rats with rosiglitazone (30 μ mol/kg) normalizes cellubrevin, VAMP-2, and syntaxin 4 protein to levels approaching those observed in lean control animals.

The onset of type 2 diabetes in obese Zucker diabetic fatty (fa/fa) rats is preceded by a striking increase in the plasma levels of free fatty acids (FFAs) and by a sixfold rise in triglyceride content in the pancreatic islets. The latter finding provides clear evidence of elevated tissue levels of long-chain fatty acyl CoA, which can impair β -cell function (430). Overaccumulation of fat in pancreatic islets of obese ZDF rats and subsequent lipotoxicity are believed to cause β -cell failure and diabetes (431). ZDF pancreatic islets have an approximately 50-fold increase in fat, maintain an increased acetyl CoA carboxylase and fatty acid synthetase activities compared with ZLC, and lack a normal proinsulin mRNA response to FFAs (432). Furthermore, the FFA induces a fourfold greater rise in β -cytotoxic nitric oxide (NO), up-regulates mRNA of inducible nitric oxide synthase (iNOS), and reduces insulin output (433). Ceramide, a fatty acid-containing inducer of apoptosis, is significantly increased in ZDF islets (434,435). Pharmacologic therapy with triacsin C, an inhibitor of fatty acyl-CoA synthetase, and troglitazone, an enhancer of FFA oxidation in ZDF islets, both significantly limit β-cell death. These agents also reduce iNOS mRNA and NO production, which are involved in FFA-induced apoptosis (434).

Changes in gene expression are also evident in islets from prediabetic and diabetic ZDF rats compared with age-matched control animals. In prediabetic animals, there is no change in levels of insulin mRNA. However, there was a significant 30% to 70% reduction in the levels of a large number of other islet

mRNAs, including glucokinase, mitochondrial glycerol-3-phosphate dehydrogenase, voltage-dependent Ca2+ and K+ channels, Ca²⁺-ATPase, and transcription factor islet-1 mRNA. In addition, there is a 40% to 50% increase in the levels of glucose-6-phosphatase and 12-lipoxygenase mRNA. Furthermore, changes in gene expression in the islets from diabetic ZDF rats include a decrease in levels of insulin mRNA that is associated with reduced islet insulin levels (422). Compared with control islets, expression of mRNA encoding C- and D-isoforms of α1subunits of β-cell L-type voltage-dependent Ca²⁺ channels was significantly reduced in islets isolated from ZDF rats. Intracellular Ca2+ concentration responses in ZDF islets after glucose, KCl, or BAY K 8644 (a Ca²⁺ channel activator) stimulation are markedly attenuated, whereas responses evoked by carbachol (a Ca²⁺ channel blocker) were unimpaired, consistent with a specific decrease in intracellular Ca²⁺ in the diabetic islets. This reduction is accompanied by loss of pulsatile insulin secretion from ZDF islets treated with oscillatory increases of external glucose concentration (436).

Genetics

The fatty (fa) gene was mapped to rat Chr 5 in crosses between 13 M/Vc fa/+ and the genetically distant BN (437,438). This region of rat Chr 5 is syntenic to mouse Chr 4 and human Chr 1. All three of these genetic segments contain the leptin receptor (Lepr). Representing a rat ortholog to the Lepr^{db} mutation in the mouse, the *fa* mutation is also a mutation in the leptin receptor. Sequencing of leptin receptor complemetary DNA (cDNA) yielded a single nucleotide mutation of $A \rightarrow C$ at position 880, causing an amino acid difference from a Q (glutamine) to a P (proline) (437,439,440). Mutations of the nucleotide sequence that lead to the substitution of proline for any other amino acid generally have devastating effects on the resulting protein structure. The fa mutation occurs in a conserved portion of the LEPR molecule and, unlike the *db* mutation, does not disrupt *Lepr* gene expression (440). The mutation is in the extracellular domain yet also has no effect on ligand binding (439). A major difference in the Lepr-fa is that this mutation imparts constitutive behavior to a heterologous intracellular signaling domain (441). This constitutive activation of the receptor-induced signaling cascade may induce a desensitization of the leptin signaling pathways.

The genetic factors that contribute to the susceptibility to type 2 diabetes of the ZDF rat have not been determined. One study has examined the phenotype of impaired β -cell function that characterizes both lean and obese ZDF rats. Although the analysis is incomplete, the authors have shown that the significantly decreased GSIS is a recessively inherited trait (442).

Complications

Animal models of diabetic complications are rare. The ZDF presents the opportunity to study important complications associated with diabetes: neuropathy and nerve damage. In studies in which ZDF rats are fed a diet high in cholesterol for 4 weeks, the rats experience decreases in velocity of peripheral nerve conduction and a diabetic neuropathy that presents, to some degree, morphologic changes resembling those of the human with type 2 diabetes (420).

Potential Research Uses

Historically, ZDF rats have been well utilized for research in many facets of diabetes, including nutritional interventions, gene expression, and drug development (443). As with many models of type 2 diabetes, caloric restriction is effective in limiting or preventing diabetes in the ZDF rat (444). The ZDF rat

has been used extensively for therapeutic interventions. Efficacy of TZDs (thiazolidinediones), such as troglitazone and rosiglitazone, has been shown, as these drugs improve many of the type 2 diabetes phenotypes. Troglitazone prevents the development of diabetes, lowers serum triglycerides, improves β -cell function (GSIS), and insulin action, and significantly decreases levels of glycosylated hemoglobin (445-448). If administered before or if started early in the diabetes, rosiglitazone prevents the onset of hyperglycemia and proteinuria, but if started late (21 weeks of age), no effect is detected (449). ZDF rats have also been used for drug discovery in the attempt to determine new non-TZD high-affinity ligands for peroxisome proliferator-activator receptor-y (PPARy). Treatment with JTT-501 from the prediabetic stage controlled glycemia and lipidemia and prevented the development of diabetic complications (450). Chronic oral administration of GW1929 to ZDF rats resulted in dose-dependent decreases in circulating glucose, FFAs, and triglycerides compared with pretreatment values, as well as significant decreases in glycosylated hemoglobin (448). Furthermore, GW1929 treatment improved both first- and secondphase insulin secretion in response to glucose (448). Conjugated linoleic acid, which also activates $PPAR\alpha$, is able to normalize impaired glucose tolerance and improve hyperinsulinemia in the prediabetic ZDF rat (451).

ZDF rats can also be used for the study of diabetic complications and for testing therapeutic interventions. Zenarestat, an aldose reductase inhibitor, has been used in ZDF rats, and when compared with untreated ZDF controls, improved nerve dysfunction in peripheral neuropathy (452). Further crosses of the ZDF with rats from strains that have been selectively bred for disease phenotypes, such as the SHR (spontaneously hypertensive rat) or the SHHF (spontaneously hypertensive heart failure), could prove valuable in creating better models of diabetic complications. F1 hybrid rats from ZDF fa/+ outcrosses with the SHHF-facp/+ (SHHF/Mcc-facp/facp rats) have been made to determine renal function, renal morphology, hemodynamics, and metabolic status (453). The ZDF \times SHHF F1 rats express insulin resistance, hypertension, obesity, and develop a more severe renal dysfunction than that seen in either parental stock homozygous for the respective *fatty* alleles

Availability

ZDF/Gmi rats can be obtained from Genetic Models (Indianapolis, IN). Control strains include the ZLC, as well as the obese Zucker (fa/fa) and lean Zucker (+/+ or fa/+). Wistar and Sprague Dawley rats have also been used as controls. Because of contractual obligations with the University of Indiana, certain restrictions apply to the ZDF rats purchased from GMI, including a no-breeding clause on all ZDF rats sold. This has severely limited studies into the genetic basis of the type 2 diabetes of ZDF rats.

Gerbil Models of Type 2 Diabetes

PSAMMOMYS OBESUS: A MODEL OF NUTRITIONALLY EVOKED TYPE 2 DIABETES

Strain Origin and Diabetic Phenotype

The *Psammomys obesus* (a member of the Gerbillinae family) also referred to inappropriately as the *sand rat*, is a model of nutritionally evoked type 2 diabetes. In the natural habitat (deserts of the Dead Sea and southern Algeria), *Psammomys* is not hyperglycemic but will transition into type 2 diabetes when fed *ad libitum* a calorie-dense laboratory feed. In the laboratory setting, the fertility of *Psammomys* can generally be maintained only

18: RODENT MODELS FOR THE STUDY OF DIABETES 319

when the animals are fed a mix of lab chow mixed with the native diet of salt bush (454). Like some rat models of type 2 diabetes, the *Psammomys* is an outbred model of type 2 diabetes, and research colonies differ in disease profile and most likely in genetic makeup. The phenotypes associated with type 2 diabetes in the Psammomys are obesity, impaired glucose tolerance, hyperinsulinemia, and finally hyperglycemia (455). A recent publication reported that Psammomys from the colony at the Hebrew University of Jerusalem, Israel, maintained on a diet that consisted of 70% starch, 17% protein, and 3% fat, had blood glucose values higher than 350 mg/dL and insulin levels of more than 15 ng/mL only 26 days after the onset of a high-calorie diet (456,457). Further, GSIS is defective in this gerbil, with blunted first- and second-phase insulin secretion (458). The defect that causes the type 2 diabetes is thought to be peripheral. Two reports (459,460) have shown that the hepatic insulin receptors bind insulin poorly. This is thought to abolish the control of insulin over gluconeogenesis, which is twice as high in Psammomys as in laboratory animals (459). Yet, fat and muscle cell insulin resistance is thought to be manifest through the overexpression of the PKC_e, which highly correlates with the failure of the insulin receptor to signal (460). Due to the insulin resistance syndrome, the islets show enhanced insulin synthesis and β -cell hypertrophy in the effort to compensate. Ten percent of the *Psammomys* proceed to the point of β -cell failure. At this time, the phenotypes are hypoinsulinemia and ketosis (455).

Complications

Diabetic cataract formation is a long-term complication of diabetes in humans. The *Psammomys* offers the unique opportunity to study the initiation of cataractogenesis under the control of hyperglycemia. Bilateral cataracts form in the *Psammomys* fed a high-calorie diet, and treatments that lower the blood glucose levels prevent the cataracts (456).

Potential Research Uses

Like other animal models of nutritionally induced diabetes, P. obesus provides the opportunity to study the interactions of diet and the phenotypes of type 2 diabetes. At this time, Psammomys has not been used in studies with TZDs. Pharmaceutical interventions have been made with both vanadium salts and lipoic acid. The effects of lipoic acid in the treatment of type 2 diabetes are questionable, but lipoic acid is effective in preventing the development of cataracts (456). Vanadium salts decrease circulating glucose and insulin levels and improved the peripheral sensitivity to insulin (457). This gerbil would be an excellent candidate for the study of the effects of exercise on the development and persistence of type 2 diabetes. The onset of ketosis is very rare in animal models of diabetes. That a small proportion of P. obesus develops ketosis indicates that this model presents an opportunity to study the ketotic state driven by natural occurrences.

Availability

P. obesus are available from Harlan Laboratories, Ein Kerem, Jerusalem, 91120, POB 12085, Israel.

Acknowledgments

The writing of this chapter was supported by National Institutes of Health grants F32DK09865, DK36175, and DK27722 and grants from the Juvenile Diabetes Research Foundation International and the American Diabetes Association. We thank Drs. Arthur Like and John Mordes (University of Massachusetts, Worcester) for providing information on the BB/Wor rats.

CONCLUSION 338

Diabetes mellitus is a heterogeneous group of metabolic disorders characterized by chronic hyperglycemia. Some forms of diabetes mellitus are characterized in terms of their specific etiology or pathogenesis, but the underlying etiology of the most common forms remains unclear. Regardless of the etiology, diabetes progresses through several clinical stages during its natural history. Persons developing the disease can be categorized according to clinical stages and other characteristics even in the absence of knowledge of the etiology.

DEFINITION OF DIABETES MELLITUS

Diabetes mellitus is characterized by chronic hyperglycemia with disturbances of carbohydrate, fat, and protein metabolism resulting from defects in insulin secretion, insulin action, or both. When fully expressed, diabetes is characterized by fasting hyperglycemia, but the disease can also be recognized during less overt stages, most usually by the presence of glucose intolerance. The effects of diabetes mellitus include long-term damage, dysfunction, and failure of various organs, especially the eyes, kidneys, heart, and blood vessels. Diabetes may present with characteristic symptoms such as thirst, polyuria, blurring of vision, weight loss, and polyphagia, and in its most severe forms, with ketoacidosis or nonketotic hyperosmolarity, which, in the absence of effective treatment, leads to stupor, coma, and death. Often symptoms are not severe or may even be absent. Hyperglycemia sufficient to cause pathologic functional changes may quite often be present for a long time before the diagnosis is made. Consequently, diabetes often is discovered because of abnormal results from a routine blood or urine glucose test or because of the presence of a complication. In some instances diabetes may be apparent only intermittently, as, for example, with glucose intolerance in pregnancy or gestational diabetes, which may remit after parturition. In some individuals the likelihood of developing diabetes may be recognized even before any abnormalities of glucose tolerance are apparent. During the evolution of type 1 diabetes, for example, immunologic disturbances such as islet cell or other antibodies are present, and these may precede clinically apparent disease by months or even years (1). In some families it is possible to recognize certain gene mutations that are strongly associated with certain forms of diabetes, such as variations in the glucokinase gene or hepatic nuclear factor genes that cause youth or early adultonset diabetes (2). These genetic abnormalities are detectable at any time.

Although a number of specific causes of diabetes mellitus have been identified, the etiology and pathogenesis of the more common types are less clearly understood. The majority of cases of diabetes fall into two broad etiopathogenetic categories, now called type 1 and type 2 diabetes (3,4), but the extent of heterogeneity among these types remains uncertain. Because of the increasing number of forms of diabetes for which a specific etiology can be recognized, the current clinical classification, proposed by the American Diabetes Association (ADA) in 1997 (3) and adopted by the World Health Organization

*In rare instances patients in these categories may require insulin for survival.

Figure 19.1. Clinical stages and etiologic types of diabetes.

(WHO) in 1999 (4) and that supersedes the previously internationally recognized 1985 WHO classification (5), now classifies diabetes according to both clinical stages and etiologic types (Fig. 19.1). The clinical staging reflects that diabetes progresses through several stages during its natural history and that individual subjects may move from one stage to another in either direction.

CLINICAL STAGES

Individuals who ultimately develop diabetes pass through several clinical stages during its development. Initially, glucose regulation is normal and no abnormality of glycemia can be identified even if these individuals undergo an oral glucose tolerance test (OGTT). This stage is followed by a period of variable duration in which glucose regulation is impaired. They may have some abnormality of the fasting glucose concentration, or if they receive an OGTT, they may demonstrate impaired glucose tolerance. Diabetes itself is characterized by either fasting glycemia or marked abnormalities of glucose tolerance, or both. Once diabetes develops, glycemia may be controlled by lifestyle changes such as diet and increased physical activity in some patients, whereas in others insulin or oral hypoglycemic agents are needed for its control or to prevent ketosis and ketoacidosis. If insulin is required to prevent ketosis, such patients are designated as "insulin requiring for survival." In all forms of diabetes, there may be remission in the extent of hyperglycemia. Patients may revert to having impaired glucose regulation or even normal glycemia, particularly if diabetes is of recent onset. This is seen most frequently in patients with recent-onset type 2 diabetes, in whom lifestyle intervention and/or early aggressive treatment of the glycemia may result in apparent reversal of the abnormality with reversion to impaired or normal glucose tolerance (6). This may also be seen in type 1 diabetes, in which after a short period of insulin treatment, there may be a variable period when insulin

is no longer required for survival and glucose tolerance may improve—the so-called honeymoon period. Eventually such patients do need insulin treatment for survival (7). Gestational diabetes often is followed by improved glucose tolerance following parturition, and for a variable period, such women may be normoglycemic. With a subsequent pregnancy, gestational diabetes is likely to recur. Many women who have had gestational diabetes develop diabetes within a few years when they are not pregnant; thus, even in the face of normal glycemia, such women can be recognized as being at high risk of developing type 2 diabetes (8).

All subjects with diabetes can be classified according to clinical stage regardless of the underlying etiology of the diabetes. The stage of glycemia may change over time, depending on the extent of the underlying disease process. The disease process may be present but may not have progressed far enough to cause clinically identifiable abnormalities of glucose metabolism. For example, antibodies to islet cells, insulin, or glutamic acid decarboxylase (GAD) in a normoglycemic individual indicate a high likelihood for ultimate progression to type 1 diabetes (9). There are few sensitive or specific early indicators of the likelihood for development of type 2 diabetes, but the disease process may be identified before the development of overt diabetes.

Impaired glucose regulation refers to the metabolic stage intermediate between normal glucose homeostasis and diabetes that can be identified by impaired glucose tolerance (IGT) or impaired fasting glucose (glycemia) (IFG) (3,4). IFG and IGT are not synonymous and may represent different abnormalities of glucose regulation, although they may occur together. Individuals with either of these states of impaired glucose regulation have a high risk of progressing to diabetes (10–12). IGT can be assessed only if OGTTs are carried out, whereas IFG refers to fasting glucose concentrations that are lower than those required for the diagnosis of diabetes but higher than those usually found in subjects with normal glucose tolerance. Subjects with IGT or IFG usually have normal or slightly elevated levels of glycosylated hemoglobin (13). IGT is frequently associated with the

presence of other indicators of the metabolic or insulin resistance syndrome (14).

ETIOLOGIC TYPES

The etiologic classification of diabetes mellitus currently recommended by WHO and the ADA is presented in Table 19.1. This classification differs considerably from the previously recommended classification, which used the terms *insulin-dependent diabetes* and *non-insulin-dependent diabetes* (5). These terms, however, were frequently misused and at best classified patients based on treatment needs rather than on etiologic characteristics. The terms *type 1* and *type 2* diabetes (with Arabic numerals) have been adopted for the most common forms of diabetes mellitus.

TYPE 1 DIABETES MELLITUS

Type 1 diabetes is the form of the disease due primarily to β -cell destruction. This usually leads to a type of diabetes in which insulin is required for survival. Individuals with type 1 diabetes are metabolically normal before the disease is clinically manifest, but the process of β -cell destruction can be detected earlier by the presence of certain autoantibodies. Type 1 diabetes usually is characterized by the presence of anti-GAD, anti-islet cell, or anti-insulin antibodies, which reflects the autoimmune processes that have led to β -cell destruction. Individuals who have one of more of these antibodies can be subclassified as having type 1A, immune-mediated type 1 diabetes (3,4).

Particularly in nonwhites, type 1 diabetes can occur in the absence of autoimmune antibodies and without evidence of any autoimmune disorder. In this form of type 1 diabetes, the natural history also is one of progressive disease with marked hyperglycemia resulting in an insulin requirement for prevention of ketosis and survival. Such individuals are classified as having type 1B, or idiopathic, diabetes (15).

Type 1A diabetes shows strong associations with specific haplotypes or alleles at the DQ-A and DQ-B loci of the human leukocyte antigen (HLA) complex (16). The rate of β -cell destruction is quite variable, being rapid in some individuals, especially in infants and children, and slower in adults. Some have modest fasting hyperglycemia that can rapidly change to

severe hyperglycemia or ketoacidosis, and others, particularly adults, may retain some residual β -cell function for many years and have sometimes been termed as having "latent autoimmune diabetes" (17,18). Such individuals may become dependent on insulin for survival only many years after the detection of diabetes. Individuals with type 1 diabetes have low or undetectable levels of insulin and plasma C-peptide. Patients with type 1A diabetes are also more likely to have other concomitant autoimmune disorders, such as Graves disease, Hashimoto thyroiditis, Addison disease, vitiligo, or pernicious anemia.

Type 1B, or idiopathic, diabetes is characterized by low insulin and C-peptide levels similar to those in type 1A. Such patients are prone to ketoacidosis, although they have no clinical evidence of autoimmune antibodies. Many of these patients are of African or Asian origin. They may suffer from episodic ketoacidosis, but the pathogenetic basis for their insulinopenia remains obscure.

TYPE 2 DIABETES MELLITUS

Type 2 diabetes is the most common form of diabetes. It is characterized by disorders of insulin action and insulin secretion, either of which may be the predominant feature. Usually, both are present at the time diabetes becomes clinically manifest. Although the specific etiology of this form of diabetes is not known, autoimmune destruction of the β -cells does not occur.

Patients with type 2 diabetes usually have insulin resistance and relative, rather than absolute, insulin deficiency. At the time of diagnosis of diabetes, and often throughout their lifetimes, these patients do not need insulin treatment to survive, although ultimately many require it for glycemic control. This form of diabetes is associated with progressive β -cell failure with increasing duration of diabetes (19). Ketoacidosis seldom occurs spontaneously but can arise with stress associated with another illness such as infection.

Most patients with type 2 diabetes are obese when they develop diabetes, and obesity aggravates the insulin resistance. Type 2 diabetes frequently goes undiagnosed for many years because the hyperglycemia develops gradually and in the earlier stages is not severe enough to produce the classic symptoms of diabetes; however, such patients are at increased risk of developing macrovascular and microvascular complications. Their circulating insulin levels may be normal or elevated yet insufficient to control blood glucose levels within the normal range because of their insulin resistance. Thus, they have relative, rather than absolute, insulinopenia. Insulin resistance may improve with weight reduction or pharmacologic treatment and results in normalization of their glycemia. Type 2 diabetes is seen frequently in women who have a previous history of gestational diabetes and in individuals with other characteristics of the insulin resistance syndrome, such as hypertension or dyslipidemia.

Patients who are not obese and who have relatives with type 1 diabetes, especially those of European origin, may present with a clinical picture consistent with type 2 diabetes but may have autoantibodies similar to those found in type 1 diabetes. Such patients have type 1A diabetes yet may appear to have type 2 diabetes unless antibody determinations are made.

The risk of developing type 2 diabetes increases with age, obesity, and physical inactivity. Type 2 diabetes shows strong familial aggregation, so that persons with a parent or sibling with the disease are at increased risk, as are individuals with obesity, hypertension, or dyslipidemia and women with a history of gestational diabetes. The frequency of type 2 diabetes varies considerably among different racial or ethnic subgroups. Persons of Native American, Polynesian or Micronesian, Asian-Indian,

Hispanic, or African-American descent are at higher risk than persons of European origin (20). Although the disease is most commonly seen in adults, the age of onset tends to be earlier in persons of non-European origin. The disease can occur at any age and is now seen in children and adolescents (21–24).

OTHER SPECIFIC TYPES OF DIABETES

Other specific types of diabetes are those in which the underlying defect or disease process can be identified in a relatively specific way or those that have other distinctive, distinguishing features. This category encompasses a variety of types of diabetes secondary to other specific conditions or associated with particular diseases or syndromes with a distinct etiology.

The categories and many of the causes of other specific types of diabetes are shown in Table 19.2. These include genetic defects of β -cell function, which encompass several types of diabetes that are associated with specific monogenic defects. Most of these are characterized by a dominant pattern of inheritance and the onset of hyperglycemia at an early age. They are often referred to as maturity-onset diabetes of the young (MODY). They are characterized by impaired insulin secretion with minimal or no defects in insulin action. They are inherited in an autosomal dominant pattern but are heterogeneous. A number of specific genetic defects have been identified, including variations in hepatic nuclear factor 4 α (HNF4 α) (MODY1), glucokinase (MODY2), HNF1 α (MODY3), insulin-promoting factor 1 (IPF1) (MODY4), and HNF3 β genes (MODY5) (2). There are also some forms of MODY for which the genetic defect remains to be identified. Another form of autosomal dominant diabetes is due to a mutation in the K_{ATP} channel subunit (SUR1) of the sulfonylurea receptor that gives rise to congenital hyperinsulimemia and loss of insulin secretory capacity in young adults, leading to impairment of glucose tolerance and diabetes in middle age (25).

Another genetic defect of β -cell function is due to a mutation in mitochondrial DNA. The mitochondrial DNA variant, Leu-Ala at position 3243, leads to diabetes mellitus associated with deafness (26). Because this form of diabetes is due to a mitochondrial defect, it may be suspected when there is evidence of maternal inheritance, particularly when associated with deafness. The same mitochondrial variant also is found in the MELAS syndrome (mitochondrial myopathy, encephalopathy, lactic acidosis, and stroke-like syndrome), although diabetes is not part of this syndrome (27).

Some forms of diabetes are associated with rare autosomal dominantly inherited genetic defects of insulin or insulin action (28). In one form affected individuals are unable to convert proinsulin to insulin. In general the glucose intolerance is mild. Structurally abnormal insulins, from specific mutations in the insulin gene, with resultant impaired receptor binding, have been identified in a few families. Affected individuals may have either mildly impaired or even normal glucose

metabolism but have high circulating levels of insulin or C-peptide. A number of specific mutations of the insulin receptor gene have been identified that also result in impaired insulin action (29). Although these are rare causes of diabetes, they should be considered if circulating insulin levels are exceptionally high and if there are other clinical characteristics of insulin resistance syndromes such as acanthosis nigricans, ovarian dysfunction, hyperandrogenism, lipodystrophy, or extreme hypertriglyceridemia. The possibility of diabetes due to antibodies in the insulin receptor should be entertained if other autoimmune diseases such as systemic lupus erythematosus, Sjögren syndrome, or ataxia-telangiectasia are present. Defects of insulin action with a genetic basis are present in leprechaunism, the Rabson-Mendenhall syndrome, and lipoatrophic diabetes.

Diabetes mellitus may be secondary to a variety of diseases of the exocrine pancreas. Fibrocalculous pancreatopathy, which was considered one of the subtypes of "malnutrition-related" diabetes in the 1985 WHO classification, is now placed in that category. Diabetes may also result from pancreatitis, pancreatectomy, neoplastic disease of the pancreas, cystic fibrosis, and hemochromatosis. One specific form of exocrine pancreatic deficiency associated with a genetic abnormality of the PEK gene is the rare Wolcott-Rallison syndrome, which is associated with early-onset diabetes and multiple epiphyseal dysplasia (30).

Diabetes mellitus may result from several endocrinopathies. It may occur in association with Cushing syndrome, acromegaly, pheochromocytoma, glucagonoma, hyperthyroidism, and somatostatinoma.

A variety of drugs or chemicals have been associated with the development of diabetes. These include glucocorticoids, nicotinic acid, diazoxide, phenytoin, and pentamidine. When diabetes is associated with such agents, it is often uncertain whether or not the drug has been the direct cause of the diabetes or the diabetes has appeared coincidentally in association with administration of the drug (31).

A few specific infections may result in diabetes mellitus, including congenital rubella and cytomegalovirus infections (32). There are also a number of other relatively rare genetic syndromes sometimes associated with diabetes.

GESTATIONAL DIABETES MELLITUS

Gestational diabetes mellitus (GDM) is carbohydrate intolerance associated with hyperglycemia of variable severity with the onset or first recognition during pregnancy (3,4). It does not exclude the possibility that unrecognized glucose intolerance or diabetes may have antedated pregnancy. Women who become pregnant who are known to have diabetes that antedates pregnancy, however, do not have GDM.

In early pregnancy, fasting and postprandial glucose concentrations are normally lower than in nonpregnant women. Any elevation of fasting or postprandial glucose levels at this time may well reflect the presence of diabetes that antedates pregnancy, but specific criteria for designating abnormality at this time of pregnancy have not been established. Furthermore, normal glucose levels in early pregnancy do not establish that GDM will not develop later.

Individuals with a high risk of GDM include older women, those with a previous history of glucose intolerance, those with a history of babies large for gestational age, women from certain ethnic groups at high risk for type 2 diabetes, and any pregnant woman who has any elevation of fasting or casual blood glucose levels. Gestational diabetes can have deleterious consequences for both the fetus and mother. Diabetes occurring before or recognized during pregnancy with elevated fasting glucose concentrations is associated with an increased risk of intrauterine fetal death during the last 4 to 8 weeks of gestation and other complications, including congenital abnormalities (33). GDM without severe fasting hyperglycemia has not been associated with increased perinatal mortality, but GDM of any severity increases the risk of fetal macrosomia (34). Neonatal hypoglycemia, jaundice, polycythemia, and hypocalcemia are other fetal complications of GDM. Offspring of women with GDM or with type 2 diabetes preceding pregnancy are at increased risk of obesity, glucose intolerance, and diabetes in adolescence or as young adults (35).

Women with high-risk characteristics for diabetes, such as marked obesity, a previous history of GDM, glycosuria, or a strong family history of diabetes, should undergo glucose testing as soon as feasible during pregnancy. Screening pregnant women from high-risk populations during the first trimester of pregnancy is appropriate to detect previously undiagnosed diabetes or glucose intolerance. Women who have a fasting plasma glucose level of 126 mg/dL or greater or a casual plasma glucose level of 200 mg/dL or greater at any time during pregnancy meet the thresholds for the diagnosis of diabetes. If confirmed, such levels preclude the need for any glucose challenge to establish the diagnosis of diabetes. Formal systematic testing for GDM usually is performed between 24 and 28 weeks of gestation.

Women with any of the following characteristics should receive formal testing for GDM between 24 and 28 weeks of gestation: those aged 25 and older, overweight women, women who are members of an ethnic group with a high prevalence of diabetes, women with first-degree relatives with diabetes, women with a history of abnormal glucose tolerance, or women with a poor obstetrical history (36). Following delivery, women who have GDM should be reclassified. Some women with GDM will have diabetes or impaired glucose regulation following parturition, but in the majority, glucose regulation will return to normal after delivery. Such women, however, carry a high risk of progressing to diabetes in subsequent years (8,37).

IMPAIRED GLUCOSE TOLERANCE

IGT is a stage of impaired glucose regulation that is present in individuals whose glucose tolerance is above the conventional normal range but lower than the level considered diagnostic of diabetes (3,4). IGT cannot be defined on the basis of fasting glucose concentrations; an OGTT is needed to categorize such individuals. Persons with IGT do have a high risk of developing diabetes, although not all do so (38). Some revert to normal glucose tolerance, and others continue to have IGT for many years. Persons with IGT have a greater risk than persons of similar age with normal glucose tolerance of developing arterial disease (39), but they rarely develop the more specific microvascular complications of diabetes, such as retinopathy or nephropathy, unless they develop diabetes (3,40).

IGT is more frequent in obese than in nonobese persons and often is associated with hyperinsulinemia and insulin resistance. IGT may be attributable to a wide variety of causes, including certain medications and many of the specific genetic syndromes or other conditions associated with diabetes (see Table 19.2). Nonetheless, in most subjects, IGT represents a transient stage between normal glucose tolerance and the development of type 2 diabetes.

Because persons with IGT have a high risk of progressing to type 2 diabetes, several randomized clinical trials have been conducted among such individuals. These trials have shown that the development of diabetes can be reduced or delayed by the use of lifestyle interventions such as dietary measures to reduce weight and increased physical activity (41–43). Several drugs, such as metformin (43), acarbose (44), and troglitazone (45), also reduce the incidence of type 2 diabetes in persons with IGT.

IMPAIRED FASTING GLUCOSE

IFG is also a stage of impaired glucose homeostasis. This category was introduced in the 1997 ADA and 1999 WHO classifications to include individuals whose fasting glucose levels were above normal but below those diagnostic for diabetes (3,4).

Individuals with fasting plasma glucose concentrations of 100 to 125 mg/dL (5.6 to <7.0 mmol/L) are now considered to have IFG (46). If an OGTT is performed, some of these individuals will have IGT and some may have diabetes (2 hours postload plasma glucose concentration \geq 200 mg/dL, or \geq 11.1 mmol/L) (Table 19.3). Consequently, it is prudent, and recommended by WHO, that such individuals, if possible, have an OGTT to exclude diabetes.

The category of IFG was introduced by the ADA in 1997 at the same time that the concentration of fasting plasma glucose for the diagnosis of diabetes was lowered to 126 mg/dL or greater (\geq 7.0 mmol/L). The range of fasting glucose concentrations for IFG was set originally at 110 to 125 mg/dL (6.1 to < 7.0 mmol) but was revised in 2003 to 100 to 125 mg/dL (5.6 to < 7.0 mmol/L). IFG and IGT identify substantially different subsets of the population (47). Although both categories contain individuals with a high risk of progressing to type 2 diabetes (10–12,48), the proportion with IFG in most populations is smaller than that with IGT (47,48). The modified cut-point recommended in the 2003 ADA report (46) is likely to be adopted by the WHO in the near future.

DIAGNOSTIC CRITERIA FOR DIABETES AND RELATED STAGES OF IMPAIRED GLUCOSE HOMEOSTASIS

If a patient has symptoms such as thirst, polyuria, unexplained weight loss, drowsiness or coma, and marked glucosuria, the diagnosis of diabetes can be established by demonstrating fasting hyperglycemia (3,4). If the fasting glucose concentration is in the diagnostic range for diabetes, an OGTT is not required for diagnosis. A confirmatory test should be performed because a diagnosis of diabetes carries considerable and lifelong consequences for the patient, and intraindividual variation or incomplete fasting may result in a spurious diagnosis. On the other hand, if the patient is asymptomatic or has only minimal symptoms and fasting blood or plasma concentrations are not diagnosis of diabetes (Table 19.4).

Normal glucose tolerance cannot be established on the basis of a fasting glucose determination alone. In healthy subjects, fasting glucose levels are less than 100 mg/dL (<5.5 mmol/L) in venous or capillary plasma and 90 mg/dL or less ($\leq 5.0 \text{ mmol/L}$) in whole blood, but subjects with fasting levels below these limits may exhibit IGT (4). Subjects with fasting glucose levels above those characteristic for healthy subjects but below those diagnostic of diabetes also have a high likelihood of having either diabetes or IGT. Such levels represent a primary indication for an OGTT to confirm or exclude the diagnosis of diabetes or IGT.

ORAL GLUCOSE TOLERANCE TEST

The OGTT should be administered in the morning after the patient has had at least 3 days of unrestricted diet (>150 g of carbohydrate daily) and usual physical activity. The test should be preceded by an overnight fast of 10 to 16 hours, during which the patient may drink water. The patient may not smoke during the test. Factors that may influence interpretation of the results of the test should be recorded (e.g., medications, inactivity,

	Glucose concentration, mg/dL (mmol/L)

TABLE 19.4 Categories of Hyperglycemia According to Venous Plasma Clucose Concentrations

IFG, impaired fasting glucose; IGT, impaired glucose tolerance. "The 1997 American Diabetes Association (ADA) and 1999 World Health Organization (WHO) recommendations for fasting plasma glucose values were as follows: normal, <110 mg/dL (6.1 mmol/L); impaired, 110–125 mg/dL (6.1–6.9 mmol/L). The values listed in the table reflect the most recent 2003 ADA Expert Committee recommendations (46). ^bThese categories are identifiable only if an oral glucose tolerance test is performed.

This category is currently classified by the ADA recommendations as IFG and IGT and by the WHO as IGT. Because these subjects have approximately twice the risk of developing diabetes as those with IFG only or IGT only, it is preferable to state that they have both IFG and IGT.

infection). Such factors should be taken into account in interpreting the results of the test.

After the fasting blood sample is collected, the subject should drink 75 g of anhydrous glucose (or partial hydrolysates of starch with an equivalent carbohydrate content) in 150 to 300 mL of water over the course of 5 minutes. For children, the glucose load should be 1.75 g/kg of body weight, up to a total of 75 g of glucose. Blood samples are drawn before (fasting) and 2 hours after the test load.

Unless the glucose concentration is determined immediately, the blood sample should be collected in a tube containing sodium fluoride (6 mg/mL of whole blood) and centrifuged promptly to separate out the plasma. The plasma should be frozen until the glucose measurement is done.

The results of the OGTT should be interpreted according to the criteria given in Table 19.3 or Table 19.4. It is important to note that the diagnostic levels differ according to whether capillary or venous blood is collected and whether the glucose concentrations are reported as plasma or whole blood glucose concentrations.

DIAGNOSTIC CRITERIA FOR GESTATIONAL DIABETES

Testing for GDM is performed between the 24th and 28th week of pregnancy in women who are not known to have diabetes. Evaluation of GDM is done by one of two approaches. An OGTT may be performed using a 75-g oral glucose load, as is done in the nonpregnant state. An alternative method, widely used in the United States, is to screen in two stages, initially measuring plasma glucose concentrations 1 hour after a 50-g oral glucose load. For women whose venous plasma glucose values are 140 mg/dL or higher, either a 100-g or a 75-g OGTT is then performed on a subsequent day. Because of the widespread use of the 100-g OGTT among obstetricians in the United States, diagnostic values for GDM with either the 100-g or the 75-g oral glucose load have been recommended by the ADA (36) (Table 19.5). WHO recommends a single standard 75-g OGTT after an overnight fast, giving an oral load of 75 g of anhydrous glucose in 250 to 300 mL of water, with measurement of plasma glucose levels fasting and after 2 hours (4).

TABLE 19.5. Diagnostic Criteria (Venous Plasma Glucose Values) for Gestational Diabetes Mellitus According to ADA Clinical Practice and WHO Recommendations

	ADA clinical practice ^a (36)		WHO(4)
	75-g Oral glucose load, mg/dL (mmol/L)	100-g Oral glucose load, mg/dL (mmol/L)	75-g Oral glucose load, mg/dL (mmol/L)
Fasting	95 (5.3)	95 (5.3)	≥126 (≥7.0)
1 Hour	180 (10.0)	180 (10.0)	or
2 Hour	155 (8.6)	155 (8.6)	
3 Hour	NA	140 (7.8)	≥140 (≥7.8)

ADA, American Diabetes Association; WHO, World Health Organization; NA, not applicable.

^aTwo or more of the venous plasma concentrations must be met or exceeded for a positive diagnosis. The test should be done in the morning after an overnight fast between 8 and 14 hours and after at least 3 days of unrestricted diet (≥150 g carbohydrate per day) and unlimited physical activity. The subject should remain seated and should not smoke throughout the test.

These tests identify different women as having high-risk pregnancies and different risks of adverse fetal outcome (49,50).

Use of the 75-g test has gained wide acceptance in many parts of the world, but less so in the United States. The WHO recommendation is that women with 2-hour venous plasma values of 140 mg/dL or higher (\geq 7.8 mmol/L), or fasting venous plasma values of 126 mg/dL or higher (\geq 7.0 mmol/L), or equivalent values if glucose is measured in whole blood, be considered to have GDM (Table 19.5).

THE IMPACT OF RECENT CHANGES IN CLASSIFICATION AND DIAGNOSTIC CRITERIA

As noted earlier, the currently recommended classification and criteria for diabetes differ from those recommended in earlier years (5). The major changes in classification have been to move toward an etiologically based classification because of increasing knowledge about some of the specific underlying causes of diabetes. This trend is likely to continue.

The terms *insulin-dependent* and *non-insulin-dependent* diabetes no longer appear in the classification. These terms were often misused, frequently reflecting the type of treatment that the patients were receiving rather than their actual type of diabetes. In addition, there is now greater certainty that type 1 diabetes is due primarily to pancreatic β -cell destruction, and this frequently can be documented by the presence of specific types of antibodies, as well as insulinopenia. The class of malnutrition-related diabetes is no longer recognized, as this was heterogenous, and one of its forms, fibrocalculous pancreatic diabetes, is clearly secondary to a specific form of pancreatic disease (4). The other form of diabetes formerly described as "malnutrition related" is now generally considered to be type 2 diabetes that occurs in malnourished persons.

Knowledge of specific forms of diabetes attributable to mutations in specific genes has expanded enormously, and such cases can now be classified very specifically if they are investigated in detail. Importantly, this information has led to circumstances in which susceptibility to the development of some types of diabetes can be identified before hyperglycemia is evident.

The introduction of clinical staging has been prompted by the recognition that all forms of diabetes pass through a number of stages associated with different degrees of metabolic dysfunction. Furthermore, it now has been established that progression from normal glucose tolerance to overt diabetes can be halted or delayed and that reversion to less severe states of dysglycemia is possible. On the other hand, hyperglycemia may be present, but specific information or knowledge enabling precise etiologic classification may not be available for many patients. Such individuals can be classified according to clinical stage in the absence of specific knowledge of causation.

The clinical stage of IFG has been introduced in the most recent classifications. This category was introduced because fasting blood or plasma glucose measurements represent the most common means used to screen or test for diabetes in clinical practice. Fasting glucose values considered diagnostic of diabetes have been lowered to be more equivalent to those found when the 2-hour plasma value after an oral glucose load is 200 mg/dL or greater (≥11.1 mmol/L) (3). This change increases the likelihood of a correct diagnosis of diabetes when only a fasting glucose concentration is determined, but the fasting level diagnostic of diabetes is well beyond the normal range in persons with normal glucose tolerance. Consequently, the stage of IFG was defined to accommodate and recognize

individuals whose fasting glucose levels were above normal yet not diagnostic of diabetes.

Application of these revised criteria has shown that only a minority of persons with IGT have IFG, and vice versa. Yet persons with IFG only or IGT only are at considerable risk for the development of diabetes. In addition, there is some evidence that IFG is more likely than IGT to be associated with a reduction in insulin secretion, whereas IGT is associated with insulin resistance (48). This suggests that different mechanisms may be responsible for these two states. Whether or not these differences will ultimately have different implications for management and intervention to prevent progression to diabetes remains to be determined.

CONCLUSION

The recent classification system for diabetes and related states of hyperglycemia has focused on etiopathogenesis whenever possible. Although the underlying causes of the more common forms of diabetes are still unknown, their characteristics are sufficiently distinct for classification to be made with reasonable certainty in most instances. This, along with defined clinical stages, provides a clinically useful framework that can be modified as more precise information on the specific etiology of certain forms of diabetes becomes known. The classification and staging also provide a framework for further research into the etiology, treatment, and prevention of the many forms of diabetes.

Clustering of Type 2 Diabetes in Families 351

In this chapter, we will review the descriptive epidemiology of type 1 and type 2 diabetes mellitus and discuss its relevance to the etiology of the disease (1). However, it is first necessary to define some of the indices used to estimate diabetes frequency in populations (2).

SOME USEFUL DEFINITIONS

Prevalence, Incidence Rate, and Cumulative Incidence

The number of persons in a particular place at a particular time who have diabetes (e.g., in Massachusetts on July 1, 2001) is a frequently cited statistic. Expressed as a proportion, this number is commonly called the prevalence rate or, preferably, *prevalence*, so it is not confused with the incidence rate, which is defined below. The prevalence in Massachusetts is the accumulation of persons who acquired diabetes before July 1, 2001, but the size of this collection depends on not only the frequency of new cases but also on how long these persons remain alive to be counted. For example, a marked increase in the prevalence of insulin-dependent diabetes followed the discovery of insulin, although we have no evidence that the number of new cases that developed each year increased.

To express diabetes frequency in a manner suitable for drawing conclusions regarding etiology of the disease, we use the *incidence rate*. The incidence rate is calculated by dividing the number of *new* cases of diabetes in Massachusetts residents during the 12 months of 2001, for example, by the number of nondiabetic individuals residing in Massachusetts during that year. Typically, the incidence rate is expressed as the number of new cases per 100,000 persons observed for a year (called *person-years*). When an incidence rate is calculated according to a characteristic such as age, sex, or race, the results are referred to as a *specific rate*. The age-specific incidence rate of diabetes varies enormously across the normal life span, and populations typically have different age distributions. Meaningful comparisons among populations must therefore be based on a particular agespecific rate or, for simplicity, on a summary of age-specific rates determined by a technique that gives each population the same age distribution (2). This produces age-adjusted or agestandardized rates. Alternatively, one can compare populations that have different age structures by calculating the *cumulative incidence* of diabetes at specific ages in each population.

Cumulative incidence or cumulative risk of diabetes is calculated from the age-specific incidence rate by use of life-table methods (2). One begins with an arbitrary number of births (e.g., 1,000 births) and applies the age-specific incidence rate to the number of persons who remain unaffected after each successive year of age. By accumulating the cases from previous ages, one obtains the proportion of the original 1,000 children born who would be affected by each successive age in a population. By extending this process to the whole life span, one obtains the lifetime risk of diabetes. In a specific instance, the prevalence of diabetes at a certain age may be a reasonable estimate of cumulative incidence at that age. For example, type 2 diabetes-related mortality before the age of 55 years is negligible. Therefore, the prevalence of type 2 diabetes in the age group 45 through 54 years is a reasonable estimate of the cumulative incidence at age 50 years. However, at older ages, prevalence typically underestimates cumulative incidence of diabetes because persons with early onset of the disease may have died.

DIFFERENCES IN DISTRIBUTION OF TYPE 1 AND TYPE 2 DIABETES

The incidence rate is the most informative measure of the frequency of diabetes in a population for the study of etiologic factors. For the computation of the incidence rate, new cases of diabetes must be recognized and counted. Type 1 diabetes is easily recognized, and virtually all new cases are ascertained in a society with access to medical care. Recognition of new cases of type 2 diabetes, however, depends on the severity of symptoms, diagnostic activity of the medical-care system, and the choice of diagnostic criteria (3).

Data on the incidence rate of diabetes in Rochester, Minnesota, as ascertained through medical-care institutions, show how the incidence rate of type 1 diabetes varies according to age (Table 20.1) (4,5). Among the nondiabetic population of Rochester, type 1 diabetes developed in 7 to 27 individuals per 100,000 per year—depending on the age group being counted. The risk increases during the first and second decades of life, levels off during the third and fourth decades, and increases again thereafter, suggesting that there are two peaks of occurrence of type 1 diabetes, one centered in the second decade and the other in the sixth and seventh decades. The incidence rate of type 2 diabetes increases steadily with age (Table 20.1), with an almost 100-fold increase from early childhood to old age.

The sets of age-specific incidence rates can be summarized as cumulative incidence rates (i.e., the cumulative risk in a cohort of individuals followed from birth and exposed to the age-specific rates). For the age-specific rates in Table 20.1, the cumulative risk by age 70 years would be 1% for type 1 diabetes and 11% for type 2 diabetes.

EPIDEMIOLOGY OF TYPE 1 DIABETES

Any hypothesis put forward regarding the etiology of type 1 diabetes must account for the characteristics of its distribution in human populations that are discussed below. Most studies of type 1 diabetes have considered only the disease occurrence in children, typically under the age of 15 years. Therefore, this review is largely restricted to a consideration of the characteristics of diabetes occurring in the first two decades of life (the first peak in Table 20.1). Little is known about the determinants of

TABLE 20.1. Age-Specific Incidence Rates of Type 1 andType 2 Diabetes per 100,000 Person-Years in Rochester,1960 through 1969

type 1 diabetes occurring in adults (the second peak in Table 20.1).

Variation in Incidence of Type 1 Diabetes with Age

Type 1 diabetes rarely occurs during the first year of life. Of nearly 10,000 incident cases included in the Finnish Childhood Diabetes Registry between 1965 and 1996, only 37 cases (0.4%) had onset before the first birthday (7). The incidence rises sharply until age 12 to 14 years, and then declines. The relationship with age is clearly seen in Figure 20.1, in which the incidence rate of type 1 diabetes in Denmark is presented according to age (8). A similar pattern is seen in most other countries, regardless of whether their overall incidence of type 1 diabetes is high or low.

Data on the incidence of type 1 diabetes with onset after the age of 30 years are scarce. In a population study of two counties in Denmark (9), the rate was 8.2 per 100,000 when very stringent diagnostic criteria for type 1 diabetes were used, and the age at onset resembled that for type 1 diabetes in Rochester, Minnesota (Table 20.1). When the criteria were relaxed to consider all patients treated with insulin from the onset of diabetes as having type 1 diabetes, the incidence rate rose to 35.8 per 100,000, with the difference being due to an increased magnitude of the peak in the oldest decades of age.

Variation in Incidence of Type 1 Diabetes among Races and Countries

Interest in the epidemiology of diabetes in the last two decades has resulted in the publication of a multitude of papers on the incidence rate in most areas of the world. A sample of these data illustrates the large magnitude of the geographic variation in the occurrence of type 1 diabetes (Fig. 20.2) (10). According to a recent compilation of data from 100 studies conducted in 50 countries, the lowest age-adjusted incidence rates for the population aged 0 to 14 years are in Asia, the Caribbean, and Latin America (ranging from 0.1 to 3.5 per 100,000 per year) and the highest are in Nordic countries, the United Kingdom, Canada, New Zealand, Portugal, and Sardinia (ranging from 21.2 to 36.8 per 100,000 per year) (11). The incidence rate of type 1 diabetes

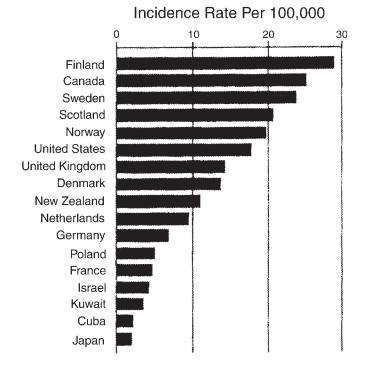

Figure 20.2. Incidence rate of type 1 diabetes in children less than 15 years old (per 100,000) in various populations. (From Patrick SL, Moy CS, LaPorte RE. The world of insulin-dependent diabetes mellitus: what international epidemiologic studies reveal about the etiology and natural history of IDDM. *Diabetes Metab Rev* 1989;5:571–578.)

in the white population in the United States, represented by three studies, ranges from 11.7 to 16.4 per 100,000 per year. This gives the United States a rank close to that for high-risk populations.

Data on the occurrence of type 1 diabetes according to race in the United States have been accumulating during the last two decades. In general, the reported incidence rate for nonwhites is lower than that for whites in the population aged 0 to 14 years. For example, in Allegheny County, Pennsylvania, the race-specific incidence rates during the 5-year period 1978 to 1983 were 16.2 and 11.8 per 100,000 for white and black children, respectively (11). During a similar calendar period in Jefferson County, Alabama, and in San Diego, California, the rates were much lower for blacks (4.4 and 3.3 per 100,000, respectively), although the rates for whites were similar in the three locales (12). Curiously, during a more recent period (1990 to 1994), the incidence rate in Allegheny County for blacks aged 10 to 14 years rose to equal that for whites and the rate for blacks aged 15 to 19 years exceeded that for whites (13). The reported rate among Hispanic children aged 0 to 14 years ranges from 9.7 per 100,000 in Colorado to 4.1 per 100,000 in California, while the incidence rate in Mexico is among the lowest in the world (12).

In summary, the accumulated data on the incidence of type 1 diabetes during the last 20 years demonstrate that type 1 diabetes occurs in most racial and ethnic groups but that the risk is highest among white populations (11). While genes may in part determine these differences among races, the range of variation within the white population is almost as great as the range among races. Therefore, an important question to be resolved is how much of the variation within and between racial groups is due to genetic differences and how much is due to exposure to different environmental factors.

20: EPIDEMIOLOGY OF DIABETES MELLITUS 343

Temporal Increase in Incidence of Type 1 Diabetes

The pattern of occurrence of type 1 diabetes over time can be important evidence in discriminating between alternative etiologic hypotheses. In particular, a lack of variability from generation to generation is a feature of many genetic traits. If, on the other hand, there is significant variability over time, nongenetic factors are presumably important. The particular pattern of variation may suggest specific environmental factors that can be investigated as components of the etiology of type 1 diabetes. Several types of variation over time have been described: long-term trends, a seasonal cycle, and episodic changes over a few years.

The few sources of data that contribute to an analysis of long-term trends in the incidence of type 1 diabetes in the United States are summarized in Figure 20.3 (6). During the first three decades of the 20th century, the incidence rate of type 1 diabetes in the white population younger than age 15 years was fairly constant. However, during the next three decades, the rate almost tripled. Data from several other countries are compatible with those from the United States. The incidence rate for children younger than age 15 years in Oslo, Norway, rose from 6.2 for the years 1925 through 1954 to 10.8 for the years 1956 through 1965 (14) and then to 20.5 for the years 1973 through 1982 (15), values quite close to those in the United States. In Finland, where the incidence of type 1 diabetes is higher than in the United States, a steady increase in the incidence rate for children aged 1 to 14 has been documented since 1965, reaching a value of 44.8 per 100,000 per year in 1996. The increase was greatest in the age group 1 to 4 years (Table 20.2) (16).

During the period 1989 to 1994, 44 centers representing most European countries collaborated in a study of the time trend in incidence rate of type 1 diabetes. The average annual increase in incidence was 3.4% overall, but it varied among centers and by age. As in the Finnish study, the increase was steepest for the age group 0 to 4 years (6.3% per year) and lowest for the age group 10 to 14 years (17). The reason for the secular increase in the incidence of type 1 diabetes in so many populations is unclear. In several regards, this long-term trend in the occurrence of type 1 diabetes resembles aspects of the emergence of poliomyelitis early in the 20th century. It has been speculated

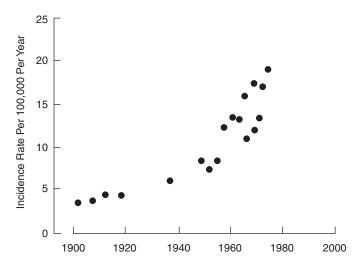

Figure 20.3. Incidence rate of type 1 diabetes in children in the white population of the United States from 1900 to 1976. (From Krolewski AS, Warram JH, Rand LI, et al. Epidemiologic approach to the etiology of type 1 diabetes mellitus and its complications. *N Engl J Med* 1987;317: 1390–1398.)

TABLE 20.2. Increase in the Incidence Rate (Per 100,000 Person-Years) of Type 1Diabetes in Children Younger Than 15 Years in Finland between 1965 and 1996				
	Incidence rates in indicated calendar time period			Increase (%)
Age group (y)	1965–1974	1975–1984	1985–1996	1965–1996
1–4	15.8	22.0	33.2	110
5–9	24.9	33.7	40.8	64
10-14	32.7	41.4	45.2	38

that, by analogy, delayed exposure to a common virus may predispose to autoimmunity involving β -cells (6).

Seasonal variability in diagnoses of type 1 diabetes attracted much attention in the 1970s (18,19). It has since been established, however, that type 1 diabetes has a long subclinical period, so the seasonal pattern in diagnoses presumably results from the seasonal occurrence of factors that precipitate the appearance of symptoms in asymptomatic cases (such as common infections) or that result in closer observation of children (such as the return to school). The issue has been revisited recently with data provided by 16 centers representing 11 countries in Europe plus Israel (20). In most populations, a sinusoidal model with the peak incidence in a winter month was statistically significant. Interestingly, the exceptions were the two Scandinavian countries represented in the analysis (Norway and Finland). The pattern did not vary by gender or age group.

Recently, some attention has focused on short-term (year-toyear) variability in the incidence of type 1 diabetes. An apparent epidemic during 1982 through 1984 was described in midwestern Poland (21). The incidence rate in children under 18 years old in those years was double that between 1970 and 1981. Similar "epidemics" in the U.S. Virgin Islands and Jefferson County, Alabama, in 1984 have been described (22,23). The basis for these variations remains unresolved, but many attempts have been made to link them with epidemics of infectious diseases. However, because the subclinical period for type 1 diabetes typically lasts for several years, it is difficult to establish an etiologic link between a specific infection and the diabetes "epidemic," if such a link does exist.

Environmental Triggers of Type 1 Diabetes

The long-term trend in the occurrence of type 1 diabetes resembles aspects of the emergence of poliomyelitis early in the 20th century and has prompted speculation that, by analogy, delayed exposure to a common virus may predispose to destruction of the β -cells (6). Epidemiologic evidence supporting this hypotheses is the low risk of type 1 diabetes associated with markers of crowding or early social mixing, such as attendance at day care centers (24,25). Evidence of the role of enteroviral infections, particularly Coxsackie B, has recently been reviewed (26). Markers of recent infection have been associated in many different circumstances with type 1 diabetes: the presence of antibodies at the time of onset of type 1 diabetes, at the onset of islet autoimmunity, and even in maternal serum obtained during the gestation of children who subsequently developed diabetes. Although acute destruction of the β -cells by a virus, as originally supposed, is incompatible with the long subclinical period during which islet-cell antibodies are detectable, viral infection may play a role as initiator of autoimmunity, as promoter of progression of autoimmunity to type 1 diabetes, or both (26).

Concern about early exposure to cow's milk protein as a trigger of β -cell autoimmunity and the subsequent development of type 1 diabetes in susceptible individuals receives a lot of attention. The epidemiologic evidence suggesting this hypothesis came from a case-control study that found a decreased frequency/duration of breastfeeding in cases. The effect could be due to a lack of a protective effect of breastfeeding or to exposure to an initiator of autoimmunity in cow's milk. Subsequent studies have been inconsistent in replicating this finding, and the overall small magnitude of the effect can plausibly be attributed to recall bias (27). Preliminary results of follow-up studies that monitor the appearance of autoimmunity to β -cells in highrisk infants and small children have not found any association with early exposure to cow's milk (28).

Clustering of Type 1 Diabetes in Families

Studies of the pattern of disease occurrence in families are another approach to evaluating the relative contributions of genes and environment to disease etiology. The study of twins provides an appealing simple design. The premise is that monozygotic twins carry identical genotypes but that dizygotic twins are no more similar genotypically than nontwin siblings. A more frequent concordance for diabetes among monozygotic twins than among dizygotic twins, therefore, favors a greater role of genetic factors. Unfortunately, the simplicity of the study design is negated by the small size of the twin population and the rarity of type 1 diabetes. The chief problems are the small sample size if the twin sample is population-based and uncertainty about ascertainment biases if it is not. With these caveats in mind, the best estimate of the concordance rate for type 1 diabetes in monozygotic twins appears to be in the neighborhood of 45%, whereas that for dizygotic twins is about 25% (29). While this result argues for a role of genes, it also supports a major role of environment. The concordance rate for monozygotic twins is far below 100%, indicating that genes are not a sufficient cause. Moreover, the concordance rate for dizygotic twins is higher than for nontwin siblings, presumably due to the greater sharing of environmental exposures by twin siblings than by nontwin siblings (29).

A more useful measure of familial aggregation is the sibling recurrence-risk ratio, which is defined as the ratio of the risk of disease in the siblings of cases to the risk in the general population. A ratio greater than 1 indicates familial aggregation. Although such aggregation is not exclusively the result of genetic factors and may reflect environmental exposures that are also shared by family members, strong familial aggregation (ratio greater than 6) is unlikely to be due solely to environmental exposures (30).

Three studies, two conducted at the Joslin Diabetes Center in Boston and one conducted at the Steno Hospital in Copenhagen, permit computation of the cumulative risk of diabetes up to age 50 years for the siblings of type 1 diabetes probands. In all three studies, the probands (patients with type 1 diabetes that brought the families into the study) were diagnosed before age 21 years. In the earlier Joslin Diabetes Center study, 289 probands were diagnosed during the years 1928 through 1938 and their 589 siblings were followed to a median age of 49 years (31). In the later Joslin study, 168 probands were diagnosed in the years 1948 through 1960 and their 335 siblings were followed to a median age of 41 years (32). In the Danish study, 187 probands were diagnosed during the years 1918 through 1944 and their 375 siblings were followed to a median age of 52 years (33). The three studies yielded almost identical estimates of the cumulative risks by age 50 years (Fig. 20.4). For comparison, the cumulative risk at age 50 years in the general population was calculated to be 0.5% (Table 20.1). Thus, the risk to siblings by age 50 years seems to be approximately 10%, or 20 times the risk in the general population.

A sibling recurrence-risk ratio of this magnitude (20 times the population risk) is strong evidence of the role of genes in the etiology of type 1 diabetes (see Chapter 23). However, it is important to note that the major histocompatibility locus (also known as *IDDM1*) on chromosome 6 is responsible for only half of the familial clustering of type 1 diabetes (34). The rest is presumably due to other genetic factors or shared family environment. Possible evidence of the impact of environment is suggested in the results of these three studies of the sibling recurrence risk. Despite the close agreement regarding the

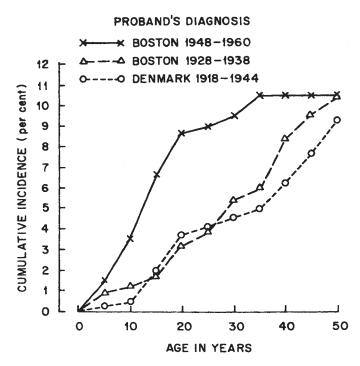

Figure 20.4. Cumulative incidence of type 1 diabetes in the siblings of probands with type 1 diabetes, as estimated in three different studies of families. (From Warram JH, Krolewski AS. Changing age-at-onset of diabetes in siblings of probands with insulin-dependent diabetes. *Am J Hum Gen* 1985;37[Suppl]:A208[abst].)

cumulative risk at age 50 years, there are interesting and statistically significant differences in the cumulative incidence rates at younger ages.

The cumulative risk of diabetes by age 15 years was 6.3% for the siblings of the 1950s cohort of the Joslin patients but only 1.7% and 1.9% for the siblings in the earlier Joslin and Danish studies, respectively. Results very similar to those of the recent Joslin study were reported for a study in Wisconsin of 194 probands with type 1 diabetes whose diagnosis was made before the age of 30 years during the years 1984 through 1987. The cumulative risk of type 1 diabetes was 10.5% by age 20 years in the sibling (35). This three- to fourfold increase in earlyonset diabetes in the siblings of recently diagnosed probands suggests that there is a shift toward a younger age at clinical onset of type 1 diabetes in a population enriched with susceptible individuals. The previously discussed secular trend in the incidence rates of type 1 diabetes in the general population of children younger than age 15 years also might reflect a shift toward earlier manifestation of type 1 diabetes in susceptible individuals (36).

Evidence consistent with this hypothesized interaction between susceptibility and a changing environment has come from a recent collaborative study of sibling recurrence risk in 15 European countries plus Israel (37). The country-specific sibling recurrence risk was highly correlated with the risk of diabetes in that country (Spearman correlation 0.71). Because the sharing of genes among siblings is the same in all populations, this correlation must be due to variation in environmental factors that have similar effects on the siblings of index cases and the general population.

Parent-offspring pairs are another type of first-degree familial relationship that can be examined for familial aggregation of type 1 diabetes. A few follow-up studies of children of a parent with type 1 diabetes permit estimation of the cumulative risk of type 1 diabetes in the offspring up to the age of 20 years. As was found for siblings, the risk is much higher than for the general population, but surprisingly, there is a significant difference between the rate for offspring of diabetic fathers and the rate for offspring of diabetic mothers. For the offspring of diabetic fathers, the cumulative incidence of type 1 diabetes by age 20 years is 6%, or 20 times that for the general population (38,39). For the offspring of diabetic mothers, the corresponding cumulative incidence is approximately 2%, which is only seven times that in the general population (40). In two small studies of offspring born to women who did not develop type 1 diabetes until after the birth of the child (41,42), the children appeared to have a risk of type 1 diabetes similar to that of the children of fathers with type 1 diabetes. These data suggest that exposure to a diabetic environment in utero may have a protective effect on the offspring, perhaps by inducing immunologic tolerance to the antigen involved in the autoimmune destruction of the pancreatic β -cells (41).

Another factor that seems to modify the clustering of type 1 diabetes in families is the age of the proband at onset of type 1 diabetes (43). Regardless of the gender of the diabetic parent in the studies just described, the risk for offspring was approximately two times higher if type 1 diabetes in the parent was diagnosed before the age of 11 years rather than later (Fig. 20.5). Similar results were obtained in a Danish study of offspring of parents with type 1 diabetes (42). These findings suggest that environmental factors played a larger role in the etiology of diabetes when the age at onset is older rather than younger.

The risk for offspring of mothers with type 1 diabetes was lower than that for offspring of fathers with type 1 diabetes regardless of the parent's age at diagnosis, and the pattern was the same if the offspring of diabetic mothers were further strat-

AGE OF DIAGNOSIS IN IDDM PARENT

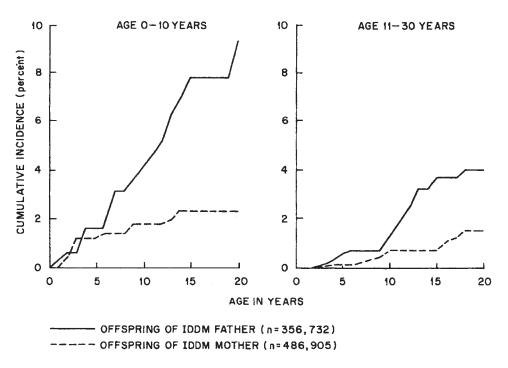

Figure 20.5. Cumulative incidence of type 1 diabetes in the offspring of a parent with type 1 diabetes according to gender and age at diagnosis of diabetes in the parent proband. (From El-Hashimy M, Angelico MC, Martin BC, et al. Factors modifying the risk of IDDM in offspring of an IDDM parent. *Diabetes* 1995;44: 295–299.)

ified by maternal age (data not shown). For simplicity, the cumulative-incidence curves in Figure 20.5 have been adjusted for maternal age by the direct method using the age distribution for the mothers of the total group of children (43). A similar agedependence of the recurrence risk in relatives has been reported for twin (29) and nontwin siblings (35).

In summary, large variation in the occurrence of type 1 diabetes within and between racial/ethnic groups has been amply demonstrated by population-based studies. The rising incidence rate in many of these populations points to the major role of environmental determinants in the occurrence of diabetes in susceptible individuals. Advances in our knowledge of genes responsible for susceptibility will depend heavily on study designs based on families. At the same time, studies of the pattern of occurrence of diabetes within families have already yielded some clues as to the nature of the environmental determinants of disease manifestation in susceptible individuals. To characterize both the genetic and environments factors underlying the complex etiology of type 1 diabetes, future research should emphasize study designs based on families rather than on geographic populations.

EPIDEMIOLOGY OF TYPE 2 DIABETES

For epidemiologic studies, diabetes that develops in adults may be considered as type 2 diabetes. While this unquestionably results in some misclassification of the type of diabetes, cases of type 1 diabetes represent a very small proportion of new cases of diabetes developing in adults (Table 20.1). In this chapter, we discuss the descriptive epidemiology of type 2 diabetes together with its major risk factors. In contrast to type 1 diabetes, data on incidence rates of type 2 diabetes are sparse. Therefore, to describe the occurrence of type 2 diabetes in human populations, we have supplemented the available incidence data with prevalence data. Data obtained on the U.S. population are preferentially cited in this chapter.

Variation in Occurrence of Type 2 Diabetes According to Age

The development of type 2 diabetes is profoundly influenced by attained age. For example, in the 1960s in the white population of Rochester, Minnesota, the incidence of type 2 diabetes increased from 10 per 100,000 to 612 per 100,000 person-years, respectively, for individuals aged 20 to 29 and 60 to 69 years (Table 20.1). Similar findings were obtained in cohort studies conducted in other populations (44–46). The profound effect of age on risk of type 2 diabetes has also been demonstrated in many cross-sectional studies, although the prevalence of diabetes in the oldest groups in such studies usually underestimates the cumulative risk due to high mortality (see Chapter 47).

The best data on the prevalence of diabetes, diagnosed as well as undiagnosed, are available from the National Health and Nutrition Examination Survey III (NHANES III) conducted between 1988 and 1994 (47). NHANES III describes a probability sample of 18,825 U.S. adults aged 20 years and older who were interviewed to ascertain the history of physician-diagnosed diabetes. A subsample of 6,587 adults had fasting plasma glucose values determined and diabetes diagnosed according to the 1997 criteria of the American Diabetes Association (47,48).

The overall prevalence of diagnosed diabetes in the adult US population was 5.1%. The prevalence of undiagnosed diabetes was 2.7%. In adults, the prevalence of diabetes in non-Hispanic blacks and Mexican Americans was 1.6 and 1.9 times higher, respectively, than in non-Hispanic whites. In all races, men and women had a similar prevalence of diabetes. The prevalence of type 2 diabetes, both diagnosed and undiagnosed, in the U.S. population according to attained age and race is shown in Figure 20.6. In all three groups, the total prevalence of diabetes rose rapidly from a range of 1.4% to 3.0% for age category 20 to 39 years to a range of 17.3% to 29.3% in age category 60 to 74 years, being lowest in all age categories for non-Hispanic whites. The prevalence of type 2 diabetes in individuals 75 years or older did not increase further, most likely as a result of higher mor-

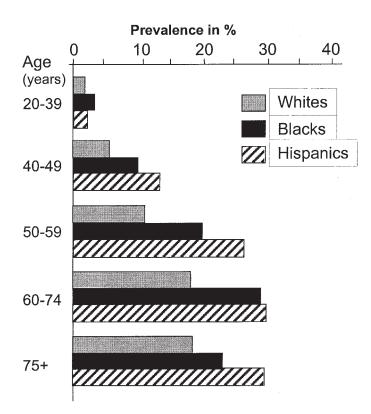

Figure 20.6. Prevalence of diagnosed and undiagnosed diabetes in U.S. adults by age and race or ethnic group based on data from the Third National Health and Nutrition Examination Survey, 1988–1994. (From Harris MI, Goldstein DE, Flegal KM, et al. Prevalence of diabetes, impaired fasting glucose, and impaired glucose tolerance in U.S. adults: the Third National Health and Nutritional Survey, 1988–1994. *Diabetes Care* 1998;21:518–524.)

tality in individuals with diabetes than in those without diabetes (see Chapter 47).

Variation in Incidence of Type 2 Diabetes According to Obesity

As early as 1921, Elliott P. Joslin published a report in which he showed that the risk of developing diabetes (type 2 according to our current criteria) was higher in obese than nonobese individuals (49). Similar findings were obtained in many subsequent case–control and cross-sectional studies, although the estimates of the effect varied due to problems associated with unreliable measurement of obesity, lack of distinction between type 1 and type 2 diabetes, and selection of unrepresentative study groups.

Over the last decade, excellent data on the risk of developing type 2 diabetes according to various indices of body weight have been obtained in several prospective studies. In the largest of these, the 14-year follow-up of the Nurses' Health Study, 2,204 new cases of type 2 diabetes were observed during 1.5 million person-years of observation (50). The age-adjusted incidence rates of type 2 diabetes increased continuously with increasing body weight (Fig. 20.7). An association of risk with increasing weight was evident even within the nonobese range. The incidence rate increased from 13 to 104 per 100,000 personyears comparing women whose body mass index (BMI) was in the range "less than 22" to those whose BMI was in the range "25 to 26.9." Although this was a steep gradient, the largest absolute increases in risk were found in the obese range. From

Incidence per 100,000 person-years

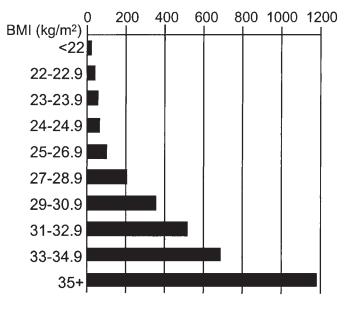

Figure 20.7. Incidence of type 2 diabetes according to body mass index (BMI) in a large cohort of US women followed up for 14 years. (From Colditz GA, Willett WC, Rotnitzky A, et al. Weight gain as a risk factor for clinical diabetes mellitus in women. *Ann Intern Med* 1995; 122: 481–486.)

the lowest BMI group in the obese range "27 to 28.9" to the highest "35+," the incidence rate rose from 200 to 1,190 per 100,000 person-years. The most extreme level of obesity (35+) represented only 3% of the population but contributed 26% of the incidence cases of type 2 diabetes. Both a high weight before age 18 years and a large weight gain during adulthood (after age 18 years) contributed significantly to the risk of subsequent type 2 diabetes. However, BMI at the baseline of the follow-up (age range, 30 to 55 years) had the most significant impact on the risk of type 2 diabetes (Fig. 20.7). Similar findings were obtained during follow-up for 5 years of a cohort of 51,529 U.S. male health professionals, 40 to 75 years of age at baseline (51), as well as in several other prospective studies (52–55).

Most studies used BMI as the measure of obesity. However, it has been postulated that fat mass, particularly visceral fat mass, is associated with insulin resistance and that indices of visceral fat such as waist-hip ratio or waist circumference might therefore be better predictors of risk of type 2 diabetes (56). These issues were examined specifically in one of the reports from the Nurses' Health Study (57). The total cohort was divided into quintiles of BMI, and each quintile was divided further according to classes of waist-hip ratio or waist circumference. In each quintile of BMI, the risk of type 2 diabetes increased steadily with higher class of waist-hip ratio or waist circumference. Interestingly, the latter was a much stronger predictor of the risk of type 2 diabetes than the former. When the data were adjusted for other covariates and controlled for BMI, the relative risk of type 2 diabetes for the 90th percentile of waist circumference (97 cm) versus the 10th percentile (67 cm) was 5.1 (95% confidence interval, 2.9 to 8.9). It is important to emphasize that, in models that included both BMI and waist circumference, BMI remained a strong predictor of risk of type 2 diabetes, although its effect was attenuated. Similar findings were reported in the follow-up study of the U.S. male health professionals (51). However, in this very large study of males, the effect of baseline BMI on the risk of type 2

348 JOSLIN'S DIABETES MELLITUS

diabetes was much stronger and the effect of waist circumference much weaker than in the Nurses' Health Study (57). Many other studies examined these issues and indicated a more significant role of visceral fat than BMI on the risk of type 2 diabetes. However, most of these studies did not have sufficient statistical power to dissect the independent effects of visceral fat as opposed to total fat reflected in BMI.

Variation in Incidence of Type 2 Diabetes According to Physical Activity

Although ecologic studies have suggested an inverse relationship between physical activity and the risk of type 2 diabetes, only recently has direct evidence of a protective effect of regular physical activity emerged from several large prospective studies. The earliest study was conducted in male alumni of the University of Pennsylvania and showed the beneficial effect of exercise primarily among those who were obese or had a family history of diabetes (52). In the Physicians' Health Study, which followed 21,271 male physicians for 5 years, a protective effect of exercise against type 2 diabetes also was demonstrated, and again the effect was mainly in obese physicians (58). Similar conclusions were drawn from a follow-up study among middle-aged Finnish men (59). In women, the protective effect of exercise against type 2 diabetes seems to be more universal. For example, the Nurses' Health Study showed that the protective effect of exercise against type 2 diabetes was similar in obese and nonobese individuals and in those with and without a family history of diabetes (60,61) (Fig. 20.8). Similar observations were made in a 12-year followup study of 34,257 women aged 55 to 69 years participating in the Iowa Women's Health Study Cohort (62).

The dose response between intensity of physical activity and risk of type 2 diabetes was estimated in most of the studies. In three studies in men (52,58,59), the risk of type 2 diabetes decreased with increasing amounts of exercise, whereas in the three other studies in women (60–62), the degree of protection against type 2 diabetes was the same in the subjects who exercised the most as it was in those who exercised only moderately. In summary, however, all studies showed that individuals with a modest level of exercise had a significantly lower risk of type 2 diabetes than did those who were completely sedentary. When adjusted for other risk factors, the relative risk of type 2 diabetes in individuals with a modest level of exercise ranged between 0.69 and 0.74 in comparison with the risk in individuals with a sedentary lifestyle.

Secular Trends in Occurrence of Type 2 Diabetes

The occurrence of type 2 diabetes has been increasing in the U.S. population over the last 50 years. The following review considers incidence and prevalence data separately. Whereas incidence measures directly the changes over time in the risk of diabetes, prevalence may reflect changes not only in risk over time but also in survival of individuals with diabetes.

The best incidence data on the occurrence of type 2 diabetes over the last 50 years were obtained in the population of Rochester, Minnesota (63). In that population, which is predominantly white and serves as a population laboratory for investigation of human diseases, all individuals older than 30 years and with newly diagnosed type 2 diabetes were identified during the period 1945 through 1989. The age-adjusted incidence rates for four periods within that interval are shown in Figure 20.9 accord-

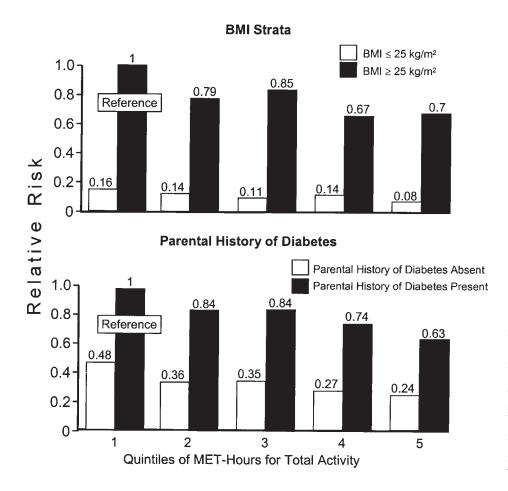

Figure 20.8. Relative risk of type 2 diabetes according to quintile of physical activity as measured by the metabolic equivalent task (MET) score, which is based on time spent per week on each of eight common physical activities, including walking. The results are stratified according to body mass index (BMI) and parental history of diabetes and were adjusted for other covariates. (From Hu FB, Sigal RJ, Rich-Edwards JW, et al. Walking compared with vigorous physical activity and risk of type 2 diabetes in women: a prospective study. *JAMA* 1999;282:1433–1439.)

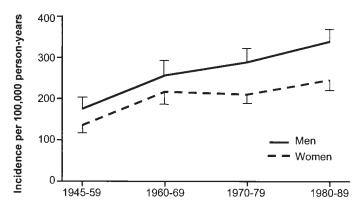

Figure 20.9. Age-adjusted, sex-specific incidence rates (95% confidence intervals represented by bars) for type 2 diabetes according to calendar time in adult residents of Rochester, Minnesota. (From Leibson CL, O'Brien PC, Atjinson E, et al. Relative contribution of incidence and survival to increasing prevalence of adult-onset diabetes mellitus: a population-based study. Am J Epidemiol 1997;146:12-22.)

ing to gender. The rates were higher in men than in women, and they increased between the periods 1945 through 1959 and 1980 through 1989: in men from 174 per 100,000 to 331 per 100,000 person-years and in women from 135 per 100,000 to 239 per 100,000 person-years. This represents an increase of 90% in men and 77% in women. Interestingly, similar methodology was used to analyze an additional period, 1990 through 1994, and the incidence rates for type 2 diabetes had further increased significantly to 449 per 100,000 person-years in men and to 319 per 100,000 personyears in women (64). These increases could not be accounted for by more active screening for undiagnosed diabetes.

There are only a few other reports that examined the incidence of type 2 diabetes according to calendar time. Reported trends in diabetes incidence rates based on data from the National Health Interview Surveys during the period 1935 through 1968 are very similar to those observed in the Rochester population over the period 1945 through 1969. Subsequently, the rates rose in the Rochester population but in the National Health Interview Survey, data showed no change in the incidence of type 2 diabetes since 1968 (65). In contrast to the latter, a study by the Centers for Disease Control and Prevention (CDC) found a 48% increase in the incidence of self-reported diabetes between 1980 and 1994 in the U.S. population (66). A study in Cincinnati, Ohio, was conducted to determine the

occurrence of type 2 diabetes in adolescents (67). The incidence of type 2 diabetes in adolescents increased in that area from 0.7 per 100,000 person-years in 1982 to 7.2 per 100,000 person-years in 1994. Recent results from the San Antonio Heart Study also showed a rapid increase in the incidence of type 2 diabetes in an adult population (68). During the period 1980 and 1987, the incidence rates of diagnosed and undiagnosed type 2 diabetes increased in Mexican Americans and non-Hispanic whites by 95% and 63%, respectively. After adjustment for other risk factors, including BMI, the increase in incidence according to calendar time was significant in Mexican Americans and borderline in non-Hispanic whites.

There have been many studies demonstrating an increasing prevalence of diabetes during the last century. Once again, the most reliable data on the prevalence of diagnosed diabetes according to calendar time were obtained for the population of Rochester, Minnesota (63). The age- and sex-adjusted prevalence of type 2 diabetes in the population aged 45 years in the census years 1970, 1980, and 1990 increased from 3.5% to 4.5% and then to 5.1%, respectively. Trends in the prevalence of self-reported diabetes were examined in telephone surveys conducted by CDC in random samples of adults in 50 states for the period 1990 to 1998 (69). Overall, the prevalence of diabetes rose from 4.9% to 6.5% during this period, and the increase was similar across sexes, races, and education levels. Table 20.3 shows the changes in diabetes prevalence according to age. The highest increase in prevalence of type 2 diabetes occurred in the age category 30 to 59 years. The interpretation of these data should be qualified, however, because only physician-diagnosed diabetes was considered. It is possible that the observed increase in prevalence was the results of improved ascertainment of patients with undiagnosed diabetes. However, this interpretation is not supported by the results on prevalence of type 2 diabetes obtained in NHANES II and NHANES III. With use of the recently adopted American Diabetes Association (ADA) criteria for a diagnosis of type 2 diabetes, the prevalence of diagnosed and undiagnosed diabetes in the U.S. population 40 to 74 years of age increased from 8.8% in 1976 through 1980 to 12.3% in 1988 through 1994 (47).

In summary, the prevalence of type 2 diabetes has been increasing in the U.S. population and this is accounted for in large part by an increased incidence of type 2 diabetes and not by increased survival of patients with diabetes (63). This increase seems to have accelerated during the last 20 years. Although there have not been direct studies, the increases in incidence and prevalence of type 2 diabetes seem to follow an increase in occurrence of obesity in the U.S. population (70).

Variation in Occurrence of Type 2 Diabetes among Races and Countries

Consideration of geographic and ethnic differences in the occurrence of type 2 diabetes can be used to evaluate environmental as well as genetic determinants of diabetes. Because the occurrence of type 2 diabetes is similar in men and women, we simplified this review by presenting the prevalence of type 2 diabetes for one sex (men) and for a specific age range (30 to 64 years). The latter can be considered a rough estimate of the cumulative incidence of diabetes by age 50 years. To the extent possible, we have used only previously published data from various population studies conducted in the late 1970s and in the 1980s that were age-standardized and included diagnosed and undiagnosed diabetes (71).

The prevalence of diagnosed and undiagnosed type 2 diabetes in various ethnic groups in the United States and around the world is summarized in Figure 20.10. The highest prevalence of type 2 diabetes is in the Pima and Papago Indians in Arizona. By age 50 years, almost one half of this Native-American population had diabetes. This is an extraordinary high prevalence of diabetes. Most likely, this results from the combination of the extremely high prevalence of obesity in that population together with a high frequency of genetic susceptibility to type 2 diabetes. Other populations of Native Americans also have a high prevalence of type 2 diabetes in the Pima and Papago Indians (77). The next highest prevalence of type 2 diabetes in the United States is in Mex-

ican Americans living in the states bordering Mexico. The prevalence in non-Hispanic whites is less than half that in Mexican Americans, while that for non-Hispanic blacks is intermediate between the two. Note that this ranking of the three racial groups according to the prevalence of type 2 diabetes (based on NHANES II in 1976 to 1980) persisted in the 1988 to 1994 NHANES III data (Fig. 20.6) despite the increasing prevalence of type 2 diabetes between the two surveys (47).

The prevalence of type 2 diabetes in European populations is similar or slightly lower than that in the non-Hispanic white U.S. population, indicating a similarity of environmental and genetic determinants in the two locations. On the other hand, the prevalence of type 2 diabetes is much lower in blacks in Africa than in non-Hispanic blacks in the United States. Although the explanation for these differences is unknown, a recent study showed that a large proportion of this variability could be accounted for by differences in BMI (78).

Significant differences in the prevalence of type 2 diabetes according to location were observed for three other racial/ethnic groups (Fig. 20.10). The prevalence of type 2 diabetes is very low in Chinese in Mainland China, intermediate in Chinese in Singapore, and very high in Chinese living on the island of Mauritius in the Indian Ocean. Prevalence data for Indians are somehow more complicated. The prevalence of diabetes is moderate in rural India, high in urban India, and high or very high in Indians in many other countries where the prevalence of type 2 diabetes in the aboriginal populations is very low (e.g., Tanzania or Fiji) (71). These data indicate that Indians as an eth-

nic group have a high risk of type 2 diabetes, most likely due to genetic susceptibility.

In summary, there is large variability in the occurrence of type 2 diabetes according to racial/ethnic group. Large variability in the occurrence of type 2 diabetes within the same racial/ethnic group (e.g., the Chinese) according to geography may be accounted for by different frequencies of environmental factors, such as physical activity and obesity in each of these locations. On the other hand, the very high or high prevalence of type 2 diabetes in Native Americans and in Indians is most likely the result of interactions between a high population frequency of genetic susceptibility to type 2 diabetes and very high prevalence of environmental factors such obesity, physical inactivity, or other, as yet unknown, risk factors.

Clustering of Type 2 Diabetes in Families

As alluded to in the previous section, type 2 diabetes has a complex etiology involving both environmental exposures and genetic susceptibility. To select the most effective study designs for evaluating the role of genetic susceptibility and to devise strategies for identifying susceptibility genes for type 2 diabetes, one has to obtain specific information about the pattern of aggregation of diabetes in families of index cases with type 2 diabetes.

A widely used measure of familial aggregation is the sibling recurrence-risk ratio, designated λ_{S} , which is defined as the ratio of the risk of disease manifestation in siblings of cases compared with the disease risk in the general population (79,80). A ratio above unity suggests familial aggregation. Pincus and White (81), almost 70 years ago, were the first to use this kind of approach to describe aggregation of diabetes in families of index cases attending the Joslin Clinic. However, they and many subsequent researchers used various choices other than the general population risk for the reference risk; for example, the prevalence of diabetes in siblings of individuals without diabetes or in siblings of individuals with diabetes who had no parent with diabetes (82–88). These values underestimate the population risk and, therefore, overestimate familial aggregation.

As part of our efforts to identify informative families for mapping genes for type 2 diabetes diagnosed in middle age, we surveyed a random sample (N = 563) of such patients at the Joslin Clinic in Boston, Massachusetts, to obtain information about the occurrence of diabetes in their relatives. In the published report, we examined the λ_s for type 2 diabetes in these families according to parental history of diabetes and selected phenotypic characteristics of index cases (89).

Estimates of the sibling recurrence risk of type 2 diabetes obtained in our study and three other studies conducted in US white families are summarized in Table 20.4. The data in the three other studies were reanalyzed, and the results of all four studies were compared with the general population risk at comparable ages based on NHANES III (47). The first study was conducted in a population-based sample of patients with type 2 diabetes enrolled into the Wisconsin Epidemiologic Study of Diabetic Retinopathy (86). Index cases (N = 923) were aged 68 years (on average) at examination and were questioned about the history of diabetes in their families. The prevalence of diabetes in their 3,965 siblings was reported according to parental diabetes status. If neither parent had diabetes, the prevalence of diabetes in the siblings was 10.4%. If one parent was affected with diabetes, the prevalence of diabetes in siblings was 17.8%, and if both parents were affected, the prevalence of diabetes increased to 25.2% (Table 20.4). The second study, involving 9,164 index cases with type 2 diabetes and their 25,659 siblings, obtained results almost identical to those of the first study (87). In addition to the two studies of siblings of index cases, a recent report described the occurrence of diabetes in the offspring of the Framingham Heart Study population according to the parents' diabetes status (88). Diabetes in the offspring was ascertained by history and by examination during 20 years of followup. Unlike the other studies, parental diabetes was ascertained directly by examination of the parents during 40 years of follow-up rather than being based on the report of an offspring. The prevalence of diabetes in the offspring with no diabetic parent was 6.1%, 16.5% in offspring with one diabetic parent, and 26.2% in offspring of two diabetic parents. It is remarkable that the prevalence of diabetes in the offspring is so similar to the prevalence of diabetes in siblings in the two other studies. Our

study is the fourth summarized in Table 20.4. The frequency of occurrence of diabetes in the siblings is presented as cumulative risk by age 65 years. The cumulative risks of diabetes in siblings of index cases with no diabetic parent, one diabetic parent, and two diabetic parents were 14.0%, 29.2%, and 41.9%, respectively.

Recurrence-risk ratios (sibling or offspring) according to parental history of diabetes (Table 20.4) were obtained by dividing the prevalence in each study by the corresponding age-specific prevalence of diagnosed diabetes in NHANES III (47). In all studies, siblings of index cases without a history of parental diabetes had a risk of diabetes similar to that in the general population, suggesting that the contribution of a genetic component was inconsequential in this subgroup. The λ_S was elevated only in families with one or two diabetic parents. The ratios are quite consistent across studies. For example, in families with one diabetic parent, it ranged from a low of 1.6 to a high of 2.6 for the estimate based on cumulative incidence. The distribution of index cases according to parental history of diabetes varied among the studies, with the proportion with a positive parental history being highest in the our study based on patients at the Joslin Clinic. An overall λ_S for comparisons among the studies of siblings was obtained by standardizing the rates specific to each type of parental history in each study to the distribution of parental histories of diabetes in the Wisconsin study, the only population-based sample of index cases. The adjusted λ_s for our study is lower than the unadjusted value because of the reduced weight given to families with affected parents. The overall estimates of λ_S from these three studies ranged from 1.2 to 1.8.

In our study we found that the λ_s of type 2 diabetes was particularly high ($\lambda_s = 3.5$) if a parent and grandparent reported diabetes. Moreover, if the family history of diabetes was an affected grandparent, aunt, or uncle *instead of a parent*, the risk was similar to that in families with no history of diabetes (13.2% \pm 2.5%) and not different from the risk in the general population. Therefore, the risk of diabetes appeared to be transmitted primarily through affected rather than unaffected parents. This is consistent with the low (meaning similar to the general population) λ_s for type 2 diabetes in families with no affected parents. In the population-based Wisconsin Epidemiologic Study of Diabetic Retinopathy, 31% of the index cases with type 2 diabetes reported a parent with diabetes, whereas the proportion with a diabetic parent in our study was 50%.

To examine whether familial aggregation of type 2 diabetes varied with the age at diagnosis of diabetes, we partitioned the families at the mean age at diagnosis in the index case (47 years) (89). The cumulative incidence of diabetes by age 65 years in the siblings of index cases with a diagnosis of diabetes at young ages (28.4%) was significantly higher than that in the siblings of index cases with a diagnosis at an older age (19.9%). This difference largely vanished when the siblings were also stratified according to the number of affected parents. A young age at diagnosis of diabetes was itself associated with a history of diabetes in one or both parents: 62.3% of the index cases who were young at diagnosis reported an affected parent as compared with 46.7% of those who were older at diagnosis.

Obesity in the index case was associated with a reduced recurrent risk of type 2 diabetes in siblings. In families with no parental history of diabetes, the siblings of obese index cases had the same diabetes risk as obese individuals in the general population ($\lambda_S = 0.9$), whereas the risk in siblings of nonobese index cases was twice that in the nonobese general population ($\lambda_S = 2.1$) (89). If the nonobese index case had an affected parent, λ_S increased to 4.1. The significant clustering of diabetes in sib-

lings of nonobese index cases points to an important role of genetic susceptibility to type 2 diabetes in the families of nonobese index cases and stands in contrast to the absence of evidence of a role of genetic susceptibility in the families of obese index cases. This conclusion is consistent with epidemiologic observations that obesity and a family history of diabetes are independent risk factors for the development of type 2 diabetes (90–93).

Overall, a family history of diabetes, particularly in parents, is a significant risk factor for the development of type 2 diabetes. However, it accounts for only a moderate proportion of cases with type 2 diabetes in the general population. At most, the proportion is 31%, which was the frequency of parental diabetes in the population-based Wisconsin study (86). The $\lambda_{\rm S}$ for type 2 diabetes is low ($\lambda_{\rm S} = 1.8$). This is consistent with a hypothesis that type 2 diabetes is a complex disease caused by both environmental and genetic factors. With such a low λ_S , the identification of the genetic factors may be a challenging task. Based on the results discussed above, an optimal strategy for collecting families for linkage studies would be to select families through nonobese probands with type 2 diabetes or probands with a history of "vertical" transmission through an affected grandparent and a parent. Restriction of family ascertainment in this manner would reduce heterogeneity at both the phenotypic and genetic levels and therefore would make the task of findings the putative susceptibility genes for type 2 diabetes feasible.

It has long been recognized that certain forms of diabetes cluster within families. In families with type 1 diabetes, the risk of developing disease increases with genetic relatedness to a proband. Defining the underlying mechanisms of genetic susceptibility has been an important goal of research in type 1 diabetes for a number of reasons. Identification of genes that contribute to the risk of type 1 diabetes should provide new insights into the underlying mechanism of disease development and create new opportunities for therapeutic intervention. Definition of the genetic factors that predispose to type 1 diabetes should enhance the ability to predict who in the population may be at risk for type 1 diabetes, and such improved prediction may facilitate the development of novel preventive therapies. For example, the size of clinical trials could be reduced and the risks of therapies with potential side effects could be balanced by increased confidence that a highly specific "at-risk" population was being targeted.

Beginning in the early 1980s, the development of new tools and technologies for genetic-linkage analysis and positional cloning has resulted in the identification of genes underlying many genetic disorders. However, for type 1 diabetes, and indeed for most autoimmune disorders, progress toward identifying the underlying susceptibility genes has been slow. At the heart of this problem is the fact that these disorders share a common complicating factor for genetic studies—their mode of inheritance is unknown. The greatest single risk factor for type 1 diabetes is having an identical (monozygotic) twin with the disorder. However, the concordance rate for monozygotic twins is far less than 100%, with most studies placing the rate in the range of 25% to 50% (1). Concordance rates in monozygotic twins reflect the total familial contribution to risk, some of which will also be environmental, further lessening the expected role of genetic risk factors. This means that environmental factors, familial and nonfamilial, likely account for a significant fraction of the risk of developing type 1 diabetes.

Risk for type 1 diabetes declines as genetic relatedness to a proband in a family declines but remains elevated relative to the population risk in first-, second-, and even third-degree relatives of a proband. The risk to siblings of a proband is not significantly different from that to offspring, suggesting that the genetic variance in type 1 diabetes is additive. Under a strictly additive model, the relationship between genetic relatedness to a proband and risk of type 1 diabetes should be a linear function of the population prevalence. However, an examination of the risk of type 1 diabetes in second- and third-degree relatives suggests a nonlinear relationship. This argues against the possibility that a single locus with reduced penetrance accounts for type 1 diabetes risk and is most consistent with models in which multiple genes combine in an additive fashion to confer risk (2).

The combination of a substantial environmental component to risk and the presumed actions of an unspecified number of genes conspires to obscure the relationship between the genotype at any specific locus and the phenotype of type 1 diabetes. The weakness of this link between the disease phenotype and underlying genotype complicates efforts to define the underlying genetic elements responsible for susceptibility by geneticlinkage approaches. In a linkage-based approach, an investigator searches the genome in a systematic manner, typically by genotyping polymorphic markers spaced at defined intervals, in the hope of identifying markers that cosegregate with disease. Linkage approaches are very powerful and have resulted in the identification of genes responsible for many inherited disorders with known modes of inheritance. However, when applied to a genetically complex disorder, like type 1 diabetes, the inability of the investigator to specify a known mode of inheritance for the disorder can dramatically reduce the power of this approach. As a result, many investigators have turned to other approaches for mapping and identifying type 1 diabetes genes that, while less powerful, are relatively model-independent. The two general categories of approaches that have been used most extensively are those designed to detect allelic association and those that use identity-by-descent methods for the detection of linkage.

GENETIC APPROACHES TO IDENTIFICATION OF SUSCEPTIBILITY GENES IN COMPLEX DISORDERS

Linkage Mapping Approaches

Because of the difficulties in applying traditional parametric approaches for detecting linkage to complex disorders, many investigators have opted for less powerful, but more flexible, nonparametric approaches. As with traditional parametric approaches, a systematic scan of the entire genome using regularly spaced polymorphic markers is carried out. However, the individuals used in these analyses are affected relative pairs most commonly affected sibling pairs (ASPs). The rationale is that relatives who share a disease phenotype are more likely to share whatever genetic elements act to increase familial aggregation for that phenotype. Thus, the investigator searches for regions of the genome that are more frequently shared among affected relative pairs than would be expected by chance. These approaches to mapping can be carried out with only the affected sibling (sib) pairs. However, substantially greater power to detect linkage can be achieved if parental genotypes are also available either by direct determination or by inference through the genotyping of additional relatives, so that alleles identical by descent can be identified in the affected offspring.

Equally as important as the methodology used for the mapping of susceptibility genes are the criteria used for assessing what constitutes significant evidence of genetic linkage. The strength of the evidence for linkage at a given site in a genome scan is typically reported in the form of a LOD (logarithm of the odds) score, a z score, or a p value. Although these different measures can all be interconverted, there are important distinctions between them. An LOD score is the log-likelihood ratio of the data under the hypothesis that the proportion of alleles shared has the observed value as compared with the hypothesis that there is no excess of allele sharing. Sometimes, this value is reported as a maximized LOD score (MLS), indicating that it has been maximized over a series of parameters. A z score represents the number of standard deviations by which the observed proportion of alleles shared between ASPs exceeds 0.50. The p value represents the chance of the observed deviation in allele sharing under independent assortment. In evaluating such significance measures, it is important to distinguish between locus-specific, or point-wise, significance and genomewide significance. Point-wise significance refers to the evaluation of a single test of a hypothesis of linkage at one point in the genome. Genome-wide significance requires that results meet a much higher standard since it reflects the evaluation of multiple tests performed at markers spanning the genome (as in a genome scan) to find the most significant results.

Completing a genome-wide scan for linkage in a collection of nuclear families with reasonable power (3) (e.g., 100 to 200) requires a significant effort. Therefore, investigators are anxious to have some positive findings to report. This enthusiasm must, however, be balanced with the recognition that accumulating large numbers of reported linkages that do not reproduce in subsequent studies is counterproductive. Several investigators have suggested guidelines for evaluating the significance of findings in human genome scans that involve a series of thresholds corresponding to the likelihood of observing a given effect on allele sharing due to random chance (4,5). These classifications are as follows: (a) *suggestive linkage* is statistical evidence that would be expected to arise one time at random in a genome-wide scan and corresponds to a *p* value of 7.4×10^{-4} or, in ASPs, to an MLS or LOD of 2.2; (b) *significant linkage* is statistical evidence expected to arise 0.05 times in a genome-wide scan and corresponds to a *p* value of 2.2×10^{-5} or an LOD of 3.6; (b) highly significant linkage is statistical evidence expected to occur only 0.001 times in a genome-wide scan and corresponds to a *p* value of 3×10^{-7} or an LOD of 5.4. These guidelines are helpful in evaluating the relative strength of findings of linkage at different sites in the genome and will be used throughout this chapter with these meanings. However, it is important to remember that these are only guidelines; excessive adherence to fixed thresholds for significance may exclude important findings.

A convenient metric for quantitating the contributions of inheritance to risk in genetically complex disorders, such as type 1 diabetes, is the term λ (6), which is the ratio of the risk to an individual with a defined relation to an affected proband to the population risk for a given disorder. For example, for type 1 diabetes in the white population in the United States, the risk to

a sibling of an affected proband is approximately 6%, whereas the population risk is approximately 0.4%, yielding a λ s value (λ for affected sib pairs) of approximately 15. Higher λ values correspond to greater familial contributions to risk. Thus, complex disorders with higher λ values are more likely to be amenable to genetic-mapping approaches targeted at identifying the genes that contribute to susceptibility. λ can also be used to quantitate the contribution of individual loci by comparing the observed frequency of ASPs who share no parental alleles for a given marker to the expected frequency if inheritance at the locus is random (0.25). Locus-specific λ values, calculated in this way, can be used to rank the contributions of individual loci and, with some assumptions about the way in which different loci might interact, to estimate the contribution of individual loci to the overall λ for the disorder. In addition, λ values can be used as a tool to estimate the power of a study to detect linkage. The number of ASPs necessary to detect a locus of a given effect can be estimated prior to collecting data, and, conversely, the power to exclude linkage for a locus with a given λ value can be calculated for an existing data set.

Association Approaches

Association studies seek to identify alleles at polymorphic markers that are significantly over- or underrepresented among unrelated cases as compared with controls. In the ideal situation, such a result arises because the polymorphism under study is directly involved in disease predisposition. Consequently, association studies tend to focus on specific candidate genes where there is some a priori expectation that the polymorphism under study might affect gene function and that the gene might be involved in the development of type 1 diabetes. A given marker tested by such an approach also may detect association that does not reflect direct involvement of the tested polymorphism in the disease process. Again, in an idealized situation, this result can occur when alleles at the true disease-predisposing locus are either physically close to the marker under study or of recent origin. Such a condition arises when there has not been sufficient time for recombination to randomize the relationship between alleles at the two polymorphic sites. Alleles at such loci are said to be in linkage disequilibrium. The ability to indirectly sample the role of multiple polymorphic loci using a single marker via linkage disequilibrium is a potential advantage of the association approach but also necessitates careful follow-up studies in the event of a positive result to determine where the biologically relevant polymorphisms are located. Allelic association with disease also can arise for spurious reasons, the most common being that there is unrecognized structure in the population being studied such that marker allele frequencies differ between cases and controls at loci that are not linked to a disease-causing polymorphism.

Association studies often are done in a case–control format in which allele frequencies or population frequencies for a marker under study are compared between affected and unaffected populations. The case–control format is appealing because it is relatively easy to ascertain subjects for such a study and the overall number of genotypes required is generally less than for family studies. However, there are also some familybased approaches for detecting allelic association that reduce the risk of errors due to unrecognized structure in the case or control population. These approaches require information from additional unaffected relatives of the cases to establish parental genotypes for the marker under study. These family-based tests fall into two broad categories. One category is typified by the "haplotype relative risk" or HRR approach, in which allele frequencies are compared using the pools of parental alleles (7–9) transmitted or not transmitted to affected offspring as the case and control groups, respectively. The other category includes variants of the transmission/disequilibrium test (TDT), in which actual transmissions from heterozygous parents to affected offspring are tallied on a family-by-family basis (10). The TDT is, in reality, a test for both linkage and association and builds on the fact that, whereas linkage at a given marker can be detected in the absence of association, true association should not occur in the absence of linkage. Family-based methods for association testing are much more resistant to errors arising from population structure. Indeed, on theoretical grounds, the TDT is unaffected by such effects, making it the method of choice in populations in which structure cannot be ruled out (11).

Although a well-designed case-control study with carefully selected subjects should be relatively free from errors arising from population substructure, family-based approaches for detecting association still have definite advantages. In the case of type 1 diabetes, where the disease has a relatively early age at onset, the challenge in obtaining biologic samples from both parents and an affected child ("trios") is much reduced. Currently, the primary applications of association testing are in the evaluation of candidate genes and the narrowing of regions implicated in linkage studies as possibly containing type 1 diabetes susceptibility genes. However, genome-wide association testing is theoretically possible and may ultimately become the preferred approach for mapping genes in complex diseases such as type 1 diabetes (12). Implementation of such an approach is currently limited by the lack of an established method for evaluating the statistical evidence for association at specific sites in the face of the huge volume of tests that would need to be performed to extend such an approach across the genome. In addition, the density of markers required to carry out a comprehensive genome-wide scan for association is theoretically quite large and could potentially overwhelm the laboratory methods currently in use for genotyping (13). However, recent studies indicating that the human genome can be parsed into "haplotype blocks" of relatively modest diversity raise hopes that whole-genome association studies might be accomplished using a selected set of polymorphic markers that effectively tag these blocks (14-17). Such an approach will require the definition of haplotype blocks present in human populations—a haplotype map.

Positional Cloning and Gene Identification

Association-based and linkage-based approaches identify only the regions that may contain susceptibility genes; a significant effort is still required in any such region to determine unambiguously the identity of the gene or genes that contribute to susceptibility. Linkage approaches have some advantages over association studies as an initial screening tool for identifying candidate regions, because linkage can typically be detected over greater distances than can association. However, this strength of linkage-based approaches is a weakness at the next step of gene identification, because the regions that are identified in such studies often span tens of millions of nucleotides and encompass numerous genes. Since it is impossible in a genetically complex disorder to identify families that are truly linked to a particular susceptibility gene and separate them from those that share parental alleles by chance alone, observed recombination events cannot be used to define a more restricted region containing the gene of interest. Indeed, the standard approach to limiting such regions further has been to carry out association studies using markers within the region. In contrast to linkage-based approaches, association studies, if positive,

implicate genes within a much narrower physical region, because linkage disequilibrium typically does not extend over large physical distances unless the study population is inbred and/or has passed through a population bottleneck in recent history (13). However, this means that most candidate markers or genes tested for association will return nonpositive results. Because association studies do not provide exclusionary data, they are difficult to apply systematically. Genome-wide linkage disequilibrium or haplotype maps, when available, should help to address this problem (14-17). Ultimately, regardless of the approach taken, genetic information alone will not identify susceptibility genes in a complex disorder such as type 1 diabetes. Biologic studies will usually be required to demonstrate that a given allele or group of alleles has an effect on the function of a gene or its product and that the gene or its product plays a role in the pathogenesis of type 1 diabetes.

THE SEARCH FOR TYPE 1 DIABETES SUSCEPTIBILITY GENES

A relatively large number of chromosomal regions have been implicated as harboring susceptibility genes for type 1 diabetes on the basis of results from genetic linkage or association studies. Two, the HLA and insulin gene regions, are generally accepted and have been designated IDDM1 and IDDM2, respectively. Both IDDM1 and IDDM2 were initially identified by association testing in a case-control format (18,19) and subsequently confirmed by linkage studies and further familybased association testing (20-23). A comparison of observed-toexpected allele sharing in ASPs for markers within the HLA region suggests that a substantial fraction (on the order of 50%) of the familial risk for type 1 diabetes is contributed by the inheritance of genes within this region (24). The contribution of the insulin gene region is substantially less and is estimated to account for only 8% to 10% of the familial risk for type 1 diabetes (20). Additional putative type 1 diabetes susceptibility loci designated IDDM3 to IDDM15 and IDDM18 have been defined on the basis of increased allele sharing in ASPs or from evidence of genetic association obtained by TDT analyses in similar collections of families. The IDDM17 locus was defined on the basis of linkage studies in a single large pedigree (25). Finally, several additional chromosomal regions, Xp13-p11, 16q22-24, and 1q42, are reported to show suggestive to significant evidence of linkage to type 1 diabetes in genome scans but have not been assigned "IDDM" designations (26-28).

Five genome-wide scans for linkage to type 1 diabetes in ASPs have been reported. The studies of Davies et al. (24) and Hashimoto et al. (29) were the first such scans completed in any genetically complex disorder. Data analysis in these studies was performed by two-point evaluation of allele-sharing data at each marker. Larger subsequent genome scans completed by Mein et al. (26) and Concannon et al. (27) partially overlapped these earlier studies in the families used but used more informative multipoint approaches for assessing the evidence for linkage, as did a completely independent genome scan in Scandinavian families by Nerup et al. (30). The results from these genome-wide scans have been interpreted as suggesting the existence of numerous susceptibility loci for type 1 diabetes in humans. However, for many of these putative loci, the evidence for linkage in the initial reports did not attain a genome-wide significance level. Subsequent follow-up studies have, in some cases, been supportive of initial reports and, in other cases, negative. This inconsistency in the findings of different studies is a significant impediment to efforts to identify the relevant genes that contribute to susceptibility. Because fine mapping of such linked

regions cannot proceed by analysis of observed recombination events, the currently accepted method of localizing susceptibility genes in such regions is to methodically test genetic markers spanning the region at high density in the hope of detecting evidence of allelic association with disease. The labor involved in performing such an analysis in even one suspected region is immense, especially because the confidence intervals for such regions are typically quite broad. Obviously, an investigator wants to apply such an approach only in those regions for which the supporting evidence is the strongest. This requires some prioritization of potential target regions based on the evidence for linkage. When independent genome-wide scans report largely nonoverlapping sets of putative linked loci, their utility for prioritizing these sites for further study is limited.

Two approaches to evaluating the significance of findings of linkage in complex diseases such as type 1 diabetes are to carry out either confirmation or extension studies. The first of these approaches, confirmation studies, relies on independent replication to strengthen the evidence for linkage. Since even when there is no linked disease susceptibility locus, a statistically significant finding will occur with a frequency of 5%, confirmation studies can play an important role by testing the reproducibility of such findings. Unlike the initial report of linkage, it may not be necessary to hold a confirmation study to the same level of statistical significance. Simulations indicate that to have sufficient power to attain replication at a genome-wide level of significance, a confirmation study might have to use impracticably large sample sizes (31). Therefore, a more appropriate standard may be to require a locus-specific significance level for a replication (p = 0.01). When an initial finding is only suggestive of linkage, then the second approach, extension studies, in which data from all studies are merged and jointly analyzed, is more appropriate until such a locus attains a genome-wide significance level (4).

Both confirmation and extension studies involve the joint analysis of data from multiple sources. A difficulty with both approaches is the challenge of making the analyses as inclusive as possible. Published data will tend to be selected for positive results. There is always a danger that negative results that might substantially affect the outcome of such analyses may not be incorporated simply because they are not reported. For extension studies, the ideal approach is to pool the raw data and carry out a single analysis. In the case of two-point analyses of allele sharing, it is possible to add reported results from different studies together in an extension study. In general, the same practice cannot be used with multipoint LOD scores except in the rare event that the independent studies that are to be merged all used the same markers, genetic maps, and methods for analysis. While two-point analyses of linkage data at specific markers allow relatively easy pooling across studies, multipoint analysis methods can extract substantially greater linkage information from a comparable collection of families. Therefore, caution is appropriate in considering significance levels reported from extension or replication studies that exclude data obtained by one method or the other.

The following sections summarize the evidence supporting the existence of reported "IDDM" loci in humans as well as some additional regions implicated by linkage studies but lacking such official designations. It is important to keep in mind that although these regions have been given locus designations, which may include the name of the most "interesting" candidate gene, in most cases what is being discussed is not a specific locus but a large chromosomal region that may contain hundreds of genes, any one or combination of which might contribute to disease susceptibility. The cytogenetic localizations provided for each of these regions are, therefore, just estimates and are taken from the relevant publications reporting the putative loci.

IDDM1 (6p21.3)

Identification of HLA Associations with Type 1 Diabetes

The first evidence of allelic association between the HLA complex and type 1 diabetes was reported for the HLA-B15 allele and was based on serology (32). In subsequent studies, a positive association of type 1 diabetes with HLA-B8 and a negative association with B7 were established (33,34). Higher risks were shown to be associated with HLA class II specificities, namely DR3 and DR4, whereas DR2 (now renamed DR15) was suggested to be involved in protection (35). DR3 is in linkage disequilibrium with B8, and DR4 is in disequilibrium with B15. More than 90% of white patients with type 1 diabetes have DR3 and/or DR4 as compared with 40% to $5\bar{0}\%$ of controls (35). The greatest risk of type 1 diabetes is conferred by the simultaneous presence of DR3 and DR4, which are found together in 30% to 50% of patients (36,37) but in only 1% to 6% of controls. These associations with HLA antigens were defined initially by serologic or cellular typing methods. Restriction fragment length

polymorphism (RFLP), allele-specific oligonucleotide typing, and direct nucleotide sequencing subsequently enabled the specific identification of genes associated with risk for type 1 diabetes. These molecular studies indicated that the primary susceptibility genes are situated in the HLA-DQ rather than the DR region (a schematic map of the HLA gene region is shown in Fig. 21.1). In most populations studied, the HLA alleles most strongly associated with type 1 diabetes are DQB1*0302 and/or DQB1*0201, which are in linkage disequilibrium with DRB1*0401 and DRB1*0301, respectively. (By convention, HLA alleles are named with a four-character alphanumeric code indicating the locus, followed by an asterisk and a four-digit number indicating the specific allele at that locus. For example DQB1*0302 refers to a specific polymorphic allele, 0302, at the DQB1 locus that encodes the β chain of the heterodimeric HLA-DO molecule.)

HLA-DQ and HLA-DR as Predisposing Alleles for Type 1 Diabetes

Although numerous studies have emphasized the primary role of HLA-DQ in predisposition to type 1 diabetes (36,38), the involvement of HLA-DR loci cannot be excluded (39–52). The DR4-DQA1*0301-DQB1*0302 haplotype is associated with sus-

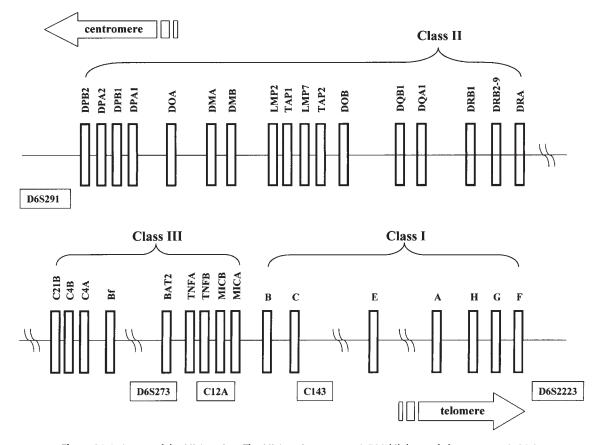

Figure 21.1. A map of the HLA region. The HLA region covers ~3,500 kilobase of chromosome 6p21.3. The HLA genes are divided into three groups. HLA class II genes encode α - and β -chains of the class II antigen-presenting molecules. HLA class I genes encode the α -polypeptide chain of the class I molecules, while the β -chain is encoded on chromosome 15 by the β -microglobulin gene. The genes in the HLA class III region encode complement proteins, some cytokines, and additional enzymes. The genes in the HLA class I and II regions are highly polymorphic, with the exception of *DRBA*, which is nonpolymorphic. Alleles of the genes are indicated by a four-digit number followed by an asterisk. The map shows only selected HLA genes among the ~150 genes mapped to the region. The distances between the loci are approximate. Microsatellite markers are shown as framed.

ceptibility to type 1 diabetes in most populations studied (36,41-43), but certain DR4 haplotypes are more prevalent among patients as compared with controls, suggesting a role for both DR and DQ molecules in the pathogenic process. Likewise, studies in the nonobese diabetic ($\bar{N}OD$) mouse, a rodent model of type 1 diabetes, suggest that more than one gene in the major histocompatibility complex (the mouse equivalent of HLA) contributes to diabetes susceptibility (see Chapter 18 for detailed discussion of the NOD mouse model). DRB1*0401, 0402, and 0405 are positively associated with type 1 diabetes, whereas DRB1*0403 is not, even though these alleles all occur on haplotypes in conjunction with DQB1*0302 (39-42,44-47). In Scandinavian populations, the DRB1*0404-DQB1*0302 haplotype is decreased in frequency among patients (48-50). In the Oriental populations, the DRB1*0406-DQA1*0301-DQB1*0302 haplotype is negatively associated with type 1 diabetes (42,51–54). The role of all DR4 haplotypes cannot be jointly evaluated in a single population because the frequency of DR4 subtypes varies considerably in different ethnic groups and some haplotypes are very rare. For example, in Scandinavia, almost all DR4 haplotypes carry the DRB1*0401 or 0404 alleles, while DRB1*0406 is observed at high frequency only in the Oriental populations. Nevertheless, based on transracial association data, the DRB1*04 alleles can be ranked in the following order with respect to risk of type 1 diabetes: DRB1*0405 = 0402 = 401 > 404> 403 ~ 0406 (48).

HLA-Encoded Protection

The DRB1*1501-DOA1*0102-DOB1*0602 haplotype is negatively associated with type 1 diabetes across multiple ethnic groups, whereas the DRB1*1301-DQA1*0103-DQB1*0603 haplotype is associated with reduced susceptibility (41,42,55). DQB1*0602 and 0603 differ only at amino acid position 30, whereas DQA1*0102 and DQA1*0103 differ only at amino acid positions 25 and 41 (56). The apparent protection from type 1 diabetes conferred by DQB1*0602 and 0603 appears to be dominant in nature (38,57-59). No patient with type 1 diabetes homozygous for DQB1*0602 or 0603 has been described so far. However, the protection conferred by these DQ alleles is not absolute, as patients positive for DQB1*0602 allele have been described (60-63). In these patients, the other DQB1 allele is typically one that is associated with high risk of disease. Another DQB1 allele that is also reduced in frequency among patients with type 1 diabetes in some populations is DQB1*0301 (36), although the protection observed with this allele is neither as global nor as significant as with DQB1*0602 and 0603. The negative association with DQB1*0301 is most prominent when it is present on DRB1*1101 haplotypes. However, it is also seen with those DR*04 haplotypes that confer susceptibility, suggesting that one protective DQ allele on a haplotype can neutralize any predisposing effect (46,47).

HLA Associations with Type 1 Diabetes in Different Ethnic Populations

The frequencies of HLA alleles and their haplotypic combinations differ greatly across various ethnic groups (41,64). There is also variance in the haplotypes associated with type 1 diabetes. For example, the DRB1*0405-DQA1*0301-DQB1*0302, DRB1* 0405-DQA1*0301-DQB1*0401, and DRB1*0802-DQA1*0301-DQB1*0302 haplotypes are positively associated with type 1 diabetes in the Japanese population, whereas DRB1*0406-DQA1*0301-DQB1*0302 has a negative association (42,51,54). DR9 is positively associated with type 1 diabetes both in the Oriental populations and in populations of African descent, but these haplotypes differ in their DQB1 loci (42,53,65). In Orientals, DR9 haplotypes carry DQA1*0301-DQB1*0303 (as in white populations), whereas in Africans, DR9 is linked with DQA1 *301-DQB1*0201. DR7 is increased only in patients of African descent with type 1 diabetes (66). This particular haplotype carries the DQA1*0301 allele, which is positively associated with disease, whereas DR7 in whites is in linkage disequilibrium with the disease-neutral DQA1*0201 allele.

The strength of DRB1*0301 as a risk allele varies among populations; DR3-associated susceptibility is stronger in southern as compared with northern Europeans. In the latter group, DRB1*0301-DQB1*0201 haplotypes alone do not confer an increased risk for type 1 diabetes, and no excess of homozygotes for this haplotype is observed among patients (67). However, in Sardinia, the major susceptibility haplotype is DRB1*0301-DQA1*0501-DQB1*0201, and homozygosity for this haplotype is significantly increased among patients (68). In the Japanese population, the DRB1*0301-DQB1*0201 haplotype is rare (42,69). In the Chinese population, DR3/9 heterozygosity is strongly associated with type 1 diabetes (70,71). This is most likely due to the low frequency of risk-associated DR4 subtypes in this population. These differences in HLA haplotype frequencies in the general population may help explain the low disease incidence in these ethnic groups.

Synergistic Effects on Risk Associated with Heterozygous Combinations of HLA Alleles

The greatest HLA-encoded risk of type 1 diabetes is conferred by the simultaneous presence of DQA1*0301-DQB1*0302 and DQA1*0501-DQB1*0201 (40,67). This combination of haplotypes is found in ~40% of the patients, whereas the frequency in healthy controls is only 3%. The increased risk associated with heterozygosity for these two haplotypes is inconsistent with a simple additive effect. One proposed explanation is that this genotypic combination might facilitate the formation of heterodimers between the α - and β -chains that are encoded by alleles present on different parental chromosomes in trans (72–74). Because both the α - and β -chains of DQ molecules display allelic polymorphism, potentially four distinct DQ molecules can be formed in a heterozygous individual. While it has been demonstrated that these trans-dimers can be formed and are very stable, no T cells restricted by these molecules have been isolated from DQB1*0302/0201 heterozygous individuals with type 1 diabetes (75,76). The heterodimers encoded in trans in heterozygous individuals are DQA1*0301-DQB1*0201 and DQA1*0501-DQB1*0302. The former is encoded in cis on DR7 and DR9 haplotypes that are common among patients of African descent with type 1 diabetes (55,77). A second possible explanation for the increased risk associated with DQB1*0302/ 0201 heterozygosity is that it reflects the effects of additional genes beyond DQ. These might be other HLA class II genes known to have an effect on susceptibility, such as DR or DP, or even genes within the HLA complex that do not encode antigen-presenting molecules. As discussed below, such effects often are attributed to the HLA-DR3 haplotype that is associated with many different autoimmune disorders beyond type 1 diabetes.

Effects of Genes outside the HLA-DR-DQ Region and the Natural History of the Disease

As discussed above, other genes within the HLA region may make important contributions to susceptibility to type 1 diabetes by modifying the risk conferred by DR or DQ alleles or independently of their role. The tight linkage disequilibrium that exists between different polymorphic HLA genes complicates the identification of primary risk-conferring genes in association studies. Transracial studies and analysis of ancestral haplotypes have been valuable tools in mapping genes in the HLA region with potential roles in disease susceptibility. The recent use of microsatellite markers in linkage studies with well-matched patients and controls has suggested the existence of additional genes within the HLA region that may be involved in disease predisposition.

Several studies have reported associations between class I alleles and the natural history of type 1 diabetes [e.g., faster progression and earlier onset of the disease in patients who are positive for the HLA-A24 (78–80) or B18 haplotypes (81,82)]. A strong correlation between complete loss of residual β-cell function and the presence of HLA-A24 has been reported among Japanese patients (83). The B18-DR3-DQB1*0201 haplotype has been associated with a higher disease risk than the B8-DR3-DQB1*0201 haplotype (81,84). A30-B18-DR3-DQB1*0201 confers an independent association with type 1 diabetes, as homozygosity for it is enough to increase risk (68), whereas A1-B8-DR3-DQB1*0201 confers significant susceptibility only when it is present together with DR4-DQB1*0302. Analyzing DR3-B8 and DR3-B18 ancestral haplotypes, Degli-Esposti and colleagues (85) predicted that the region between HLA-B and the BAT2 loci could contain a gene or genes that contributed to risk for type 1 diabetes. A role of HLA-B alleles (or a gene in the region surrounding the HLA-B locus) also was suggested in a study in which HLA-B39 was shown to be increased in DRB1*0404-positive disease-associated haplotypes (49,50).

Recent studies on extended DR3 or DR4 haplotypes using dense sets of microsatellite markers suggested that at least two different genes in the HLA region beside the DQ and DR loci could be involved in disease susceptibility. A Belgian case-control study with DQB1*0302/0201-positive subjects tested for association with eight microsatellite markers spanning a region extending from 6-centiMorgan (cM) telomeric of HLA-F to 2-cM centromeric of HLA-DP. The study provided evidence for an association of one additional region with type 1 diabetes beside DQ. This region mapped near the microsatellite locus D6S273, just centromeric of tumor necrosis factor (86). This finding was confirmed in a northern white/British family study using a variant of the TDT called "homozygous parent TDT analysis." In this approach, transmissions of marker alleles from heterozygous parents are tallied only in families in which the parents are homozygous for known type 1 diabetes susceptibility alleles (DRB, DQA, and DQB) (87). An independent study of Finnish patients and controls stratified for DRB1*0401/301 or DRB1*0404/301 suggested that a genomic region near HLA-B contributes to diabetes susceptibility (88). The 240-kilobase (kb) region between C12A and C143 mapped in this study included the HLA-B, HLA-C, MICA, and MICB genes, as well as the less well-characterized P5-1 3.8-1.1 genes (89). The regions identified in these various microsatellite marker studies may well overlap, since the boundaries of the regions are not clearly defined with the markers utilized. Both sets of studies, when considered together with the previous data on ancestral haplotypes, suggest that there is an unrecognized diabetes susceptibility gene that maps to the centromeric end of the class I region near HLA-B.

A second region reported to display positive association with type 1 diabetes independent of the class II genes has been localized telomeric to the class I region (87). The allelic association in this region is detected with the microsatellite marker D6S2223, which is located 2.5-kb telomeric to HLA-F. This study also used the homozygous parent TDT in 225 selected families. The observed association was further confirmed in cases and controls matched for DR and DQ alleles. Presence of allele 3 at the D6S2223 loci appeared to decrease the risk conferred by the DR3-DQA1*0501-DQB1*0201 haplotype. This supports the notion that there is heterogeneity in DR3-positive haplotypes in their contribution to diabetes risk, as discussed above. It is interesting that the same microsatellite polymorphism also was found to display a similar association with celiac disease, another DR3-associated disorder (90). Further analyses will be required to determine if a gene or genes in this region contribute to diabetes susceptibility and whether it has a broader predisposing effect in autoimmunity.

The TAP1 and TAP2 genes in the class II region encode a heterodimeric molecule that is involved in the transport of peptides into the endoplasmic reticulum, where they are bound by class I molecules. The TAP protein is required for efficient loading and presentation of peptides in class I molecules and thus is an attractive candidate gene for diabetes susceptibility. Other candidate loci in the same region centromeric to DQ are LMP2/7 and DMA/B that encode proteins involved in antigen processing and the loading of peptides onto class II molecules, respectively. TAP1 and TAP2 polymorphisms have been extensively studied, and positive associations have been reported between TAP2 alleles and type 1 diabetes, but these associations appear to be secondary to DQ (91-96). An independent positive association of LMP2 and LMP7 with diabetes has been described in a case-control study in patients in the United States (97), while other reports have been negative (98,99). The association of LMP2 and/or LMP7 polymorphisms with type 1 diabetes also was studied using TDT analysis in Norwegian and British white families, but, once again, no independent association was observed (100,101). There is similar controversy with regard to the independent association of DMA and DMB with diabetes. No primary association between DMA or DMB and type 1 diabetes was found in a French case-control study (102). This was confirmed in an Italian study that analyzed transmission of DQA-DQB-TAP2-DMB haplotypes in affected individuals in type 1 diabetes families (103). In contrast, a German case-control study described a positive association of DMB*0101 and a negative association of DMA*0102 with diabetes (104). In this study, the patients and controls were stratified only for DQA1*0501. Therefore, association due to linkage to DQ could not be excluded.

Studies of HLA-DP alleles have provided evidence both for and against an independent role of DP in predisposition to type 1 diabetes. A positive association between DPB1*0301 and diabetes has been described in some white populations (105–107) and DPB1*0201 in the Japanese population (108). However, in other studies no significant difference in the distribution of DP alleles was observed between patients and controls (42,109,110).

Summary of the Role of Genes within the HLA Region in Susceptibility to Type 1 Diabetes

Allelic associations between type 1 diabetes and genes within the HLA complex were first observed more than 20 years ago, and these associations have been confirmed in numerous casecontrol and linkage studies since then. The strong linkage disequilibrium that exists between the polymorphic sites within the HLA complex has hampered the identification of the genes that are primarily involved in disease susceptibility or protection. However, most studies have shown that DQB1*0302 as a single allele confers a higher risk than DRB1*04, although a modifying effect of the *DRB1* gene is obvious in the haplotypes that represent different DRB1*04 subtypes. Positive association of the DRB1*03-DQA1*0501-DQB1*0201 haplotype with diabetes might be due to DRB1*03 or another, still unknown, gene linked

362 JOSLIN'S DIABETES MELLITUS

to it. Since the presence of the DR3 haplotype predisposes to many autoimmune disorders, this association may not be specific for type 1 diabetes but could be related to a more general dysfunction in immune regulation. HLA-encoded protection is generally dominant over susceptibility. Protective effects of the alleles DQB1*0602 or 0603 and DRB1*403 or 406 can be seen across ethnic populations, whereas the frequency and strength of the most common risk-associated alleles, DQB1*0302 and 0201, vary in different populations. In most populations, ~75% to 90% of the patients are positive for DQB1*0302, which apparently is the predominant susceptibility allele, whereas the DR3-DQB1*0201 haplotype seems to be a more minor predisposing genetic factor. However, the presence of these two haplotypes together greatly amplifies the risk of type 1 diabetes.

IDDM2 (11p15.5)

Genetic association between type 1 diabetes and a polymorphic region located immediately 5' of the insulin gene was first reported in a case–control study in 1984 (19). The marker used was a "variable number of tandem repeats" (VNTR) polymorphism consisting of many copies of a 14-nucleotide repeat. Initial studies classed these alleles into three groups—short (class I), intermediate (class II), and long (class III)—based on the size of the repeated region. The short class I alleles were observed to be associated with type 1 diabetes.

The finding of an association between class I alleles of the insulin VNTR polymorphism and type 1 diabetes suggested that a gene or genes in the region contributed to disease susceptibility. Because the VNTR did not obviously affect the coding region of any known gene, additional polymorphisms in and around the insulin gene and the flanking insulin-like growth factor and tyrosine hydroxylase genes were identified and tested for linkage and association with type 1 diabetes (111). These polymorphic sites all displayed similar degrees of association with type 1 diabetes in cases and controls (22). Stratification of cases by HLA type suggested higher relative risks associated with homozygosity at these insulin gene polymorphisms in patients who had the HLA-DR4 haplotype. Assays of transmissions of insulin alleles from heterozygous parents in multiplex families revealed an excess of transmission of alleles at two markers, the 5' insulin VNTR and a PstI RFLP, specifically to DR4⁺ affected individuals. This effect was significant only for paternal transmissions, raising the possibility that imprinting, which is known to occur in this region of chromosome 11, might play a role in susceptibility to type 1 diabetes through an effect on IDDM2. These studies have been interpreted as mapping the IDDM2 locus to a region of 4.1 kb surrounding the insulin gene, although alternative interpretations have been proposed (111,112).

The 4.1-kb region flanking the insulin gene contains four candidate polymorphisms that exist in near-complete linkage disequilibrium (22). Three of these polymorphisms are biallelic, whereas the fourth, the 5' VNTR polymorphism, is characterized by variation both in the length of individual repeats and in their nucleotide sequences. Bennett et al. (20) carried out a detailed analysis of the association between marker haplotypes at *IDDM2* and type 1 diabetes. They identified specific marker haplotypes that were either predisposing or protective for type 1 diabetes and concluded, on the basis of a comparison of the alleles at various markers present on these haplotypes, that susceptibility to type 1 diabetes at the *IDDM2* locus mapped to the VNTR polymorphism itself. Similar results were reported by Owerbach and Gabbay (113). Subdivision of the pool of class I alleles at the VNTR revealed that, although the alleles in this

size class were generally associated with susceptibility to type 1 diabetes, there were differences in the frequencies with which specific alleles were transmitted to affected offspring in multiplex families. Whether these differences reflect specific predisposing or protective effects of different allele sizes or random variation in the analyses due to small sample sizes remains unresolved (113–115).

The strong statistical evidence of association between type 1 diabetes and alleles of the insulin VNTR polymorphism suggests that variation at that site contributes to disease susceptibility; a biologic mechanism is then required to explain this effect. By examining the pancreatic expression of the insulin gene in individuals heterozygous for a polymorphism within the gene, Bennett et al. (20) demonstrated that, although expression was biallelic, the ratio of transcripts from each allele varied with the identity of the insulin VNTR alleles present. Kennedy et al. (116) further demonstrated that the VNTR region was active as a transcriptional regulator in pancreatic β -cells. However, the two studies reported discordant results as to which class of VNTR alleles was associated with increased transcription of the insulin gene in islets. Since insulin is a known β -cell autoantigen in type 1 diabetes, variation in expression level or in the tissue specificity of transcription could play a role in regulating induction of immunologic tolerance independent of expression in islet cells. Consistent with this possibility, two studies have reported transcription of the insulin gene in the thymus (117,118). In both cases, the protective class III VNTR alleles were associated with increased steady-state levels of insulin messenger RNA (mRNA) in the thymus. These studies suggest a model for the role of the insulin gene VNTR in type 1 diabetes susceptibility in which negative selection of insulinspecific autoreactive T cells depends on the overall expression level of insulin in the thymus.

IDDM3 (15q26)

Using the approach of linkage mapping in ASPs, Field et al. (119) defined the *IDDM3* locus on chromosome 15q26 on the basis of increased allele sharing at the microsatellite marker D15S107. In 250 families of Canadian (N = 25), British (N = 100), or American (N = 125) origin, the maximum two-point LOD score was 2.54. Most evidence for linkage at D15S107 appeared to derive from families in which affected sibs did not share HLA-DR alleles, suggesting the possibility of genetic heterogeneity.

Multiple follow-up studies have tested for linkage with type 1 diabetes at *IDDM3*. Two-point analyses of allele sharing at D15S107 failed to provide significant supporting evidence (120–122), although modestly increased allele sharing was observed in two of three studies. Summing the sharing data from individual nonoverlapping follow-up studies provides only modest supporting evidence for *IDDM3* (p = 0.05) (120). Multipoint analysis of linkage data from genome-wide scans in collections of American or British families overlapping with those used to originally define *IDDM3* similarly provides little supporting evidence (26,27). In one study, a locus with $\lambda s \ge 1.5$ could be excluded from the region with a LOD of -3.6 (27).

IDDM4 (11q13)

Three independent studies reported initial evidence for a type 1 diabetes susceptibility locus on chromosome 11q that was designated *IDDM4*. Davies et al. (24) reported evidence of increased allele sharing for a marker near the *FGF3* (fibroblast

growth factor 3) gene from a genome-wide scan of 96 UK families with type 1 diabetes. Hashimoto et al. (29) reported similar evidence for the same marker in a collection of French and U.S. families. Both groups used a two-stage approach in which they carried out their genome-wide scan in a subset of their available families and then genotyped only markers displaying increased allele sharing in a second set of families. Field et al. (119) also reported evidence of linkage at *FGF3* in their report describing IDDM3. In none of these reports did the evidence for linkage attain a genome-wide significance level. Summing the raw allele-sharing data across these initial studies and excluding possible overlapping families, the evidence still attains only a *p* value of 0.01. All three initial studies further stratified the families studied by HLA sharing and by the presence of specific HLA-DR alleles but with conflicting results. In the first report, the evidence for linkage was contributed largely by those families sharing one or zero parental alleles (24), whereas in the second, the evidence for linkage came from those families sharing two parental alleles at HLA (29). The third report saw no significant effect from HLA stratification (119). These discordant results raise the question of whether such stratified analyses are actually helpful as a tool for initial identification of linked regions or are more appropriate as a method for further investigation of already confirmed findings. Repeated analyses under different models of gene-gene interaction will tend to increase the possibility of obtaining false-positive results.

Several confirmation studies have been performed in the *IDDM4* region. Luo et al. (120) summed the allele sharing across multiple studies, including their own, to obtain a MLS of 5.0 in the *IDDM4* region. Some caution in the interpretation of this value is warranted, however, because two of the sets of data included in this meta-analysis contain families from the same collection and may overlap. Also, these data are from two-point analyses that were summed despite their not having been performed with the same markers. Nevertheless, even if previously published data are eliminated and the analysis is confined to only those families genotyped by Luo et al., a significant MLS value of 3.9 is obtained.

Fine-mapping of the *IDDM4* region has provided some evidence for allelic association within the region with several markers. In an international study of 707 ASPs, an MLS of 2.7 was reported in the *IDDM4* region (123). Furthermore, there was evidence of decreased transmission of a specific haplotype of two markers in the region to affected offspring in families ($p = 4.3 \times 10^{-4}$). Additional evidence of association with alleles of a microsatellite marker in the region, D11S987, was reported by Eckenrode et al. (124), who also tested for, but failed to detect, allelic associations with polymorphisms within two candidate genes, Fas-associated death domain and galanin.

More recently, multipoint analyses of two large genome scans that together scanned more than 750 independent families failed to provide any significant evidence of linkage to IDDM4 (MLS = 0.5 and MLS = 0.43) (26,27).

IDDM5 (6q25–q27)

IDDM5 was originally identified on the basis of modestly increased allele sharing at the marker ESR (MLS = 1.5) located on the long arm of chromosome 6 (24). Stratification by either HLA sharing or the presence of specific HLA-DR alleles did not increase the evidence for linkage. In an extension study, Davies et al. (125) genotyped additional markers in this region and performed multipoint analyses. The increased linkage information afforded by these two approaches strengthened the evidence for linkage (MLS = 2.42). However, further extension of these

results through the addition of data from a second genome scan reduced the evidence of linkage to an MLS of 1.3 (26). One independent confirmation study provided significant two-point evidence of linkage at ESR (MLS = 4.5) (120). However, an independent genome scan that used multipoint analyses of genotyping data from a set of families overlapping with those used in this report did not find significant evidence of linkage in this region (MLS = 1.46) (27).

IDDM6 (18q21)

A potential susceptibility locus for type 1 diabetes on chromosome 18q12-q21 was originally suggested in 1981 on the basis of evidence of genetic linkage at the Kidd blood group locus (126). The original type 1 diabetes genome scan by Davies et al. (24) revealed modest but not significant evidence of linkage in this region (MLS = 1.1). A large-scale extension study using data from 1,457 families did not greatly strengthen the evidence for linkage (MLS = 1.6) (127). Nevertheless, a search for association with common alleles at various microsatellite markers in the region by TDT was carried out in the same set of families, providing nominally significant evidence of linkage disequilibrium after correction for multiple testing (p = 0.036). Addition of more families to this analysis (to a total of 1,708) and testing for association with specific marker haplotypes modestly increased the strength of the allelic association in this region (p = 0.01) (128). Neither of two large genome scans analyzed by multipoint methods yielded significant evidence of linkage at IDDM6 (26,27).

IDDM7 (2q31–q33)

Like *IDDM6*, the *IDDM7* locus corresponds to a region where modest evidence of linkage to type 1 diabetes was observed in an early genome scan (24) and that was followed up by association testing using TDT. No study to date has reported significant or even suggestive evidence of linkage at *IDDM7*, with the highest reported MLS in any study being 1.53 (129). However, later studies of the chromosome 2q regions assigned two additional loci to this region, *IDDM12* and *IDDM13*. The relationship between these three loci that cluster within a 20- to 30-cM region is unclear. A joint multipoint analysis of linkage data from several genome scans in ASPs of U.S. and U.K. origin revealed a single peak on 2q with an MLS of 2.62 that may reflect the effects of one or more of these loci (130).

In the case of *IDDM7*, the primary evidence supporting its existence has come from association studies. In the initial description of *IDDM7*, there was evidence of allelic association with type 1 diabetes at the marker D2S152, but only in certain populations (e.g., patients from the United States but not from the United Kingdom) and only prior to correction for multiple testing. A subsequent focused test for association at just the implicated allele of D2S152 in 1,551 families provided nominally significant evidence of association (p = 0.05) (131). Studies by other groups have reported similarly modest results. Evidence of association was reported in Danish families (p = 0.034) (132). However, there was no evidence in independent studies of U.S. families (133) or of Basque families (134). Case–control studies of U.S. and of Chinese patients also failed to reveal evidence of association (133).

IDDM8 (6q25–q27)

In addition to the evidence of linkage at ESR (*IDDM5*), a second marker on chromosome 6q, D6S264, provided some modest evi-

dence of linkage in the initial genome scan of Davies et al. (24) (MLS = 1.2). These data were extended by Luo et al. (121), who obtained an MLS of 2.0 at D6S264 and an MLS of 2.8 at a nearby marker, D6S281, in an independent set of families. When the two-point linkage data at D6S264 from these studies were added together, the MLS was suggestive of linkage (MLS = 3.4), and this region was designated IDDM8. A further extension study by Luo et al. (120) resulted in significant two-point evidence of linkage at D6S281 (MLS = 3.6). Neither of two subsequently reported genome scans analyzed by multipoint methods yielded even suggestive evidence of linkage at IDDM8 (MLS = 1.9 and MLS = 1.14) (26,27). However, when data from these genome scans are merged and jointly analyzed, there is increased evidence for linkage in the IDDM8 region in families in which both ASPs have early age at onset (130). In addition, a linkage disequilibrium study of the IDDM8 region reported that several marker haplotypes in the region displayed preferential transmission to affected offspring by TDT (uncorrected p= 0.01) (135).

IDDM9 (3q22–q25)

IDDM9 was defined on the basis of increased allele sharing at the marker D3S1303 after stratification by HLA sharing in the initial genome scan in type 1 diabetes by Davies et al. (24). The highest reported MLS in the region in any study is 1.1, although HLA-stratified analyses have yielded LOD scores as high as 2.4 (26).

IDDM10 (10p11–q11)

In the genome scan of Davies et al. (24), an MLS of 1.3 was detected at the marker D10S193 at 10p11. An extension study incorporating data from 312 families and multipoint analysis increased the evidence for linkage in the region (MLS = 2.44) (136). TDT analyses with microsatellite markers in the region, or with a marker immediately flanking the *GAD65* gene (137), failed to reveal significant evidence of association after correction for multiple testing. A further extension study incorporating data from 356 families from the United Kingdom provided significant evidence of linkage in the *IDDM10* region (MLS = 4.7) (26). There was little evidence of linkage in a comparable study of U.S. families (MLS = 0.4) (27). However, when data from these latter two genome scans are merged and analyzed together, there is suggestive evidence of linkage in the *IDDM10* region (MLS = 2.8) (130).

IDDM11 (14q24.3–q31)

Significant two-point evidence of linkage was reported at the marker D14S67 in a study of 254 multiplex type 1 diabetes families (MLS = 4.02), defining the *IDDM11* locus (138). All of the evidence for linkage appeared to derive from the subset of families with 50% or fewer sharing of HLA alleles. No other study has reported significant evidence of linkage in this region, including two other genome scans that together incorporated 225 of the 254 families used in the initial report (26,27).

IDDM12 (2q33)

Studies in the NOD mouse model of type 1 diabetes have localized a putative susceptibility locus, *Idd5*, to proximal mouse

chromosome 1, a region that is homologous with the long arm of human chromosome 2 (139,140). On the basis of this observation, Nistico et al. (141) tested for linkage or association between markers in the 2q33 region and type 1 diabetes. In a set of 48 Italian families, they observed suggestive evidence of linkage at the marker D2S72 (MLS = 3.39). However, in larger collections of families from the United Kingdom (N = 284), Sardinia (N = 123), and the United States (N = 180), there was no evidence of linkage at D2S72. D2S72 is located close to the CTLA4 gene, an appealing candidate for a type 1 diabetes susceptibility gene due to its role in regulating cellular immune responses. A biallelic polymorphism (A/G, Thr/Ala) of unknown functional consequences located in the leader peptide of CTLA-4 was analyzed by TDT within type 1 diabetes families. Preferential transmission of the "G" allele of this marker to affected individuals was observed (p = 0.002).

No subsequent study has reported any significant evidence of linkage to type 1 diabetes in the 2q33 region. Numerous studies, both family-based and population-based, have, however, examined the evidence of association between polymorphism in the CTLA4 gene and type 1 diabetes utilizing the A/G polymorphism in the leader peptide, a C/T polymorphism 318 nucleotides upstream from the transcription start site, or a dinucleotide repeat polymorphism in the 3' untranslated region. There is some evidence that the A/G polymorphism may have effects on the expression or function of the CTLA-4 protein (142). Kristiansen et al. (143) jointly analyzed the reports of association between CTLA4 alleles and type 1 diabetes. Across the 813 families genotyped in the studies they reviewed, there was persistent, although modest, evidence of preferential transmission of the "G" allele of the A/G polymorphism to affected offspring (p = 0.002). Case–control studies have also provided some sporadic evidence of an association of this allele with type 1 diabetes.

It is important to recall that *CTLA4* was originally investigated as a candidate gene, and follow-up studies have focused on only a narrow collection of polymorphisms. Association at the A/G polymorphism in *CTLA4* may reflect the effect of another nearby polymorphism with actual etiologic effects. For example, the *CD28* gene is located immediately adjacent to *CTLA4*, and, given its role in T-cell costimulatory events, it is also a potential candidate gene. Marron et al. (144) have begun to address this issue by testing multiple markers in the D2S72-CTLA4-D2S105 region for association with type 1 diabetes, both alone and in haplotypes. These studies reveal that the most significant evidence of association clusters immediately in and around the *CTLA4* gene, suggesting that further screening for new polymorphisms in this region may be warranted.

IDDM13 (2q34)

As in the report of *IDDM12*, other studies have searched for linkage between type 1 diabetes and markers on human chromosome 2q based on the localization of *Idd5* in the NOD mouse and the syntenic relationship between mouse chromosome 1 and human chromosome 2 (145). Suggestive evidence of linkage was observed slightly distal to *IDDM12*, with an MLS of 3.3 at the marker D2S164 (145). This evidence for linkage was enhanced when first-degree relatives positive for islet cell antibodies who had not progressed to frank diabetes were included in the analysis as affected, suggesting that the putative susceptibility gene in the region might be involved in the early stages of development of type 1 diabetes. This finding would be consistent with an orthologous relationship to the *Idd5* locus in the NOD mouse that controls the development of insulitis (139,140). *IDDM13* is one of three putative susceptibility loci for type 1 diabetes localized to a 20- to 30-cM region of chromosome 2q. It has proven difficult to confirm these reports of linkage or to determine if they represent distinct susceptibility loci. One subsequent large genome scan has provided suggestive evidence of linkage on 2q (MLS = 2.62), but the distribution of increased LOD scores that was observed in this region did not provide compelling evidence for multiple loci (130). A few markers in the region of *IDDM13* have been tested for association with type 1 diabetes, as have a few candidate genes such as insulin growth factor–binding proteins 2 and 5, but none have provided significant confirmatory evidence (146–148).

IDDM15 (6q21)

The HLA locus dominates the evidence of linkage to type 1 diabetes on chromosome 6. Delépine et al. (149) noted that evidence of linkage to HLA extended over a surprisingly large interval and hypothesized the existence of an additional susceptibility locus, independent of *IDDM1*, *IDDM5*, and *IDDM8*. They reported suggestive evidence for linkage at the marker D6S283 located 32 cM away from HLA (p = 0.0002 after correction for the effect of HLA). Additional suggestive evidence of linkage at D6S283 was reported in a separate genome scan (MLS = 1.71 to 2.27, dependent on mapping function used) (27). However, there is likely some overlap in the families used in these two studies. A completely independent genome scan of 424 families (464 ASPs) of Scandinavian origin revealed significant evidence of linkage at *IDDM15* (MLS = 4.8) (30).

IDDM17 (10q25)

IDDM17 is unique among IDDM loci in that it was defined by linkage studies in a single large Bedouin Arab pedigree rather than by the analysis of many small nuclear families (25). In this pedigree, autoimmune diabetes is reported to display oligogenic inheritance and is associated with two HLA-DR3 haplotypes. Studies of this pedigree provided the strongest evidence of linkage to markers in the chromosome 10q25 region. All affected individuals share a common haplotype of microsatellite markers in this region spanning approximately 8 cM. Whether the *IDDM17* locus plays a substantial role in predisposition to type 1 diabetes in the general population remains to be resolved. Genome scans have reported only modest evidence of linkage in this region. However, in one study, 10q25 was highlighted as one of only nine genomic regions in which LOD scores greater than 1.0 were observed (27).

IDDM18 (5q33-q34)

The *IDDM18* locus was defined based on a candidate gene study focusing on the *IL12B* gene (150). *IL12B* is an excellent candidate for a gene involved in the development of type 1 diabetes because it promotes the differentiation of the T_{H1} subset of T cells, and cells of this phenotype are thought to play a critical role in the diabetogenic process. Linkage analysis with markers in the 5q33-q34 region, where the *IL12B* gene is localized, in a collection of British and Australian families with type 1 diabetes yielded suggestive evidence of linkage (MLS = 2.3) when the data were stratified by HLA status. A single nucleotide polymorphism in the 3' untranslated region of the *IL12B* gene displayed a strong allelic association with type 1 diabetes in each of two independent sets of families tested by

TDT (58.4% of 283 transmissions, p = 0.0025, in the first set and 64.7% of 156 transmissions, p = 0.00014, in the second set). The steady-state mRNA levels for *IL12B* were compared in two B-cell lines, each homozygous for different alleles at the polymorphism in the 3' untranslated region. The cell line homozygous for the allele that had displayed an excess of transmissions in the TDT analyses expressed higher levels of *IL12B* mRNA.

Several follow-up studies have sought to confirm the reported evidence of linkage and association at the IDDM18 locus as well as to examine the relationship between the specific polymorphism in the 3' untranslated region and the expression of the IL12B gene. A study of American, British, Finnish, Romanian, and Sardinian families failed to detect evidence of linkage or association with type 1 diabetes at the IDDM18 locus (151). In this same study, an examination of a panel of 19 B-cell lines revealed substantial variation in the level of *IL12B* mRNA and no clear correlation with the genotype of the polymorphism in the 3' untranslated region. A second study of the same set of American families also failed to observe the reported association between the polymorphism in the 3' untranslated region of the IL12B gene and type 1 diabetes but did observe 50% increased expression from the implicated allele in lymphocytes from three individuals (152). Additional studies of Norwegian families with type 1 diabetes and an Italian case-control population did not detect evidence of association at the IDDM18 locus (153,154).

ADDITIONAL LOCI (Xp13–p11, 16q22–q24, 1q42)

Several additional linkages to type 1 diabetes have been reported in genome scans but have not been assigned "IDDM" designations. Cucca et al. (28) reported evidence for linkage at Xp13–p11. While overall evidence for linkage was weak, within the subset of patients who were DR3/X heterozygotes (where X was not DR4), an MLS of 3.5 was obtained. Recently, the *scurfin* gene, which, when mutated, results in a recessive neonatal autoimmune diabetes, was mapped to this region and is a potential candidate (155–157).

In a study of 356 type 1 diabetes families from the UK that extended the original genome scan of Davies et al., suggestive evidence of linkage was detected at chromosome 16q22-q24 (MLS = 3.4) (26). Subsequent merging of the data from this genome scan with that from several scans of U.S. families strengthened the evidence for linkage in this region (MLS = 4.13) (130).

Finally, suggestive evidence of linkage (MLS = 3.31) was reported at the marker D1S1617, on chromosome 1q42 in one study. This was the strongest evidence of linkage at any site other than HLA in a genome scan of 212 ASPs (27). Increasing the sample size and marker density for this region reduced the strength of the evidence for linkage (MLS = 2.46) but provided some evidence of allelic association with several closely spaced markers in the region.

The largest single genome scan completed in type 1 diabetes studied families from Denmark, Sweden, and Norway (30). Despite the use of a standardized ascertainment protocol and the greater homogeneity of genetic background in this population compared with others that had previously been studied by genome-wide scanning, only the *IDDM1* and *IDDM15* regions yielded significant evidence of linkage. However, three unique regions yielded LOD scores greater than 2.0, chromosome 2p (near the marker D2S113), chromosome 5 (near the marker D5S407), and chromosome 16p (in the interval between D16S407 and D16S287).

SUMMARY

Given the efforts of multiple investigators that have gone into mapping susceptibility loci for type 1 diabetes using genomewide scans in ASPs, why have results, such as those summarized in the foregoing, appeared to be so inconsistent? There are a number of possible explanations. First, it needs to be recognized that failure to replicate a finding in an independent set of families does not imply that the initial report was incorrect. A series of studies, each reporting only modest evidence of linkage at a particular site, might well attain genome-wide significance in aggregate if the raw data were to be pooled and analyzed.

A second issue is that of power to detect linkage. The current set of genome scans for type 1 diabetes, although each an ambitious undertaking, have only good power to detect loci with very strong effects (e.g., $\lambda s > 2.0$). This is adequate to detect the effect of *IDDM1* in all studies but may not be adequate to allow consistent detection of other, non-HLA, loci that make more modest contributions to familial aggregation.

A third issue that may impact the ability to detect type 1 diabetes susceptibility genes by linkage studies is the possibility of heterogeneity in the patient population. Although the clinical diagnosis of type 1 diabetes can be made with confidence at the time β -cells have been largely ablated, there may be a variety of biochemical and immunologic pathways whereby patients reach this point. These different pathways may reflect the impact of polymorphism in different sets of genes. In such a situation, the extensive pooling of families required for genome scans may be counterproductive. It may be useful to consider incorporating additional phenotypic information into such studies. For example, the use of age at onset as a tool to identify a subset of patients whose disease is more strongly "genetic" has a long and successful history. Similar approaches in type 1 diabetes linkage studies that use not only age at onset but also other phenotypic manifestations to generate more homogeneous collections of families or patients for linkage or association studies may be warranted (130,158,159).

A fourth issue to consider regarding the variability in results between linkage studies in type 1 diabetes is the difficulty of accounting for the joint effects of multiple genes on susceptibility. Some of the reported type 1 diabetes linkages (e.g., IDDM4) attain statistical significance only when families to be analyzed are stratified on the basis of inheritance at other loci, usually IDDM1 or IDDM2. It is a very reasonable hypothesis that there are statistically significant interactions between loci in type 1 diabetes. However, care must be exercised in testing multiple models of interaction as a means of searching for these loci. Repeated reanalysis of linkage data under different models, while a well-intentioned approach to uncover susceptibility loci, also increases the likelihood of false positive results. Carrying out analyses on various subsets of families requires that any findings meet a higher level of significance. When such a correction is applied, some reported linkages based on stratified analyses no longer attain statistical significance (160). Further development of statistical methods that can efficiently take into account the joint effects of multiple susceptibility genes might dramatically improve our ability to extract linkage information even from existing sets of data.

Finally, some of the reported loci may simply be false-positives. While it is not possible to rule out very small contributions to risk at any of these loci, it is worth noting that some are supported by only the most modest evidence, well below the thresholds cited earlier for even suggestive evidence and lacking convincing supporting evidence from association studies. Other loci are supported by suggestive or significant evidence of linkage in only a single study and are not supported by other studies. Finally, there is discordance between results obtained by two-point, as compared with multipoint analyses, for some loci, even in cases in which there is substantial overlap in the collection of families analyzed by the two different approaches.

FUTURE DIRECTIONS

To the famous fictional detective, Sherlock Holmes, even the absence of evidence could provide useful clues to solve a mystery.

"Is there any point to which you would wish to draw my attention?"

"To the curious incident of the dog in the night-time."

"The dog did nothing in the night-time."

"That was the curious incident,"

remarked Sherlock Holmes. (161)

How can the mystery of the apparently discordant results for type 1 diabetes susceptibility loci be resolved? The "curious" behavior of the IDDM2 locus in previously published genome scans may similarly provide an important clue. There is highly significant evidence from association studies that a gene or genes in the IDDM2 region contribute to susceptibility to type 1 diabetes (20). Despite this, genome-wide scans completed to date have consistently failed to provide significant evidence of linkage at IDDM2 (24,26,27,29,30,130). These genome-wide scans do provide strong exclusionary evidence for loci with effects comparable to and even somewhat less than IDDM1 (e.g., loci with $\lambda s \ge 2.0$). However, the λ value for *IDDM*2 is likely less than 1.3. If IDDM2 is typical of the remaining susceptibility loci for type 1 diabetes, the sporadic nature of reports of linkage at other locations in the genome may simply represent a basic problem in sampling. In 1994, when Davies et al. (24) published the first genome-wide scan for linkage in type 1 diabetes, the collection of 96 families they used for their scan seemed quite large. However, if most type 1 diabetes susceptibility loci actually have λ s values much lower than 1.5, significantly larger collections of ASPs will be necessary to have adequate power to detect their effects (3). It is clearly feasible to ascertain much larger collections of multiplex type 1 diabetes families than have been studied to date. However, in the near term, power could easily be increased by merging and jointly analyzing the raw genotyping data from already completed studies.

Some insight into the value of such an approach can be gained from the study of Cox et al. (130), who merged the primary data from what were currently the two largest published genome scans (26,27) and added new data from a further unpublished scan to obtain a data set that included 767 multiplex type 1 diabetes families. Within this collection, 667 of the families had been genome-scanned at a marker density of at least one marker for every 10 cM. The remaining 100 families had been used for targeted follow-up studies of regions where linkage had previously been reported. Multipoint analyses in this large set of data revealed three regions where the evidence for linkage was significant, IDDM1 (LOD = 65.8), IDDM2 (LOD = 4.28), and 16q22–q24 (LOD = 4.13). There was suggestive evidence of linkage at four more sites, IDDM10, IDDM7, IDDM15, and 1q42. Two points are of particular importance with regard to this study. First, addition of more families clearly increased the power to detect linkage. Of particular note was the magnitude of the evidence for linkage IDDM2, which was not anticipated based on the results in prior individual analyses of

genome scans. This was not solely the result of genotyping markers, such as the insulin VNTR, that were known in advance to be located immediately at the IDDM2 locus. If the data in this analysis for the 11p15 region are restricted to just the framework set of markers used in a typical genome scan, the evidence for linkage is still suggestive (LOD = 2.53). This brings up the second point that increasing marker density also increases power to detect linkage at an established site such as IDDM2.

These points, that increasing sample size and marker density can increase the power to detect linkage, are obvious to geneticists but merit emphasizing in the context of the genetics of type 1 diabetes. It may well be that to obtain unambiguous mapping of at least the most important type 1 diabetes susceptibility genes it will be necessary to study many more families at higher marker densities than has been done in the past. As a first step toward such a goal, investigators in the genetics of type 1 diabetes could help themselves by taking a consortium approachmerging all of the existing data from published studies and carrying out joint analyses. At the time of this writing, an effort to establish a type 1 diabetes genetics consortium to facilitate such an approach is under way. Such an effort should clarify some of the apparent conflicts in the current data regarding type 1 diabetes susceptibility loci and help prioritize those chromosomal regions most likely to contain susceptibility loci for the even harder work ahead of identifying the relevant genes.

Maturity-Onset Diabetes of the Young 373 Genetic Syndromes of Extreme Insulin Resistance 375 Mitochondrial Diabetes 376

Type 2 diabetes, or non–insulin-dependent diabetes (NIDDM), appr is one of the most common metabolic disorders affecting Alth humans. Approximately 14 million Americans have been stud

diagnosed with this disease, and at least one third more are estimated to be affected without knowing it (1,2). Recent population surveys also indicate a striking increase in the prevalence of this disease in the United States, especially in younger people, with a 33% increase overall and a 70% increase in the 30- to 39-year age group during the 8-year period from 1990 to 1998 (2). Type 2 diabetes is now also a common diagnosis in the pediatric age group (3). The increasing number of affected people, together with the extensive list of long-term complications, including accelerated atherosclerosis, nephropathy, retinopathy, and neuropathy, makes type 2 diabetes a major health problem (4). The economic burden of diabetes is in excess of \$100 billion annually in the United States alone. These factors have created a compelling need to understand the important role of genetic and environmental alterations in the etiology of this disease-to provide critical clues to the primary defects in this disorder, to allow tests that identify individuals at high risk of type 2 diabetes who may benefit from preventive programs, and to foster the development of new drugs to treat or prevent it.

GENES AND TYPE 2 DIABETES

Unlike type 1 diabetes, which is due to a single pathophysiologic defect (autoimmune destruction of β -cells resulting in a lack of endogenous insulin), most patients with type 2 diabetes exhibit two apparently different defects: (a) an impairment in the ability of muscle and fat to respond to insulin with increased glucose uptake and of liver to respond with decreased glucose output, i.e., insulin resistance; and (b) a failure of the β -cell to compensate for this insulin resistance by

FUTURE DIRECTIONS 390

appropriately increasing insulin secretion (5) (Fig. 22.1). Although there are notable exceptions, in most longitudinal studies, insulin resistance can be demonstrated early in life before any evidence of glucose intolerance, whereas the β -cell failure develops somewhat later, in association with impaired glucose tolerance (5–8).

The contribution of genetic factors to the development of insulin resistance, impaired insulin secretion, and type 2 diabetes has been known for many years (9,10). Supporting evidence includes the familial clustering of these traits (9-11), the higher concordance rate of type 2 diabetes in monozygotic versus dizygotic twins (12-14), and the high prevalence of type 2 diabetes in certain ethnic groups (e.g., Pima Indians or Mexican Americans) (8,15) (see Chapter 20 for further discussion of this topic). On the other hand, environmental factors also appear to play a role, as indicated by the increasing incidence of type 2 diabetes during the past decade, the wellknown links to diet and lifestyle, and the differences in risk of type 2 diabetes among genetically similar populations living in different areas (2,16). Thus, diabetes can be viewed as a complex disorder, with genetic factors conferring an increased susceptibility upon which environmental factors must act in order for hyperglycemia to develop (Fig. 22.2). This model is analogous to those proposed for other multifactorial disorders such as cancer and hypertension (17). It is estimated that between 25% and 70% of the occurrence of type 2 diabetes can be attributed to genetic factors (14).

Studies of the patterns of inheritance indicate that multiple genes probably are involved, although their number and relative contributions are uncertain (18,19). As schematically illustrated in Figure 22.3, different loci may contribute to the etiology of type 2 diabetes by interacting with each other within the same causal complex (*epistasis*). However, genes may also belong to different causal pathways, each being responsible for the development of diabetes in different subsets of indi-

372 JOSLIN'S DIABETES MELLITUS

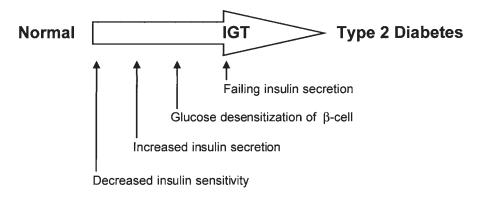

Figure 22.1. Model of the progressive pathogenesis of type 2 diabetes. In most individuals, there is a slow progression from normal or impaired glucose tolerance (IGT) to overt diabetes. This depends on interaction between genetic and environmental factors that regulate insulin sensitivity or the ability of β -cell to secrete insulin.

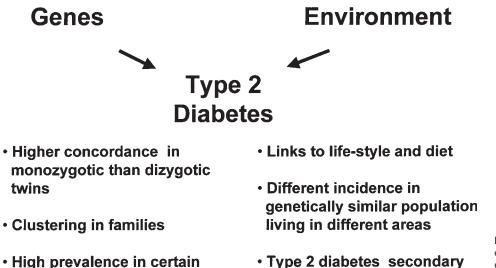

viduals (genetic heterogeneity). Some loci may be necessary but not sufficient (e.g., locus A in Fig. 22.3), whereas others may be neither necessary nor sufficient for the development of diabetes (e.g., loci B, C, and D). In this context, certain genes may predominate, their effects being more important than others (major gene effects). Some genetic characteristics may act only if patients are in the homozygous state (recessive inheritance), while for others the presence of only one allele may suffice (dominant inheritance). Furthermore, genetic susceptibility and environmental factors may interact in several different ways. For instance, environmental factors, such as excess caloric intake or sedentary lifestyle, may be responsible for the onset (initiation) of the metabolic abnormalities or β -cell damage, while genetic factors may be involved in regulating the rate of progression to overt diabetes. In other cases, genetic characteristics may be necessary from the very beginning for environmental factors to initiate the cascade of events leading to diabetes. Some of these genes may act at the level of insulin action while others may be involved in the regulation of insulin secretion.

This complexity makes the task of finding the genes for type 2 diabetes a formidable one. For instance, because of the important role played by environmental factors, cases of type

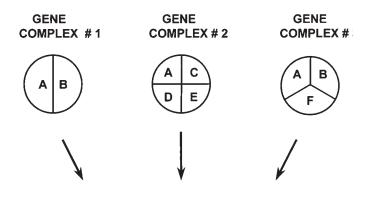

ethnic groups (e.g. Pima,

Mexican-Americans).

2 diabetes that are due entirely to nongenetic causes (socalled *phenocopies*) may be relatively frequent, especially in older populations. Conversely, diabetes may not develop in a substantial proportion of individuals carrying a susceptible genetic background because they have not been exposed to a diabetogenic environment or because they are not old enough (so-called *nonpenetrants*). Under these circumstances, research approaches that have been successful in identifying genes for mendelian disorders are difficult and of limited power. These problems, however, are counterbalanced by several major developments that have occurred during the past decade, namely the development of the polymerase chain reaction (20), the discovery of the class of DNA polymorphisms known as microsatellites and their systematic characterization as markers (21), the construction of genetic and physical maps of the human genome (22), the development of nonparametric methods of analysis of genetic data (23), and, finally, the completion of the Human Genome Project, which has provided the full human genome sequence and an initial catalogue of human genetic variation (24,25). The availability of these new tools carries with it the promise of finding the genes responsible for complex disorders, including type 2 diabetes.

 Type 2 diabetes secondary to other conditions **Figure 22.2.** Contribution of genes and environment to the pathogenesis of type 2 diabetes. Available evidence supporting a role of genetic factors is listed on the left; the evidence for environmental factors is on the right.

Increased genetic susceptibility to type 2 diabetes

Figure 22.3. Illustration of the complex genetics of type 2 diabetes. Multiple type 2 diabetes genes (indicated by different letters of the alphabet) interact one with each other within different causal complexes that all lead to increased genetic susceptibility to the disease.

THE SEARCH FOR TYPE 2 DIABETES GENES

A powerful approach to the identification of genetic variants that predispose to type 2 diabetes is to investigate their association with the disease in human populations (26,27). In their simplest version, these studies compare the distribution of the alleles of a polymorphic locus between unrelated cases with type 2 diabetes and nondiabetic controls representative of the population from which cases have arisen (26). Any significant difference in allele distribution between cases and controls can be considered as evidence that this polymorphism or one associated (i.e., in *linkage disequilibrium*) with it contributes to the susceptibility to type 2 diabetes. Being case-control studies, association studies can be analyzed with the standard epidemiologic tools for evaluating disease risk according to various exposures, so that the presence of interaction between two loci or between a locus and environmental exposures can easily be tested. While straightforward in concept, association studies must be designed and analyzed according to established epidemiologic principles (26). False-positive results may arise due to unrecognized population differences between cases and controls (population stratification), while false-negative results can result from inappropriate study design such as inadequate sample size or inappropriate selection of cases and controls. The detection of small genetic effects may require several hundreds of cases and controls, especially if the linkage disequilibrium between the marker and the candidate susceptibility locus is weak (26,27). Despite these potential problems, association studies have nevertheless proved to be useful tools for detecting genetic contributions to human disorders, including diabetes. This is best exemplified by the case of HLA and type 1 diabetes (28).

It is estimated that about 11 million common variants (*polymorphisms*)—about 1 every 300 base pairs (bp)—are present along the human genome (29). Different combinations of these sequence differences account for heritable variation among individuals, including susceptibility to type 2 diabetes. Despite the remarkable progress in biotechnology, testing all 11 million variants for association with type 2 diabetes is not a feasible task at this time. To circumvent this problem, it has been proposed that the analysis be limited to a subset of polymorphisms

22: THE GENETICS OF TYPE 2 DIABETES 373

that are spaced at regular intervals along the genome and serve as markers for intervening variants in linkage disequilibrium with these. The Human Genome Project has generated an extensive map of single-nucleotide polymorphisms (SNPs) that can be used for this task (25), but the number of markers needed to cover the whole genome may be disproportionally high [up to 500,000 according to one simulation (30)]. Another issue of concern is the stochastic variance of linkage disequilibrium throughout the genome, making the prospect of an effective whole-genome screen through this approach uncertain (31,32). Because of these constraints, association studies have thus far been focused on specific candidate genes selected according to two different strategies: (a) the study of genes that have been demonstrated to have a role in glucose homeostasis (functional candidate genes), and (b) the investigation of genes placed in chromosomal regions that are found to be inherited together (linked) with type 2 diabetes in whole-genome screens of families (positional candidate genes) (33). Such genome scans for linkage are not as sensitive as association studies, especially in the case of multifactorial disorders, but have the great advantage of not being limited to genes that are known to play a role in glucose metabolism (27). Both strategies have been widely used during the past decade and have led to the identification of many potential genes for type 2 diabetes (34). The most important of these loci, along with their positions along the genome, are reported in Figure 22.4.

MONOGENIC FORMS OF DIABETES

The search has been particularly successful for special types of familial diabetes that are transmitted with a mendelian mode of inheritance and share some clinical features with type 2 diabetes. While these syndromes are fairly rare, their study has provided insights into the etiology of more common forms of type 2 diabetes and has led to the identification of new classes of candidate genes. Three main categories of monogenic forms of diabetes have been identified to date: maturity-onset diabetes of the young (MODY), genetic syndromes of extreme insulin resistance, and mitochondrial diabetes.

Maturity-Onset Diabetes of the Young

The term MODY was first introduced by Tattersall and Fajans in 1975 to indicate type 2–like diabetes with early onset (before age 25) and an autosomal dominant mode of inheritance (35). It is now clear that forms of autosomal dominant diabetes can occur after age 25 and that the inheritance pattern is more important than age at onset for the diagnosis (36–38). Autosomal dominant diabetes probably accounts for 1% to 3% of all cases of diabetes, although precise estimates of its prevalence are not available. The presence of large families with multiple affected members, coupled with the simple pattern of inheritance, has facilitated genetic studies of this disorder. Six different forms of MODY have been identified to date, each involving a mutation in a different gene located on a different chromosome (Table 22.1).

The first MODY gene to be recognized was glucokinase (*GCK1*) (39–42), followed by hepatocyte nuclear factors (HNF) 1 α and 4 α (43,44). Glucokinase is the first enzyme involved in glucose metabolism in the β -cell (45), whereas HNF1 α and HNF4 α are transcription factors that regulate the expression of several genes in the liver and the β -cell (46,47). Glucokinase mutations are present in greater than 50% of French patients with MODY but are less frequent in other populations, repre-

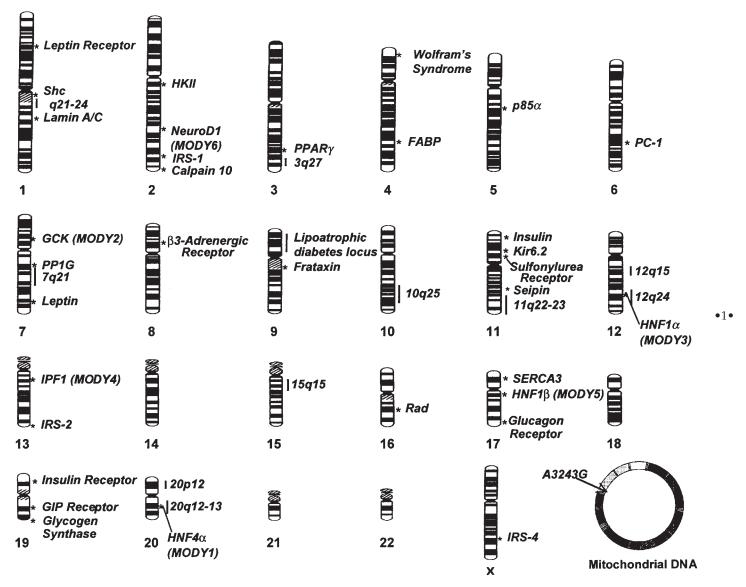

Figure 22.4. Location of potential type 2 diabetes genes in the human genome. (Modified from Almind K, Doria A, Kahn CR. Putting the genes for type II diabetes on the map. *Nat Med* 2001;7:277–279.)

TABLE 22.1. Genes Found to Be Mutated in Autosomal Dominant Diabetes or Maturity-Onset Diabetes of the Young				
Gene	Chromosomal region	Clinical characteristics	Study	
Glucokinase	7p15	Mild diabetes or impaired glucose tolerance, young age at diagnosis, rare microvascular complications	Vionnet et al. (41) Stoffel et al. (42)	
HNF1α	12q24	Severe diabetes, young age at diagnosis, frequent need for insulin therapy, microvascular complications	Yamagata et al. (43	
HNF4α	20q12-q13	Mild to severe diabetes, young age at diagnosis, subtle liver abnormalities	Yamagata et al. (44)	
IPF1/PDX1	13q12	Mild diabetes, variable age at diagnosis, pancreatic agenesis (homozygosis)	Stoffers et al. (37)	
HNF1β	17q12–q21	Mild to severe diabetes, young age at diagnosis, nondiabetic kidney disease, genital malformations	Horikawa et al. (50 Lindner et al. (52)	
neuroD1/BETA2	2q32	Mild to severe diabetes, variable age at diagnosis	Malecki et al. (38)	

senting 10% to 25% of cases in the United States and the United Kingdom and only 1% of cases in Japan (48). Mutations in HNF1 α and HNF4 α account for approximately 70% of cases of MODY in the United States and the United Kingdom (48,49). Rarer forms of MODY have also been found associated with mutations in other three transcription factors expressed in the liver and the β -cell, namely insulin promoter factor 1 (IPF1, also known as PDX1, IDX1, or STF1), HNF1β, and neuroD1 (also known as BETA2) (37,38,50). MODY due to mutations in IPF1 has been described in a single family, in which the homozygous proband had pancreatic agenesis and the heterozygous parents had diabetes (51). Diabetes due to mutations in HNF1 α is also very rare and often associated with kidney cystic disease, genital malformations, or both (52,53). Two mutations in neuroD1 have been described, one in a typical MODY pedigree, the other in a family with "typical" type 2 diabetes, but with an autosomal dominant mode of inheritance (38).

A prominent feature of all forms of MODY is a defect of insulin secretion (54,55). In the case of glucokinase mutations, this is due to an impairment of the β -cell glucose sensor caused by a decrease in the ability of glucokinase to phosphorylate glucose, resulting in inappropriately low fasting concentrations of insulin in relation to glycemic levels (45). For mutations in transcription factors, the cause of diabetes is less clear. One hypothesis is that a reduced activity of these transcription factors may impair the differentiation of islet cells during development, thereby reducing the number of functional β cells in affected individuals (56–59). Another possibility is that these mutations directly affect the expression of genes required for glucose transport and metabolism in the β -cell (60). Also a direct effect on the expression of the insulin gene cannot be ruled out, especially for IPF1 and neuroD1, which are known regulators of insulin gene transcription (61,62). A clarification is expected from the postmortem analysis of islets from mutation carriers and from expression profile studies aimed at identifying the target genes of these transcription factors.

From a clinical standpoint, mutations in the glucokinase gene cause a rather mild form of diabetes (Table 22.1). Hyperglycemia is often diagnosed early in life, but fasting blood glucose values rarely exceed 130 mg/dL and the occurrence of diabetic complications is rare (54,63). Diabetes associated with mutations in HNF1 α , HNF4 α , and HNF1 β is generally more severe (Table 22.1) (55). The insulin response to a glucose load is severely impaired, with insulin levels during an oral glucose tolerance test (OGTT) rarely exceeding 20 to 30 μ U/mL (36,55). About 50% of diabetic carriers need insulin therapy, and diabetic complications are more common than in MODY due to glucokinase mutations (55,63). Diabetes due to IPF1 mutations is milder and is diagnosed at a slightly older age than is MODY due to HNF mutations (37). Of the two families thus far described as carrying neuroD1 mutations (38), one has a phenotype resembling that of MODY due to HNF1 α mutations (young age at diagnosis, low prevalence of obesity, low insulin levels), while the phenotype in the other is more similar to that of common type 2 diabetes (older age at diagnosis, high prevalence of obesity, conserved insulin secretion).

While these are the general features of diabetes associated with different MODY genes, there is wide variability in the clinical presentation within the same MODY subtype. Some of this variability may be accounted for by the different nature of mutations segregating with diabetes in different families (*allelic heterogeneity*). However, large variation in the age at onset and severity of diabetes also is observed among carriers of identical mutations. This variability may be due to the presence of environmental or genetic factors that act as modifiers of the phenotype associated with each mutation. For instance, it has been hypothesized that co-inheritance of common type 2 diabetes susceptibility genes may determine a more severe presentation of MODY (64). Thus, MODY might not be the simple, monogenic disorder that has usually been considered, and further study of known MODY forms may lead to the discovery of new loci playing important roles in glucose homeostasis.

Finally, the six genes thus far identified do not account for all cases of autosomal dominant diabetes. In France and England, approximately 25% of MODY pedigrees do not show linkage with glucokinase, HNF1 α , or HNF4 α (48,65). The proportion of cases not accounted for by known genes appears to be even higher among families with an older age at diagnosis of diabetes (36). Available data suggest that some of these families are characterized by a pure insulin secretion defect, similar to that of HNF1 α diabetes, whereas others are predominantly insulinresistant, similar to common type 2 diabetes (36) (Fig. 22.5). Thus, a high degree of genetic heterogeneity is expected. Recent data from the laboratories of the Joslin Diabetes Center indicate that a locus accounting for diabetes in some of these families may be placed on chromosome 12q, 50 cM centromeric to HNF1 α (66).

Genetic Syndromes of Extreme Insulin Resistance

Although rarer than MODY, syndromes of severe insulin resistance have been known for several years. Forms that have been described include leprechaunism, Rabson-Mendenhall syndrome, type A and type B syndromes, and lipodystrophies (67–71). Leprechaunism is a congenital syndrome characterized by severe insulin resistance of peripheral tissues, intrauterine and neonatal growth retardation, elfin facies, and early death (67). The Rabson-Mendenhall syndrome becomes evident during childhood, with severe insulin resistance, abnormal nails and dentition, accelerated growth, precocious pseudopuberty, and pineal hyperplasia (68). The type A syndrome of insulin resistance primarily affects young women, who present with severe hyperinsulinemia (>50 μ U/mL in the fasting state), hyperandrogenism, polycystic ovary, and acanthosis nigricans (hyperpigmented and hyperkeratotic lesions in skinfold areas) (69). The type B syndrome has features similar to those of type A but affects older women and is often accompanied by autoimmune features (69). Finally, lipodystrophies are characterized by complete (lipoatrophic diabetes) or partial lack of adipose tissue, hepatosplenomegaly, hyperlipidemia, and severe insulin resistance, which can be present at birth or appear later in life (70.71).

Mutations in the insulin-receptor gene (INSR) impairing insulin action underlie all cases of leprechaunism and Rabson-Mendenhall syndrome described to date (72). Mutations in this gene are also responsible for a good proportion of cases of type A syndrome (72,73). Some of these sequence differences lead to a lower number of receptors because of decreased synthesis, increased degradation, or abnormal translocation from the endoplasm to the cell membrane (72). Other mutations are instead associated with decreased affinity of the receptor for insulin or impaired tyrosine kinase activity (72,73). In many instances, these forms are inherited in an autosomal recessive fashion, with some patients being homozygotes for a single mutation and others being compound heterozygotes who inherited two different mutant alleles, one from each parent. A few patients appear to have mutations in only one allele, suggesting an autosomal dominant pattern of inheritance, but the

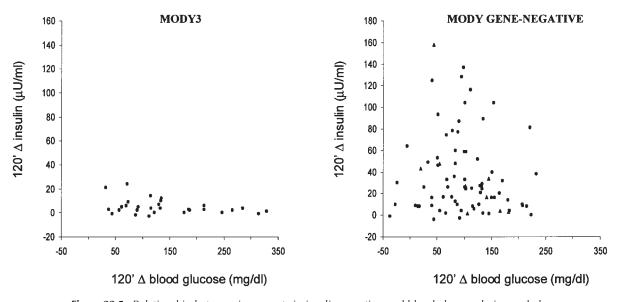

Figure 22.5. Relationship between increments in insulin secretion and blood glucose during oral glucose tolerance test (OGTT; 120' Δ , change 2 hours after glucose ingestion) in maturity-onset diabetes of the young (MODY). Data are reported on the left for diabetic carriers of HNF1 α mutations (MODY3) and on the right for diabetic members of families with early-onset, autosomal dominant type 2 diabetes not accounted for by known MODY genes (MODY gene–negative). Only individuals not treated with insulin were considered. MODY 3 subjects are characterized by a pure insulin secretion defect, while a more heterogeneous pattern is visible among MODY gene–negative subjects. (Copyright © 1999. From Doria A, Yang Y, Malecki M, et al. Phenotypic characteristics of early-onset autosomal-dominant type 2 diabetes unlinked to known maturity-onset diabetes of the young (MODY) genes. *Diabetes Care* 1999;22:253–261, with permission from the American Diabetes Association.)

presence of as yet unidentified mutations in the "healthy" allele cannot be excluded in these cases.

Autosomal dominant forms of partial lipodystrophy (Dunnigan-Kobberling type) have recently been found to be due to mutations in the lamin A/C gene (LMNA) on chromosome 1q21 (74,75). Lamins are the main components of the nuclear lamina, the proteinaceous layer that is apposed to the inner nuclear membrane (76). The LMNA gene codes for two of these proteins, lamin A and C, through alternative splicing. Most of the mutations associated with partial lipodystrophy cluster on a 15bp region of exon 8 of the LMNA gene and affect the globular Cterminal domain of the lamin A/C proteins (74,75). Especially frequent are substitutions of a highly conserved arginine at position 482. Little is known, however, about the mechanisms linking these mutations to lipodystrophy, insulin resistance, and hyperlipoproteinemia. Lamins are expressed in all tissues, where they play a role in DNA replication, chromatin organization, nuclear-pore arrangement, and anchorage of nuclear envelope proteins (76). Of note, mutations in the LMNA gene have also been found to be associated with Emery-Dreyfuss muscular dystrophy and dilated cardiomyopathy and conductionsystem disease (77,78). In contrast with partial lipodystrophy, mutations in these disorders are distributed across several exons. Thus, the region around residue 482 in the globular domain of lamins A/C may determine specific functions in the adipocyte, the impairment of which leads to lipodystrophy. Mutations in the LMNA gene, however, do not appear to be involved in the etiology of generalized lipodystrophy [lipoatrophic diabetes or Berardinelli-Seip syndrome (BSCL)] (79). A locus linked with some of these forms (BSCL2) has recently been mapped to chromosome 11q13 and shown to correspond to the human homologue of the murine guanine nucleotidebinding protein (G protein), γ 3-linked gene (*GnG31g*) (80). *BSCL2* is most highly expressed in brain and testis and codes for a protein, called seipin, of unknown function. Another *BSCL* locus (*BSCL1*) has been mapped on 9q34 in *BSCL2*-negative families, but the identity of the gene that is involved is unknown (80).

Mitochondrial Diabetes

The mitochondrial genome consists of a circular 16,569-bp DNA molecule containing the genes for ribosomal and transfer RNAs and for some proteins of the respiratory chain. This DNA (mtDNA) has several unique features. First, it is transmitted only through the maternal side, since the sperm sheds its mitochondria during penetration into the ovum (81). Second, it exists in the cell in several copies—as many as a few thousand in cells with a high mitochondrial content. Finally, it is prone to a high degree of mutation and rearrangement, which, however, often affect only a fraction of the mtDNA, a phenomenon known as *heteroplasmy*. For each mutation, levels of heteroplasmy vary, being much higher in nondividing tissues such as muscle and brain than in rapidly dividing cells such as leukocytes.

A variety of syndromes associated with point mutations or deletions in the mtDNA have been described. Most of these concern tissues that have a high demand for energy, such as skeletal muscle and brain. The maternally inherited diabetes and neurosensory deafness (MIDD) syndrome is caused by a single nucleotide mutation (A3243G) in the mtDNA encoding the transfer RNA (tRNA) for leucine (82–85). Rare cases of MIDD have also been observed in association with mtDNA deletions or duplications (86). These mitochondrial defects are thought to result in altered oxidative metabolism in the β -cell, leading to an impairment in the production of ATP that is needed for glucose-stimulated release of insulin (87,88). A reduction in the oxidative metabolism of glucose in peripheral tissues may also contribute to the development of hyper-glycemia, but its role is uncertain. The MIDD syndrome accounts for approximately 1% of individuals with diabetes.

Mitochondrial diabetes usually is characterized by an early onset of hyperglycemia (often before age 30), which is due to impaired insulin secretion and is followed by a rapid progression to insulin dependence (84,85). In some instances, MIDD can be misdiagnosed as type 1 diabetes (if insulin is required from the onset) or type 2 diabetes (if it can be managed with diet or oral medications), but patients are generally negative for islet-cell antibody and do not show increased prevalence of obesity (85). Impaired hearing, which can be so severe as to require the use of a hearing aid, is present in the majority of patients with MIDD and becomes manifest as a loss of high-frequency perception. The A3243G mutation also may lead to the so-called MELAS syndrome (mitochondrial myopathy, encephalopathy, lactic acidosis, and stroke-like episodes), which may or may not be associated with diabetes (89). Differences in phenotypic expression of the mitochondrial defects may be due to variations in the degree of heteroplasmy and to the tissue distribution of heteroplasmic mtDNA (85). The variable degree of heteroplasmy may also be responsible for difficulties in identifying the mitochondrial mutations responsible for the MIDD syndrome.

MULTIFACTORIAL FORMS OF TYPE 2 DIABETES

Because of the complex genetics, the search for genes involved in common, multifactorial type 2 diabetes has not been as successful. Many potential type 2 diabetes genes have been identified (Fig. 22.4), but findings have been difficult to replicate in most cases. Several factors contribute to these variable results. An important issue may be the presence of genetic heterogeneity, with different genes contributing to type 2 diabetes in different populations. Even within the same ethnic group, different subtypes of type 2 diabetes may be accounted for by different genes, making the results of association studies heavily dependent on how affected cases or families are selected. Discrepancies also can occur because of population differences in the linkage disequilibrium between markers and causal variants. Other important factors concern methodologic issues regarding the study design and the analysis of data. False-positive results can arise from multiple hypothesis testing or, in association studies, from unrecognized ethnic differences between cases and controls (so-called population stratification). Conversely, studies may fail to replicate true positive results because of inadequate statistical power or of failure to account for gene-gene or gene-environment interactions. All these factors must be carefully considered when weighing the evidence supporting or excluding the role of a certain locus. As discussed above, two main approaches have been followed to identify genes for multifactorial forms of type 2 diabetes: (a) studies of functional candidate genes and (b) whole-genome screens followed by the study of positional candidate genes.

Studies of Functional Candidate Genes

Selection of this class of candidate genes for type 2 diabetes has been based upon the biochemical function and expression pattern of the encoded proteins, which, if altered, might be implicated in the pathogenesis of the disease. Since both insulin resistance and a deficit of insulin production are involved in the etiology of type 2 diabetes (5), genes known to be involved in insulin action or β -cell function have been intensely investigated. Because of the strong links between obesity and type 2 diabetes, many studies have also considered genes involved in the regulation of the energy balance and in the development and metabolism of adipose tissue.

GENES INVOLVED IN INSULIN ACTION

Insulin action at the cellular level is the result of a complex network of signaling events (90) (Fig. 22.6). Binding of insulin to its

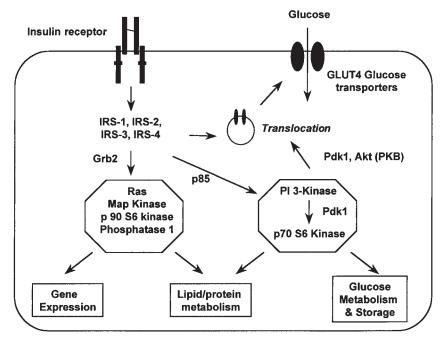

Figure 22.6. Schematic model of the cellular pathways involved in insulin signaling. IRS, insulin-receptor substrate; PDK, phosphoinositide-dependent protein kinase; PKB, protein kinase B; Grb, growth factor receptor–bound protein; p 90 S6 kinase and p 70 S6 kinase, 90 kDa and 70 kDa ribosomal kinase, respectively; PI, phosphatidylinositol.

receptor leads to activation of the insulin receptor tyrosine kinase, which results in phosphorylation of tyrosine residues on a family of insulin receptor substrates. These tyrosine-phosphorylated substrates then bind to and activate a number of intracellular proteins in the insulin signaling cascade, the most important of which for metabolic effects is phosphatidylinositol (PI) 3-kinase. Docking of these proteins in turn activates specific signal transduction pathways (for instance, the translocation of glucose transporters to the plasma membrane) mediating the cellular effects of insulin.

Insulin Receptor. Despite the relatively high frequency of insulin-receptor mutations in syndromes of severe insulin resistance, genetic variability in the insulin receptor gene does not appear to play a major role in common forms of type 2 diabetes. Initial studies demonstrated several polymorphisms in the coding regions, some affecting the amino acid sequence, but none of these were shown to be more frequent in subjects with type 2 diabetes as compared with controls (91,92). Results were similarly negative in populations with a high prevalence of insulin resistance such as Pima Indians and in linkage analyses of families (93-95). More recently, a significant association has been reported between type 2 diabetes and the Val985Met variant in two Dutch populations (96). This polymorphism appears to confer a twofold increase in the risk of type 2 diabetes but, being rather rare, can account for only a handful of cases of type 2 diabetes. Since the INSR gene is rather large, noncoding regions have not been extensively screened for variation. Thus, one cannot rule out the existence of variants in as-yet unscreened regulatory elements that increase susceptibility to diabetes by impairing insulin-receptor expression. Indeed, a decrease in the number of insulin receptors is observed in type 2 diabetes, although this is common to all hyperinsulinemic states and is thought to be due to downregulation of the receptor through increased degradation (97). An additional factor is the alternative splicing of the messenger RNA, which originates

two forms of the receptor differing by 12 amino acids near the C-terminus of the α -subunit (98,99). These two receptor isoforms exhibit subtle differences in binding affinities, tyrosine kinase activities, and internalization kinetics (100–102). Differences in the expression of these two subtypes between patients with type 2 diabetes and nondiabetic controls have been reported in the literature, but the significance of this result is controversial because not all studies have found this difference and the functional differences between the two isoforms are rather small (103–105). Whether the alternative splicing is under the control of genetic variants is unknown at this time.

Insulin-Receptor Substrates. One of the best-characterized molecules in the intracellular insulin action cascade is insulinreceptor substrate-1 (IRS-1), a 131-kilodalton (kDa) cytosolic protein that is tyrosine phosphorylated by the insulin receptor (106,107). In animal models, heterozygous disruption of IRS-1 does not lead to frank hyperglycemia but acts epistatically to potentiate other genetic defects in the production of diabetes (108,109). A total of nine amino acid substitutions have been identified in this molecule to date in white and Japanese populations (110-122). The most prevalent of these is a glycine-toarginine substitution placed at codon 972 between two potential tyrosine phosphorylation sites binding the p85 subunit of PI 3-kinase (110). This variant has been examined for association with type 2 diabetes in more than 14 populations (110-122). While initial studies suggested an association with type 2 diabetes (110), the carrier frequency varies considerably among different populations (from 0.01 to 0.19) and an association with type 2 diabetes has not been observed in all populations (Fig. 22.7). If all these studies are considered together in a metaanalysis, the relative risk of type 2 diabetes associated with the Gly972Arg variant is not significantly different from 1 [odds ratio (OR): 1.05, 95% confidence interval (CI) 0.83-1.33]. Results are similar if the meta-analysis is performed separately for whites and Asians.

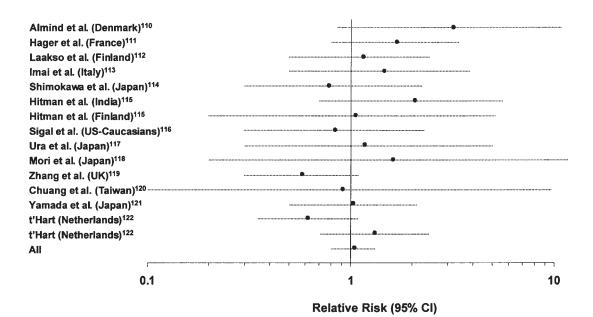

Figure 22.7. Estimated risk of type 2 diabetes associated with the IRS-1 Gly972Arg variant. For each study, the solid circles represent the odds ratio for 972Arg carriers and the dotted line indicates the 95% confidence interval. Odds ratios were not significantly different across studies (p = 0.50, Breslow-Day test). "All" indicates the Mantel-Haenszel estimate of the common relative risk based on all published studies (4,306 individuals).

Despite these negative results, IRS-1 cannot be easily dismissed as a possible type 2 diabetes gene. All the studies above considered cases of type 2 diabetes that were not selected on the basis of patients' insulin sensitivity or body weight. In contrast, it has been shown that the Gly972Arg is specifically associated with a subset of type 2 diabetes characterized by obesity and marked insulin resistance (115,123). Furthermore, functional data support a role for this variant in the etiology of insulin resistance. Transfection studies have consistently shown that the Arg⁹⁷² allele is associated with a 40% decrease in IRS-1-associated $\rm \widetilde{PI}$ 3-kinase activity and a 25% to 40% decrease in binding of the p85 subunit of PI 3-kinase to IRS-1 (124,125). It is interesting that expression of this variant in β -cells decreases both glucose and sulfonylurea-stimulated insulin secretion and that carriers of this allele have lower insulin-secretion rates during hyperglycemic clamp than do noncarriers (126,127). Thus, the Gly972Arg variant has the potential to contribute to both insulin resistance and the defective β-cell compensation characteristic of type 2 diabetes.

IRS-2 has been also at the center of intense investigation following the report that homozygous disruption of this gene in mice results in a phenotype similar to human type 2 diabetes (128). However, all three amino acid substitutions that have been identified in humans (Leu647Val, Gly879Ser, and Gly1057Asp) do not appear to be associated with type 2 diabetes, although nondiabetic Asp¹⁰⁵⁷ homozygotes may have decreased insulin levels both in the fasting state and during OGTT (129–131). Variability in the coding region of the IRS-4 gene (placed on chromosome X) has also been excluded as a possible genetic determinant of type 2 diabetes (132). No information is available on the role of IRS-3, as the gene for this protein has been identified in mouse and rat but not in humans.

PI 3-Kinase. PI 3-kinase is the major protein that is bound and activated by phosphorylated IRSs (90). This molecule phosphorylates the inositol ring of phosphatidylinositol, producing phosphatidylinositol 4-phosphate (P), -4,5-P2, and 3,4,5-P3, which propagate the insulin signal to downstream pathways (133). A reduction in the insulin response of this enzymatic activity has been reported in muscle and adipose tissue from insulin-resistant subjects with type 2 diabetes (134). The enzyme consists of a catalytic subunit (p110) coupled to a regulatory subunit (p85) having two isoforms (α and β) encoded by different genes (135). A third regulatory subunit with lower molecular weight has also been isolated (p55y) along with low-molecular-weight splice variants of p85a (136). A relatively common amino acid substitution (Met326Ile) has been identified in the p85 α isoform (137). This residue is highly conserved across species and is placed in proximity to one of the two SH2 domains that interact with phosphorylated IRSs. While the Ile326 allele is not associated with type 2 diabetes, it was correlated with reductions in whole-body glucose effectiveness and intravenous glucose disappearance in healthy Danish subjects (137). In sharp contrast with these findings, the variant had an "antidiabetogenic" effect in Pima women, as indicated by a significantly higher acute insulin response during OGTT in Ile/Ile homozygotes (138). No effect was observed in Japanese patients (139). Results of *in vitro* experiments have failed to show significant difference in insulin-stimulated lipid kinase activity and phosphotyrosine recruitment between Met326 and Ile326 allele (140). Thus, if this polymorphism affects insulin action, its effect is probably minor. A rare variant of p85α (Arg409Gln) has been described in one subject with extreme insulin resistance and appears to be associated with lower insulinstimulated PI 3-kinase activity (140). A screening of the p110 catalytic unit in Finnish subjects has identified two polymorphisms in the 5' flanking region, but these are not associated with diabetes (141). The effect of genetic variability in the p85 β and p55 γ isoforms has not been investigated to date.

Genes Involved in Glucose Transport and Metabolism. While insulin has pleiotropic effects on cellular functions, the actions that have been specifically shown to be impaired in type 2 diabetes are those related to glucose uptake and incorporation into glycogen (5). In muscle and fat cells, insulin stimulates glucose uptake by inducing the translocation of glucose transporter 4 (GLUT4) from intracellular compartments to the cell surface and activates glycogen synthase by promoting its dephosphorylation (90). Both effects appear to involve the activation of the phosphoinositide-dependent protein kinase-1 (PDK1) and protein kinase B (PKB, also known as AKT) (Fig. 22.6), which have been both screened for amino acid variants in subjects with insulin resistance. However, only silent polymorphisms have been found (142). Likewise, variability in the GLUT4 gene (17p13) does not seem to contribute to type 2 diabetes. Sequence differences in GLUT4 promoter and coding sequence have been identified, but are either extremely rare or equally frequent in type 2 diabetic cases and nondiabetic controls (92,143-145).

The glycogen synthase gene (19q13) has been intensively investigated because of the finding of multiple defects in the activity of this enzyme in the skeletal muscle of patients with type 2 diabetes (146). An XbaI restriction fragment length polymorphism (RFLP) placed in intron 14 has been reported to be associated with type 2 diabetes, impaired nonoxidative glucose metabolism, and arterial hypertension in Finland (147). This finding has been replicated by the same authors in a different sample of unrelated Finnish individuals and in affected sibpairs (148,149) but has not been confirmed in populations from France, Japan, and the United States (150,151, and A. S. Krolewski, personal communication). An association has been found in Pima Indians and Japanese but concerns a dinucleotide repeat rather than the XbaI polymorphism (152). A possible explanation is that both the XbaI polymorphism and the dinucleotide repeat are markers in linkage disequilibrium with as-yet-unidentified disease variants that are characteristic of specific populations. None of the amino acid polymorphisms identified to date appear to contribute to insulin-resistant phenotypes, although the very rare Pro442Ala variant has been shown to significantly decrease the ability of the enzyme to synthesize glycogen (153,154). A polymorphism in the regulatory G subunit of the glycogen synthase-activating protein phosphatase 1 (Asp905Tyr) may have a minor impact on insulin sensitivity in Danes, while a common variant in the 3'-untranslated region (UTR), causing a tenfold difference in reporter mRNA half-life, may contribute to insulin resistance in Pima Indians and aboriginal Canadians (155-157).

Inhibitors of Insulin Action. All the candidate genes described above have been selected based on the hypothesis that a genetically determined deficiency in elements of insulin action pathways leads to insulin resistance. An alternative concept is that insulin resistance may be due to a genetically determined excess in the expression or activity of inhibitors of insulin action. Several proteins that inhibit insulin signaling have been identified to date, and some of these have been investigated for a genetic contribution to type 2 diabetes (Fig. 22.8).

Rad is a member of a unique family of Ras-related guanosine triphosphatases that was identified by subtraction cloning between skeletal muscle of a type 2 diabetic individual and a nondiabetic subject (158). Rad expression is

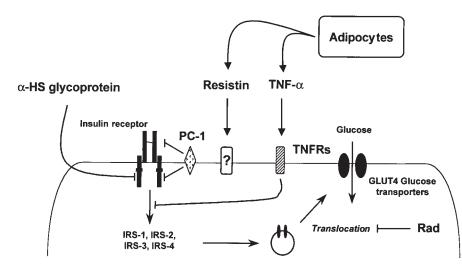

Figure 22.8. Natural inhibitors of insulin signaling and their action sites. TNF, tumor necrosis factor; TNFRs, TNF receptors; IRS, insulin-receptor substrate; PC, plasma cell membrane glycoprotein.

increased in about 20% of subjects with type 2 diabetes, its content being correlated to body weight and resting metabolic rate. The overexpression of this protein in cultured myocytes and adipocytes inhibits insulin-stimulated uptake of glucose through an effect on the intrinsic activity of GLUT4 molecules rather than on their translocation (159,160). The gene coding for Rad consists of 5 exons spanning about 3.7 kb on chromosome 16q (161). In a white population from the United States, a significant association was found between type 2 diabetes and the rare alleles of a composite trinucleotide repeat polymorphism placed in intron 2 (162). Carriers of these alleles had a threefold increase in the risk of diabetes as compared with noncarriers. This association, however, was not confirmed in Finns (163). By contrast, an association was detected in Japanese, but the alleles associated with type 2 diabetes are different from those found in whites in the United States (164). These discrepancies may reflect ethnic differences in the pattern of linkage disequilibrium between the trinucleotide repeat marker in exon 2 and a causal variant at the Rad locus or its vicinity.

Another potential inhibitor of insulin action is the plasma cell membrane glycoprotein-1 (PC-1), a transmembrane protein with phosphodiesterase and pyrophosphatase activity (165). When overexpressed in cultured cells, PC-1 inhibits insulin receptor tyrosine kinase activity by a direct interaction with the insulin receptor α -subunit (166). In nonobese, nondiabetic subjects, the PC-1 content of skeletal muscle is inversely correlated to both in vivo insulin action and in vitro stimulation of the insulin receptor tyrosine kinase activity (167). An amino acid variant identified in PC-1 (Lys121Gln) has been reported to contribute to insulin resistance in a nondiabetic population from Sicily, primarily by impairing insulin receptor kinase activity (168). Gln¹²¹ carriers have a threefold increase in the risk of being hyperinsulinemic and insulin resistant but have no increase in risk of developing type 2 diabetes (168). Fibroblasts from these subjects show an impairment of insulin-receptor autophosphorylation in the presence of normal PC-1 levels. Similar findings of association have been obtained in a familybased study from Sweden but not in a large population-based study from Denmark (169,170). In Mexican Americans, a major locus for fasting insulin concentrations and insulin-resistance traits has recently been mapped to the same region of the PC-1 gene on chromosome 6q22-q23 (171). Whether this locus corresponds to the PC-1 gene in this population awaits further investigation.

Other studies have considered circulating inhibitors of insulin action. pp63, also known as α -HS glycoprotein, was identified in extracts of rat liver (172). In both rodents and humans, this protein is present at relatively high levels in the circulation, where it might act on peripheral tissues involved in insulin action. pp63 has been shown to inhibit the insulin receptor tyrosine kinase and insulin-stimulated DNA synthesis (173). Thus far, however, there is no evidence for genetic alterations in expression, secretion, or action of this protein in type 2 diabetes. A circulating inhibitor that has been more intensively studied is tumor necrosis factor- α (TNF- α), a potent cytokine with a wide range of proinflammatory activities (174). TNF- α may contribute to the insulin resistance of infection or stress and also to type 2 diabetes, since TNF- α is hypersecreted by adipocytes in obesity (175). Exposure to TNF- α decreases glucose uptake in vitro and in vivo, and homozygous disruption of the TNF- α gene protects mice from obesity-induced insulin resistance (175,176). However, whether genetic variability in this cytokine contributes to the development of type 2 diabetes in humans remains unclear. The human TNF- α gene lies in the class III region of the major histocompatibility complex, centromeric to the HLA-B locus and telomeric to HLA-DR. The rare allele of a polymorphism in the promoter region (G/A at position -308) is associated with increased TNF- α expression and more severe disease in infections such as malaria and leishmaniasis (177,178). The same polymorphism was found to be associated with indices of insulin resistance in a Spanish population but not in studies from the United States, Germany, Denmark, United Kingdom, Japan, and Hong Kong (179–184). Another promoter variant (G/A at -238) was reported to be associated with impaired insulin sensitivity in the United Kingdom, but this was not confirmed in other populations (179–185). The role of variability in the two TNF- α receptor (TNFR1 and TNFR2) has been less investigated. Only one report has been published to date describing lower insulin sensitivity in carriers of an allele in the 3' UTR of TNFR2 (186).

GENES INVOLVED IN INSULIN SECRETION

Pancreatic β -cells sense glucose and other nutrients and respond to this signal by synthesizing and secreting insulin to promote the utilization and storage of these substrates (45). The signal for insulin secretion is provided by the utilization of glucose in the β -cell (Fig. 22.9). After being transported into the cell by a high-capacity, Na⁺-independent carrier (GLUT2),

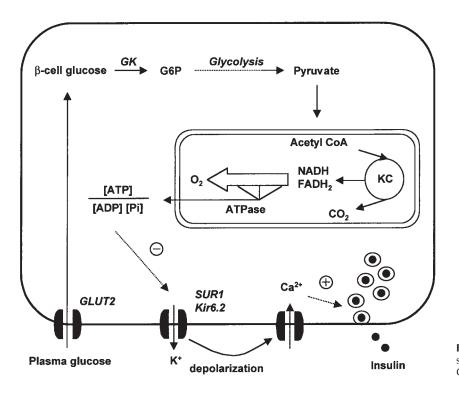

Figure 22.9. Schematic model of the β -cell glucose sensor and insulin secretion pathways. GK, glucokinase; G6p, glucose 6-phosphate; KC, Krebs cycle.

glucose is phosphorylated by the enzyme glucokinase and is metabolized in glycolysis and the Krebs cycle. The ensuing increase in energy production raises the intracellular ATP/ADP ratio, which in turn inhibits adenine nucleotide-sensitive potassium channels (45). The resulting depolarization opens voltage sensitive Ca2+ channels, leading to an increase in cytosolic Ca²⁺, which ultimately induces the fusion of insulin granules with the plasma membrane and insulin release. β-Cells also respond to glucose by increasing preproinsulin biosynthesis in the endoplasmic reticulum, although the mechanisms by which glucose exerts transcriptional and translational control of preproinsulin mRNA are poorly understood. All genes whose products are placed in these pathways are obvious candidate genes for type 2 diabetes. Additional candidate genes are those that are involved in the development and turnover of β -cells (e.g., β -cellspecific transcription factors) or are part of hormonal systems regulating β -cell activity.

GLUT2 and Glucokinase. Because of their central role in glucose sensing, GLUT2 and glucokinase were among the first genes to be investigated for association or linkage with type 2 diabetes. An additional reason to study glucokinase was the finding that glucokinase mutations cause MODY (54). This raised the hypothesis that sequence differences resulting in a milder impairment of glucokinase activity may be responsible for forms of diabetes with a later onset. It is now clear that genetic variability at these two loci does not play a major role in common type 2 diabetes. An association between a TaqI RFLP in the GLUT2 gene and type 2 diabetes was reported in British individuals but has not been confirmed in other populations (187-190). A mutation (Val197Ile) abolishing GLUT2 activity, and possibly causing diabetes, has been described in a single patient with type 2 diabetes (191). Several other allelic variants have been detected in this gene, but none has shown association with overt type 2 diabetes or glucose intolerance (192). Results have been similarly negative for glucokinase. Initial studies reported an association between some

microsatellite alleles and late-onset type 2 diabetes in African Americans, Mauritian Creoles, and Japanese, but mutations affecting glucokinase expression or structure were not found in these populations (193–197). More recently, a common variant in the islet-specific promoter of this gene (-30 G to A) has been reported to be associated with reduced insulin secretory responses to oral glucose, although results have not been consistent across populations (198–200). Attempts to demonstrate linkage between the glucokinase locus and type 2 diabetes have also been negative in family studies from France, England, and Utah (201–203).

Ion Channels. Adenine nucleotide-sensitive potassium channels (KATP) play a pivotal role in coupling glucose metabolism to insulin release. The K_{ATP} channels of β -cells consist of two subunits: the inward rectifier K⁺ channel Kir6.2 and a regulatory subunit, which also serves as the sulfonylurea receptor (SUR1) (204). The genes coding for the two subunits are clustered at 11p15, with the Kir6.2 gene (also known as KCNJ11) placed immediately 3' of SUR1 (also known as ABCC8). Rare mutations in both subunits have been observed in persistent hyperinsulinemic hypoglycemia of infancy, a rare disorder characterized by unregulated insulin secretion despite severe hypoglycemia (205,206). However, the evidence for a contribution of these two loci to type 2 diabetes is controversial. Two polymorphisms in the SUR1 gene have received particular attention. One corresponds to a C-to-T substitution placed in intron 15 at a short distance (3 bp) from the exon 16 acceptor side; the other is a synonymous polymorphism in exon 18 (a Cto-T substitution at codon 759). In the first report to be published, the allele "C" in intron 15 and the allele "T" in exon 18 were both significantly associated with type 2 diabetes in two different white populations (207) (Table 22.2). However, the association with the SNP in intron 15 was not unequivocally confirmed in subsequent reports (208-217). Among 10 studies, only three detected significant differences between cases and controls, and in one of these, the allele "T" rather than "C" was associated with diabetes (Table 22.2). Results are more convinc-

TABLE 22.2. Results of Association Studies Concerning the SUR1 Gene in Type 2 Diabetes

ing for the SNP in exon 18. In this case, a significant or suggestive association with type 2 diabetes has been found in four of five replication studies, although the proportion of diabetes cases accounted for by this variant is probably small (208,210,213,215,216). A role of this variant in glucose homeostasis also is supported by studies among nondiabetic individuals showing lower C-peptide fasting levels and acute insulin response in nondiabetic carriers (210). Being a synonymous substitution, this SNP is probably a nonfunctional marker in linkage disequilibrium with an as-yet-unidentified causal variant. Variability in the Kir6.2 gene could also play a role in type 2 diabetes, but the evidence is controversial (218,219).

Preproinsulin Gene. Six extremely rare mutations have been identified to date in the insulin gene on 11p15 [reviewed by Steiner et al. (220)]. Three of these concern the primary sequence of the A- or B-chains: insulin Chicago (B Phe25Leu), insulin Wakayama (A Val3Leu), and insulin Los Angeles (B Phe24Ser). These mutations impair the binding of insulin to its receptor and are associated with high circulating levels of insulin, modest hyperglycemia, and an increase in the half-life of the hormone (because much of insulin clearance is due to receptor-mediated uptake). The other three mutations result in an impairment of the processing of proinsulin to insulin. Two of these are localized at the proinsulin-processing site (Arg65His and Arg65Leu) and prevent the recognition by the dibasic protease that cleaves the C-peptide from the proinsulin molecule. The other (a His-to-Asp substitution at position 10 of the Bchain) alters the processing of proinsulin by interfering with its binding to zinc and its crystallization in β -cell secretory granules. These three mutations have minor effects on glucose metabolism and are characterized by high circulating concentrations of proinsulin. Since these mutations are very rare, carriers are usually heterozygotes. It is unclear whether so few (pro)insulin variants have been reported because of the mild or nonexisting phenotype, because of the lack of screening, or because of a low mutation frequency at this site.

As mutations in the coding region of the preproinsulin gene have not been found to be involved in common forms of type 2 diabetes, it has been hypothesized that the observed deficit of insulin secretion in type 2 diabetes might be related to abnormalities in regulatory elements of the gene. In this regard, considerable interest has been drawn to a complex polymorphism located 5' of the insulin gene in the proximity of promoter/ enhancer sequences, which could affect, at least theoretically, expression of the insulin gene (221). The polymorphism consists of a variable number of tandem repeats (VNTR), which can be subdivided into three classes (I, II, and III) according to their length. While an association has consistently been found between homozygosity for class I alleles and type 1 diabetes, this does not seem to be the case for type 2 diabetes (222-224). A recent U.K. study using a family-based design (transmission disequilibrium test) has detected a preferential transmission of class III alleles from heterozygous fathers, but not mothers, to type 2 diabetic probands (225). This result, which would implicate imprinted genes in the pathogenesis of type 2 diabetes, has not yet been confirmed by any other group. Another study has described a rare 8-bp insertion/deletion in the insulin gene promoter among African Americans, but its contribution to type 2 diabetes seems to be small, if any (226).

The enzymes processing preproinsulin to mature insulin (prohormone convertases 1 and 2 and carboxypeptidase E) have also been investigated as possible type 2 diabetes loci. These studies were based on the hypothesis that the relative insulin-deficiency characteristic of type 2 diabetes may be due to the release of disproportionate amount of biologically inactive insulin precursors. Indeed, subjects with type 2 diabetes show a marked increase in the proportion of circulating proinsulin, and mice carrying mutations in carboxypeptidase E (fat/ fat mice) develop obesity and diabetes (227,228). However, several studies have excluded a role of processing enzyme polymorphisms to the development of type 2 diabetes in humans (229,230). Mutations in prohormone convertase 1 have been identified but only in a rare genetic syndrome characterized by childhood obesity, gestational diabetes, and other endocrine disorders (231).

 β -Cell Transcription Factors. The development of β -cells is regulated by a complex network of transcription factors organized in a hierarchical fashion (Fig. 22.10) (56,232). Some of these factors also control β -cell physiology in the adult life by modulating the expression of genes involved in glucose metabolism and the insulin gene itself (60–62). The discovery that rare mutations in these factors cause MODY has also implicated

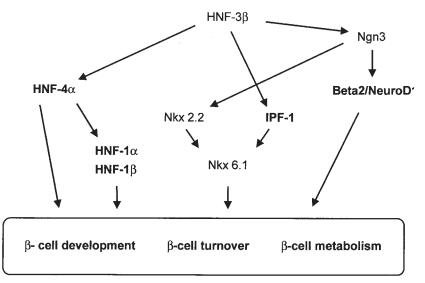

Figure 22.10. Transcriptional network in β -cells. Transcription factors that are mutated in maturity-onset diabetes of the young (MODY) are indicated in bold.

these genes in type 2 diabetes. In particular, it has been hypothesized that common variants, distinct from MODY mutations, may determine a slight impairment of β -cell function that may become evident only if there is an increased demand for insulin as in the presence of insulin resistance. Indeed, the chromosomal region of HNF1 α (MODY3) on 12q24 has been found to be linked with type 2 diabetes among families with poor insulin response from Botnia (Finland), and in a single family from Australia (233,234). No mutations, however, were identified in the HNF1 α coding region in these families, indicating that either the mutations are placed in as-yet unscreened regulatory regions or the gene responsible for these findings is a different one. Other studies have also suggested that polymorphisms in HNF1α do not play a major role in common type 2 diabetes, although these may be associated with slight abnormalities of insulin secretion (235-238). Linkage with type 2 diabetes has also been found in the HNF4α region on 20q in many studies, but genetic variability in this gene does not seem to be responsible for these findings (239-243). No association has been found between variants in neuroD1 and "garden variety" type 2 diabetes (38,244).

In contrast with these negative results, two recent papers have reported associations between IPF1 variants and type 2 diabetes. In England, Macfarlane et al. (245) have detected three missense mutations (C18R, D76N, and R197H) that are associated with decreased IPF1-binding activity and impaired activation of the insulin gene in response to hyperglycemia. These variants are rare overall (present in 1% of the population) but are associated with a threefold increase in the risk of type 2 diabetes. One of these mutations (D76N) has also been detected by researchers in France, where it is also significantly associated with type 2 diabetes (246). In the latter study, another variant was identified (InsCCG243) that was linked to type 2 diabetes in two families (246). Thus, it appears that genetic variability in IPF1 may indeed contribute to the development of type 2 diabetes, although this effect probably concerns a small proportion of cases and is not present in all populations (247). Several other transcription factors (HNF3β, HNF4γ, HNF6, neuroD4, PAX4) have been screened for sequence differences associated with type 2 diabetes with negative results (248-253). A weak association has been reported for a polymorphism in the neurogenin gene, but this has not been confirmed in other populations (251–253). New candidates in this class are expected to emerge from the expression profiling of β -cells.

Incretins. Another hypothesis is that the impairment in insulin secretion in type 2 diabetes is due to genetic alterations in extrapancreatic hormonal systems regulating β -cell function. GLP-1 (glucagon-like peptide-1) and GIP (glucose-dependent insulinotropic polypeptide) are gut hormones that act as incretins, activating specific receptors on the β-cell and augmenting insulin release after oral ingestion of carbohydrates, as compared with the intravenous intake (254-256). The effectiveness of GIP is generally diminished or lacking in patients with type 2 diabetes, whereas the efficacy of GLP-1 is maintained (257,258). One variant (Gly198Cys) in the GIP receptor identified in Japanese patients exhibits increased GIP-induced cAMP response in transfected CHO cells (259), and a common Glu354Gln variant is associated with decreased C-peptide levels during fasting and 30-minute post-OGTT in normal glucosetolerant Danish white subjects (260). However, none of the identified amino acid variants showed associations with type 2 diabetes (259,260).

OBESITY GENES

Because obesity is closely correlated to the development of type 2 diabetes and has some degree of heritability (261), genes with a potential role in obesity have also been considered in the search for type 2 diabetes genes. Body weight is finely regulated by hypothalamic pathways controlling the balance between energy intake and expenditure (262). This control is achieved through effects on behavior, the autonomic nervous system and the neuroendocrine system, regulating feeding and physical activity, energy expenditure, and the utilization of metabolic substrates. Much progress has been made over the past decade in understanding the molecular mechanisms mediating these effects, in part through the cloning of genes responsible for animal models of obesity (261,262). These studies have generated a long list of potential candidate genes, many of which have been investigated for contributions to obesity and type 2 diabetes.

Central Nervous System Mediators. Effects promoting weight gain are mediated in the hypothalamus by orexigenic (feeding-inducing) neuropeptides, the best characterized of which are NPY and AgRP, whereas effects promoting weight loss involve anorexigenic neuromediators such as α -MSH and CART (the cocaine- and amphetamine-regulated transcript) (263). All these peptides propagate their signals by interacting with specific receptors (e.g., MC4R receptor for α -MSH and AgRP) expressed in downstream neurons (263). Mutations caus-

ing rare forms of morbid obesity have been found in the precursor of α -MSH [propiomelanocortin (POMC)] and in the enzyme involved in its processing (prohormone convertase 1) (231,264). However, because of the concomitant lack of adrenocorticotropic hormone (ACTH) activity, these mutations are associated with hypoglycemia rather than hyperglycemia. Mutations are more frequent in the MC4R receptor and may be responsible for up to 4% to 5% of cases of morbid obesity [body mass index (BMI) >40 kg/m²], especially those showing an autosomal dominant mode of inheritance (265–268). However, no association with common, multifactorial forms of obesity or diabetes has been found to date for any of these genes (229,230,269–272).

Leptin and Leptin Receptor. A major breakthrough in obesity research was the discovery that adipose tissue regulates its own mass and metabolism through a feedback circuit involving the hormone leptin (273). Leptin is produced by the adipose tissue, crosses the blood-brain barrier, and interacts with specific receptors in the hypothalamus, where it inhibits the release of orexigenic mediators NPY and AgRP while inducing the anorexigenic peptides α -MSH and CART (274–276). Mutations in leptin or the leptin receptor cause severe obesity in mice (273,275,276). The importance of this pathway has also been demonstrated in humans by the discovery of three rare mutations: one that causes a truncated receptor and early-onset obesity, a second rare mutation associated with low serum leptin levels, and a rare frame-shift mutation causing a truncated form of leptin that is associated with severe early onset obesity (277-279). Nevertheless, several population studies indicate that such variants are rare and not a common cause of obesity or type 2 diabetes in humans (280,281).

 β_3 -Adrenergic Receptor and Uncoupling Proteins. The β_3 adrenergic receptor (B3AR) stimulates lipolysis and thermogenesis in adipocytes and has been intensively examined for potential implications in obesity and diabetes (282). Carriers of a Trp64Arg polymorphism have been suggested to have increased capacity to gain weight and accelerated onset of type 2 diabetes (283-285). These findings, however, have not been uniformly replicated (286,287). In vivo and in vitro investigations also have provided conflicting results. Two studies have shown a reduced agonist response associated with the Arg64 variant (288,289), whereas other studies demonstrate no functional effect (290-292). A recent meta-analysis of 31 published studies including more than 9,000 individuals indicates that the Arg64 alleles may indeed be associated with increased body weight, but this effect is quite small $(0.3 \text{ kg/m}^2 \text{ BMI difference between})$ carriers and noncarriers) (293). A minor effect on the natural history of diabetes may also be present, with Arg64 carriers developing hyperglycemia about 2 years earlier than noncarriers (293).

Uncoupling proteins (UCPs), which promote the dissipation of energy as heat in the mitochondria of adipocytes and other tissues (294,295), have also been intensively investigated. Three UCP genes (UCP1, UCP2, UCP3) coding for proteins with different activities and patterns of expression have thus far been identified and searched for sequence differences (295). Results have been particularly interesting for a C/T polymorphism placed in the UCP3 promoter, 55 bp upstream of the transcription start (-55T/C) and in proximity of the putative TATA box (296–299). Subjects homozygous for the C allele have a significantly lower expression of UCP3 mRNA in skeletal muscle (296). The same allele also was associated with increased body weight in a study in the United Kingdom and with increased risk of type 2 diabetes in two populations from France (297-299). Other variants have been implicated in obesity or insulin-resistance phenotypes, but results have been less consistent.

Peroxisome Proliferator-Activated Receptor-y (PPARy). PPARy is a transcription factor that plays a key role in regulation of adipocyte differentiation and is also the receptor for insulin-sensitizing drugs of the thiazolidenedione class (300). This factor has two isoforms (PPARy1 and PPARy2) that result from alternative splicing (301). Both have ligand-dependent and ligand-independent transcriptional activities. PPARy2 has 28 additional amino acids at its amino-terminus that make its ligand-independent activity 5 to 10 times higher than that of PPARγ1. Two rare mutations (Pro467Leu and Val290Met) in this transcription factor have recently been found to be associated with severe insulin resistance and diabetes in addition to hypertension (302). Both of the identified variants are markedly transcriptionally impaired, and the mutated receptors are able to inhibit the action of coexpressed wild-type PPARy, indicating a dominant negative effect (302). Another amino acid variant identified in a German population (Pro115Gln) was found exclusively in obese subjects (BMI >29 kg/m²) (303). A functional study of the variant showed reduced phosphorylation of a nearby serine residue (Ser114) and accelerated differentiation of the cells into adipocytes (303). This variant has not been observed in other populations. A more frequent amino acid polymorphism, also affecting the transcriptional activity, has been described in PPARy2 (Pro12Ala) (304,305). In one of the first reports, the Ala12 allele (frequency of 0.12) was significantly associated with lower BMI and improved insulin sensitivity, with Ala12 carriers having four times less risk of diabetes than carriers (304). Another report, published at the same time on a different journal, showed instead an association between Ala12 allele and higher BMI in a lean to moderately obese cohort and a cohort of very obese subjects from North America (305). These conflicting results were in part reconciled by a Danish study indicating that the variant might have divergent modulating effect on BMI, being associated with higher BMI in obese subjects and lower BMI in the control group (306). Although studies from other populations have not always been able to confirm these associations, most have shown a tendency to a lower risk of diabetes among Ala12 carriers (306-316) (Fig. 22.11). This has been confirmed by a recent report based on both family-based and population-based studies including a total of 3,000 individuals (310). However, the protection associated with the Ala12 allele appears to be modest (relative risk, 0.80, corresponding to a 1.25-fold risk of diabetes for the Pro12 allele). Similar risk estimates are obtained when all studies performed to date are considered in a meta-analysis (Fig. 22.11). The protection conferred by the Ala12 variant appears to be much more pronounced in Japanese (OR, 0.50; 95% CI, 0.4-0.65) than in whites (OR, 0.86; 95% CI, 0.76–0.98). The reasons for these racial differences are unclear, but a possible explanation is that the Ala12 variant must interact with other genetic or environmental factors to confer strong protection. Some of these may be characteristic of the Japanese population.

OTHER CANDIDATE GENES

Homozygous expansion of a GAA repeat in the frataxin gene has been linked to Friedreich ataxia. Thirty percent of patients suffering form the disease have abnormal glucose tolerance, with about 10% having overt diabetes (317). A study of populations in Germany and the United States have shown that intermediate expansions of the frataxin gene are associated with type 2 diabetes (318). This association, however, has not been observed in France, The Netherlands, Denmark, and United Kingdom (319–322). *In vitro* frataxin has been shown to play a role in mitochondrial oxidative metabolism (323).

An association between type 2 diabetes and a glucagon receptor variant at codon 40 was found in French and Sardinian

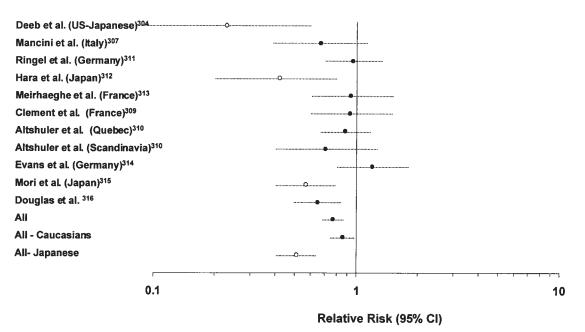

Figure 22.11. Estimated risk of type 2 diabetes associated with the peroxisome proliferator-activated receptor- γ (PPAR γ) Pro12Ala variant. For each study, the solid circle represents the odds ratio for 12Ala carriers and the dotted line indicates the 95% confidence interval. For consistency with other reports, only population-based data from the study by Altshuler et al. (310) are included. Mantel-Haenszel estimates of the common relative risks are reported for all published studies (All, n = 10,227), for studies in caucasians (All-caucasians, n = 5,713), and for studies in Japanese only (All-Japanese, n = 4,514). The risk estimate in caucasians was significantly different from that in Japanese.

populations (324). This variant has been shown in transfection studies to confer a reduced sensitivity to glucagon (325), suggesting that an impairment in the insulinotropic effects of glucagon might be the link with diabetes. However, also in this case, the association has not been replicated in other populations (326,327).

Genome-Screen and Positional Candidate Genes

While functional candidate gene studies can be successful in some cases [a good example is the discovery of glucokinase as a MODY gene (39,40)], this approach is limited by two important factors. First, only a small proportion of the estimated 30,000 or more genes that exist in the human genome have known biologic function (24). Second, our knowledge of the cellular pathways involved in insulin action and secretion, and more generally in glucose homeostasis, is far from complete. These limitations can be overcome by an alternative approach based on the systematic screening of the whole genome for chromosomal regions that are linked, i.e., are transmitted together with the disease in families. Genes in these regions, which are defined as *positional* as opposed to functional candidate genes, can then be screened for sequence differences associated with type 2 diabetes. This strategy (positional cloning) has been extremely successful in identifying the genes for a variety of mendelian disorders (33,328,329). Many of these genes were not previously known, or if they were, they would not have been chosen as candidates because of their functions. A notable example is the identification of lamin A/C, coding for nuclear envelope proteins, as the gene responsible for partial lipodystrophy (74,75). The price to pay for extending the search to the whole genome is the lower sensitivity of linkage studies as compared with direct tests of associations (27).

Genome-wide screens for linkage are performed by genotyping members of affected families at many polymorphic loci that are spaced at regular intervals throughout the genome. This task has been greatly facilitated during the last decade by the construction of dense maps of highly polymorphic markers (microsatellites) that can be analyzed in an automated fashion (21,22). Most genome screens are based on 400 of such markers, corresponding to a 10 cM spacing. The marker information is used to test whether any of the chromosomal regions represented by each marker co-segregates (i.e., is linked) with the disease. For Mendelian disorders, this is accomplished by comparing the likelihood that a segregation pattern is due to linkage with the disease to the likelihood that it is due to chance. Results are expressed as LOD scores, i.e., the log₁₀ of the ratio of the two likelihoods (330). A LOD of 3.0, corresponding to odds of 1,000:1 in favor of linkage, is usually taken as a significant result. This approach is quite powerful but requires the specification of parameters defining the mode of inheritance (hence the name of *parametric* analysis) and the availability of large, multigenerational families that can be analyzed individually.

These constraints limit the application of these analytic methods to multifactorial forms of type 2 diabetes. In many instances, the mode of inheritance is ambiguous, making the task of defining the parameters for linkage analysis extremely difficult. The late onset of the disease may also hamper the assembling of large families, because the parents of affected individuals are often deceased and the offspring are too young to develop hyperglycemia. Thus, genome screens for type 2 diabetes genes have usually relied on *nonparametric* methods of analysis. A common nonparametric approach consists of investigating whether affected sibling pairs share any chromosomal region more frequently than expected on the basis of chance (331). Because of the complexity and heterogeneity of type 2 diabetes, large numbers of sib-pairs must be studied to have

enough power to detect significant genetic contributions. More elaborate and powerful study designs based on the same principle are possible using different kinds of affected-relative pairs from extended families (e.g., uncle-nephew) (332,333). In general, nonparametric studies are not as powerful as parametric approaches but are easier to assemble, do not need specification of a mode of inheritance, and, since only affected subjects are considered, avoid the problem of nonpenetrants. Nonparametric methods can also be used to evaluate linkage with quantitative traits relevant to type 2 diabetes (e.g., fasting or postchallenge glycemia or insulinemia, BMI) rather than with diabetes itself (334,335). This approach assumes that genes influencing variation in these traits among nondiabetic subjects may also be involved in regulating susceptibility to type 2 diabetes.

At least 12 genome screens for type 2 diabetes genes have been performed during the past 5 years using a combination of these techniques (233,336–346). Similar to functional candidate gene studies, these screens have produced conflicting results and their interpretation is often challenging. In addition to the issues discussed above (genetic heterogeneity, variable power of studies), there are other important factors contributing to these variability. One concerns the definition of significant linkage. Some studies have reported results based on the stringent criteria proposed by Lander and Kruglyak (347) to account for the multiple comparisons that are performed in a wholegenome screen. In other cases, results are reported according to less stringent criteria, increasing the chances of not missing significant gene effects but also inflating the false-positive rate. Results of different studies may also be difficult to compare because of differences in study designs (e.g., sib-pairs vs. extended families) or recruitment criteria (e.g., younger vs. older onset of diabetes). These differences may confer different power to studies of similar size. As clarified by the work of Risch in the early 1990s (348), the power of sib-pair studies is a function of the recurrence-risk in siblings, or λ_{s} , a measure of the genetic component of a disease that is defined as the ratio between the risk of the disease in siblings of affected cases and the risk in the general population. Several recent studies have estimated the overall λ_s for type 2 diabetes to be only 1.2, suggesting that environmental factors, as opposed to genetic factors, contribute to a large proportion of the disease in the general population (349–351). However, the λ_s is elevated to 1.6 to 2.2 in families with one diabetic parent and higher in families with two diabetic parents (349–351). In a study of the families of 600 patients of the Joslin Diabetes Center, the λ_s is even higher (3.5) in those families in which the affected parent also had an affected parent (J. Warram and A. Krolewski, personal communication). Thus, by focusing on families with vertical transmission through three generations, the likelihood of identifying susceptibility genes for type 2 diabetes is greatly increased, but results obtained with these families may be difficult to replicate in unselected collection of sib-pairs. Because of the frequent use of different marker maps and study design, it may also be difficult to judge whether the type 2 diabetes locus of one study corresponds to the locus found in another report. Nonetheless, despite these problems, several chromosomal regions have been identified that appear to be significantly linked to type 2 diabetes in different genome screens (Table 22.3), and efforts are in progress to identify the genes responsible for these findings through association studies.

CHROMOSOME 2q37 AND CALPAIN 10

The chromosomal region at 2q37 was the first locus to be identified as being significantly linked with type 2 diabetes in a whole-genome screen (336). This study included a total of 440 affected sib-pairs recruited in Star County, Texas, where 97% of the population is Mexican American. The reason to study this ethnic group was the high incidence of type 2 diabetes in this population (severalfold higher than in the general U.S. population) and the high a priori likelihood that a few major genes could account for diabetes. The genome screen was based on a map of 490 markers (8-9 cM spacing), through which four regions, placed on chromosomes 2, 15, 7, and 3, were identified as potentially linked with type 2 diabetes (336). The best evidence was found at 2q37, where marker D2S125 showed a LOD score of 4.0, meeting the genome-wide criteria for significant evidence of linkage (LOD score >3.6). This locus, named NIDDM1, was subsequently found to interact with another locus on chromosome 15 near CYP19, with the combined analysis of the two loci raising the LOD scores from 4.0 to 7.3 at NIDDM1 and from 1.3 to 4.0 at CYP19 (Fig. 22.12) (352). No evidence for these two loci could be found in non-Hispanic whites of different origins and in Japanese, suggesting that these genes may be specific to the Mexican-American population (336,353). This hypothesis, however, is contradicted by the absence of linkage at this location in Mexican Americans from the San Antonio Family Diabetes Study and in Pima Indians, who share part of their genetic background with Mexican Americans (337,338).

Recent evidence from the same research group indicates that *NIDDM1* may correspond to the gene coding for the cysteine protease calpain 10 (354). In the original screen, the one-LOD support interval (the region in which the LOD score is within one unit from the peak score) spanned 7 cM, corresponding to a physical size of 1.7 Mb. Because none of the known genes placed in this interval was an obvious candidate for type 2 dia-

Population	Study design	Linked regions	Study
Mexican Americans (County Starr)	Affected sib-pairs	2q37, 15q21, 3p14	Hanis et al. (336)
Whites (Botnia)	Extended families	12q24	Mahtani et al. (233)
Pima Indians (Arizona)	Affected sib-pairs	1q21–q23, 11q23, 7q22–q31	Hanson et al. (337)
Mexican Americans (San Antonio)	Extended families	10q25, 6q22–q23	Duggirala et al. (171,338

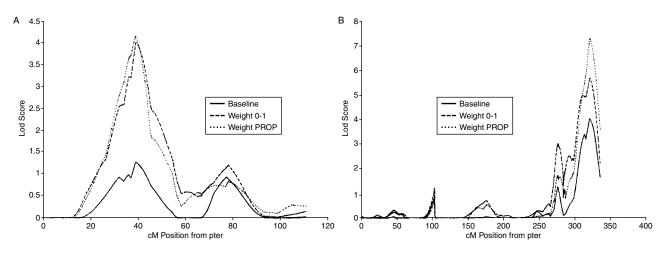

Figure 22.12. Interaction between *NIDDM1* and *CYP19* locus. **A:** Multipoint allele-sharing analysis of chromosome 15 weighted for linkage at *NIDDM1* on chromosome 2. **B:** Multipoint allele sharing analysis of chromosome 2 weighted by the evidence for linkage at *CYP19* on chromosome 15. The analysis was performed by assigning weight 0 to families with negative LOD score and 1 to families with positive LOD scores (Weight 0–1), or by assigning weights proportional to the evidence for linkage (Weight PROP). (Reprinted from Cox NJ, Frigge M, Nicolae DL, et al. Loci on chromosomes 2 (NIDDM1) and 15 interact to increase susceptibility to diabetes in Mexican Americans. *Nat Genet* 1999;21:213–215, with permission.)

betes, anonymous markers placed in this region were tested for association with type 2 diabetes. Results turned out positive for several SNPs placed in the region of the calpain 10 gene. The association with diabetes was particularly evident for a haplotype resulting from the combination of three SNPs (SNP-43 in intron 3, -19 in intron 6, and -63 in the 3' region). Most important, this association could account for the linkage observed in the genome screen. The most common haplotype combination observed in Mexican Americans with type 2 diabetes was 112/121, which was associated with a threefold increase in the risk of diabetes as compared with the risk in carriers of other genotypes. A similar association was found in white populations from Finland and Germany, although this haplotype combination was rarer than in Mexican Americans. Variation at this locus is estimated to account for about 15% and 5% of type 2 diabetes in Mexican Americans and whites not of Mexican ethnicity, respectively (354).

While these results may represent the first example of positional cloning of a gene for a complex disorder, several issues must be addressed before calpain 10 can be unequivocally accepted as a type 2 diabetes gene. It is unclear, for instance, whether the three SNPs, which are all placed in noncoding regions, have biologic effects themselves or simply define a haplotype that is in linkage disequilibrium with the causal variant. SNP-43 has been shown to affect the binding of nuclear proteins from islet extract and to modulate gene expression in vitro in experiments with reporter genes (354). These data have been confirmed by in vivo experiments showing an association between SNP-43 and calpain-10 expression in skeletal muscle (355). Whether this is true for the other two SNPs and whether the combination of the three SNPs has a specific effect on expression of calpain 10 remains to be determined. It is also unclear why the association concerns 112/121 heterozygotes but not 112/112 or 121/121 homozygotes. A possible explanation is that two causal variants, one in linkage disequilibrium with haplotype 112 the other with 121, must interact to increase susceptibility to type 2 diabetes. However, none of the variants in the calpain 10 coding sequence are in tight linkage disequilibrium with the risk haplotypes, and the same appears to be true for all SNPs in the two flanking genes: *RNEPL1*, encoding for a protein homologous to aminopeptidase B; and *GPR35*, encoding for a G-protein–coupled receptor. Finally, there are uncertainties about whether these findings can completely account for the evidence of linkage at the *NIDDM1* locus. Since the initial screening for association was performed with a rather sparse SNP map (1 SNP every 80 kb, on average), one cannot exclude that another, perhaps more important, type 2 gene exists at this location and has been missed in this screen.

If the calpain 10 is really a type 2 diabetes gene, this implicates a completely new pathway in the regulation of glucose metabolism. Calpains (or calcium-activated neutral proteases) are a family of nonlysosomal cysteine proteases that are found in all human tissues (356). These enzymes modulate intracellular signaling and cellular differentiation and proliferation by cleaving specific substrates and causing activation or inactivation of protein functions (357). The presence of CAPN10 mRNA in pancreatic islets, muscle, and liver suggests that calpain 10 may affect insulin secretion, insulin action, and hepatic glucose production. Indeed, carriers of the SNP-43 risk allele, who have lower calpain 10 expression in skeletal muscle, show decreased rates of fasting- and insulin-induced glucose turnover as a result of a decreased rate of glucose oxidation (355). If alterations of oxidative metabolism also occur in the pancreatic islets, variability at the calpain 10 locus might then explain both insulin resistance and the impairment of β -cell compensation observed in type 2 diabetes. Other calpain genes may be involved in the proportion of cases of type 2 diabetes that are not accounted for by calpain 10, and it is particularly interesting that one of these, CAPN3, is located in the region of chromosome 15 that interacts with NIDDM1 (352).

CHROMOSOME 12q

At least two type 2 diabetes loci may exist on the long arm of chromosome 12. One (termed *NIDDM2*) corresponds to the same location of *MODY3* (*HNF1* α) at the telomeric end of 12q (233). Linkage at this locus was found in a genome screen of extended pedigrees from the Botnia district on the western coast of Finland, a region that was chosen for genetic studies

388 JOSLIN'S DIABETES MELLITUS

because of the genetic homogeneity of its population and the availability of many large families. Analysis of the full collection of families (26 extended pedigrees) revealed no significant or even suggestive evidence for susceptibility loci predisposing to type 2 diabetes. However, significant linkage (LOD score = 3.65) was found in the MODY3 region among the families in the lowest quartile of insulin levels during OGTT. The age at diabetes diagnosis in these families (58 years) was indistinguishable from that among the remaining families in the study, indicating that these findings were not due to misclassification of MODY as type 2 diabetes. Significant linkage at this location has subsequently been reported in a single, large family of Pacific Island origin (LOD score = 3.6), although this pedigree is characterized by insulin resistance and obesity rather than a defect in insulin secretion (234). Some evidence of linkage, although far from significant levels, has been found in white families by Bowden et al. and Ehm et al. (LOD scores = 1.4 and 1.45, respectively) (240,341) but not by other authors. The overlap between NIDDM2 and MODY3 initially suggested that these two loci may correspond to different alleles of the same gene, with severe mutations causing MODY and milder polymorphisms leading to later-onset type 2 diabetes. However, this hypothesis seems unlikely since no sequence differences associated with common type 2 diabetes have been identified in the MODY3 gene HNF1 α to date (235–238). No other obvious candidate gene is present at this site.

The second locus that has been identified on 12q is placed 50 cM centromeric to *NIDDM2/MODY3*. Suggestive linkage (LOD score = 3.1) was found at this location by Bektas et al. (66) in 26 white families with early-onset type 2 diabetes transmitted with an autosomal dominant mode of inheritance. Similar to the Botnia study, the evidence of linkage was particularly strong among families with poor insulin response to glucose (Fig. 22.13). The critical region defined by the recombinants spans 5 to 6 cM around marker *D12S1052* (358). A LOD score of 2.8 was found in the same region in the GENNID study, a large, multiethnic family collection sponsored by the American Diabetes Association (341). This finding, however, could not be replicated in a second GENNID population (so-called phase 2 famili

lies), and other genome screens have not detected linkage at this location. These discrepancies highlight the difficulties that are generally encountered in trying to replicate linkage results for multifactorial disorders. In the presence of genetic heterogeneity and epistasis, replication may require a much more powerful set than that needed for the original detection, since the fortuitous circumstances that led to detection of linkage in the first sample are unlikely to be replicated in the second sample unless a much larger number of families are examined.

CHROMOSOME 20

The long arm of chromosome 20 contains one of the most interesting regions that has been thus far identified in the search for type 2 diabetes genes. Attention initially was drawn to this chromosome by the mapping of MODY1 on 20q13 (359). Testing the hypothesis that this locus, later identified as $HNF4\alpha$, may also be involved in common forms of type 2 diabetes, several groups have performed linkage studies specifically targeted at this chromosome. While initial efforts failed to obtain positive results, three subsequent studies employing more informative markers and larger collections of families found suggestive linkage at this location. One study, conducted by Ji et al. in large white families with multiple affected members, showed evidence of linkage in a subset of families with age at diagnosis older than 47 years (239). The multipoint nonparametric LOD score reached 2.4 for two tightly linked markers (D20S178 and D20S197) placed 8 cM telomeric to $HNF4\alpha$. The addition of more markers and families subsequently raised the LOD score to 6.1 ($P = 1.8 \times 10^{-5}$) and refined the mapping to the 10 cM between markers D20S119 and D20S428 (Fig. 22.14) (360). It is interesting that the families showing evidence of linkage were characterized by insulin resistance rather than by poor insulin secretion, suggesting that this was a true type 2 diabetes locus rather than a MODY locus. The second study, also conducted in white pedigrees, suggested linkage in the very same region (LOD score = 1.5), despite the small number of sib-pairs that were used in this analysis (240). With slight differences in location, linkage at chromosome 20q13 also was observed in a study from France examining a total of 301 affected sib-pairs from 148

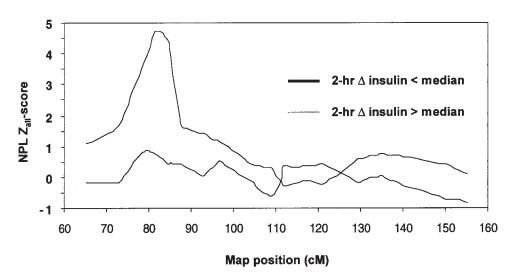

Figure 22.13. Type 2 diabetes locus on chromosome 12q15 in 32 families from the Joslin Diabetes Center with early-onset, autosomal dominant type 2 diabetes (66). Multipoint analysis was performed using GENEHUNTER (333) after families were subdivided into two groups based on the median within-family insulin increment during oral glucose tolerance testing (OGTT; 2-hr Δ , change after glucose ingestion). Evidence of linkage was present only among the families with insulin response below the median. NPL Z scores can be converted to LOD scores through the equation LOD = $Z^2/4.62$.

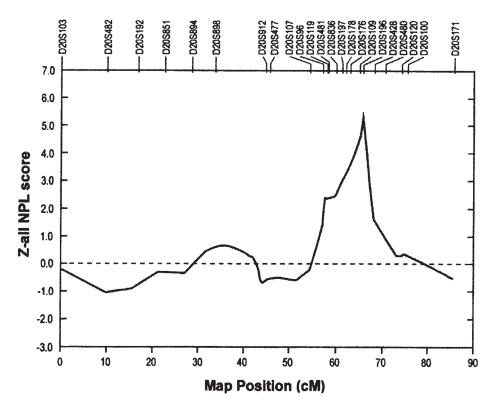

Figure 22.14. Evidence of a type 2 diabetes locus on chromosome 20q12–q13 in 43 Joslin families. Results were obtained by multipoint analysis using GENEHUNTER (332). The maximum score was obtained at marker D20S196 and corresponded to a *p* value of 1.8×10^{-5} in the entire set of families. (Copyright © American Diabetes Association. From Klupa T, Malecki MT, Pezzolesi M, et al. Further evidence for a susceptibility locus for type 2 diabetes on chromosome 20q13–q13.2. *Diabetes* 2000;49: 2212–2216, with permission from the American Diabetes Association.)

type 2 diabetes pedigrees (241). The evidence was particularly strong in a subset of families with age at diagnosis younger than 45 years, in which a linkage peak (LOD = 2.7) was found 10 cM telomeric to the locus reported in the other two studies. A smaller peak (LOD score = 1.8) was also observed 15 cM centromeric to this locus.

Confirmation of the existence of at least one type 2 diabetes locus on 20q13 has recently come from the results of the FUSION (Finland-United States Investigation of NIDDM Genetics) study, an international collaborative effort to map and positionally clone genes predisposing to type 2 diabetes in Finnish subjects (242). The Finnish population is believed to derive from a small group of founders with little subsequent immigration, a feature that minimizes the chances of genetic heterogeneity. The FUSION study includes 719 affected sibpairs from 478 families. In a 10 cM genome screen, the strongest evidence of linkage was found on chromosome 20, where three peaks were identified, at 0 to 25 cM (LOD score = 1.99), 50 to 60 cM (LOD score = 2.04), and 63 to 72 cM (LOD score = 2.15) (242). The last two peaks, which might correspond to two separate loci or might be the expression of a single type 2 diabetes locus, are located in close proximity to the intervals linked with type 2 diabetes in previous studies. This locus or loci may interact with a putative locus on 2p, as suggested by a joint analysis of the two chromosomes increasing the 20q13 LOD score to 5.5 (342). Additional evidence for a type 2 diabetes locus on 20q has been provided by a genome screen in Ashkenazi Jews and studies of nondiabetic families demonstrating linkage with obesity, percent body fat, and fasting insulin levels (344,361,362).

Although other reports could not replicate these findings, the fact that six independent studies point to the same chromosomal region is highly indicative of the existence of a type 2 diabetes gene around 20q13. The identity of this gene or genes is unknown at this time. Extensive screening for mutations has failed to identify sequence differences associated with type 2 diabetes in the $HNF4\alpha$ gene (MODY1) (243). The finding of association between type 2 diabetes and a marker placed 8 cM telomeric of $HNF4\alpha$ also makes a role of this gene unlikely (360). Other good candidate genes in this region include protein tyrosine phosphatase-B, a regulator of insulin signaling that may influence insulin sensitivity, and CAAT/enhancer-bind-ing-protein β , which is an inhibitor of insulin gene transcription (363,364). Collaborative efforts are under way to map this locus precisely and to positionally clone the gene or genes that are responsible for the linkage with type 2 diabetes. The sequence information and the SNP map generated by the Human Genome Project (24,25) are invaluable tools for this task.

CHROMOSOME 1q21-q23

Evidence for linkage at this location was first provided by a genome screen in Pima Indians, a Native-American population with an exceptionally high incidence of type 2 diabetes and obesity (365). This study included 551 affected sib-pairs with diabetes diagnosed before age 45 years, who were recruited from a longitudinal study of the Gila River Indian Community in central Arizona. While the best evidence for linkage was found at 11q in the overall population, a LOD score of 4.1 was observed at 1q21 near marker D1S2127 (192 cM) in the subset of sib-pairs who were younger than 25 years old at diabetes diagnosis (Fig. 22.15) (337). Suggestive evidence of linkage near this location also was found in the overall group in an analysis comparing sib-pairs concordant for diabetes with discordant sib-pairs (LOD score = 2.5 at 171 cM). The presence of a type 2 diabetes locus at 1q21-q23 has subsequently been confirmed by genome screens in white populations. The first one, considering 42 extended families of northern European ancestry from Utah, detected a LOD score of 4.3 between CRP and APOA2 (204 cM) under a recessive model of inheritance (339). Results were similarly positive in a nonparametric analysis, although they could not be confirmed in a replication set of 20 similarly ascertained but smaller families. The second study, considering 148 nuclear families from France, detected a LOD score of 3.0 at APOA2 in

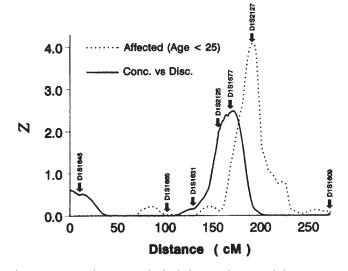

Figure 22.15. Multipoint results for linkage with type 2 diabetes at 1q21 in Pima Indians. In the analyses comparing concordant with discordant sib-pairs, the age at onset of diabetes was <45 years. (Reprinted from Hanson RL, Ehm MG, Pettitt DJ, et al. An autosomal genomic scan for loci linked to type II diabetes mellitus and body-mass index in Pima Indians. *Am J Hum Genet* 1998;63:1130–1138, with permission.)

a subset of 57 families with a lean phenotype (BMI <27 kg/m²), suggesting that this may be a true diabetes locus rather than an obesity-susceptibility locus (343). Preliminary data from the British Diabetic Association Warren 2 consortium (812 affected sib-pairs) indicate that evidence of linkage at 1q21–q23 may also be present in that population (345). Similar to the original finding in Pima Indians, linkage seems to be stronger among families with early onset of diabetes (LOD score = 2.2). Furthermore, familial combined hyperlipidemia, which is characterized by insulin resistance and a propensity to glucose intolerance, has been also mapped to the same region of chromosome 1 in a study from Finland (366). By contrast, no evidence of linkage at this location has been found in the FUSION and GENNID studies or in Mexican Americans (338,341,342).

The 1-LOD support interval at 1q21-q23 spans 6-19 cM, depending on the study. This region is very rich in genes, many of which are plausible candidates for susceptibility to type 2 diabetes. An example is KCNJ9, a G-protein-coupled inwardly rectifying potassium channel, which might be involved in insulin secretion. A significant association has been found in Pima Indians between diabetes and several noncoding SNPs of this gene, but it does not account for the linkage observed at this location (367). Another interesting gene placed in this region is LMNA, which is mutated in autosomal dominant forms of partial lipodystrophy and insulin resistance (74,75). A silent polymorphism in intron 10 of the LMNA gene is associated with large adipocyte size in the abdominal subcutaneous tissue (a phenotype that predicts insulin resistance) but not with type 2 diabetes itself (368). No study has been published to date on apolipoprotein A2 (APOA2), which is placed in the middle of the linked interval and could play a role in the susceptibility to type 2 diabetes through an effect on free fatty acid metabolism.

OTHER CHROMOSOMAL REGIONS

Suggestive or significant linkage with type 2 diabetes has been found at several other chromosomal regions, although some of these results still await replication. In Mexican Americans from the San Antonio Family Diabetes Study, Duggirala et al. (338)

have found significant evidence of a susceptibility locus on chromosome 10q influencing age at onset of diabetes (LOD score = 3.75) and linked with type 2 diabetes itself (LOD score = 2.9). This locus may account for up to 65% of the total variation in age at diagnosis of diabetes observed in this population. Another locus has been identified in the same population at 6q22-q23 that is linked with fasting insulin levels and other insulin resistance-related phenotypes such as BMI and triglycerides (171). Insulin-action inhibitor PC-1 is placed in this region, but whether variability in this gene accounts for the finding of linkage remains to be determined. A locus for type 2 diabetes (LOD score = 1.7) and BMI (LOD score = 3.6) has been identified at 11q23-q25 in Pima Indians (337). More recently, significant linkage has been demonstrated by Vionnet et al. (343) at 3q27 in French families with diabetes diagnosed before age 45 (LOD score = 4.7). Suggestive LOD scores have been found at the same location in Pima Indians for quantitative trait loci (QTL) controlling acute insulin response, insulin resistance, and waist-hip ratio (369). A locus may also be present on chromosome 18p11 conferring susceptibility to type 2 diabetes in association with obesity (346).

FUTURE DIRECTIONS

The magnitude of the search for genetic determinants of type 2 diabetes has increased exponentially during the past decade, evolving from a limited set of small association studies based on few RFLPs to whole-genome screens employing hundreds of polymorphisms genotyped in an automated way. In the process, our general understanding of the genetics of type 2 diabetes has become more mature. We now know that the existence of type 2 diabetes genes having effects as strong as that of HLA in type 1 diabetes is unlikely. We have also learned that type 2 diabetes may be much more genetically heterogeneous than expected, and new analytic methods have been developed to account for this heterogeneity as well as for gene-gene interactions (352). The crucial importance of finding replication has also been established, and it is now the rule to take positive results with extreme caution until these are confirmed in other populations.

Although major type 2 diabetes genes have yet to be identified (perhaps with the exception of calpain 10), several interesting leads have been produced that will be pursued during the next few years. The first task on the agenda is to identify the genes that are responsible for the linkage peaks detected by genome screens. Despite the imminent availability of the finished human genome sequence, finding these genes will not be an easy endeavor. In contrast with mendelian disorders, linkage peaks for complex diseases are rather large, being often defined on the basis of probabilities rather than firm recombination events. Hundreds of genes may be placed in a linked interval, and prioritizing the analysis of these genes may be misleading, as illustrated by the surprising role of lamins in some forms of lipoatrophic diabetes (74,75). Thus, there will be the need to narrow linked loci to diabetes-associated haplotypes by typing large numbers of cases and controls for hundreds of anonymous SNPs. The public SNP database that is being developed (25) will be a valuable tool for this task, but fine mapping through SNPs may prove difficult if there is allelic heterogeneity (different variants at the same locus contributing to diabetes in different people), as observed in MODY (43). If SNPs associated with diabetes are identified, extensive functional analysis at the molecular level will be necessary to distinguish the causal variants from all other SNPs that are in linkage disequilibrium.

Studies of functional candidate genes will be instrumental in identifying moderate gene effects that are below the detection threshold of linkage studies. Thus far, two important factors have been limiting functional candidate gene studies: the slow pace at which candidate genes have been identified by cellular physiology studies and the low throughput with which genes could be screened and typed for polymorphisms. So far, only a very small proportion of the genes involved in insulin action and secretion have been screened for association with type 2 diabetes. However, this scenario is rapidly changing. A large number of genes with putative roles in insulin action or secretion and the pathophysiology of diabetes are being identified by expression-profiling efforts making use of microarray technology. Many of these loci can be extensively screened for sequence variants by high-throughput technologies. Thus, the scope of association studies will quickly broaden to the analysis of hundreds of candidate genes in very large populations.

All these studies will require good physiologic phenotyping to identify more homogeneous disease subgroups together with a precise characterization of environmental exposures to analyze gene-environment interactions. Ultimately, however, it seems likely that over the next decade most cases of type 2 diabetes will be genetically classified and a new era of prediction and attempts at prevention may begin.

FORMS OF TYPE 1 DIABETES

During the past two decades, an accumulating body of information has led to the recognition that the predominant form of insulin-dependent diabetes mellitus (IDDM) is of immune etiology, that the disease can present at any age, and that individuals are not insulin-dependent early in the course of disease (1–6). Given this body of information, an expert committee of the American Diabetes Association has divided the "idiopathic" (e.g., not pancreatitis, mitochondrial DNA mutations) forms of diabetes resulting from β -cell loss and/or severe insulin secretory deficiency into type 1A and type 1B (1). Type 1A is the

CONCLUSION 418

immune-mediated form and is best characterized by the presence of islet autoantibodies (see below) and insulitis (7,8), with selective destruction of islet β -cells (e.g., glucagon-producing cells are spared). In addition, type 1A diabetes is strongly associated with specific human leukocyte antigen (HLA) alleles (4,9,10) and almost always progresses to severe insulin deficiency (11). The term type 1B diabetes is reserved for forms of diabetes with severe insulin deficiency without evidence of β cell autoimmunity (1). An interesting form of potential type 1B diabetes was reported in Japan (12). The patients had lymphocytic infiltration of the exocrine pancreas (with increased serum amylase levels) and an acute development of diabetes such that,

at the time of diabetes onset, levels of glycosylated hemoglobin (HbA_{1c}) were normal despite marked hyperglycemia. Japan has one of the lowest incidences of type 1A diabetes in the world, and thus type 1B forms of diabetes are likely to represent a larger proportion of their cases of childhood type 1 diabetes than that seen in other countries. In Europe and the United States, fewer than 10% of non-Hispanic white children presenting with diabetes do not have type 1A diabetes. In contrast, among African-American children and Hispanic-American children, almost one half do not have type 1A diabetes, with the majority believed to have early onset type 2 diabetes and relatively few having type 1B diabetes. In particular, a subset of African-American children can present with ketoacidosis but do not express islet autoantibodies, lack HLA alleles associated with type 1A diabetes, and often can be treated with oral hypoglycemic medications after resolution of their acute illness (13-15).

The present "etiologic" classification of diabetes is not completely satisfactory, since specific diagnostic markers are lacking for many forms of "idiopathic" diabetes (type 2 and type 1B), and some individuals with type 1A diabetes may even lack islet autoantibodies if they are tested only once at diagnosis. In addition, no combination of HLA alleles is completely diagnostic for type 1A diabetes. Only 20% to 50% of the patients with type 1A diabetes have the highest-risk HLA genotype (DR 3/4 DQ2/ DQ8 heterozygous) compared with the 2.4% of individuals without diabetes who have this genotype (16). Approximately 1% of children with type 1A diabetes have highly "protective" HLA alleles (e.g., DQB1*0602) compared with 20% of the general public with these alleles. Given "biochemical" assays for islet autoantibodies with specificity set at greater than the 99th percentile, the terms autoantibody-positive and antibody-negative diabetes are perhaps more precise descriptors. Caveats for such designations include the loss of islet autoantibodies prior to the development of overt diabetes that occurs in a subset of children and the observation that individuals can have both type 1 and type 2 diabetes (17,18). Figure 23.1 illustrates first-phase insulin secretion (1+3 minute insulin on intravenous glucose tolerance testing) for a markedly obese teenager who progressed to overt diabetes. At the time of diagnosis of diabetes, the fasting insulin level was approximately 25 µU/mL, and although the sum of insulin at 1+3 minutes (50 μ U/mL) was above the first percentile (of 48 μ U/mL), there was essentially no glucose-stimulated insulin secretion. This child with islet autoantibodies and pro-

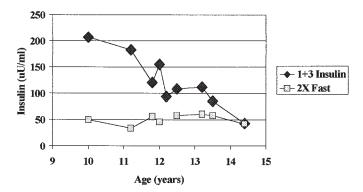

Figure 23.1. Progression to diabetes of an overweight teenager (BMI 30–35) with evidence of both type 1 and insulin resistance. Fasting insulin ranged between 17 μ U/mL and 36 μ U/mL during the prodrome to diabetes (normal children fasting insulin usually <5 μ U/mL), suggesting insulin resistance. At time of diagnosis of diabetes, fasting insulin decreased to 21 μ U/mL, and twice the fasting insulin was equivalent to the 1+3 minute insulin post-glucose, indicating no first-phase insulin response to glucose.

gressive loss of first-phase insulin secretion has both type 1A diabetes and evidence of insulin resistance (marked by high fasting levels of insulin and obesity).

The category of diabetes that will expand with increased knowledge is that of "other specific forms of diabetes," which will include the subset of "immune-mediated diabetes." At present the best example of a defined form of type 1A diabetes is that in patients with diabetes as part of the autoimmune polyendocrine syndrome type 1 caused by a mutation of the *AIRE* (autoimmune regulator) gene on chromosome 21 (19) (see below).

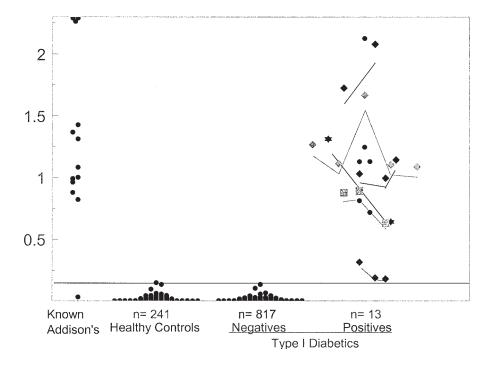

Does the classification of diabetes matter? Most children presenting with diabetes have type 1A diabetes, and most adults have type 2 diabetes. We believe it does matter when providing prognostic information (20), information concerning likely associated disorders [e.g., autoimmune disorders for type 1A diabetes (21) and manifestations of insulin resistance for type 2 diabetes], for assessing genetic risk for relatives (22), and in providing some guidance concerning therapy [insulin versus oral medications (e.g., insulin secretagogues and insulin sensitizers)] (23). Patients with islet autoantibodies and who have diabetes are probably best treated with insulin even if they are not currently "insulin dependent (24)." Oral agents rapidly lose their efficacy in adults with type 1A diabetes.

CLINICAL RAMIFICATIONS OF AN AUTOIMMUNE DIATHESIS

In that type 1A diabetes is of immune etiology, it marks an inherited failure in the maintenance of self-tolerance. It is thus not surprising that individuals with diabetes and their relatives are at increased risk for a series of autoimmune disorders (25–28). The presence of type 1A diabetes is also a "marker" for the presence of specific HLA alleles that are associated with many immunologic disorders. The associated disorders are so prevalent among patients with type 1A diabetes, and some are so devastating when not diagnosed early, both a high index of suspicion and screening for asymptomatic disease are warranted. Four important disorders are Addison's disease (28), celiac disease (29–36), thyroid autoimmunity (37–40), and pernicious anemia (41–43). In addition, two major autoimmune polyendocrine syndromes are recognized, termed autoimmune polyendocrine syndrome type-I (APS-I) and APS-II (44).

Addison's Disease

When Addison's disease develops in a patient with type 1 diabetes, insulin requirements often decrease, with accompanying hypoglycemia. Such a decrease in insulin requirements can occur in the absence of the characteristic hyperpigmentation associated with Addison's disease. Excellent radioassays for 21hydroxylase autoantibodies associated with Addison's disease now exist that have a sensitivity greater than 95% and a specificity exceeding 99% (28,45). Figure 23.2 illustrates the expression of 21-hydroxylase autoantibodies in patients with type 1A diabetes. We have screened more than 2,000 patients for 21hydroxylase autoantibodies, and approximately 1 (1.5%) of 60 are positive for autoantibody. Among 30 with 21-hydroxylase autoantibodies, five had Addison's disease at initial testing. For three of the patients, the diagnosis of Addison's disease could have been made on the basis of symptoms and signs, including a severe hypotensive crisis in one (46). For one patient with apparent Addison's disease, the diagnosis was made only at age 17, but the child had missed a year of school at age 10 because of fatigue. Although the diagnosis for this child pre-

sumably could have been made before detection of 21-hydroxylase autoantibodies on screening, it was not. The typical clinical history for patients with Addison's disease includes years of symptoms before diagnosis.

For the remaining 25 non-Addison's patients with 21hydroxylase autoantibodies, we annually measure adrenocorticotropic hormone and cortisol after Cortrosyn. Determined in part by their HLA alleles (highest risk with HLA genotype DR3 and DR4 with DRB1*0404, lower risk with DRB1*0401), some patients with autoantibodies are unlikely to progress to overt disease (28). Studies using immunofluorescent assays for adrenal autoantibodies (47) indicate that approximately one third to one half of those who are positive for this autoantibody are likely to progress to Addison's disease and that the risk of Addison's disease among patients with type 1 diabetes will exceed 1 per 200, in contrast to a risk in the general population of 1 per 10,000 (Table 23.1).

Celiac Disease

Celiac disease, both in the general population and in patients with type 1A diabetes, is usually asymptomatic (29,31,48). In the United States, it is likely that celiac disease is not diagnosed in more than 90% of the patients with the disease. Similar to Addison's disease and type 1 diabetes, celiac disease is associated with HLA alleles DR3 and DR4 (the DQ allele DQ2 in particular). As for Addison's disease, there now exist excellent assays for

Figure 23.2. 21-Hydroxylase autoantibodies among patients with type 1A diabetes. Connected lines represent sequential measurements in the same patient. Positivity set at an index greater than all 241 healthy controls. A total of 957 patients with type 1 diabetes were included in the analysis, 15 of whom were positive. (Reprinted from Yu L, Brewer KW, Gates S, et al. DRB1*04 and DQ alleles: expression of 21hydroxylase autoantibodies and risk of progression to Addison's disease. *J Clin Endocrinol Metab* 1999;84:328–335, with permission. Copyright 1999, The Endocrine Society.)

autoantibodies associated with celiac disease. The endomysial autoantigen has now been cloned and found to be the molecule tissue transglutaminase (49). Approximately one third of patients with type 1 diabetes who are DQ2 homozygous are positive for transglutaminase autoantibodies (30). Twelve percent of patients with type 1A diabetes express transglutaminase autoantibodies, and one half of these have high levels of the autoantibody.

Approximately one-half of patients with type 1 diabetes who express transglutaminase autoantibodies have celiac disease, as determined by biopsy. A higher level of transglutaminase autoantibodies correlates with findings indicative of celiac disease on an intestinal biopsy. In the general population, 0.5% of the population have celiac disease (screening for transglutaminase autoantibodies followed by intestinal biopsy). Asymptomatic patients with transglutaminase autoantibodies show evidence of metabolic abnormalities, particularly decreased growth. Osteoporosis and gastrointestinal malignancy (50) are associated with untreated symptomatic disease.

Celiac disease is a remarkable immune-mediated disorder in that an inducing environmental factor is known, namely the wheat protein gliadin (51–53). Removal of wheat from the diet results in the loss of transglutaminase autoantibodies and resolution of the intestinal lesions (54). A gluten-free diet also reduces the development of intestinal malignancies (55). There is evidence that oats need not be proscribed for patients with celiac disease (54). A wheat-restricted diet, combined with the

TABLE 23.1. Patients with Type 1 Diabetes Mellitus Screened forAutoantibodies: Examples of Associated Autoimmune Disorders in aPopulation of Patients with Type 1A Diabetes Mellitus			
Disease	% Autoantibody-positive	% Developing disease

dietary restrictions associated with type 1 diabetes, is a considerable burden. Nevertheless, given the high prevalence of celiac disease among patients with type 1A diabetes, we recommend screening with measurement of transglutaminase autoantibodies. Following the diagnosis of celiac disease, lifetime avoidance of wheat and other gliadin-containing proteins is recommended.

Thyroid Autoimmunity

Thyroid autoimmunity is very common among patients with type 1A diabetes. Approximately one fourth of patients with type 1A diabetes express thyroid autoantibodies. Only a subset of individuals with thyroid autoantibodies progress to overt thyroid disease (Hashimoto thyroiditis resulting in hypothyroidism or Graves disease). Thus, rather than assaying for thyroid autoantibodies, we routinely measure thyrotropin levels (approximately every 2 years with sensitive assays), allowing diagnosis of both early thyroid failure and Graves disease.

Other Autoimmune Disorders

In addition to their risk for Addison's disease, thyroid autoimmunity, and celiac disease, patients or their relatives with type 1A diabetes are at risk for a series of other autoimmune disorders. With specific autoimmune diseases (e.g., myasthenia gravis, Addison's disease, celiac disease, Graves disease), there is a reciprocal increased risk of type 1A diabetes. Anecdotal reports indicate that it is more frequent to observe type 1A diabetes in siblings of patients with multiple sclerosis than in the patients themselves. The high-risk haplotype for multiple sclerosis, DRB1*1501 and DQB1*0602, is one of the most important haplotypes protective against type 1A diabetes. Juvenile rheumatoid arthritis is a "non-organ"-specific disorder apparently also associated with type 1A diabetes. Disorders such as lupus erythematosus that are treated with glucocorticoids that induce insulin-resistant diabetes are difficult to assess for association with diabetes. Pernicious anemia occurs at an earlier average age in patients with endocrine autoimmunity, but even among patients with diabetes, pernicious anemia usually occurs in adults. A detailed study using the Belgian Diabetes Registry found pernicious anemia in approximately 10% of patients with parietal cell antibodies (38,42).

Autoimmune Polyendocrine Syndromes

Two important autoimmune syndromes are autoimmune polyendocrine syndrome type I (APS-I) (56) and autoimmune polyendocrine syndrome type II (APS-II) (27). Although APS-I is extremely rare, it is one autoimmune syndrome for which a mutation causing the disease has been defined (19,57)-a mutation of a gene termed autoimmune regulator, on the long arm of chromosome 21. APS-I characteristically develops in early infancy with mucocutaneous candidiasis, Addison's disease, and hypoparathyroidism. An individual may have one or all three disorders, and his or her affected siblings may have different disorders of the syndrome. These patients are also at risk for autoimmune hepatitis. Approximately 18% of patients with APS-I develop type 1 diabetes (56). It appears that more patients have anti-glutamic acid decarboxylase (GAD) autoantibodies than progress to overt diabetes, but similar to patients with standard type 1A diabetes, those with multiple autoantibodies (insulin and islet cell antibody [ICA] 512 in addition to GAD) are at high risk of progression (20).

The APS-II syndrome is characterized by two or more organspecific autoimmune disorders, including Addison's disease, Graves disease, type 1A diabetes, and thyroiditis (27). This syn-

drome is strongly influenced by HLA alleles, and the majority of patients with Addison's disease have high-risk alleles DR3 and DR4 (DQ2 and DQ8), similar to patients with type 1A diabetes (21). In comparison to patients with type 1A diabetes, patients with APS-II syndrome have an excess of DRB1*0404 alleles, while most patients with type 1A diabetes have DRB1*0401, 0402, and 0405 alleles. There is a tendency for patients with APS-II syndrome with Addison's disease to develop type 1A diabetes later in life, and prediction of disease again relies on the presence of multiple islet autoantibodies. There is also a tendency for more patients with type 1A diabetes in the setting of APS-II to have "protective" or non-high-risk HLA alleles compared with the usual patient with only type 1A diabetes. At present, the genes outside of the HLA region that underlie risk of APS-II have not been identified, although some studies of type IA diabetes have reported an association of Addison's disease and Graves disease with polymorphisms of the genes CTLA-4 (58-61) and MIC-A (62,63)

The XPID syndrome (X-linked syndrome of *p*olyendocrinopathy, *i*mmune dysfunction and *d*iarrhea) (64–67) was mapped to the X chromosome and results from mutations of the Foxp3 gene. This rare syndrome with overwhelming immunologic abnormalities results in type 1 diabetes, enteropathy with villous atrophy, chronic dermatitis, variable immunodeficiency, and death in infancy. The diabetes often presents in neonates. Mice with the *scurfy* mutation develop lymphoproliferative disease, increased cytokine release, and wasting potentially associated with high levels of tumor necrosis factor- α . Similar to the etiologic gene *AIRE* for the APS-I syndrome, the *scurfy* gene is thought to be a transcription factor. The specific genes whose abnormal regulation results in this spectrum of illnesses are unknown, but it is now known that the Foxp3 gene is essential for the generation of CD4+ CD25+ regulatory T cells.

STAGES IN THE DEVELOPMENT OF TYPE 1A DIABETES MELLITUS

Type 1A diabetes can develop at any age. For example, Cilio and colleagues have described a child with fulminant autoimmunity and diabetes presenting at birth and we have followed the mother of a child with diabetes who developed type 1A diabetes at age 69 (67). Given this wide spectrum of age at diagnosis, long-term prospective studies are necessary to define the course of the disease. Such studies have benefited from the discovery of islet autoantibodies (68) and from the realization that type 1A diabetes is a chronic autoimmune disorder (69). We divide the development of type 1A diabetes into a series of stages beginning with genetic susceptibility (Fig. 23.3) and ending with complete or nearly complete β-cell destruction associated with a lack of C-peptide secretion. Studies of monozygotic twins illustrate many of the stages associated with type 1A diabetes. In that monozygotic twins are identical for all germline-encoded polymorphisms and mutations, if diabetes develops in one twin of a pair, the other twin is at high risk of developing diabetes (70,71). However, because diabetes does not develop in all such twins or activate autoimmunity (as evidenced by a lack of islet autoantibodies) (72), a subset of genetically susceptible individuals do not progress beyond stage I.

Factors that induce the expression of islet autoantibodies are currently poorly defined. The great majority of individuals expressing islet autoantibodies that react with multiple islet antigens progress to loss of first-phase insulin secretion on intravenous glucose tolerance testing and eventually to overt diabetes (73,74). Islet autoantibodies can appear during the first year of life but also can first develop in adults. Figure 23.4 illus-

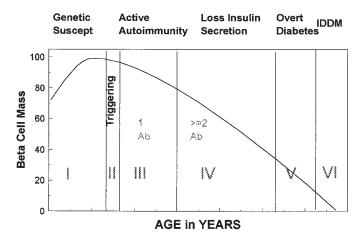

Figure 23.3. Stages in the development of type 1A diabetes. (Modified from Eisenbarth GS. Type I diabetes mellitus. A chronic autoimmune disease. *N Engl J Med* 1986;314:1360–1368, with permission. Copyright © 1986, Massachusetts Medical Society. All rights reserved.)

trates the course of an identical twin whose islet autoantibodies were first detected at age 42 at the time of diagnosis of diabetes, even though his twin mate developed diabetes at age 12. A subset of individuals who express islet autoantibodies are found not to progress to diabetes with long-term follow-up. These individuals usually express a single islet autoantibody, such as antibodies that react only with the molecule GAD (75,76). Progressive loss of first-phase insulin secretion characteristically precedes the development of hyperglycemia (77–79).

The detection of progressive loss of first-phase insulin secretion in the presence of islet autoantibodies led to the hypothesis that type 1A diabetes is a "chronic" autoimmune disorder (69). In that data concerning the prediabetic pancreas are limited, chronic progressive islet destruction remains a hypothesis. An alternative hypothesis is that chronic loss of first-phase insulin secretion results from functional inhibition of insulin secretion by the immune system and that the actual destruction of pancreatic β -cells is acute and follows a long latency period during which islet autoantibodies are expressed (80,81). We believe this is unlikely, given the available histologic data and the observation that loss of β -cell mass correlates with loss of first-phase insulin secretion (82). In particular, the pancreases of identical twins of patients with type 1A diabetes, when biopsied (on the occasion of living related donor transplantation), appear normal (83). Pancreases from individuals who have died at the

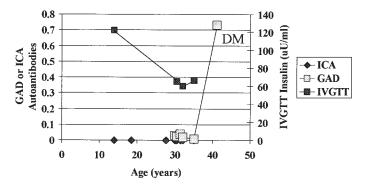

Figure 23.4. Late appearance of anti-islet autoantibodies in an initially discordant monozygotic twin of a patient with type 1A diabetes. IVGTT, intravenous glucose tolerance test; ICA, islet cytoplasmic antibodies; GAD, antibodies to glutamic acid decarboxylase.

onset of diabetes often have lost most β -cells but still have a significant mass of islet β -cells remaining (84). Several years after the onset of diabetes, as reflected by loss of C-peptide secretion, this remaining β -cell mass is lost. It thus appears that the chronic destruction that precedes type 1A diabetes continues after the development of hyperglycemia.

The histology of the pancreas in individuals at the onset of diabetes shows a diversity of islet lesions. Within islets, β -cells are selectively destroyed (84). This specificity of β -cell destruction is very dramatic, and for islets containing no β -cells, there is no insulitis. Thus, the same section of the pancreas may contain normal islets, islets with β -cells and insulitis, and islets lacking all β -cells and without insulitis (pseudoatrophic islets). This spotty process is conceptually similar to vitiligo, with destruction of patches of melanocytes. This destruction of β -cells of individual islets probably underlies the chronic progression to type 1A diabetes.

GENETICS OF TYPE 1A DIABETES MELLITUS

Familial Aggregation

The great majority of individuals in whom type 1A diabetes develops do not have a first-degree relative with the disorder (85% to 90%). If one has a first-degree relative with type 1A diabetes, the risk of diabetes is, however, much greater than that for the general population. In the United States, type 1A diabetes develops in approximately 1 in 300 individuals, compared with 1 in 20 first-degree relatives (85). The risk of diabetes in relatives can be stratified according to their relationship to the proband and by laboratory testing (e.g., HLA typing and determination of autoantibody expression).

Monozygotic twins of a patient with type 1A diabetes have an overall risk of developing type 1A diabetes of approximately 50% (72,86–89). This overall concordance for monozygotic twins is likely to be a composite of a number of different genetic syndromes resulting in type 1A diabetes, each syndrome potentially with a different concordance. In that only some of the genes contributing to the development of type 1A diabetes are currently known, concordance rates for specific genetic syndromes cannot be calculated accurately.

We have analyzed the development of diabetes in two large series of monozygotic twins, one from the United States (72) and the other from Great Britain (90). All twins in the study were selected to be discordant at the time of initial study. Both diabetes concordance and expression of islet autoantibodies were studied. Over time, diabetes develops in more twins. There is no duration of discordance at which the risk of diabetes disappears. Approximately 20% of those twins who became concordant did so after 15 years of discordance (91). With statistical methods to correct for pairs of twins who were both concordant at initial study and for discordant twins still being observed, the overall concordance is 50%. There is a marked difference in the hazard rate of progression to diabetes related to the age of the proband at diabetes onset (92). If the index twin (first diabetic twin) developed type 1A diabetes after age 20, concordance was less than 5%, compared with a concordance greater than 50% if the index twin developed diabetes before age 20. If the first twin developed type 1A diabetes before the age of 10, almost 5% of discordant twins per year developed diabetes in the first years of discordance, and the rate decreased to 1% per year only by 20 years of follow-up. In contrast, if diabetes developed in the first twin after age 20, the initial hazard rate was low and remained at approximately 1% per year for the duration of follow-up. These differences in concordance and hazard rates may reflect differences in genetic forms of type 1A diabetes for groups of twins subdivided by the age of the proband twin at diagnosis of diabetes.

Discordant dizygotic twins have a diabetes risk that is similar to that of non-twin siblings of patients with diabetes: approximately 6% (72). The difference between monozygotic and dizygotic twins most likely represents a difference in the inherited genes shared with the proband (100% for monozygotic twins; mean of 50% for dizygotic twins). There is one report that dizygotic twins have a very high prevalence of islet autoantibodies (87), but with reanalysis and exchange of sera, the high prevalence of islet autoantibodies was not confirmed. Dizygotic twins do not have increased expression of islet autoantibodies compared with that in their siblings (72), and when monozygotic twins express islet autoantibodies, they usually progress to overt diabetes (72,92).

Offspring of a father and siblings of patients with type 1A diabetes have a similar risk of type 1A diabetes, while offspring of a mother with type 1A diabetes have a somewhat decreased risk (93). The difference in risk between offspring of mothers versus fathers with type 1A diabetes has not yet been explained. Preliminary data from the Diabetes Autoimmunity Study in the Young (DAISY) (94) suggest that offspring of fathers with type 1 diabetes more often are DQ8/DQ2 heterozygous than are offspring of mothers with type 1 diabetes. This may contribute to a slightly higher diabetes risk (Table 23.2).

As will be discussed, the ratio of the overall risk of diabetes of a sibling of a patient with type 1 diabetes is 6% and the general population risk is 0.4%, giving a sibling familial aggregation ratio, λ -s of 15 (6/0.4) (10). This number provides some estimate of the influence of being a sibling in terms of familial (shared genetic and sibling environmental background) risk of developing type 1A diabetes. For genetic disorders, a λ -s of 15 is a moderate association. The most important locus for type 1A diabetes is the HLA region of chromosome 6. Polymorphisms 5' of the insulin gene also contribute to the familial aggregation. A major portion of the genetic risk of type 1 diabetes cannot currently be assigned to specific genes (10,95,96).

The Major Histocompatibility Complex

The most important determinants of type 1A diabetes are genes within the major histocompatibility complex (MHC) on chromosome 6p21 (33,97). The MHC is approximately 4 million base pairs long with more than 200 known or predicted transcripts (5). The region is divided into class I [containing the classical histocompatibility antigens HLA (human leukocyte antigens) A, B, and C], class II (containing immune response genes, HLA- DP, -DQ, and -DR), and the class III region with genes of the complement cascade, as well as other genes influencing immune function. There are also other genes within this complex not related to immune function, such as the gene for 21-hydroxylase, an enzyme of adrenal steroidogenesis, and the gene determining hemochromatosis telomeric to the MHC.

HLA-DQ, -DR, -A, -B, and -C molecules are extremely polymorphic, with hundreds of different alleles (e.g., as of January 2000, 241 alleles for DRB1 had been identified) (98). An individual inherits one allele of each gene from each parent. The series of alleles on a given chromosome inherited from a parent are termed a haplotype. By typing alleles of multiple family members, one can determine the four haplotypes of a nuclear family (two haplotypes for each parent). Alleles of different genes in a population are often not randomly associated with each other on the same chromosome; it is then stated that the alleles are in linkage dysequilibrium. For example, the class I HLA alleles A1 and B8 and the class II alleles DR3 and DQ2 (DQ2=DQA1*0501, DQB1*0201) are commonly associated with each other on chromosomes (99–101). The term *linkage dysequilibrium* implies that not enough evolutionary time has elapsed for these allelic associations to be randomized by crossing-over events between alleles. This "DR3" haplotype that encodes a high risk for diabetes has been termed an ancestral or extended haplotype (102, 103). Because all of these alleles, as well as alleles of other genes within this extended haplotype, are inherited as a unit, the specific combination of alleles determining diabetes risk is difficult to pinpoint. Other HLA haplotypes do not show as extensive linkage dysequilibrium, and the primary importance of DQ and DR alleles to diabetes risk is apparent.

The nomenclature for HLA alleles has changed almost with each modern edition of the Joslin text but is unlikely to change again because it is now based on variants of nucleotide sequence of the HLA genes rather than serologic typing (98). For DQ molecules, both the α and β chain of the molecule are polymorphic; thus to specify a DQ molecule, one must specify both chains (e.g., DQA1*0501, DQB1*0201). In contrast, for DR molecules, the DR α chain is not polymorphic and only the DR β chain is specified (DRB1*0301). If a chain has a "silent" nucleotide polymorphism (amino acid sequence not changed), a fifth digit is added (e.g., DRB1*03011). The nucleotide sequences are typically determined with direct sequencing and computer analysis. With automated sequencers and polymerase chain reaction amplification of DNA, direct sequencing is relatively simple. The direct sequencing of two alleles (one for each chromosome) of an individual can result in a small amount of ambiguity for certain combinations of alleles. This is usually not a problem, and the sequences provide

TABLE 23.2. Approximate Frequency of Islet Autor	antibodies (Ab+) and
Development of Diabetes Mellitus for Initially No	ondiabetic Relatives

Relationship	% DM	% Ab+ (GAD, 512, or insulin)	Comment
Monozygotic twin	50%	50%	Almost all Ab+ progress to DM
Dizygotic twin	6%	10%	Risk similar to sibling
Sibling	3.2% ^a	7.4%	_
Offspring father	4.6%	6.5%	Diabetes risk greater than offspring of diabetic mother
Offspring mother	3%	5%	Lower risk relative to offspring of diabetic father
Parent	1%	4.1%	Many parents with single Ab+
DR3/4,DQ8 sibling	>25%	>50%	Highest risk for non-twin relative

^aLifetime diabetes risk is approximately 6% for siblings followed from birth. The difference in the percentage of dizygotic twins and siblings with diabetes mellitus is within the error of the estimates.

TABLE 23.3. Risk of Type 1A Diabetes Mellitus Associated with DR and	d DQ Haplotypes
--	-----------------

much more information concerning exact alleles compared with that obtained with older methods of typing for HLA alleles.

One can define HLA disease associations with individual alleles of single genes (e.g., alleles of DQB or DRB), with haplotypes (e.g., alleles of HLA-A, -B, -DQ, -DR on a single chromosome), and with genotypes (alleles of both chromosome 6 haplotypes possessed by an individual). In a physiologic sense, genotypes contribute to diabetes risk (104-108). With so many different alleles, and different haplotypes, there are millions of theoretical genotypes. In practice, the genotypes associated with type 1A diabetes risk or protection are relatively limited, and specifying genotypes for DQ (DQA and DQB) and DRB alleles provides the great bulk of relevant information (Table 23.3). The disease associations of genotypes can be complex. For instance, DQA chains coded for by one haplotype can combine with DQB chains of the other haplotype and influence diabetes risk. DQB1*0301 is in linkage dysequilibrium with DR4 but is not a high-risk allele (and is relatively protective). Thus, most white patients with type 1A diabetes have the DQB1*0302 allele on their DR4 haplotypes and not DQB1*0301 (109). The DQB1*0301 appears to be protective primarily in patients who also have a DR3 haplotype (with DQA1*0501, DQB1*0201) on their other chromosome. However, in combination with other haplotypes, such as the DR1(DQA1*0101, DQB1*0501), DQB1*0301 increases diabetes risk (110-112).

The prevalence of given genotypes (and haplotypes) varies among populations, but given the same DQ and DR genotypes, the influence of HLA on type 1A diabetes is similar for populations throughout the world (113). Thus, even in populations with a very low incidence of type 1A diabetes (e.g., Korea and Japan), when similar genotypes are present, they confer increased or decreased risk of diabetes. Investigators have attempted to encapsulate the HLA-DQ risk by reference to several specific amino acids. The most common rule is that aspartic acid at position 57 of the DQB is protective and that arginine at DQA 52 is associated with increased diabetes risk, but there are many exceptions (114). Figure 23.5 illustrates the transmission of a series of DQB alleles from parents to children with type 1A diabetes (115). The transmission test corrects for differences in the prevalence of alleles in the population, as transmissions are counted only from parents heterozygous for the specific allele (115,116). If DQ alleles did not influence diabetes risk, all alleles would be transmitted 50% of the time to children with diabetes. As is apparent from the figure, there is a tremendous spectrum of transmission frequencies for different alleles, and a similar spectrum is documented by studies of large populations (117). The rules concerning aspartic acid at position 57 provide little predictive power. For instance DQB1*0402 is one of the alleles

with the highest transmission frequency, DQB1*0301 is intermediate, and DQB1*0602 is one of the most protective alleles. All have aspartic acid at position 57 of their DQB chain. Since we currently can define all of the polymorphisms of these chains, knowledge of the complete sequence rather than of single amino acid polymorphism is preferred for assessing diabetes risk.

HLA-associated protection from type 1A diabetes is dominant relative to susceptibility (108,118). The three most protective molecules are DQA1*0102 with DQB1*0602, DQA1*0201 with DQB1*0303, and DRB1*1401. The latter two molecules are relatively rare, whereas in most populations, more than 20% of individuals have DQA1*0102, DQB1*0602 and fewer than 2% of children with type 1A diabetes have this allele. Note that both DQ and DR alleles can protect against the development of type 1A diabetes; this observation is similar to findings in animal models, in which alleles of the equivalent genes (I-A, DQ; and I-E, DR) both can provide protection (119,120). Transmission of haplotypes from parents to affected offspring was analyzed for the Norwegian NODIAB study (116) and the HBDI (Human Biologic Disease Interchange) repository (121). This allowed analysis of rare "recombinant" haplotypes such as DRB1*0101 or 1404 with DQA1*0101, DQB1*0503 in comparison to the usual DRB1*1401, DQA1*0101, DQB1*0503 haplotype (Table

23.4). The DRB1*1401 allele was transmitted to none of 40 diabetic offspring, whereas DQB1*0503 without DRB1*1401 was transmitted to 2 of 4 diabetic offspring. In this case, DRB1*1401 apparently determines protection. DQB1*0602 was transmitted to 0 of 6 diabetic offspring for haplotypes without DRB1*1501; transmission of DQB1*0602 with DRB1*1501 was also rare (2 of 313). In contrast, DRB1*1501 without DQB1*0602 was transmitted to 5 of 11 diabetic offspring. For this haplotype, DQB1*0602 apparently provides protection (Table 23.4).

To date we have found 13 (1.5%) of 877 individuals with type 1A diabetes (as evidenced by positivity for islet autoantibody and the presence of diabetes) with DQB1*0602. Their DQB sequence did not differ from the standard sequence (97,118). One patient had the APS-I syndrome, although overall it is likely that, in patients with APS-1, DQB1*0602 is also protective for diabetes but not for Addison's disease (26,56). Another child had high levels of 21-hydroxylase autoantibodies, often associated with polyendocrine autoimmunity. Thus, we suspect that some individuals with DQB1*0602 and type 1A diabetes are likely to have variant genetic forms of type 1A diabetes. Among the patients with DQB1*0602, the other allele is usually a high-risk HLA allele [10 (77%) of 13 DQ8 or DQ2]. Two of the three patients lacking DQ8 and DQ2 had DQB1*0402 (n = 2). Analysis of islet autoantibody–positive relatives of Diabetes Prevention Trial Type-1, for which the presence of DQB1*0602 is an exclusion criteria, indicates that 7% of cytoplasmic islet cell antibody (ICA)-positive relatives are positive for DQB1*0602 (122). There was an increased prevalence of DQB1*0602 among African-American ICA-positive relatives, again suggesting genetic heterogeneity (122).

The highest risk genotype for type 1A diabetes consists of DRB1*0301/DQA1*0501, DQB1*0201 (DQ2) with DRB1*0401 (or 0402, or 0405)/DQA1*0301, DQB1*0302 (DQ8) (9). This genotype occurs in approximately 2.4% of newborns in Denver, Colorado, and in approximately 40% of children with type 1A diabetes (16). A newborn with this genotype without a relative with type 1A diabetes is estimated to have a risk of diabetes of approximately 6%. In contrast, a sibling of a patient with type 1A diabetes with the same genotype has a risk of developing diabetes that is greater than 25%. We believe the greatly enhanced risk for a relative relates both to non-MHC genes inherited by such relatives and to other HLA alleles associated with increased diabetes risk. A number of other HLA genotypes are associated with high to moderate risk for type 1A diabetes, including DR 4/4, DQ 8/8 (DQ8 = DQA1*0301, DQB1*0302); DR 3/3, DQ 2/2 (DQ2 = DQA1*0501, DQB1*0201); DR 1/4, DQ 1/8; DR 1/4, DQ 1/7 (DQ7 = DQA1*0301, DQB1*0301). The DRB1 allele DRB1*0403 modifies the risk of diabetes associated with DQA1*0301, DQB1*0302 (DQ8) such that the haplotype DRB1*0403, DQA1*0301, DQB1*0302 is slightly protective (105, 123).

Genotypes consisting of both DR and DQ alleles appear to underlie the bulk of MHC-associated susceptibility. Neverthe-

less, there are likely to be alleles of other genes within the MHC contributing to susceptibility to diabetes. Class I alleles that present peptides to cytotoxic CD8 T lymphocytes are likely to influence disease risk or the age of development of type 1A diabetes. The allele A24 is reported to be associated with a younger age of onset of type 1A diabetes, and there is evidence that HLA-A2 influences diabetes risk (124). Alleles of the nontypical HLA allele, termed MIC-A, have been reported to be associated both with type 1A diabetes and with Addison's disease (63). Alleles of several microsatellite markers (repeat elements) that simply mark chromosomal regions are reported to be associated with diabetes risk and subdivide haplotypes with fixed DR and DQ alleles. Such analyses are particularly difficult because of the extensive linkage dysequilibrium of alleles of genes within the MHC and the importance of class II alleles

(DR and DQ, as well as influence of DP) (125,126).

The Insulin Gene

Another locus clearly associated with risk for type 1A diabetes is the insulin gene locus (127-129). Alleles of a variable nucleotide tandem repeat 5' of the insulin gene influence the risk of type 1A diabetes. This tandem repeat has been divided into three major sizes, and the longest tandem repeats are associated with decreased risk of type 1A diabetes. The longer tandem-repeat group is also associated with increased expression of insulin messenger RNA within the thymus (130,131). In animal models, expression of minute amounts of insulin message within the thymus correlates with protection from diabetes and insulitis (132,133). An attractive hypothesis is that insulin is a key molecular target and that greater thymic expression of insulin leads to tolerance and thus decreased risk of diabetes.

Oligogenic versus Polygenic Inheritance

Genes within the MHC and the insulin locus account for approximately 50% of the familial aggregation of type 1A diabetes. The remaining familial aggregation is probably due to additional inherited polymorphisms/mutations, and the lack of 100% concordance of identical twins could be due to somatic mutation, random rearrangement of genes (e.g., rearrangements in the T-cell receptor), differences in environmental exposures, or stochastic events. We believe that non-MHC genetic loci are of major importance. For one of the best animal models of type 1A diabetes, the NOD mouse, the inheritance is polygenic, with more than 15 different genetic loci influencing susceptibility to diabetes (134-136).

Diabetes in the NOD mouse is a potential example of a single form of human type 1A diabetes. This is not strictly accurate, in that NOD mice are brother-sister mated for more than 20 generations (inbred) and thus have no genetic variability. NOD mice are not diallelic at any locus. Humans have different alleles at more than 100,000 loci, many within coding regions of

TABLE 23.5. Confirmed and Putative Loci Associated with Type 1A Diabetes Mellitus

genes. The inbred nature of the NOD mouse may relate to the ease with which multiple small genetic changes, as well as therapeutic interventions, prevent diabetes (135). Such ease of prevention is less likely in humans. Other animal models do not show a polygenic form of inheritance but show an "oligogenic" inheritance, with a few major loci (including the histocompatibility complex) determining diabetes risk (137,138).

Whether human type 1A diabetes is polygenic or oligogenic is currently debated. Practical ramifications of the mode of inheritance are likely to relate to the ease of defining genes underlying susceptibility, identifying at-risk individuals, and discovering pathways for prevention of diabetes. We favor the hypothesis that type 1A diabetes is oligogenic but heterogeneous (139). Namely, in most families, one to three loci determine diabetes susceptibility but different families have different major "diabetogenes." The bulk of the effort to define diabetogenic loci has involved the study of hundreds of families with two siblings (sib pairs) with type 1A diabetes. These studies have implicated more than 15 loci associated with diabetes risk but have been difficult to replicate (96). For example, several studies have suggested that a polymorphism of CTLA-4 may contribute to diabetes risk in certain populations but not in others (Table 23.5) (140-145). A missense mutation of the LYP gene (PTPN22; lymphocyte tyrosine phosphatase) is a major "autoimmune" allele (Arg620Trp) and has an odds ratio of approximately 1.7 for type 1 diabetes (145a).

If type 1A diabetes is heterogeneous and if no specific genetic syndrome accounts for more than 20% of cases of type 1A diabetes, one may need to define relevant genes by studying specific families before application to mixed populations. We have studied a Bedouin Arab family from Israel that has 21 members with type 1A diabetes. In this family, diabetes is associated with typical HLA alleles and with a locus on chromosome 10, currently termed IDDM17 (139). Individuals homozygous for related 10q25.1 haplotypes and with DR3 have a 40% risk of developing type 1A diabetes. In contrast, relatives lacking DR3 or who are not homozygous have a risk of type 1A diabetes lower than 2%. This suggests that a major diabetogene on chromosome 10 is segregating with diabetes and that diabetes develops from a combination of this locus and high-risk HLA alleles.

None of the putative non-MHC loci except for LYP and the insulin gene contribute to the assessment of risk for type 1A diabetes, and it is likely that genes, rather than loci, will need to be defined before such studies will be of major influence. The Genome Project should greatly facilitate studies to identify these genes, and it is now possible to create detailed maps of any region of the human genome and, thus, to analyze transmission and linkage dys-equilibrium for specific haplotypes.

ENVIRONMENTAL FACTORS

A number of potential environmental causes of type 1 diabetes have been reported, but few have been established beyond doubt. However, there are examples of autoimmune diseases that not only are caused by environmental factors but also can be prevented or treated through avoidance of these factors (e.g., celiac disease). These diseases occur only through a strong interaction between environmental factors and specific alleles of mainly HLA genes, suggesting the futility of defining "genetic" versus "environmental" etiology.

Celiac disease, discussed earlier in this chapter, is induced by ingestion of wheat protein gliadin (146–148) in a person with DQ2 or DQ8 haplotypes. Removal of wheat from the diet results in the loss of transglutaminase autoantibodies and resolution of the intestinal lesions (149). There is some evidence that the delayed introduction of wheat into infant feeding in recent years has prevented a substantial number of symptomatic cases, although some of such prevented cases may manifest with milder symptoms later in life. Rheumatic fever, another autoimmune disease, is induced by streptococcal infection of a host with an HLA-DR4 genetic background. It has been nearly eradicated in many countries with the introduction of antibiotics and guidelines for diagnosis and treatment of streptococcal infections.

Diabetes in patients with congenital rubella syndrome is perhaps the only form of type 1A diabetes proven to be caused by a viral infection (150–152). Non-congenital rubella infection does not appear to be associated with diabetes risk. At present it is not clear whether congenital rubella is associated with endocrine autoimmunity caused by direct infection of target tissues, the triggering of autoimmunity (153), or the induction of changes in the immune system that lead to autoimmunity (154). Although only a small proportion of cases of type 1A diabetes have been found to be caused by congenital rubella infection, this is the only type of autoimmune diabetes that we currently can prevent (using live attenuated rubella vaccine, a component of the MMR vaccine).

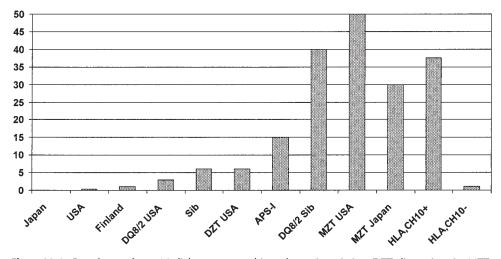

Figure 23.6. Prevalence of type 1A diabetes: geographic and genetic variation. DZT, dizygotic twin; MZT, monozygotic twin; HLA,Ch10+, patient from a Bedouin Arab family with HLA DR3 and homozygous for IDDM17 diabetes-associated haplotypes (Japan, 0.02%; USA, 0.3%; Finland, 1%).

Figure 23.6 contrasts prevalence of type 1A diabetes for a series of countries with dramatic differences in its incidence and compares such diabetes prevalence to diabetes risk, taking into account genetic information. The incidence of type 1A diabetes varies geographically by more than 45-fold (e.g., in Japan the approximate incidence is 1 in 100,000 compared with Finland, where it is 45 in 100,000) (155–159). Nevertheless, even the highest-risk Scandinavian countries have a prevalence of type 1A diabetes less than 3%, while an identical twin of a patient with type 1A diabetes from Japan has a diabetes concordance of approximately 30% (88).

A sibling or offspring of a patient with type 1A diabetes with HLA DQ8/DQ2 has a diabetes risk of approximately 20% to 40% (17,160), and an individual with this genotype from the general U.S. population has a risk of approximately 6%. In addition, a dizygotic twin of a patient with type 1A diabetes has a risk of diabetes very similar to that of a sibling (72). This suggests that, if there are environmental factors triggering the development of type 1A diabetes, they account for a relatively small amount of the familial aggregation of the disease. This may explain the difficulty finding such environmental factors. One exception previously discussed is the rare congenital rubella syndrome that is strongly associated with the development of thyroiditis and type 1A diabetes (161–163) and recent reports from two studies that introduction of cereal before 3 months of age increases risk (160a,160b).

TRIGGERING OF AUTOIMMUNITY

The most prominent proposed environmental triggers for type 1A diabetes are infections (particularly viruses), vaccination, and dietary factors (163). There is lack of clear consensus concerning the etiologic role of any of these factors. For both the NOD mouse and the BB rat, the development of diabetes is enhanced when animals are raised in a germ-free environment (164). This suggests that, for both of these animal models, infections are not necessary for the development of diabetes. In fact, when either animal becomes infected with relatively common viruses, the development of diabetes decreases. The BB rat has a severe T-cell lymphopenia inherited in an autosomal recessive manner (165–169). For strains of BB rats termed DR (diabetes resistant) that lack the T-cell lymphopenia locus, diabetes can be

induced with a number of immunostimulatory maneuvers, including infection with the rat Kilham virus or with induction of the expression of interferon-α with injection of poly-IC (poly-inosinic-polycytidylic acid, a synthetic double-stranded RNA) (170). Of note, administration of poly-IC induces diabetes and insulitis or just insulitis in a broad range of rat strains with "HLA" class II U alleles (diabetes and insulitis strains: lew1.WR1, PVG.RT1^u, PVG.R8, WF, and WAG; only insulitis-LOU strain). In animal models, several forms of "vaccination" prevent diabetes (e.g., BCG vaccination for NOD mice), and dietary modification, usually with removal of complex proteins from the diet, decreases the development of diabetes (171–173). Thus, such manipulations are potential triggers of autoimmunity or may provide therapies (e.g., removal of triggering factors) of relevance to diabetes prevention.

HUMAN DIABETES

Viruses

Viral infections may initiate autoimmunity or precipitate diabetes in subjects with autoimmunity. Cytoplasmic ICA or insulin autoantibodies have been detected after mumps (174), rubella, measles, chickenpox (175), Coxsackie virus (176), and ECHO-4 virus (177) infections, but most reported studies have used assays of questionable specificity—not the current fluidphase GAD65 and ICA512 (IA-2) autoantibody assays. Fetuses and newborns may be particularly at risk because of their propensity to develop persistent infection, as shown by the example of congenital rubella infection (162).

Congenital rubella infection is clearly associated with the development of type 1A diabetes and is associated with the development of a series of autoimmune disorders (especially autoimmune thyroid disease). Diabetes occurs in individuals with high-risk HLA alleles and occurs years after the rubella infection (178). Other congenital infections, particularly enteroviral infections (179), have been reported to be associated with type 1A diabetes.

Both β -cell autoimmunity (180) and diabetes (181) may be caused by enteroviral infections, perhaps acquired in utero (180,182). A molecular mimicry between the P2-C protein of Coxsackie virus and the GAD protein (183) could have a role.

Presence of antibodies to enteroviruses in persons with autoimmunity does not, however, prove a causal relationship. People with autoimmunity may be more prone to enteroviral infection, may have a stronger humoral response to infection because of their particular HLA genotypes, or may be in a nonspecific hyperimmune state marked by elevation in levels of antibody to a variety of exogenous antigens (184). However, if the enteroviral infections are indeed associated with triggering of both autoimmunity and diabetes, one of the following mechanisms could operate: (a) enteroviral infections may act in a manner similar to poly-IC (mimic of double-stranded RNA) that induces diabetes in MHC-susceptible rat strains (170); (b) several distinct infections may be necessary, the first, early in ontogenesis, leads to a low-grade persistent infection while the subsequent infections with a similar virus initiate and sustain autoimmunity until the final "hit" results in β -cell loss sufficient to cause diabetes (185,186); (c) enteroviral infection does not trigger autoimmunity, but recurrent acute lytic infections of β -cells promote β cell loss and diabetes in persons with autoimmunity; (d) persistent enteroviral infection of β-cells impairs insulin secretion without cell lysis and promotes diabetes in persons with autoimmunity; or (e) an acute or chronic enteroviral infection of peri-insular tissue leads to β-cell destruction from abundance of free radicals-the "innocent bystander theory." These hypotheses are based on extensive studies in animal models [reviewed in reference (187)] but have been extremely difficult to test in human populations because of the need to follow prospectively large groups of young children at risk for type 1 diabetes (188). Most early studies have attempted to correlate evidence (either antibodies or enteroviral RNA) with diabetes at onset. With current knowledge of the long prodromal phase that precedes type 1A diabetes, evidence that β -cell function is severely compromised years prior to diabetes, and the current ability to predict diabetes, it is unlikely that infections at the onset of diabetes have a primary pathogenic role. Thus, infections at onset may simply represent one of a number of stresses that either bring a patient to medical attention or increase the need for insulin and is thus associated with development of overt hyperglycemia. A recent prospective study of development of islet autoantibodies failed to find an association between enteroviral infections during pregnancy and the development of islet autoantibodies in offspring (2 mothers [10%] with infection of 21 children developing autoantibodies versus 17 mothers [16%] with infection of 104 control children). In contrast, the same study reported that 26% (33 of 125) of the prospectively observed children in whom islet autoantibodies developed and 18% (103 of 567) control children had evidence of enteroviral infection and that enteroviral infection and RNA were more often present during the 6-month interval before the development of islet autoantibodies. A very similar study from the United States addressing the same question failed to find an association of enteroviral infection with development or appearance of islet autoantibodies (189). The lack of confirmatory studies and small differences in enteroviral infections even in "positive" studies suggests that, if enteroviral infections do have a role, it is minor. It is certainly possible that only some strains of enteroviruses induce type 1A diabetes, but to date identification of specific strains in prospective studies, such as those from Finland, are negative, with a wide variety of enteroviral infections documented in young children developing islet autoimmunity.

In that type 1A diabetes is thought to be a T cell-mediated disease rather than autoantibody-mediated, studies of T-cell responses to enteroviruses are of interest. Hyoty and coworkers recently reported that children with recent-onset diabetes less often had T-cell responses to Coxsackie B4 virus than did control children and children with long-standing diabetes (190).

They interpret this as suggesting that enterovirus-specific T cells are within the islets. The alternative hypothesis that enterovirus-specific T cells are unrelated to diabetes onset is perhaps as probable.

If infections are related to the development of type 1A diabetes, it is likely that the environmental factor is relatively ubiquitous, in that diabetes develops in the majority of individuals with high genetic susceptibility (e.g., monozygotic twins and DQ8/DQ2 siblings of patients). Honeyman and coworkers, following up evidence that a peptide of rotavirus is similar to GAD and IA-2 (ICA512), reported that rotavirus infection, a common cause of childhood gastroenteritis, was associated with an increase in levels of islet autoantibodies, although rotaviral infections were equally frequent for controls and cases (191). On many occasions, islet autoantibodies appeared without rotavirus infection, and the small change in autoantibodies used to correlate with rotavirus infections makes it essential that the reported findings be confirmed in other studies.

Vaccination

The NOD mouse model of type 1A diabetes is finely balanced in terms of the development of diabetes, and as recently reviewed, more than 100 different therapies can prevent the development of disease in this model. Thus, it is not too surprising that a number of vaccines administered to NOD mice prevent the development of diabetes. It was initially observed that complete Freund adjuvant administered to mice prevented diabetes, and follow-up studies indicated that the related vaccine, BCG, also prevented disease. This has led to trials in humans, in which BCG administration was found to have no influence on the loss of C-peptide secretion after diagnosis of diabetes (192,193).

A more important consideration is whether standard vaccines or the schedule of vaccination increases or decreases the development of childhood diabetes. A recent editorial in the *Journal of Epidemiology and Community Health* discussed the propensity in "postmodern medicine" to focus on risks of vaccination, with most reported adverse events falling in categories of "no data" or "data inadequate to assess causality" (194). This perhaps appropriately encapsulates claims that standard childhood vaccination is related to development of type 1A diabetes. Studies such as the DAISY study in Denver with prospective evaluation of children for the first appearance of islet autoantibodies and then progression to diabetes provide no evidence for changes in vaccination timing or regimen as related to islet autoimmunity (189).

Dietary Factors

For both the NOD mouse and the BB rat, modification of diet can modify the development of diabetes. In particular, diets that lack complex proteins (amino acids rather than proteins) are associated with decreased development of diabetes. In the NOD mouse model, a diet with gluten restriction (the dietary factor in celiac disease) decreases development of diabetes. The area of greatest interest has related to milk proteins; particularly bovine albumin given to young children.

In humans, a proposed protective effect of breast feeding on the incidence of type 1 diabetes (195) has attracted enormous interest. The association between cow's milk and autoimmunity and diabetes remains controversial (196–198). If this association is real, it could be due to a molecular mimicry between bovine serum albumin (BSA) and pancreatic autoantigen ICA69 (196,197) or to the effect of β -casein immunostimulating hexapeptide present in enzymatic hydrolysate of milk from *Bos taurus* cows but

410 JOSLIN'S DIABETES MELLITUS

not from Bos indicus cows (R. B Elliott and N. J. Bibby, unpublished data). Subsequent human studies have given a variety of results: (a) diabetic children were significantly less likely than nondiabetic children to have been breast-fed (199-201); (b) there was no significant difference between the frequency of breast feeding in diabetic and nondiabetic children (202-211); or (c) diabetic children were significantly more likely than nondiabetic children to have been breast-fed (212). Certain studies suggested that the longer children had been breast-fed, the lower their risk for developing diabetes (200,201,213,214), whereas other studies did not show that protection increased with a longer duration of breast feeding (208,210,212,215). A meta-analysis of selected studies suggested that children with diabetes are 60% more likely than nondiabetic children to have had an early exposure to cow's milk (216). A major limitation of most of the aforementioned studies is that the data on infant diet were based on long-term maternal recall, which is subject to error (217). In fact, studies using prospectively collected records to assess infant diet (208,210,218) did not find the associations between type 1 diabetes and infant diet exposures that were found in studies that relied on recalled data. This suggests that there may be bias in the retrospective assessment of infant diet. The DAISY study has found no association between early exposure to cow's milk and β -cell autoimmunity in young siblings and offspring of patients with diabetes (219); this lack of association was also seen when the analyses were restricted to the highest-risk HLA genotypes: DR3/4,DQB1*0302, DR3/3 or DRx/4,DQB1*0302. Groups propose to gather definitive data concerning avoidance of cow's milk through a trial in newborn relatives with high-risk HLA genotypes (220,221). In a pilot study, type 1 diabetes developed in one child in the intervention group (n = 10) at the age of 14 months despite compliance with the intervention (breastfeeding or casein hydrolysate until the age of 9 months) and prevention of the development of antibody to BSA (222). This raises questions of whether BSA exposure is not relevant or whether it should be avoided for a period longer than 9 months, perhaps for life, similar to the elimination of gluten in celiac disease.

There are many other potential dietary factors, including vitamins, that may influence the development of diabetes. Toxic doses of nitrosamine compounds can cause diabetes (223–225) because of the generation of free radicals. The effect of dietary exposure to nitrate, nitrite, or nitrosamine on risk for human type 1 diabetes is less clear (226–228). Breast milk and vitamin supplements are important sources of antioxidants and theoretically may reduce the concentration of free radicals and thus the risk of β -cell damage. A number of additional environmental toxins have been implicated in the etiology of type 1 diabetes (225,229) but have never been fully explored in a cohort study. Multiple exposures to dietary β -cell toxins may render genetically resistant individuals susceptible to diabetogenic viruses, leading to type 1 diabetes (230).

In that the incidence of type 1A diabetes has increased dramatically in many countries during the past four decades, it is likely that some factors in the environment are changing. At present, these factors are unknown. An alternative explanation could be the explanation proposed for the recent increase in childhood asthma (231), that is, that the prevalence of suppressive environmental factors is decreasing. A candidate for such suppressive factors, in analogy to animal models, is the possibility that many childhood infections decrease, rather than increase, such risk. Evidence for such a protective effect in humans is not available. Measles immunization, but not polio immunization, has been reported to be associated with lower risk of type 1 diabetes (232); however, the effects of current mass immunization programs against potentially diabetogenic viruses are virtually unknown.

HUMORAL AUTOIMMUNITY

During the past 15 years, remarkable progress has been made in defining target autoantigens recognized by islet autoantibodies (233-235). The earliest test for islet autoantibodies was the cytoplasmic islet cell antibody (ICA) assay (68). This test uses frozen sections of human pancreas. The binding of immunoglobulin from patients to islets, as contrasted to binding with acinar pancreas, forms the basis for the test. Studies of cytoplasmic islet cell autoantibodies greatly aided studies of pathophysiology and facilitated the prediction of type 1A diabetes (236-238). The cytoplasmic ICA assay detects autoantibodies reacting with the ICA512 (IA-2), GAD, a ganglioside, and additional islet antigens (239-242). When cytoplasmic ICA autoantibodies react only with GAD, the antibodies react with human pancreas but fail to react with mouse pancreas; and on rat pancreas, the antibodies react specifically with islet β -cells. These antibodies are called "restricted" or "selective" and are usually associated with a relatively low progression to diabetes. The pattern of reactivity relates to the almost complete absence of GAD from mouse islets, β -cell specificity of GAD expression in rat islets, and the presence of GAD in all islet cells (e.g., α , β , γ , and δ) of human islets. Restricted ICA staining can be totally absorbed by incubating sera with GAD while standard ICA staining is not absorbed with GAD.

Quantitative assays are now available for autoantibodies reacting with three major islet autoantigens: insulin, GAD65, and ICA512 (IA-2) (20). Determination of autoantibodies reacting with these three molecules has supplanted, to a great extent, the determination of ICA, although there are ICA autoantibodies that are not GAD- or ICA512-reactive. Nevertheless, the detection of ICA in the absence of the previous three autoantibodies is associated with a very low risk of progression to diabetes (74,243,244), and the ICA test suffers from difficulty in standardization (20) and, in a number of laboratories, in reproducibility. Thus, we presently do not use the ICA test but measure insulin, GAD, and ICA512 (IA-2) autoantibodies.

INSULIN

Insulin was the first islet autoantigen to be characterized. Insulin autoantibodies were found to be present in children at the onset of type 1 diabetes before the administration of exogenous insulin (245). Insulin antibodies develop in essentially everyone treated with subcutaneous insulin (including human insulin) after several weeks to months of therapy. Thus, positivity for insulin autoantibodies/antibodies of insulin-treated patients provides no information relative to the diagnosis of type 1A diabetes.

Insulin is the smallest of the defined protein islet autoantigens (51 amino acids), consisting of disulfide-linked A and B chains. Insulin autoantibodies react with a conformational determinant of insulin, requiring residues of both the A and B chains. Perhaps related to the small size of the insulin molecule, almost all of the autoantibodies react with a similar determinant, centered at a pocket with the A13 leucine residue at its base (246). In that this pocket is relatively invariant for most species of insulin, insulin autoantibodies react well with human, bovine, porcine, and even rat insulin. In contrast, guinea pig insulin is nonreactive, and changing a single amino acid, A13 leucine, to tryptophan decreases binding of insulin autoantibodies by more than 100-fold. There are reports that proinsulin autoantibodies, distinct from insulin autoantibodies, are associated with type 1 diabetes (247). Most studies indicate that proinsulin autoantibodies can be absorbed by insulin, and

the measurement of proinsulin autoantibodies does not increase the sensitivity of detecting autoantibodies (246).

Insulin autoantibodies are of high apparent affinity and very low capacity (10⁻¹² M), and this may relate to the poor performance of the enzyme-linked immunosorbent assay (ELISA) for insulin autoantibodies (246). At the time of the initial discovery of insulin autoantibodies, there was debate about whether fluid-phase radioassays or assays with insulin bound to plastic (ELISAs) should be used. ELISAs are the standard assay format for many immunologic assays. It rapidly became apparent that ELISAs for insulin autoantibodies did not detect diseaserelevant autoantibodies (248), although such assays readily detected the insulin antibodies generated after subcutaneous insulin therapy.

Until recently, the fluid-phase radioassays essential for detection of insulin autoantibodies were cumbersome and required a large volume of serum (20). Williams and coworkers modified the standard insulin autoantibody assays that used polyethylene glycol precipitation of antibodies to an assay that used protein A bound to Sepharose beads (249,250). Serum volumes were dramatically decreased with such an assay. Perhaps more important, several situations in which the polyethylene glycol–based assays artifactually indicated the presence of autoantibodies do not give false-positive results with protein A–based assays (250). Polyethylene glycol precipitation depends on decreasing the solubility of proteins in sera and is thus not specific for antibodies. In contrast, Sepharose–protein A precipitation is antibody-specific. Both cord blood and hemolyzed sera produce false-positive signals for insulin antibodies with polyethylene glycol precipitation (250–252).

The protein A–Sepharose-based assay for insulin autoantibodies has been modified to allow high throughput (253). In particular, we use assays with 96-well membrane filtration to separate autoantibody-bound from free ¹²⁵I-insulin. Scintillation fluid is added directly to the 96-well plates; these assays are, in many respects, as convenient as ELISA-based assays, but require working with low levels of radioactivity. With such an assay, not only are prediabetic humans found to produce insulin autoantibodies but similar antibodies are found in prediabetic NOD mice (Fig. 23.7) (253).

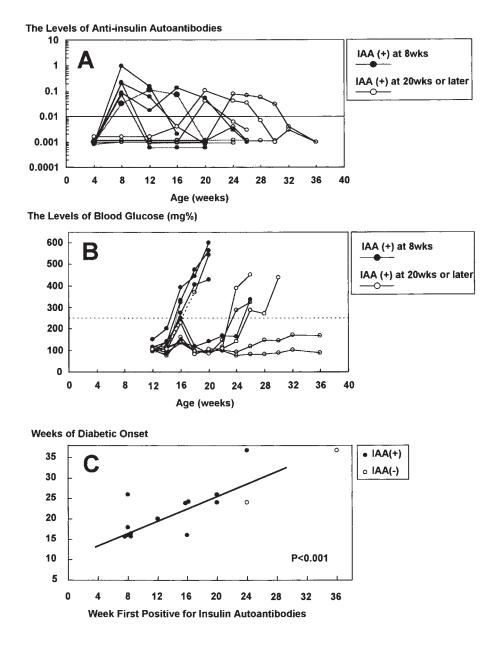

Figure 23.7. Insulin autoantibodies (IAA) of NOD mice. Mice developing insulin autoantibodies at 8 weeks of age develop diabetes earlier. A: Time course of insulin autoantibodies. B: Time course of glucose (open symbols: mice with late development of insulin autoantibodies). C: Correlation of first appearance of insulin autoantibodies and age of diabetes onset. (Reprinted from Yu L, Robles DT, Abiru N, et al. Early expression of anti-insulin autoantibodies of man and the NOD mouse: evidence for early determination of subsequent diabetes. *Proc Natl Acad Sci U S A* 2000;97:1701–1706, with permission. IABLE 23.6. Caveats of Autoantibody Determination			
Caveat	Suggestion		
Assays vary dramatically in sensitivity/specificity and ability to standardize (20,354)	Do not use cytoplasmic ICA assay. Use "biochemical autoantibody" assays with documented proficiency testing and specificity ≥99% (i.e., <.01 normal controls positive)		
Insulin antibodies appear after insulin therapy	Do not measure insulin antibodies several weeks after insulin treatment		
Specific autoantibodies expressed vary, with insulin autoantibodies most common in young children and GAD autoantibodies, in adults (24,253)	Measure multiple "biochemical" autoantibodies		
Single autoantibodies, such as restricted ICA that is only GAD antibodies, confer low risk (76,355)	Measure multiple "biochemical" autoantibodies. If GAD or ICA is only antibody, test absorption of ICA with GAD		
Subset of patients who are apparently type 1A express no known autoantibody	HLA typing, insulin secretion, and clinical history (e.g., autoimmunity) may aid diagnosis		
Autoantibodies can appear at any age and often develop sequentially (253,281)	Measurement over time is important		
 Antibodies reacting with a single islet autoantigen do not always indicate β-cell autoimmunity (73,74) Autoantibodies can disappear, and "mistakes" in handling sera can approach true positive rate in low-risk populations (294) 	Antibodies reacting with multiple epitopes of a single molecule or multiple islet antigens are more likely to be disease associated Do not rely on determination of autoantibodies in single serum sample		

TABLE 23.6. Caveats of Autoantibody Determination

Insulin is the only identified β -cell–specific islet autoantigen. The autoantibodies reacting with insulin are also unique in that there is a remarkable inverse relationship between the age at which diabetes develops and the levels of insulin autoantibodies (254–256). Essentially all children in whom type 1A diabetes develops before the age of 5 years express insulin autoantibodies, while approximately one half of individuals in whom type 1A diabetes develops after the age of 15 years lack insulin autoantibodies. We believe this relationship is the result of an association between higher levels of insulin autoantibodies and a more rapid course of β -cell destruction and thus a more rapid progression to diabetes (257). An important exception to this correlation is that progression of diabetes is limited in individuals who have only insulin autoantibodies (e.g., no ICA512 or GAD65 autoantibodies) (243).

For children younger than 2 years of age, insulin autoantibodies are usually the first autoantibodies to appear and, characteristically, their appearance is followed by the development of GAD65 autoantibodies and then of ICA512 autoantibodies (17,252,253,257–259). For many children in whom type 1A diabetes develops during the first few years of life, multiple autoantibodies appear over several months to 1 year, with the first autoantibody often present by the time they are 6 months old. Transplacental insulin antibodies usually disappear by 6 months of age but, as with other autoantibodies (particularly GAD autoantibodies), they can be present in some infants for up to 1 year. It is well recognized that infants of mothers with diabetes frequently have transplacental islet autoantibodies. Such transplacental antibodies may be present even when the mother does not have diabetes, in that a nondiabetic mother may express islet autoantibodies that are then detectable in her children (Table 23.6).

GLUTAMIC ACID DECARBOXYLASE

The discovery that the 64-kDa islet autoantigen was GAD provided one of the most important assays for islet autoantibodies (260). Patients with the rare neurologic disorder stiff man syndrome were found to express autoantibodies reacting with Purkinje cells, and these antibodies reacted with GAD (261). Although stiff man syndrome is rare, the expression of GAD autoantibodies is relatively common for patients with type 1A diabetes and their relatives and is rarely associated with stiff man syndrome. Mapping of the epitopes recognized by GAD65 autoantibodies indicates that essentially the entire surface of the molecule is a target for GAD autoantibodies (262). This suggests that the native folded GAD65 is the immunogen during β -cell destruction. Most autoantibodies react with conformational epitopes of GAD65, and few react with GAD67. With extremely high titer GAD autoantibodies (e.g., patients with stiff man syndrome or restricted ICA), GAD67-reactive antibodies also are present. Both GAD65 and GAD67 are present in cytoplasmic microvesicles of neurons and in multiple different endocrine cells. Within human islets, GAD65 is expressed in all islet cells $(\alpha, \beta, \gamma, PP)$, even though only β -cells are destroyed.

ICA512 (IA-2)/IA-2 β (PHOGRIN)

The molecule ICA512 was originally identified as an islet autoantigen with the screening of an islet expression library with sera from patients with diabetes (263,264). The initial sequencing of the ICA512 clone had several errors in base calling that resulted in an altered predicted reading frame, and thus initial ELISAs for ICA512 autoantibodies used a Cterminus–shortened clone (265). Even with the shorter clone and the use of the ELISA methodology, the presence of ICA512 autoantibodies in patients developing type 1A diabetes was apparent. The ICA512 molecule also was identified in studies of insulinoma cells and was given the designation IA-2 (266). Several investigators independently discovered a related molecule termed IA-2 β (267), or phogrin (268,269). The importance of autoantibodies to this family of molecules for prediction of

413

the development of diabetes was demonstrated before the sequences of ICA512 and IA-2 β were defined. Patients' sera precipitated enzymatic digests of metabolically labeled islet molecules (270,271).

ICA512 and IA-2 β are structurally related, and both have sequence homology to tyrosine phosphatase–like molecules, although no enzyme activity has been demonstrated for either molecule (272). ICA512 and IA-2 β are widely distributed in neuronal and endocrine tissues, and the molecules are associated with islet secretory granules. The autoantibodies react with the portion of the molecule that remains intra-cytoplasmic when secretory granules fuse with the plasma membrane. Most of the autoantibodies react with the ICA512 molecule and may cross-react with IA-2 β . Relatively few individuals developing diabetes have IA-2 β autoantibodies without ICA512 autoantibodies, whereas approximately 10% of patients developing diabetes have ICA512 autoantibodies in the absence of IA-2 β autoantibodies (272–277). In addition, almost all anti–IA-2 β reactivity can be adsorbed with the ICA512 molecule.

Similar to their producing autoantibodies that react with the GAD65 molecule, individuals developing type 1A diabetes produce autoantibodies reacting with a large number of epitopes of ICA512 (273,276). Included among the epitopes is an alternatively spliced form of ICA512 that lacks the transmembrane exon (exon 13). This ICA512 clone [termed ICA512bdc (bdc = Barbara Davis Center)] was found with the screening of an islet expression library with patient sera, similar to the original studies by Rabin and coworkers (278, 279). A subset of patients has autoantibodies reacting with full-length ICA512 but not ICA512bdc, and vice versa, with approximately 10% of sera specifically reacting with only one of the two molecules. Recent studies indicate that expression of messenger RNA for the two forms differs between thymus and islets, with islets expressing both forms and the thymus expressing only the ICA512bdc form (280)

ICA512 autoantibodies are probably the most specific of the "biochemical" autoantibodies identified to date. When ICA512 autoantibodies are detected, individuals usually already express antibodies reacting with insulin or GAD65 (281). Nevertheless, a significant number of individuals with new-onset diabetes express only ICA512 autoantibodies. For a few individuals, ICA512 autoantibodies may be the only autoantibody detected in the prediabetic phase of the disease. With so many epitopes of ICA512 recognized by autoantibodies, it is relatively easy to construct autoantibody assays that use portions of the molecule. Mennuni and colleagues utilized a phage display library to define a number of ICA512 epitopes (282); they cloned non-overlapping fragments of ICA512 and developed autoantibody radioassays. Disease-associated autoantibodies react with multiple ICA512 epitopes, while the rare control individual expressing ICA512 antibodies appears to have antibodies reacting with only a single epitope. We believe it is likely that many such antibodies in controls are not related to islet β -cell destruction but may simply represent cross-reactivity of a given serum antibody (among millions) with a portion of the sequence of ICA512.

T-CELL AUTOIMMUNITY

A large series of diabetogenic T-cell clones have been derived from the NOD mouse model of type 1 diabetes. These T-cell clones are able to transfer diabetes to young or immunodeficient recipients, indicating that T cells are sufficient to transfer diabetes. These clones are both CD8 (cytotoxic) and CD4 "helper" (Th1, Th2, Th0) and recognize a series of different islet autoantigens (283–289). The Th1 (T-helper 1) CD4 clones can produce diabetes without CD8 T cells, probably through the cytokines that they produce. Th2 clones are complex, with some producing diabetes and others protecting from diabetes. The target antigen of many of the clones is unknown. An interesting series of clones react with peptides of insulin—particularly insulin B-chain peptide amino acids B:9–23—and others with a beta cell–specific molecule termed IGRP (islet-specific glucose-6-phosphatase catalytic subunit–related protein) (289a). Many of these clones were developed by isolating T cells directly from islets of NOD mice.

In contrast to T-cell clones of the NOD mouse, the production of T-cell clones and the assessment of the T-cell reactivity of patients with type 1A diabetes have been limited. For humans, T lymphocytes are obtained from peripheral blood, rather than from islets or lymphoid organs. It has been difficult to measure T-cell autoreactivity reliably in a way that would distinguish a patient with diabetes from a normal control. In an international T-cell workshop, with "blinded" peptides sent to multiple laboratories, none of the laboratories were able to distinguish T cells of controls versus those of patients with new-onset type 1 A diabetes. It is likely that more sensitive and specific assays will need to be developed to allow accurate T-cell determination. Newer techniques are being applied, including MHC+peptide avidin conjugates ("tetramers") reacting with T-cell receptors, assays that measure cytokine secretion of specific cells (ELISPOT), and assays dependent on separation of T-cell subsets. The potential importance of T-cell assays is illustrated by studies in which monitoring of islet transplants detected T-cell autoreactivity and alloreactivity (290).

NATURAL HISTORY OF TYPE 1A DIABETES

Childhood Onset

A number of recent studies have reported on children followed from birth for the expression of autoantibodies and the development of type 1A diabetes (252,253,257,291,292). Three of the largest of these studies are the DAISY study from Denver, Colorado (16), the BabyDiab study from Germany (253), and a series of studies from Finland [e.g., DIPP (Diabetes Prediction and Prevention) and TRIGR (Trial in Genetically at Risk)] (258,292). The DAISY and studies from Finland have evaluated both first-degree relatives of patients with type 1A diabetes and individuals from the general population following HLA typing. The BabyDiab study has evaluated primarily the offspring of mothers with type 1 diabetes. In general, results of the evaluation of these different populations appear concordant, despite wide geographic differences and some differences in autoantibody methodology (e.g., reliance or lack of reliance on the cytoplasmic ICA assay). Transplacental autoantibodies disappear relatively slowly, with a small percentage of infants having antibodies persisting until 1 year of age. Islet autoantibodies can be present during the first several months of life but often develop by 9 months of age (252,253,257,258,293). An increasing percentage of children develop autoantibodies between the ages of 9 months and 3 years. The first autoantibodies in infants are usually insulin autoantibodies-usually at very high levels. A subset of these infants lose antibody expression as they progress to overt diabetes, while most progressors express multiple islet autoantibodies until the onset of diabetes (20,75,294). The autoantibodies are usually persistent, although a few individuals lose antibody expression without progressing to diabetes (294). Very few children who express autoantibodies that react with more than a single islet antigen have only transient expression of autoantibodies.

Persistent, but not transient, autoantibodies are strongly related to genetic risk factors of type 1A diabetes (294). In the

TABLE 25.7. Caveats of intravenous Glucose forerance resting			
Caveat	Suggestion		
In young children, a "first"-test lack of response is not infrequent (356)	Never rely on a single test		
Lack of carbohydrate intake may blunt first-phase insulin secretion	Dietary preparation similar to oral glucose tolerance testing		
Type 1A diabetes mellitus and severe insulin resistance may coexist in the same individual	Subtracting 2× the fasting insulin from the 1+3 minute insulin may reveal lack of glucose-stimulated insulin secretion		
When below the first percentile, first-phase insulin secretion may remain low for a number of years before onset of diabetes (357)	Long-term follow up is recommended		
A subset of normal individuals has, by definition, first-phase secretion at the first percentile (78)	In the absence of islet autoantibodies, especially in athletes, low first-phase insulin secretion may not be significant		
First-phase insulin secretion varies considerably and increases at puberty	Never rely on a single test and interpret small changes in first-phase secretion with caution		

TABLE 23.7. Caveats of Intravenous Glucose Tolerance Testing

DAISY study, none of the children with transient islet autoantibodies had the highest-risk HLA genotype, DR3/4, DQ2/8. Transient islet autoantibodies occur in less than 2% of both firstdegree relatives and individuals from the general population, and the incidence of transient antibodies was not increased in relatives of patients with diabetes. In contrast, persistent islet autoantibodies are greatly increased among first-degree relatives and especially relatives with the genotype DQ8/2. Siblings of patients with type 1A diabetes with the genotype DQ8/2 have more than a 50% risk of developing islet autoantibodies by age 3 years. The risk in offspring with DQ8/2 is also very high, but approximately one-half that of siblings. In contrast, DQ8/2 individuals from the general population have a risk of less than 5%. Given the presence of islet autoantibodies in such young children, most go on to express multiple islet autoantibodies, and life-table analysis suggests a high rate of progression to overt diabetes.

Loss of first-phase insulin secretion precedes the development of type 1A diabetes, and severe abnormalities of insulin secretion (below the first percentile) are a risk factor in children for rapid progression to diabetes (77,79,238,295–299). The Australian family study has confirmed earlier reports of progressive loss of first-phase insulin secretion before overt diabetes (79). At present, most groups assess first-phase insulin secretion with the ICARUS protocol, measuring fasting insulin, and insulin 1 and 3 minutes after a bolus of intravenous glucose (300). Caveats concerning first-phase insulin testing are listed in Table 23.7.

It has long been recognized that many individuals have type 2 diabetes and are not aware of their illness. In a similar manner, with glucose tolerance testing (GTT), "silent type 1A diabetes" is found to be present in high-risk populations (e.g., islet autoantibody–positive relatives), even among children (122). Such children typically have normal fasting glucose levels, but glucose levels exceed 200 mg/dL at 2 hours with oral GTT. Almost all such individuals we have followed have progressed to overt diabetes, and given the classification of the American Diabetes Association Expert Committee, with an oral GTT diagnosis of diabetes, we institute insulin therapy (298). A subset of these individuals may be treated with relatively low doses of long-acting insulin for several years. In contrast to this recommendation, some diabetes experts treat only those individuals with fasting hyperglycemia.

Latent Autoimmune Diabetes of Adults

It is now clear that type 1A diabetes can occur at any age. The oldest individual we have followed to the development of diabetes was 69 years old, the mother of a patient with type 1A diabetes. She expressed multiple islet autoantibodies, with firstphase insulin secretion below the first percentile for more than a year before the onset of diabetes. Multiple studies indicate that between 5% and 30% of patients initially thought to have type 2 diabetes have type 1A diabetes (24,104,301). If type 1A diabetes develops in an adult, usually, but not always, the disease course is very slow. Such patients are best identified by the expression of islet autoantibodies, and of GAD65 autoantibodies in particular. Given the presence of islet autoantibodies, such individuals as a group "rapidly" (usually within 3 years) progress and require insulin therapy (24). Their HLA alleles more closely resemble those of patients with type 1A diabetes, although the frequency of DQ8/DQ2 is lower (104). Given the large number of patients with a diagnosis of type 2 diabetes (estimated to be ten times more than the number with type 1A diabetes), patients with latent autoimmune diabetes of adults (LADA) probably comprise almost one half of all patients with type 1A diabetes. In some countries, such as Japan, it is hypothesized that the majority of cases of type 1A diabetes develop in adults (302).

At present it has not been proven that patients with LADA should be treated with insulin at the onset of diabetes. Although oral hypoglycemic therapy will rapidly be ineffective in these patients and they are at increased risk for ketoacidosis, they are often treated with oral agents and observed for failure to maintain adequate glucose control. One small study from Japan suggested that immediate insulin therapy, in comparison to therapy with oral hypoglycemic agents, was associated with longer preservation of C-peptide secretion (303). In general, we treat autoantibody-positive adult patients with insulin, often with relatively low doses of long-acting insulin, early in their disease course.

PREDICTION OF DIABETES

Given current knowledge of the "natural" history of type 1A diabetes, the disorder can be predicted, such that trials for diabetes prevention have been instituted. The closer an individual

is to the development of overt diabetes, the more accurate the prediction. Large-scale prediction of type 1A diabetes will likely not be essential until there is a proven preventive therapy. At present, most prediction of type 1A diabetes is coupled to trials for the prevention of diabetes. There are isolated individuals for whom disease screening is warranted. The clearest such indication relates to relatives of patients with type 1A diabetes who will donate either a kidney or a portion of their pancreas. It is generally felt that such individuals expressing islet autoantibodies or with abnormal metabolic function (e.g., oral and intravenous GTT) are not good candidates as living-related donors.

Approximately 1 of 200 children with diabetes have been reported to die at the onset of type 1A diabetes (304,305). The clinical histories for most of these children are similar, with symptoms of diabetes overlooked by the first health care professionals who evaluate the child. The child then presents with ketoacidosis and develops cerebral edema. This can occur even when a family member has type 1 diabetes. It is believed that slow correction of hyperosmolarity helps to prevent cerebral edema, but this catastrophic complication is not predictable. With improved critical care facilities and early mannitol therapy, a number of children are now surviving cerebral edema, although many with stroke-like complications. In a family in which a high risk of diabetes for a child has been identified, most children are diagnosed before severe metabolic decompensation and then treated at onset of hyperglycemia as outpatients (305a). Given these risks, individual families request screening for diabetes risk.

During stress, a significant number of children develop hyperglycemia that is transient (306,307). The majority of these individuals do not progress to overt diabetes and appear to not be at increased risk for type 1A diabetes. Transient hyperglycemia is more common in children without a family history of type 1A diabetes and in children in whom hyperglycemia develops in the setting of severe stress (e.g., infection, steroid therapy). Type 1A diabetes develops in approximately 5% to 10% of children with transient hyperglycemia. These children usually express islet autoantibodies and have a severe loss of first-phase insulin secretion. Overt type 1A diabetes usually develops within months to several years.

Type 1A diabetes develops in approximately 5% of women with gestational diabetes (308). In contrast to the majority of women with gestational diabetes, those with type 1A diabetes usually express islet autoantibodies. Monitoring of such women is warranted, with institution of therapy (usually insulin) at the first indication of metabolic decompensation.

The current mainstays of diabetes prediction can be divided into three categories, genetic, autoantibody, and metabolic. At present, the only known environmental factor that increases the risk of type 1A diabetes is congenital rubella infection.

Genetic

A family history of type 1A diabetes increases risk of diabetes, as do specific HLA genotypes (309). Table 23.2 subdivides risk by relationship to proband with diabetes and HLA genotypes. High risk indicates individuals heterozygous for HLA DR3/4, DQ2/8. Moderate-risk genotypes include DR4/4 and DR1/4. Low-risk genotypes include most other genotypes not indicated as high-risk, moderate-risk, or protective. Protective genotypes include those with DQA1*0102, DQB1*0602, DQA1*201, DQB1*0303, or DRB1*1401 (71) (Table 23.8).

Autoantibody

The best current predictor for the development of type 1A diabetes is the expression of two or more biochemically assayed

TABLE 23.8.	Approximate Genetic Risk of Type 1A
	Diabetes Mellitus

	Identical twin	Sibling	Offspring	General population
Unknown HLA	50%	6%	4%	0.3%
High-risk HLA	70%	40%	20%	6%
Protective HLA	Unknown	Unknown	Unknown	0.03%

islet autoantibodies (insulin, GAD65, and ICA512 specifically set at \geq 99th percentile) (74,242,244). Approximately 80% of individuals developing type 1A diabetes express two or more of these autoantibodies. With assays for the autoantibodies set at the 99th percentile of normal controls, on a single serum sample, approximately 3% of normal individuals express one or more antibodies, while fewer than 1 in 300 express two or more of these autoantibodies. In that the expression of multiple islet autoantibodies is approaching the prevalence of type 1A diabetes in the general population, it is likely that prediction of type 1A diabetes is now feasible for both relatives and the general population. Limited experience suggests that the positive predictive value of multiple autoantibodies for the development of diabetes will be as good (or within a factor of two) as prediction among relatives (75,253,310–312).

A large number of studies have confirmed the utility of what has been termed "combinatorial" autoantibody prediction (20, 313). Figure 23.8 illustrates the progression to diabetes of firstdegree relatives of patients with type 1A diabetes subdivided by expression of zero, one, two, or three autoantibodies reacting with insulin, GAD65, or ICA512). We do not include determination of cytoplasmic ICA in the counting of autoantibodies expressed, in that cytoplasmic ICA may represent GAD65 or ICA512 autoantibodies and not a distinctive specificity. A number of studies have indicated that the presence of both cytoplasmic ICA and GAD65 autoantibodies increases risk of diabetes relative to the presence of either autoantibody alone. This is likely related to using the ICA assay and its correlation with the presence of ICA512 autoantibodies or the presence of higher titer GAD65 autoantibodies (73,75).

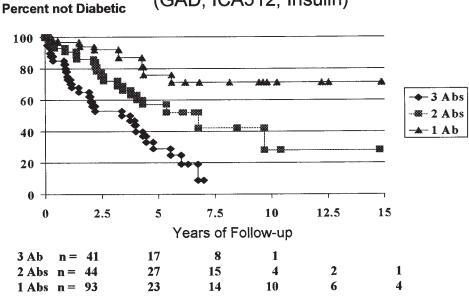

At present, not enough information is available to define the prognosis of individuals with multiple islet autoantibodies with DQB1*0602 (106,118,121,122,314). Many such individuals with DQB1*0602 express only a single autoantibody. Some DQB1*0602 relatives expressing multiple islet autoantibodies have been followed to the development of diabetes.

Metabolic

Progressive metabolic deterioration precedes type 1A diabetes and, similar to type 2 diabetes, asymptomatic hyperglycemia is present in a significant number of individuals. Oral GTT is the "gold" standard for the diagnosis of diabetes but is unnecessary if fasting hyperglycemia is present (fasting glucose \geq 126 mg/dL). Before hyperglycemia develops, individuals progressing to diabetes lose insulin secretion following intravenous administration of glucose. Almost all individuals who become hyperglycemic secondary to type 1A diabetes have first-phase insulin secretion below the first percentile of normal months to years before diabetes develops.

Dual-Parameter Model

Different patients with type 1A diabetes progress to diabetes at very different rates. The presence of multiple islet autoantibod-

Progression to Diabetes vs Number of Autoantibodies (GAD, ICA512, Insulin)

Figure 23.8. Progression of diabetes of relatives subdivided by number of autoantibodies (Abs) (GAD, ICA512, insulin) recognizing different autoantigens. (Copyright © 1996 American Diabetes Association. From Verge CF, Giannani R, Kawasaki E, et al. Prediction of type I diabetes in first-degree relatives using a combination of insulin, GAD, and ICA512 bdc/IA-2 autoantibodies. *Diabetes* 1996;45:926–933. Reprinted with permission from the American Diabetes Association.)

ies indicates a high risk of progression. A combination of loss of first-phase insulin secretion and the presence of higher levels of insulin autoantibodies aids in predicting approximate time to onset of diabetes, accounting for approximately one half of the variance in time to the development of overt diabetes (256).

PREVENTION OF DIABETES

Rationale for Maintenance of C-Peptide

At the diagnosis of type 1A diabetes, most patients have significant insulin secretory capacity. The amount of islet β -cells remaining probably ranges between 10% and 50% of normal islet mass. When a patient presents with overt diabetes, and especially with ketoacidosis, there is little insulin secretion, probably as a consequence of the toxic effects of hyperglycemia on insulin secretion. Following insulin therapy and normalization of glucose levels, many patients develop a "honeymoon" phase of their diabetes, with normalization of glucose, increased insulin secretion, and a need for relatively low doses of insulin. C-peptide, the connecting peptide of proinsulin, is secreted in equimolar concentrations with insulin and is a measure of insulin secretion for patients who are receiving exogenous insulin. With time (ranging from months to years) after the diagnosis of diabetes, additional β-cells are killed and C-peptide secretion decreases progressively. By 3 to 5 years of type 1A diabetes, most children produce no C-peptide [in the Diabetes Care and Complications Trial (DCCT), at 5 years of diabetes, 8% of adults, but 3% of adolescents, had a meal-stimulated C-peptide level greater than 0.2 nmol/L]. This loss of C-peptide correlates with increasing insulin needs; metabolic deterioration, including risk of severe hypoglycemia with exclusive dependence on exogenous insulin therapy; and a marked increase in variation in blood glucose levels. Studies from the DCCT indicate that even minimal residual preservation of C-peptide correlates with improved diabetes control (315). Given this information, preservation of C-peptide is a major outcome measure in trials to prevent β -cell destruction after the onset of diabetes (315a).

Prevention of further β -cell destruction after diabetes onset is an important clinical goal. Studies of cyclosporin A demonstrated that this potent immunosuppressive agent is sufficient to prevent C-peptide loss for as long as it is administered (316-319). It does not, however, prevent recurrence of hyperglycemia when it is administered after onset of diabetes, but it does moderate the metabolic dysfunction. Recurrent hyperglycemia in the patients treated with cyclosporin A at diagnosis of diabetes reflects increasing insulin resistance in the setting of limited β-cell mass. In addition, once cyclosporin A is discontinued, C-peptide secretion is lost and insulin dependence rapidly ensues. Risks of cyclosporin A include the risks of immunosuppression and, of importance, nephrotoxicity. These risks make it a poor choice for preventing further β-cell destruction. Trials of less toxic therapies, such as azathioprine (320, 321), methotrexate (322), BCG vaccination (323), nicotinamide (324–326), anti-thymocyte globulin (327), and oral insulin (328, 329), have had minimal, if any, positive benefits. Trials of newer modalities [e.g., "non-activating" anti-CD3 monoclonal antibodies (330) and mycophenolate mofetil] are under way with promising data for initial anti-CD3 trial (329a). From studies of pancreas and islet transplantation, it is clear that there are drug regimens that can halt immune-mediated β-cell destruction, and it is likely that safe modalities to preserve β -cell mass will be developed.

Primary/Secondary/Tertiary Prevention

Given the stages in the development of type 1A diabetes illustrated in Figure 23.3 and the ability to identify individuals in these stages, one can envision prevention trials for each of the stages. We have already discussed prevention after diabetes onset. As one goes backwards in the natural history of type 1A diabetes, prediction of diabetes becomes less secure, and thus analysis of the risk-to-benefit ratio requires modalities with minimal to "no" toxicity. One can envision primary prevention trials, aimed at preventing the development of islet autoimmunity; secondary prevention trials, aimed at preventing β-cell destruction after the activation of islet autoimmunity (currently usually marked by the presence of multiple islet autoantibodies); and tertiary prevention trials after the onset of diabetes or following islet transplantation. It is not clear that modalities effective earlier in the course of the disease will be effective later in disease. In animal models, there is one example of a therapy that is effective at the onset of diabetes but not earlier (331). In addition to these considerations, trials for prevention before the presence of autoimmunity or the development of diabetes require relatively large screening programs to identify individuals at risk. With the many agents that prevent diabetes in animal models, it is likely that initial trials will be carried out in patients with new-onset disease. Therapies effective and safe at that stage would be applied to autoantibody-positive, high-risk relatives of patients with diabetes, and depending on the agent, potentially to genetically at-risk individuals. As discussed, islet autoimmunity develops in approximately 40% of siblings of patients with type 1A diabetes with DR3/4; thus, trials can also be designed for this group. If a safe and effective therapy is identified, it should be possible, with current technology, to identify individuals at risk for diabetes, both for relatives and for the general population among whom the bulk of type 1A diabetes develops (156).

Current Prevention Trials

The two largest current prevention trials were a nicotinamide trial (ENDIT), primarily in Europe, and a trial of oral or parenteral insulin therapy [Diabetes Prevention Trial-1 (DPT-1)] carried out by the National Institutes of Health in the United States and Canada. Both trials were based initially on animal data, followed by pilot trials in humans (324,332,333). One small negative nicotinamide trial has been reported since the start of the large ENDIT trial (334). Trials of oral insulin after diabetes onset have not shown preservation of C-peptide (328,329). The ENDIT trial has closed enrollment, and there was no influence of nicotinamide or progression to diabetes.

The DPT-1 consists of two separate trials, one of oral insulin (to induce oral tolerance) and the other of parenteral insulin with daily subcutaneous low-dose insulin and annual intravenous insulin. More than 90,000 first-degree relatives have been screened for expression of islet autoantibodies; of those with autoantibodies, relatives either with loss of first-phase insulin secretion (parenteral trial) or with insulin autoantibodies and normal first-phase insulin secretion (oral trial) are eligible for trial participation. A manuscript describing the oral trial is awaited, while the parenteral trial showed no prevention of diabetes. (334a)

Finland is the country with the highest incidence of type 1 diabetes. The childhood incidence is now approximately 50 in 100,000, which is twice the current approximate incidence in the state of Colorado and more than 50 times that in Japan. Given this high incidence, two major prevention trials are under way. The DIPP (Diabetes Prediction and Prevention) trial is evaluating mucosal administration (nasal) of insulin for individuals expressing islet autoantibodies (335). The trial initially screens newborns with HLA typing to identify those with high-risk HLA alleles. The TRIGR (Trial in Genetically at Risk) is targeting high-risk infants with diet modification (removal of cow's milk), with a hypothesis that exposure to bovine albumin before 9 months of age induces diabetes (220).

Future Prevention Trials

A remarkable number of new agents for immunotherapy are being introduced into clinical research and practice. Many of these agents are potentially applicable to the autoimmunity of type 1A diabetes. With the current knowledge of the genetics and natural history of type 1A diabetes, these agents are likely to be studied for prevention of autoimmune β -cell destruction.

It is very likely that potent immunosuppressive agents can prevent β -cell destruction similar to that achieved with cyclosporin A. The drug rapamycin, part of a protocol for successful islet transplantation (336), will probably be evaluated in the near future if its toxicity profile does not change with wider use in transplantation. Mycophenolate mofetil is an inhibitor of de novo purine biosynthesis. It is more potent than azathioprine and has replaced azathioprine in pancreas transplant regimens, thereby allowing a decrease in the use of glucocorticoids. Trials to prevent progressive β -cell destruction with mycophenolate mofetil in patients with new-onset type 1A diabetes are about to be initiated.

A number of monoclonal antibodies targeting T lymphocytes are being studied or are likely to be studied in patients with new-onset diabetes. CD3 autoantibodies have been used for more than a decade in organ transplantation, but the standard antibody activates a cytokine "storm." Newer monoclonal antibodies, altered such that they do not bind complement, have been used to induce long-lasting disease remission in NOD mice and are now being studied in patients with newonset type 1A diabetes (329a,330,331,337). Similar concepts apply to monoclonal antibodies to the interleukin-2 (IL-2) receptor, one of which was used for islet transplantation in combination with rapamycin and low-dose FK506.

Perhaps the most exciting group of reagents entering clinical trials for diabetes prevention go under the rubric of "immunologic vaccination." In animal models, a series of autoantigens can be administered to prevent disease. Both an altered peptide ligand of insulin peptide B:9–23 (338) and a heat-shock peptide (p277) (339) are now in clinical trials. Following phase I trials, initial trials will evaluate patients with recent-onset diabetes. In that the tools for monitoring the relevant immune response to such therapies are in their infancy, the success of such trials are far from assured.

UNUSUAL DIABETES-RELATED AUTOIMMUNITY

Insulin Autoimmune Syndrome (Hirata Syndrome)

High levels of insulin autoantibodies are associated with hypoglycemia (340). It is thought that the hypoglycemia is the result of nonregulated release of insulin from bound autoantibody. Such high levels of insulin autoantibodies can be the result of the production of monoclonal antibodies by plasmacytomas. This is even less common than the rare Hirata syndrome (340,341), in which patients spontaneously produce polyclonal insulin autoantibodies. This latter syndrome is strongly HLArestricted, with more than 90% of patients having DRB1*0406 (342). Most patients with the syndrome are Asian, and disease induction is associated with sulfhydryl-containing drugs and methimazole, in particular (343). Therapy usually consists of discontinuing the inducing medication.

Autoantibodies to Insulin Receptor

Autoantibodies reacting with the insulin receptor also can produce hypoglycemia (344). In addition, some patients present with insulin resistance and hyperglycemia, and individuals

418 JOSLIN'S DIABETES MELLITUS

with the syndrome can have both hypoglycemia and hyperglycemia. This suggests that autoantibodies reacting with the insulin receptor can act as both agonists and antagonists (344). Patients with this syndrome often have non-organ-specific autoimmunity (e.g., DNA autoantibodies) (345). Therapy has included plasma exchange, immunosuppression, and one report of treatment with insulin-like growth factor-1 (346).

Insulin "Allergy/Hypersensitivity"

Lipohypertrophy and lipoatrophy of the site of injection, painful inflammation following insulin injection, and systemic reactions to insulin are all potential reactions to insulin (347). Delayed hypersensitivity and allergic reactions, uncommon even with animal insulin, appear to be even less common with human insulin (348). In the past when such reactions occurred, individuals were switched from one species of insulin to another (e.g., bovine, porcine, human) or to one form of insulin to another (NPH versus lente insulin). With current use of human insulin, the formulation of insulin is still of importance (regular, NPH, lente), and there exists the possibility of utilizing genetically altered insulin such as lispro (349) insulin, and there is one report of successful pancreatic transplantation (350). Although lispro insulin represents a modified insulin, it does not appear to be more immunogenic than regular human insulin, perhaps because of its more rapid absorption (IgE-mediated allergic reactions even to lispro insulin are reported) (351).

IgE-mediated allergy to insulin, if mild, usually is treated with an antihistamine such as cetirizine (351) and, if severe, usually is treated with insulin desensitization. Desensitization to both protamine and insulin has been reported. Patients with local delayed hypersensitivity reactions to insulin may also be treated by the addition of small amounts of dexamethasone injected directly with the insulin (352). There is one report of pancreatic transplantation to treat intractable insulin allergy (350).

Islet/Pancreas Transplantation

Islet and pancreas transplantation for type 1A diabetes faces two immunologic barriers, recurrent autoimmunity and transplant alloimmunity (353). The importance of autoimmunity was demonstrated by transplantation of the tail of the pancreas between identical twins (83). The twins receiving the pancreas developed diabetes years before transplantation, whereas the donor twins were normal (83). Although the transplants initially restored euglycemia, they were rapidly destroyed. Such transplants, even though they are between identical twins, are now performed only with immunosuppression of the recipient.

Until recently, although pancreas transplantation with immunosuppression was successful, islet transplants almost universally failed. Investigators in Edmonton have recently reported sequential successful islet transplants using a new immunosuppressive protocol (336). Their protocol uses anti-IL-2R antibodies and a combination of rapamycin and low-dose FK506. Among the transplant recipients, insulin antibodies were suppressed while GAD autoantibodies were unchanged, with as yet a limited duration of follow up (<1 year). These studies suggest that the very aggressive destruction of islet transplants can now be overcome with immunosuppression. The Edmonton regimen also prevents the development of increased levels of islet autoantibodies that have been associated with the failure of transplants with other regimens. Clinical experience with rapamycin is, however, relatively limited, and further study and clinical experience will be needed to assess risks and benefits of this therapy.

CONCLUSION

Type 1A diabetes results from immune-mediated destruction of islet β -cells. The disorder, with a long chronic progressive phase, is now predictable for the great majority of individuals. Trials of potential preventive therapies are presently under way, but no therapy has demonstrated safety and efficacy. With excellent animal models and extensive studies in humans, we believe it is only a matter of time before insulitis, like hepatitis, becomes a treatable disorder. Once treatments are available, depending on the stage of disease for optimal intervention, it is likely that type 1A diabetes will become one of the first autoimmune disorders for which there is screening on a public-health scale. It is important to recognize the autoimmune disorders that are frequently associated with type 1 diabetes and to institute therapies before the development of irreversible morbidity. In the future, it is hoped that the family of organ-specific autoimmune diseases will be addressed as preventable publichealth menaces.

CONCLUSIONS 440

The term *insulin resistance* generally refers to resistance to the metabolic effects of insulin, including the suppressive effects of insulin on endogenous glucose production, the stimulatory effects of insulin on peripheral (predominantly skeletal muscle) glucose uptake and glycogen synthesis, and the inhibitory effects of insulin on adipose tissue lipolysis.

Following its discovery by Banting and Best in 1921, insulin rapidly entered the clinical arena and dramatically extended the life spans of individuals with type 1 diabetes mellitus. Chronic treatment with exogenous insulin permitted the recognition of individuals with very high insulin requirements, indicating resistance to the hormone (1). Many such individuals had secondary causes for insulin resistance, including high titers of antibodies to insulin after chronic treatment with insulin from animal sources (2), as well as rare genetic defects in insulin signaling (3). However, the thriving of patients with type 1 diabetes into their later years and the treatment of individuals with type 2 diabetes with insulin revealed the phenomenon of insulin resistance secondary to obesity and aging, which was widely recognized by the 1970s (3). Many of the considerable advances of the past three decades in understanding the pathogenesis of insulin resistance will be reviewed below.

CLINICAL FEATURES AND SIGNIFICANCE OF INSULIN RESISTANCE

The clinical importance of insulin resistance cannot be overstated, given the mortality and morbidity associated with the many disorders that are likely a consequence of this condition. Indeed, there is considerable epidemiologic evidence linking insulin resistance with glucose intolerance and type 2 diabetes, hypertension, dyslipidemia, atherosclerosis, and many cancers (4-8). It is generally accepted that insulin resistance plays a major role in the development of type 2 diabetes (9). Because currently an estimated 170 million people worldwide have type 2 diabetes (10), this is clearly an important association. Indeed, prospective studies have revealed that insulin resistance predates the onset of type 2 diabetes by 10 to 20 years and is the best clinical predictor of subsequent development of type 2 diabetes (11,12). Furthermore, insulin resistance is a consistent finding in patients with type 2 diabetes (3,13-15). However, the development of frank diabetes mellitus appears to require an additional defect in insulin secretion (11). In the absence of a defect in β-cell function, individuals can compensate indefinitely for insulin resistance with appropriate hyperinsulinemia (11). Hence, many individuals with marked insulin resistance

may never progress to type 2 diabetes. However, the risk of atherosclerosis is apparently comparable in nondiabetic, insulinresistant individuals and in those with type 2 diabetes (16).

Metabolic Syndrome

Reaven formally recognized the clinically significant association between insulin resistance and cardiovascular risk factors in his description of the syndrome of insulin resistance in 1988 (17). The most recent definition of the metabolic syndrome was established as a consensus by the National Cholesterol Education Program (NCEP) Adult Treatment Panel III (ATPIII) in 2001 (18). Based on the panel's guidelines, diagnosis of the metabolic syndrome requires the presence of at least three of the following five criteria: elevated fasting plasma glucose levels (>110 mg/dL), visceral obesity (waist circumference >35 inches in women and 40 inches in men), hypertension (>130/85 mm Hg), hypertriglyceridemia (>150 mg/dL), and low high-density lipoprotein (HDL) cholesterol (<40 mg/dL in men and <50 mg/dL in women). By this definition, the estimated prevalence of the metabolic syndrome in the United States is currently greater than 20% among all adults older than 20 years of age, and greater than 40% among the population older than 50 (19).

Other recognized components of the syndrome include systemic inflammation, a prothrombotic state, and increased oxidant stress (20). The increased circulating levels of tumor necrosis factor- α (TNF- α), interleukin-6 (IL-6), and other proinflammatory cytokines may contribute to some of the metabolic features of the metabolic syndrome, whereas the increased levels of plasminogen activator inhibitor-1 (PAI-1) appear to heighten the risk of atherothrombosis (21). Indeed, an increased risk of atherosclerotic disease mortality and morbidity is conferred by the metabolic syndrome. Other associated clinical disorders include polycystic ovarian syndrome, nonalcoholic fatty liver disease, and sleep apnea (14).

Contributions of Tissue-Specific Insulin Resistance

Defects in the ability of insulin to stimulate skeletal muscle glucose uptake and to suppress hepatic glucose production and adipose tissue lipolysis all tend to coexist in insulin-resistant individuals with established type 2 diabetes (22). It has been speculated that the onset of insulin resistance in some tissues may precede the onset in others. Although it has been proposed that insulin resistance develops later in the liver than in skeletal muscle, hepatic glucose production is inappropriately unsuppressed in the presence of hyperinsulinemia during the development of insulin resistance (23). Additionally, marked hepatic insulin resistance precedes the onset of peripheral insulin resistance secondary to moderate fat feeding (24). Various experimental models have been developed to define organ-specific contributions of insulin resistance to hyperglycemia and other metabolic abnormalities.

SKELETAL MUSCLE

A universally recognized feature of type 2 diabetes is skeletal muscle insulin resistance, secondary to either genetic or metabolic factors (25). Insulin clamp studies have permitted the measurement of peripheral and hepatic glucose fluxes in the presence of fixed glucose and insulin levels by means of continuous intravenous infusions and frequent measurement of plasma glucose levels (26,27). These sophisticated physiologic measures have revealed that skeletal muscle is quantitatively the most important tissue involved in systemic glucose homeostasis, because it accounts for ~80% of glucose disposal following glucose infusion or ingestion (11). Thus, decreased ability of insulin to stimulate glucose disposal by this tissue is of considerable importance to whole-body glucose homeostasis.

Indeed, impaired insulin-dependent glucose uptake and phosphorylation have been documented at early stages in the development of type 2 diabetes (28). Several transgenic mouse models have examined the impact of isolated defects in skeletal muscle insulin action on whole-body glucose intolerance. Conditional inactivation of the insulin receptor in skeletal muscle by Cre-mediated recombination gave rise to a model of the metabolic syndrome, with increased fat stores and hypertriglyceridemia (29). Despite the changes in fat metabolism, these muscle-specific insulin receptor knockout (MIRKO) mice did not develop hyperinsulinemia and diabetes, suggesting that there was adequate shunting of glucose utilization from muscle to adipose tissue to prevent excursions in blood glucose (30). Another model of severe skeletal muscle insulin resistance was generated by crossing mice heterozygous for a systemic insulin receptor knockout with mice bearing a dominant-negative insulin receptor transgene in muscle. Despite a greater than 90% decrease in insulin receptor kinase activity and reduced insulin-stimulated glucose uptake, these mice still did not develop diabetes (31).

The findings stand in sharp contrast to studies showing that ablation of the insulin-dependent glucose transporter GLUT4 in skeletal muscle can cause diabetes (32). There are several explanations for this apparent contradiction. In mice lacking the insulin receptor in muscle, both the contraction-activated pathway (33,34) and the insulin-like growth factor I (IGF-I) signaling pathway (35) can compensate for the ablation of insulin signaling. The former, which activates adenosine monophosphate (AMP)-activated protein kinase and thereby stimulates translocation of glucose transporters (36), remains intact in MIRKO mice. The importance of the IGF-I signaling system in muscle metabolism is highlighted by a mouse model of combined ablation of insulin and IGF-I receptor function in skeletal muscle (37). Unlike mice with isolated ablation of the insulin receptor in skeletal muscle, these mice develop frank diabetes and other metabolic features characteristic of insulin resistance. Together, these models confirm the central role of skeletal muscle as a site of insulin action, yet indicate that there are alternate pathways leading to glucose uptake and GLUT4 translocation in skeletal muscle that can compensate in mice lacking the insulin receptor.

Insulin-stimulated 3-O-methylglucose transport into isolated skeletal muscle from patients with type 2 diabetes is substantially lower than in normal controls, demonstrating that decreased skeletal muscle uptake contributes to impaired peripheral glucose uptake (36,38). A uniform finding in both obesity and type 2 diabetes is decreased insulin receptor substrate-1 (IRS-1)-associated tyrosine phosphorylation and 1-phosphatidylinositol 3-kinase (PI 3-kinase) activity in skeletal muscle (39-41). Of note, insulin action on glucose transport is normalized in isolated muscle strips from patients with type 2 diabetes after a 2-hour in vitro incubation in the presence of 5 mM glucose (42). Similarly, a more recent report provided evidence that proximal insulin signaling parameters elicit a normal response in cultured myotubes prepared from muscle biopsies from insulin-resistant nondiabetic subjects (43). These findings support the hypothesis that insulin resistance of skeletal muscle in individuals with type 2 diabetes is at least in part secondary to an altered metabolic milieu, as will be explored further under "Environmental" Factors Contributing to Insulin Resistance.

In addition to this downregulation of proximal insulin signaling, several negative regulators of insulin signaling are upregulated in insulin resistance. Plasma-cell differentiation factor-1 (PC-1) is a membrane glycoprotein with ectonucleotide pyrophosphatase activity that seems to act as an intrinsic inhibitor of insulin receptor tyrosine kinase activity (44,45). In healthy subjects with no clinically significant defects in glucose metabolism, PC-1 expression in muscle is negatively correlated with insulin sensitivity and *in vitro* stimulation of muscle insulin receptor tyrosine kinase activity (46,47). It has been suggested that increased expression of PC-1 in skeletal muscle of obese subjects is more strongly associated with downregulation of insulin receptor tyrosine phosphorylation than with decreased insulin receptor expression, but this requires further investigation (48).

Phosphotyrosine phosphatases (PTPases) are enzymes that dephosphorylate the insulin receptor and its substrates, thereby turning off the insulin signal. Total membrane-bound tyrosine phosphatase activity is increased in skeletal muscle of patients with type 2 diabetes (49), particularly protein-tyrosine phosphatase-1B (PTP-1B) (50), which negatively regulates phosphorylation of the insulin receptor and IRS-1 (51). Mice with ablation of the PTP1B gene demonstrate increased insulin sensitivity and enhanced insulin-stimulated phosphorylation of the insulin receptor in both skeletal muscle and liver (52). These mice are also resistant to weight gain on a high-fat diet, demonstrating the potential importance of this enzyme in mediating the central effects of insulin on appetite, discussed under Brain. Selective reduction of PTP1B protein and messenger RNA (mRNA) in liver and fat normalized plasma glucose levels, reduced hyperinsulinemia, and reduced expression of gluconeogenic enzymes in genetically obese and diabetic mice (53). These promising in vivo rodent data have prompted a highly motivated search for pharmacologic inhibitors of this enzyme (54).

ADIPOSE TISSUE

Insulin resistance in adipose tissue is characterized by decreased suppression of adipose tissue lipolysis by insulin, resulting in elevated circulating levels of free fatty acids (FFAs). Indeed, the suppressive effect of insulin on FFA levels is impaired in obese insulin-resistant individuals (55,56) and in type 2 diabetes (57). The presence of the same defect in glucose-tolerant first-degree relatives of patients with type 2 diabetes (58,59) suggests that abnormal insulin-mediated suppression of plasma FFA is an early defect in those with a genetic predisposition to insulin resistance. Although it has been suggested that increased FFA levels in obese individuals are due primarily to expansion of body-fat depots (60,61), the suppressive effect of insulin on FFA levels is also reduced in nonobese insulin-resistant individuals (62).

Transgenic models of adipocyte-specific disruption of insulin signaling have been generated to address the impact of decreased adipocyte insulin action on systemic fat and glucose metabolism. Conditional ablation of the insulin receptor in white and brown adipocytes with an adipose-specific fatty acid binding protein aP2 promoter (63) caused a marked decrease in gonadal fat mass and whole-body triglyceride content. Moreover, these fat-specific insulin receptor knockout (FIRKO) mice are resistant to weight gain with aging or hypothalamic insult and are protected against hyperphagia-induced glucose intolerance. Since the aP2 promoter would also target macrophages, these mice may also have been spared the adverse metabolic effects of systemic inflammation, discussed below. Thus, although insulin signaling is required for triglyceride storage in adipocytes, it may not be essential for normal glucose metabolism.

By contrast, knockout of the insulin-dependent glucose transporter GLUT4 in fat induced hepatic and skeletal muscle insulin resistance and glucose intolerance (64). However, fasting serum FFA levels were suppressed appropriately in

response to insulin in these knockout mice, suggesting that the insulin resistance was relatively selective for glucose uptake. Furthermore, these mice displayed normal muscle triglyceride content and normal levels of leptin and TNF- α . Thus, the insulin resistance observed in these mice may be secondary to chronic hyperinsulinemia or to altered secretion of adipocyte-derived molecules that mediate insulin action in other tissues (see below).

Ob/ob mice that lack the adipose tissue fatty acid binding protein aP2 have reduced adipose tissue lipolysis and increased adipose tissue mass, together with a paradoxical reduction in plasma lipids and an improvement in insulin sensitivity and insulin secretion (65). This suggests that enlargement of adipose tissue mass may have protective effects against insulin resistance. This concept of adipose tissue providing a "sink" to protect other tissues from the toxic effects of excessive fatty acids is supported by the observation that overexpression of GLUT4 in adipose tissue of transgenic mice causes both an increase in adipose tissue mass and an improvement in whole-body insulin sensitivity (66,67). Further evidence for beneficial effects of adipose tissue will be provided in the subsequent discussion of lipodystrophy and fatless mice and the reversal of insulin resistance with adipose tissue transplantation in those transgenic models.

LIVER

There has been considerable controversy about whether hepatic glucose production is directly regulated by insulin or is mediated via extrahepatic metabolic effects. In particular, it has been proposed that insulin suppresses glucose production by reducing flux of amino acids and FFA from muscle and adipose tissue to the liver, thereby also reducing gluconeogenesis (68–72). Normal inhibitory action of insulin on hepatic glucose production appears to require normal insulin responsiveness at the level of adipose tissue. Indeed, the ability of peripheral insulin to regulate glucose production appears to be at least in part due to its ability to suppress circulating FFA levels (73,74).

Evidence for a direct effect of insulin on hepatic glucose production is provided by a mouse model in which the insulin receptor is ablated in muscle and adipose tissue, with normal insulin signaling in the liver (75). These mice maintain normal hepatic insulin sensitivity and do not progress to diabetes despite impaired glucose tolerance, suggesting that hepatic insulin resistance is required for the onset of overt diabetes. This model may also suggest that insulin resistance in the liver is an intrinsic abnormality of insulin signaling in the hepatocyte. Indeed, mice with conditional, liver-specific knockout of the insulin receptor (LIRKO) exhibit marked insulin resistance, glucose intolerance, and an inability of insulin to suppress hepatic glucose production and regulate hepatic gene expression (76,77). Furthermore, the liver might actually affect peripheral insulin action. Some evidence for an association between hepatic fat accumulation and peripheral insulin resistance is presented below in the discussion of the metabolic effects of intrahepatocellular triglyceride.

BRAIN

Hypothalamic resistance to the central appetite-suppressing and metabolic effects of insulin may play seminal roles in the development of insulin resistance. The insulin receptor is widely expressed in several brain areas (78) and has been implicated in the regulation of satiety (79). Although glucose disposal in the majority of neurons occurs in an insulin-independent manner, neurons in the hypothalamus and other discrete brain areas express the insulin-responsive glucose transporter GLUT4 (80). The potential role of brain insulin signaling has been studied by

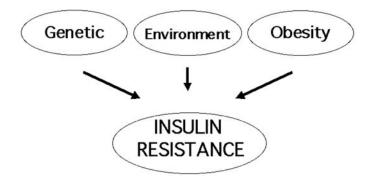

Figure 24.1. Pathogenesis of insulin resistance: contributions of genes, obesity, and environment. "Environment" refers to a variety of factors, including hormones, increased nutrient availability, and age.

generating a neuron-specific insulin receptor knockout (NIRKO), resulting in increased food intake and moderate diet-dependent obesity (81).

The metabolic effects of insulin action in the brain have recently been examined using intracerebroventricular injections of antisense oligonucleotides and blocking antibodies to the insulin receptor (82). These manipulations caused a targeted impairment in hypothalamic insulin receptor function in rats, with a rapid onset of hyperphagia and a significant increase in fat mass after only 7 days, similar to the NIRKO mouse. Of particular note, this central inhibition of insulin action also dramatically reduced the ability of exogenously infused insulin to blunt hepatic glucose output, demonstrating an important role for the hypothalamic insulin receptor in the regulation of hepatic glucose metabolism (83).

An Integrated Model of Insulin Resistance

As shown in Figure 24.1, it is likely that several factors contribute to impaired insulin action in most individuals with insulin resistance. The following sections will discuss the interrelationship between genetic inheritance, obesity, and environmental factors in the pathogenesis of insulin resistance.

GENETIC CAUSES OF INSULIN RESISTANCE

Defects in both insulin action and insulin secretion are present in type 2 diabetes, and both are believed to be genetically predetermined (84). A strong genetic basis for insulin resistance is suggested by the high prevalence in certain populations, particularly the Nauru Islanders of the Pacific (85), the Pima Indians in Arizona (86), and the urban Wanigela people in Papua New Guinea (87). Although the current epidemic levels of insulin resistance and type 2 diabetes in these populations have followed the introduction of a "Westernized" lifestyle characterized by high caloric intake and physical inactivity, their prevalence is much higher in these populations than in populations of other ethnic groups with the same lifestyle. Furthermore, there is a nearly 100% concordance in diagnosis of type 2 diabetes between monozygotic twins but only a 20% concordance between dizygotic twins (88). To date, documented monogenic inheritance of insulin resistance has been limited to a few families with extreme forms of the disorder, as described in the next section.

Extreme Insulin Resistance

To date, several rare mutations in genes associated with insulin action have been linked to extreme insulin resistance (Fig. 24.2). Although these are all rare conditions, their study has been helpful in elucidating issues pertinent to more general pathophysiology of insulin resistance. All of the following genetic conditions are associated with typical clinical manifestations: hyperinsulinemia, dyslipidemia, hypertension, and impaired glucose tolerance or insulin-resistant diabetes (89). Acanthosis nigricans is a characteristic skin lesion in insulin resistance, consisting of velvety and papillomatous pigmented hyperkeratosis of the flexures and neck (90). In women, extreme insulin resistance is also associated with hyperandrogenism, hirsutism, menstrual abnormalities, and polycystic ovarian disease.

INSULIN RECEPTOR MUTATIONS

Severe insulin resistance has been reported in conjunction with more than 100 naturally occurring mutations in the insulin receptor gene (91,92), as well as in the complete absence of insulin receptors (93). The varying severity and diversity of their phenotypes have resulted in the description of several clinical syndromes of severe insulin resistance (94).

Leprechaunism is the most extreme form of these syndromes, characterized by intrauterine growth retardation and characteristic dysmorphic features including prominent eyes, thick lips, upturned nostrils, low-set posteriorly rotated ears, and thick skin with lack of subcutaneous fat (95). Life expectancy is extremely short, with death usually before 1 year of age. Milder syndromes of insulin resistance have been reported in patients whose insulin receptor mutations do not lead to a complete loss of insulin receptor function (96). Children with the somewhat milder Rabson-Mendenhall syndrome have life expectancies of up to 15 years and display different dysmorphic features, with premature or dysplastic teeth and gingival hyperplasia, as well as growth retardation. Despite postprandial hyperglycemia, affected children with either syndrome demonstrate fasting hypoglycemia due to inappropriately elevated fasting insulin levels. Type A insulin resistance is the mildest syndrome of insulin receptor gene mutations and is characterized by a classic triad of insulin resistance, acanthosis nigricans, and hyperandrogenism (in females) (97). Most patients with type A insulin resistance are heterozygous for a single mutant allele, most frequently a mutation in the tyrosine kinase domain of the receptor (98), and most such patients do not develop diabetes. However, patients with two mutant alleles tend to develop overt diabetes in childhood or adolescence (99).

The pronounced mitogenic features and fasting hypoglycemia in individuals with the above syndromes, despite the marked resistance to the metabolic effects of insulin, suggest that the high circulating insulin levels may be mediating these mitogenic effects through the homologous IGF-I receptor (100). Indeed, this receptor homology has been exploited therapeutically in the treatment of diabetes in these patients. Daily injections of IGF-I were effective in lowering both fasting and postprandial plasma glucose concentrations for up to 16 months in 11 patients with extreme insulin resistance (101). Even more dramatically, a recent report demonstrated that treatment of a patient with leprechaunism from infancy until 7 years of age with recombinant human IGF-I maintained her growth rate and hemoglobin A_{1C} level nearly within the normal range (102).

INSULIN-MEDIATED PSEUDOACROMEGALY

A syndrome of severe insulin resistance has been described in which patients develop pathologic tissue growth similar in appearance to that of acromegaly but without elevated levels of growth hormone or IGF-I (103). Although neither insulin nor IGF-I can activate PI 3-kinase or stimulate glucose uptake in cultured skin fibroblasts from these individuals, mitogen-activated protein kinase (MAPK) phosphorylation and downstream mitogenic signaling by both hormones are intact. No defects have

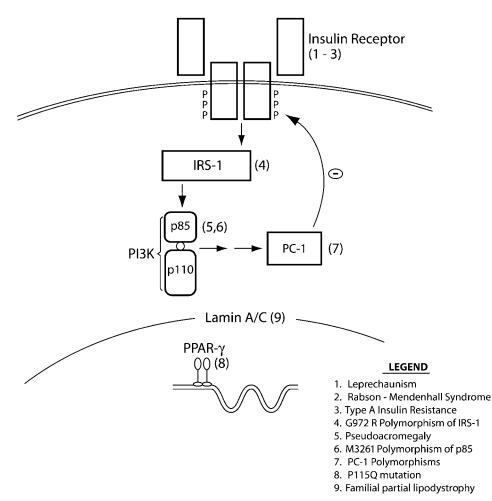

Figure 24.2. Genetic causes of insulin resistance identified in humans. This schematic representation depicts the cellular localization of proteins in which mutations or polymorphisms have been identified in association with extreme insulin resistance. In the case of the insulin receptor, multiple mutations have been identified that contribute to the syndromes indicated. Numerically, the mutations/polymorphisms/syndromes are as follows: (1) leprechaunism; (2) Rabson-Mendenhall syndrome; (3) type A insulin resistance; (4) G972R polymorphism of insulin receptor substrate-1 (IRS-1); (5) pseudoacromegaly; (6) M3261 polymorphism of p85; (7) Plasma-cell differentiation factor-1 (PC-1) polymorphisms; (8) P115Q mutation of peroxisome proliferator-activated receptor γ (PPAR γ); (9) familial partial lipodystrophy (lamin A/C mutations). PI3K, 1-phosphatidylinositol 3-kinase.

been documented in the structure, expression, or activation of the insulin receptor, IRS-1, or $p85\alpha$, suggesting a selective defect of postreceptor insulin signaling to metabolic pathways. The acromegaloid tissue growth is likely due to activation of the intact mitogenic signaling pathways by the severe hyperinsulinemia (104).

MUTATIONS IN THE PEROXISOME PROLIFERATOR-ACTIVATED RECEPTOR $\boldsymbol{\gamma}$

The nuclear receptor peroxisome proliferator-activated receptor γ (PPAR γ) appears to play a vital role in both adipocyte differentiation and insulin action, underscoring the important interactions between these two phenomena (105-107). A direct link between insulin sensitivity and PPARy action in humans was strongly suggested by the discovery of a small number of individuals with heterozygous loss-of-function mutations within the ligand-binding domain of the PPARy receptor (108-110). These dominant-negative and other mutations result in the clinical features of severe insulin resistance described above and partial lipodystrophy of the limbs and buttocks, sparing the face and central abdominal adipose depots (111). The associated lipodystrophy appears to result from the inability of subcutaneous abdominal adipose tissue to trap and store FFA postprandially (112). Although thiazolidinediones are of limited benefit in this syndrome, the tyrosine-based receptor agonist farglitazar corrected defects in ligand binding and restored transcriptional function in cells from affected individuals and may offer a therapeutic approach to improving insulin action in these patients.

By contrast, a missense mutation at codon 115 (Pro115Gln) was associated with severe obesity in four unrelated German subjects (113). Overexpression of the mutant receptor in murine fibroblasts led to accelerated differentiation of the cells into adipocytes and greater cellular accumulation of triglyceride when compared with the wild-type receptor. Although it might be expected that this constitutively active form of PPARy might cause heightened insulin sensitivity, interpretation of the lower insulin levels in these subjects relative to obese controls was complicated by the fact that three of the four subjects had type 2 diabetes.

Of potentially more general relevance to type 2 diabetes, a common polymorphism in the $PPAR\gamma$ gene may confer protection from type 2 diabetes (114,115). A Pro12Ala polymorphism in the PPARy gene was associated with improved insulin sensitivity among more than 1,000 middle-aged and elderly Finns (114). This mutation occurs in the region of the $PPAR\gamma$ gene that encodes a protein segment unique to the PPARy2 isoform and is within the domain of PPARy that enhances ligand-independent activation (116). Subsequently, an analysis of more than 3,000 Scandinavian individuals in a study using a multilayered design revealed that this common polymorphism was associated with a small but significant reduction in risk of type 2 diabetes (relative risk 0.78) relative to the prevalent proline form (115). In contrast with an earlier report (114), a recent meta-analysis demonstrated an increase in body mass index (BMI) among obese (but not lean) Ala12 homozygotes (117). The disparate effects of the *PPARy* gene Pro12Ala polymorphism on BMI in obese and lean individuals suggest that the impact of this genetic variant can be modified by other environmental and/or genetic factors. In general, PPAR γ expression is increased in the adipose tissue of obese subjects, but a low-calorie diet can downregulate its expression (118). It has been shown that when the dietary ratio of polyun-saturated fat to saturated fat is low, the BMI in Ala12 carriers is greater than that in Pro12 homozygotes, but when the ratio is high, the opposite is seen (119). This gene-nutrient interaction may explain, in part, the disparate effects of the Ala12 variant on BMI in obese and lean subjects.

LIPODYSTROPHY

This diverse group of disorders is characterized by severe insulin resistance and partial or complete absence of adipose tissue. The study of these rare genetic variants is important in gaining understanding of the relationship between body-fat distribution and insulin resistance. Following earlier descriptions of affected individuals, Dunnigan (120) first described a family with the syndrome of familial partial lipodystrophy (FPLD) in 1974. Patients with FPLD appear normal at birth but lose subcutaneous fat from their extremities and the gluteal region after puberty. This results in prominent, well-defined musculature in these areas, while fat deposition within the face and neck, axillae, back, labia majora, and abdominal cavity is markedly increased (121). Magnetic resonance imaging studies of these individuals have revealed a complete lack of subcutaneous fat in affected areas, with preservation of intermuscular, intraabdominal, intrathoracic, and bone-marrow fat and excessive accumulation of intramuscular fat (122). Recent genetic studies in families with FPLD have identified several mutations in the LMNA gene, which encodes lamin A and C (123,124). These proteins perform important structural functions in the nuclear membranes of adipocytes and myocytes and participate in DNA replication in these terminally differentiated cells (125). The reason for the regional distribution of the lipodystrophy remains to be determined.

By contrast, congenital generalized lipodystrophy is characterized by a total lack of adipose tissue and by insulin resistance from birth or infancy. The clinical features of insulin resistance (described above) are accompanied by an anabolic syndrome with muscular hypertrophy, hepatomegaly, and hypertrophic cardiomyopathy, the last being frequently lethal by early adulthood (126). This striking clinical syndrome is associated with mutations of two distinct genes on different chromosomes: the gene (AGPAT2) encoding 1-acylglycerol-3-phosphate-Oacyltransferase and a gene homologous to the murine guanine nucleotide-binding protein (G protein), BSCL2. Because the AGPAT2 enzyme catalyzes the acylation of lysophosphatidic acid to form phosphatidic acid, a key intermediate in the biosynthesis of triacylglycerol and glycerophospholipids, mutations in AGPAT2 probably cause congenital generalized lipodystrophy by inhibiting triacylglycerol synthesis and storage in adipocytes (127). The gene BSCL2 is most highly expressed in brain and testis and encodes a protein (seipin) of unknown function. Most of the variants are null mutations and probably result in a severe disruption of the protein (128). Potential mechanisms whereby lipodystrophy may cause insulin resistance are discussed below.

The various *monogenic* syndromes of insulin resistance described above reveal that there is considerable heterogeneity of phenotype among those affected with the identified mutations. Because this heterogeneity does not necessarily appear to be explained by gene penetrance or degree of defect in insulin signaling, it suggests that other factors (genetic or environmental or both) may be important in determining phenotype, even in these extreme genetic variants.

Commonly Occurring Polymorphisms

In addition to the extreme forms of insulin resistance associated with the rare genetic mutations described above, analysis of more commonly occurring polymorphisms of genes with relevance to insulin action has revealed the association of several such polymorphisms with increased incidence of type 2 diabetes.

INSULIN-SIGNALING PATHWAY

In a Caucasian population, individuals homozygous for a common codon 326Met>Ile variant of the p85 subunit of PI 3-kinase demonstrated reduced insulin sensitivity, although no increased incidence of type 2 diabetes (129). Several IRS-1 polymorphisms are more common among individuals with type 2 diabetes than among nondiabetic controls and have been studied extensively in many populations (130). Obese carriers of the G972R polymorphism in a Caucasian population demonstrated decreased insulin sensitivity and increased prevalence of metabolic cardiovascular risk factors (130). Transfection of this common IRS-1 variant into myeloid progenitor cells stably overexpressing the insulin receptor resulted in decreased binding of the p85 regulatory subunit of PI 3-kinase to IRS-1 and decreased IRS-1-associated PI 3-kinase activity (131). In a Japanese population, the combined prevalence of several IRS-1 polymorphisms was threefold greater among patients with type 2 diabetes, and both diabetic and nondiabetic carriers of the various polymorphisms demonstrated reduced insulin sensitivity (132).

Several genetic studies have examined whether polymorphisms in the locus for *adiponectin*, 3q27, could affect the circulating levels of adiponectin and whether these polymorphisms were associated with increased risk for the development of type 2 diabetes. Evidence for the effects of this adipose-specific circulating protein on insulin action will be discussed below. The results of one study showed evidence of linkage with the metabolic syndrome (133), whereas another showed evidence of a type 2 diabetes susceptibility locus at 3q27 in a French population with early-onset diabetes (134). Polymorphisms within the adiponectin locus were also linked with increased risk for type 2 diabetes in a Japanese cohort (135).

DIGENIC

There are a few examples of potential interactions between separate genes in conferring increased risk of insulin resistance (136). The combined effect of PC-1 (K121Q) and PPAR γ 2 (P12A) polymorphisms results in significant increases in BMI and insulin levels and impairments in both insulin sensitivity and insulin secretion. Additionally, a family has been described in which five individuals with severe insulin resistance (but no unaffected family members) were doubly heterozygous for frameshift/premature stop mutations in two unlinked genes, *PPARG* and *PPP1R3A*. These genes encode PPAR γ and protein phosphatase 1 regulatory subunit 3, the muscle-specific regulatory subunit of protein phosphatase 1.

TRANSGENIC MOUSE MODELS OF HUMAN POLYGENIC BASIS OF DIABETES INHERITANCE

Given the complex genetic interactions that likely contribute to human diabetes, insulin receptor (Ir) heterozygous mutants have been used to mimic genetic interactions leading to type 2 diabetes. A first step in this direction was the development of a polygenic model of insulin-resistant diabetes by generating mice with combined heterozygous Ir and Irs1 mutations. Whereas Irs1 heterozygotes are normal and only ~5% of Ir^{+/-} heterozygotes develop diabetes, mice doubly heterozygous for both Ir- and Irs1-null alleles (Ir/Irs1^{+/-}) develop severe

hyperinsulinemia and hyperplasia of pancreatic β -cells. Nearly half of these mice ultimately become frankly hyperglycemic (137), similar to the increased risk of diabetes in firstdegree relatives of patients with type 2 diabetes (138). These characteristics of the Ir/Irs1+/- mouse are consistent with an oligogenic mode of inheritance of type 2 diabetes, in which two subclinical defects of gene function could account for virtually the entire genetic susceptibility to the disease. Even further increases in the incidence of diabetes occurred when these mice were crossed with mice doubly heterozygous for Ir and IRS-2 (Ir/Irs2^{+/-}). Diabetes developed in 40% of the triple heterozygotes (139), providing a useful experimental model for the complex genetic interactions that are likely to contribute to the inheritance of type 2 diabetes. Thus, even such a major predisposing allele as the null insulin receptor mutation has a modest effect alone but can contribute importantly to a predisposing background. This is confirmed by the widely variable prevalence of diabetes (<2% to 85%) observed when the double-heterozygous knockout mice are bred onto different genetic backgrounds (140).

"THRIFTY GENOTYPE" VERSUS "THRIFTY PHENOTYPE"

These concepts highlight interesting aspects of geneenvironment interactions. The high prevalence of insulin resistance and type 2 diabetes in certain population groups is consistent with effects of nutrient availability on gene selection over a long time. Because food supply was neither predictable nor consistent throughout most of the history of Homo sapiens, it is likely that ancestral hunter-gatherers experienced alternating cycles of feast and famine (141). It is postulated that the evolutionary pressures in the late Paleolithic era favored the selection of "thrifty genes" for efficient intake and utilization of fuel stores (142), thereby promoting storage of fuel for periods of impending famine. It does not appear that the genome has changed appreciably over the past 10,000 years, and certainly not with the explosion in the prevalence of type 2 diabetes during the past 40 to 100 years (143). Indeed, genes that favored survival in the late Paleolithic era would be maladaptive in the face of the current combination of continuous food abundance and physical inactivity. The complexity of gene-gene and geneenvironment interactions discussed above suggests that the thrifty genotype is polygenic and includes genes that would impact an individual's response to environmental factors.

There is also considerable epidemiologic evidence suggesting that nutrient availability may condition the patterns of an individual's gene expression at early developmental stages. Indeed, intrauterine growth retardation is strongly linked with subsequent development of obesity or insulin resistance or both in later life (144). Many animal models have been generated to explore possible mechanisms for this association (145). In particular, maternal protein restriction has been shown to be associated with many metabolic defects in adult offspring, including resistance to the effects of insulin on peripheral glucose uptake (146) and hepatic glucose production (147), as well as defective insulin signaling in adipocytes (148) and hypertension (149). As opposed to the evolutionary pressures described above, the effects of fetal deprivation have been termed the "thrifty phenotype" (150). This suggests that the metabolism of the liver, muscle, and adipose tissue may be programmed by maternal nutrition during gestation and lactation and that an individual programmed to survive on minimal nutrients in utero may suffer adverse consequences in adult life in response to plentiful nutrition. Early growth restriction combined with subsequent supranormal nutrition in these experimental models results in the clinical features of the insulin resistance syndrome.

IMPACT OF OBESITY ON INSULIN ACTION

The quantity of body fat varies widely in mammals, ranging from 2% to 50% of body mass (151). This large variation in fat mass is apparently determined both by an individual's genetic background (152) and by environmental factors, including diet and physical activity (153). Excess body fat, or obesity, is an important factor in the pathogenesis of insulin resistance and substantially increases the risk of type 2 diabetes.

The Obesity Epidemic

In the United States of America, successive cross-sectional nationally representative surveys such as the National Health and Nutrition Examination Surveys (NHANES I: 1971-1974; NHANES II: 1976-1980; NHANES III: 1988-1994) permit the study of trends in weight over time. Disturbingly, the prevalence of obesity (BMI \geq 30.0) showed a large increase from NHANES II to NHANES III: NHANES I, 14.1%; NHANES II, 14.5%; and NHANES III, 22.5% (154). In NHANES III, the crude prevalence of overweight and obesity (BMI > 25.0) among adults was 59.4% for men, 50.7% for women, and 54.9% overall. During this time of rising prevalence in obesity, the levels of physical activity have decreased and important shifts in diet have occurred (155), including increased consumption of sugars and energy-dense foods (156). Average daily caloric intake by people in the United States aged 2 years and older increased by 194 kcal/day from 1977 to 1996, with the largest increases in caloric intake among adolescents and young adults (157).

This highly disturbing trend is not limited to the United States or even to developed countries (158). Analyses of economic and food availability data for 1962 through 1994 have revealed a major shift in the structure of the global diet, with an uncoupling of the classic relationship between incomes and fat intakes (159). Global availability of cheap vegetable oils and fats has resulted in greatly increased fat consumption among people in low-income nations, including many countries in Asia, Latin America, North Africa, the Middle East and the urban areas of sub-Saharan Africa. Consequently, obesity is becoming a significant health issue even in countries with lower levels of gross national product and is aggravated by high urbanization rates (160). As expected, dramatic increases in the consumption of low-cost fat and simple carbohydrate calories have resulted in steep increases in incidence of overweight and obesity even among the poorest individuals in these countries (161).

The following section will highlight the metabolic effects of obesity and putative mechanisms whereby obesity contributes to insulin resistance. The impact of increased nutrients will be examined separately below, in light of substantial evidence that both factors impact insulin action.

Adipose Tissue as an Endocrine Organ

Besides being the body's principal site for energy storage, white adipose tissue influences whole-body insulin action both through release of FFAs and by secretion of adipose-derived proteins. The latter include both proinflammatory peptides, discussed below, and several newly identified hormones that appear to have dramatic effects on glucose metabolism and insulin action (162,163).

ADIPONECTIN

Adiponectin (also known as Acrp30, AdipoQ, and GBP28) is a 30-kDa adipose-specific secretory protein that appears to enhance insulin sensitivity (164,165). Decreased circulating

levels of this hormone accompany obesity and insulin resistance in both humans and animal models (166–168). Indeed, adiponectin levels were negatively correlated with hyperinsulinemia and degree of insulin resistance in both Pima Indian and Japanese groups (168,169). As described above, genetic polymorphisms of the adiponectin gene are associated with increased incidence of insulin resistance and diabetes. Although there do not appear to be acute effects of nutrient excess or deprivation on adiponectin levels, chronic caloric restriction (which enhances insulin action) increases adiponectin levels (170,171). Furthermore, high baseline plasma levels of adiponectin are associated with a substantially reduced risk of development of type 2 diabetes (172). The experimental models discussed below suggest that low plasma levels of adiponectin contribute to the pathogenesis of insulin resistance and type 2 diabetes.

Pharmacologic treatment with adiponectin in rodents increases hepatic insulin sensitivity, with decreased glucose production. It was first noted that a single injection of purified recombinant adiponectin caused a transient decrease in basal glucose levels in various mouse models, with temporary correction of hyperglycemia without affecting insulin levels in ob/ob, nonobese diabetic, and streptozotocin-treated mice (173). Additionally, adiponectin increased the ability of subphysiologic levels of insulin to suppress glucose production in isolated hepatocytes (173). Infusion of adiponectin in conscious mice resulted in improved hepatic insulin action measured during euglycemic hyperinsulinemic clamp studies, with enhanced suppression of glucose production (174). Adiponectin stimulated phosphorylation and activation of the 5'AMP-activated protein kinase (AMPK) in skeletal muscle and in liver, together with stimulation of fatty acid oxidation and glucose uptake in myocytes, reduced gluconeogenesis in the liver, and reduction of glucose levels in vivo (175). Blocking AMPK activation inhibited all of these effects, suggesting that stimulation of glucose utilization and fatty acid oxidation by adiponectin occurs through activation of AMPK.

The phenotypes of adiponectin-deficient and transgenic adiponectin-overproducing animal models further substantiate an important role for adiponectin in mediating insulin action. Using a dominant mutation in the collagenous domain of adiponectin to generate a transgenic mouse, Combs et al (176). demonstrated that approximately threefold elevations in circulating adiponectin levels were associated with enhanced insulin-mediated suppression of endogenous glucose production and increased phosphorylation of AMPK in liver. Conversely, mouse models with a disruption of the adiponectin locus display moderate insulin resistance and impaired FFA clearance on a normal chow diet and an earlier onset of dietinduced insulin resistance (177,178).

It has recently been reported that adiponectin circulates in two discrete forms: as a relatively low-molecular-weight (LMW) hexamer and as a high-molecular-weight (HMW) multimeric structure (179). The ratio of these two oligomeric forms (HMW/LMW) has recently been shown to correlate more tightly with insulin action than do total circulating adiponectin levels (180). Furthermore, although pharmacologic activation of PPAR γ with thiazolidinediones increases adiponectin levels, the most striking effect is a selective proportional increase in the HMW form with close association with improved hepatic insulin action (180). This suggests that the HMW form is the active circulating form of adiponectin, and that its favorable effects on glucose metabolism are predominantly at the level of the liver.

LEPTIN

Leptin is a 16-kDa protein secreted from adipose tissue, the product of the defective obesity gene identified by positional cloning in the obese, hyperinsulinemic *ob/ob* mouse (181). Circulating leptin concentrations in humans correlate closely with fasting insulin concentrations and the percentage of body fat, making leptin a marker of obesity and the insulin resistance syndrome. Leptin infusion acutely increases glucose uptake under euglycemic, hyperinsulinemic conditions in rats (182). Indeed, acute leptin administration enhances the ability of insulin to inhibit hepatic glucose production but does not affect peripheral insulin action (183). By contrast, chronic leptin administration induces metabolically favorable changes in body composition that include decreased visceral adiposity and reduced muscle accumulation of triglyceride (184). These leptin-induced changes in body composition are associated with improved sensitivity to the metabolic effects of insulin on skeletal muscle (184).

Recent findings suggest that these favorable effects on body composition and lipid storage may be due to leptin-induced stimulation of β-oxidation via activation of AMPK in muscle and liver (185,186). When activated, AMPK decreases adenosine triphosphate (ATP)-consuming anabolic pathways such as glucose-regulated transcription, protein synthesis, cholesterol synthesis, and fatty acid and triglyceride synthesis and increases ATP-producing catabolic pathways such as increased glucose transport, β -oxidation, glycolysis, and mitochondrial biogenesis. Other potential mechanisms whereby leptin could influence insulin action include its regulation of immune function and hormone secretion (187). Profound leptin deficiency in ob/ob mice is accompanied by impaired T-cell immunity (188). Furthermore, the immunosuppression associated with acute starvation is reversed when exogenous leptin is administered (189). Leptin also alters the regulation of hormones in the hypothalamuspituitary-adrenal axis and affects growth hormone, prolactin, and a number of other anterior pituitary hormones (190), many of whose effects on insulin action are discussed above. A discussion of mechanisms whereby leptin deficiency contributes to hyperinsulinemia and insulin resistance in lipodystrophy is provided below. Thus, defective leptin action may contribute to insulin resistance in the metabolic syndrome.

It has been postulated that leptin resistance can develop in the face of high circulating levels of the hormone. This is supported by the fact that leptin levels are increased in most mouse models of insulin resistance associated with obesity. Furthermore, diet-induced obese mice are resistant to the effects of leptin administration (191). Indeed, resistance to the central anorectic effects of leptin develops rapidly in the face of nutrient excess (192). However, leptin was effective in increasing energy expenditure in obese individuals after a sustained weight reduction of ~10% of their previous body weight (193). This suggests that it may be possible to regain leptin sensitivity with weight loss and/or nutrient restriction, which may also have favorable implications for insulin action.

RESISTIN

Resistin is a 10-kDa adipose tissue–specific hormone recently identified in a screen for transcripts upregulated during adipogenesis and downregulated by treatment with a PPAR γ agonist (194). Whereas injection of resistin into wild-type mice impaired glucose tolerance and insulin action, neutralizing antibodies improved insulin action in obese diabetic mice (194). When resistin was infused at near-physiologic levels in normal rats, lower rates of glucose infusion were necessary to maintain basal glucose levels during a hyperinsulinemic clamp study (195). The insulin resistance caused by resistin infusion was wholly accounted for by an increase in the rate of glucose production, suggesting that resistin has rapid inhibitory effects on hepatic rather than peripheral insulin sensitivity.

Despite this compelling evidence for acute effects of resistin on in vivo insulin action, there remains considerable uncertainty about the significance of resistin to the long-term regulation of insulin action in animals and humans. Indeed, resistin mRNA appears to be downregulated in most mouse models of insulin resistance (196). Additionally, resistin expression was very low in isolated adipocytes from human adipose tissue explants (197) and was actually higher in monocytes (198) and other nonadipocyte cells of adipose tissue (199) than in adipocytes. Furthermore, although some studies suggest a link between resistin levels and BMI or insulin sensitivity in humans (200-202), others have failed to reveal such a connection (203-205). However, it is possible that serum levels do not correlate with tissue mRNA or protein levels, a phenomenon observed for other adipokines under certain conditions (206). Given the challenges of reliably measuring plasma levels of resistin, most published papers on this topic report only tissue resistin transcript levels, and therefore more studies will be necessary to determine the clinical relevance of resistin in obesity and in the development of insulin resistance.

Obesity and Inflammation

There is growing evidence that the relationship between inflammation and insulin resistance is not merely correlative but actually causative (207). Epidemiologic data from several large studies have demonstrated a link between insulin resistance and systemic inflammation in both type 2 diabetes and nondiabetic populations (208–210). Adipose tissue produces many proinflammatory molecules, including TNF- α , IL-6, transforming growth factor- β , C-reactive protein, and monocyte chemotactic (chemoattractant) protein-1 (MCP-1), and circulating levels of these "adipokines" are increased in obesity (211–216).

Adipose-derived proinflammatory molecules are believed to induce systemic insulin resistance and to contribute to the pathogenesis of many metabolic complications of obesity, including type 2 diabetes and atherosclerosis (210). Although definitive human evidence is still accumulating, substantial experimental evidence links proinflammatory molecules with insulin resistance. The proinflammatory cytokine TNF- α has been demonstrated to mediate insulin resistance as a result of obesity in several rodent models (217). Expression of TNF- α was increased in white adipose tissue from different rodent models of obesity and diabetes (217), with elevations in TNF- α protein both locally and systemically. Neutralization of TNF-α in insulin-resistant rats caused a significant increase in the peripheral uptake of glucose in response to insulin (217,218). Furthermore, mice lacking either the TNF- α ligand or one of its receptors were partially protected from obesity-induced insulin resistance (219,220). TNF- α directly decreases insulin sensitivity and increases lipolysis in adipocytes (221,222). Expression of TNF- α is increased in white adipose tissue in obese and insulinresistant states (223). Multiple mechanisms have been suggested to account for these metabolic effects of TNF- α , including direct effects on insulin signaling, downregulation of genes that are required for normal insulin action, induction of elevated FFA levels via stimulation of lipolysis, and negative regulation of PPAR α (224).

Although neutralizing TNF- α with circulating antibodies did not cause metabolic improvement in humans with type 2 diabetes (225), this does not exclude the possibility of important paracrine effects of this cytokine on fat tissue. Despite the protean studies demonstrating a link between TNF- α and insulin resistance, there is no evidence that TNF- α directly causes insulin resistance in skeletal muscle. Indeed, TNF- α activates NF-B, a transcription factor that regulates the expression of many inflammatory molecules (226). It is therefore possible that the predominant effects of TNF- α are to stimulate the production of other cytokines, some of which ultimately exert direct effects on muscle. In addition to TNF- α , other cytokines are known to have metabolic effects. IL-6 also increases lipolysis and has been implicated in the hyper-triglyceridemia and increased serum FFA levels associated with obesity (227). Additionally, IL-6 induces cellular insulin resistance in hepatocytes (228). Recently, the chemokine MCP-1 also was shown to impair adipocyte insulin sensitivity (229).

Historically, it has been known that high doses of salicylates are able to lower blood glucose concentrations (230). Indeed, TNF- α activates NF-B by stimulating IB kinase complex (IKK) activity, and salicylate has been demonstrated to inhibit TNF- α -induced stimulation of IKK activity (231). It was recently shown that reduced signaling through the IKKβ pathway, a key pathway in tissue inflammation, either by salicylate-based inhibitors or decreased IKK β expression, is accompanied by improved insulin sensitivity in vivo (232,233). Ultimately, aspirin treatment inhibits serine phosphorylation of IRS-1 in TNF- α -treated cells through targeting multiple serine kinases (234). High-dose aspirin treatment for 2 weeks resulted in significant reductions in fasting plasma glucose in nine patients with type 2 diabetes, with reduced basal rates of hepatic glucose production and improved insulin-stimulated peripheral glucose uptake (235).

Independent studies have recently indicated that obesity in rodents and humans is associated with increased infiltration of macrophages into adipose tissue (236-238). These findings suggest an intriguing mechanism for the increased production of proinflammatory peptides by adipose tissue in obesity. With the onset of obesity, secretion of low levels of TNF- α by adipocytes is believed to stimulate preadipocytes to produce MCP-1, a chemoattractant specific for monocytes and macrophages (237). Increased secretion of leptin by adipocytes may also contribute to macrophage accumulation by stimulating transport of macrophages to adipose tissue (239) and promoting adhesion of macrophages to endothelial cells, respectively (240). Adipocytes also produce colony-stimulating factor-1 (CSF-1), the primary regulator of macrophage differentiation and survival (241). Therefore, increasing adiposity may result in adipose-derived signals such as MCP-1, causing increased monocyte influx. The production of CSF-1 by adipocytes may then create a permissive microenvironment for these monocytes to differentiate and survive as mature adipose tissue macrophages. Once activated macrophages are present in sufficient numbers within adipose tissue, it is likely that they cooperate with adipocytes and other cell types to perpetuate a vicious circle of macrophage recruitment and production of inflammatory cytokines, ultimately causing systemic insulin resistance.

Adipocyte cell size is highly correlated with indicators of systemic insulin resistance, dyslipidemia, and risk for developing type 2 diabetes (242–245). Potential mechanisms whereby adipocyte hypertrophy may perturb adipocyte function and thereby influence systemic glucose and lipid metabolism (246) include induction of sterol regulatory element binding protein-2 (SREBP-2) and its target genes (247) and secretion of increased quantities of secreted products such as leptin (248) or TNF- α (249). The data for humans and mice show that adipocyte size is a strong predictor of the percentage of macrophages in adipose tissue (237). The close relationship between adipocyte size and the abundance of macrophages in adipose tissue suggests that the influence of adipocyte size on adipocyte function may be conveyed through a paracrine pathway involving adipose tissue macrophages (237).

Visceral fat mass, which includes both mesenteric and omental intraabdominal fat depots, is more closely correlated with obesity-associated pathology than is overall adiposity (250-252). Proposed mechanisms for the negative metabolic effects of visceral fat include unrestrained lipolysis with increased circulating FFA levels, a specific increase in portal delivery of FFA, and unfavorable secretion profiles of adiposederived proteins. Relative to subcutaneous fat cells, visceral fat cells are more sensitive to the lipolytic effect of catecholamines and less sensitive to the antilipolytic effect of insulin (253). Furthermore, the venous effluent of visceral fat depots leads directly into the portal vein, resulting in greater FFA flux to the liver in viscerally obese individuals (254). Increased hepatic delivery of fatty acids results in hepatic insulin resistance and in decreased insulin clearance, with secondary effects of peripheral insulin resistance (254).

Additionally, visceral versus subcutaneous fat might display different secretion profiles of proteins with systemic metabolic roles. Comparisons of the relative expression of metabolically relevant genes have revealed a few depot-specific expression patterns that may be consistent with a metabolically adverse role of visceral adipose tissue. These include increased expression of resistin in visceral fat, versus increased expression of leptin and IRS-1 in subcutaneous fat (255). Possible explanations for hormonal contributions to visceral adiposity include the observed increase in gene expression of receptors for glucocorticoids and androgens in this depot (255). However, there are some noteworthy limitations to these comparisons, including the observation that the insulin-sensitizing protein adiponectin is expressed at higher levels by visceral adipocytes (256). The example of adiponectin may provide important insights into the secretion patterns of these adipose depots, because plasma adiponectin levels fall markedly with visceral adiposity (257), in concert with decreased adiponectin expression in visceral fat with obesity (258). This suggests that adipocyte size and/or degree of lipid engorgement affects its secretion profile and that visceral adipose tissue may display altered secretion of proteins with expansion of this depot.

The relative contribution of the above factors to the metabolic effects of visceral fat has recently been examined in elegant studies with several rodent models of insulin resistance. Surgical removal of epididymal and perinephric fat pads dramatically lowered insulin levels and improved insulin action in both diet-induced and genetically obese rodent models without altering portal or peripheral FFA levels (259,260). Intriguingly, removal of the visceral fat pads also resulted in marked decreases in the gene expression of TNF- α and leptin in subcutaneous fat. This suggests that there may be "cross-talk" between adipose depots, and indicates an important role for the secretory products of visceral fat both in the biology of subcutaneous fat and in the induction of insulin resistance.

Abnormalities of Fat Deposition

LIPODYSTROPHY

In apparent contradiction to the above models of obesityinduced insulin resistance, similar metabolic features are paradoxically observed in the presence of decreased body fat, including insulin resistance, hyperlipidemia, and diabetes (121). The severity of the metabolic abnormalities varies widely and correlates roughly with the degree of fat deficiency.

Lipodystrophies can be subdivided into two major types: familial and acquired. The main subtypes of familial lipodystrophies (congenital generalized lipodystrophy and FPLD) have been described above. Whereas patients with acquired generalized lipodystrophy (Lawrence syndrome) have generalized loss of subcutaneous fat, those with acquired partial lipodystrophy (Barraquer-Simons syndrome) have fat loss limited to the face, trunk, and upper extremities (261–263). These acquired lipodystrophy syndromes occur approximately three times more frequently in women, begin during childhood, and are associated with underlying autoimmune disorders such as dermatomyositis and scleroderma.

Lipodystrophy is also encountered frequently in patients infected with human immunodeficiency virus (HIV), particularly among those receiving HIV-1 protease inhibitors (264,265). This HIV-associated lipodystrophy is characterized by loss of subcutaneous fat from the extremities and face but excess fat deposition in the neck and trunk. Among the proposed mechanisms for this finding is the possibility that HIV protease inhibitors impair adipocyte differentiation, because they have been shown to block preadipocyte differentiation in vitro (266). However, lipodystrophy has also been observed in HIVinfected patients treated with other antiretroviral agents who have never received protease inhibitors (267). This opens the possibility that HIV-associated lipodystrophy may not be caused by a specific drug regimen but may instead be a consequence of HIV infection per se in effectively treated patients (267). Other causes of acquired localized lipodystrophies include drugs, pressure, injection of insulin or growth hormone, and panniculitis (268).

Several fatless transgenic mouse models may be helpful in elucidating the mechanism (or mechanisms) whereby lipodystrophy causes insulin resistance. In the models described below, selected genes were selectively expressed in adipose tissue by means of the promoter/enhancer of the Ap2 (adipocyte fatty acid binding protein) gene. With Ap2-targeted expression of an attenuated diphtheria toxin, mice displayed progressive adipose tissue atrophy and necrosis, with a 90% reduction in fat-pad weight by 10 months of age (269). Adiposeselective expression of a dominant-negative protein called A-ZIP/F inactivates several transcription factors implicated in adipocyte growth and differentiation, resulting in complete absence of visible white adipose tissue at all times during development (270). Unexpectedly, white adipose tissue-deficient mice were also generated by adipose-specific expression of a constitutively active form of the transcription factor SREBP-1c, which stimulates transcription of genes regulating fatty acid biosynthesis (271).

These rodent models are all severely insulin resistant and have a phenotype similar to that of patients with severe lipodystrophy, including increased accumulation of triglyceride in muscle and liver. Indeed, the lack of white adipose tissue causes leptin deficiency, which probably contributes to the insulin resistance and tissue triglyceride accumulation (272,273). However, although leptin normalized glucose levels and nearly normalized insulin levels in the aP2-SREBP-1c mice (274) and in humans with lipodystrophy (275), it had a more modest effect on glucose and insulin levels in A-ZIP/ F-1 mice (276). Although it is possible that higher doses and/ or more prolonged treatment with leptin would be more effective in the latter model, this may underscore the loss of other important functions or factors provided by adipose tissue. The lack of white adipose tissue to take up and store fat leads to increased blood levels of FFA and triglycerides and to tissue triglyceride accumulation. Increased circulating FFAs and increased tissue triglyceride deposition have also been proposed as a cause of insulin resistance, through purported mechanisms discussed below. Probably more important, there

is an accumulation of intracellular fatty acid metabolites (fatty acyl-CoAs [coenzyme A], diacylglycerol, and ceramides, among others) in these insulin-responsive tissues, which leads to acquired defects in insulin signaling and insulin resistance. Another important factor contributing to hyperinsulinemia in fatless mice may be the reduced plasma leptin levels, because leptin has been shown to negatively regulate insulin secretion (277,278).

As further evidence for multiple metabolic effects of fat tissue, the severe metabolic defects in these rodent lipodystrophy models are reversed in a dose-dependent manner by surgical transplantation of wild-type adipose tissue (279–283). However, it is intriguing to note that transplantation of adipose tissue lacking leptin is unable to reverse the metabolic abnormalities associated with lipoatrophy (284). The modest effects of leptin alone in the same model (280) suggest the potential importance of other secreted proteins from leptin-primed adipose tissue.

By contrast to the above models, fatless Irs1/Irs3 double knockout mice do not have increased triglyceride levels in liver or muscle yet manifest metabolic characteristics similar to those in lipodystrophic patients and in other transgenic mouse models (285,286). The fact that tissue triglyceride accumulation is not an essential component of lipodystrophic insulin resistance raises important questions about whether abnormal muscle and liver fat causes insulin resistance, as discussed below. Of note, the hyperglycemia and hyperinsulinemia of the Irs1/Irs3 double knockout mice are reversed by adenovirus-mediated expression of leptin in the liver.

Thus, both too little and too much fat can cause insulin resistance. Perhaps obesity and lipodystrophy have more similarities than may initially be apparent. In both cases, a storage defect within adipocytes (due either to massive engorgement with lipid or to a paucity of differentiated adipocytes) leads to excess accumulation of triglyceride in nonadipose tissues (discussed below) and decreased secretion of certain adipokines with favorable metabolic effects. In the case of obesity, the greater overall fat mass in obese individuals will result in an elevation of fatty acid flux to nonadipose tissues, even in the absence of a qualitative abnormality in adipose tissue metabolism (287). Also, increased adiposity may result in proportionally greater secretion of hormones and other adipokines that negatively impact insulin action and in decreased secretion of those with favorable effects. Notable examples would include the decrease in adiponectin and increase in inflammatory mediators with obesity.

INTRAMYOCELLULAR TRIGLYCERIDE ACCUMULATION

Intramuscular triglyceride accumulation is associated with muscle insulin resistance in lean and obese, nondiabetic, and type 2 diabetic humans (288–290). Sophisticated nuclear magnetic resonance (NMR) spectroscopy imaging of muscle lipid accumulation permits the clear distinction of intramyocellular triglyceride (IMTG) deposition from intercellular striation (291,292) and has demonstrated that IMTG is strongly associated with insulin resistance (293). Despite a considerable amount of interest in this area, it remains to be determined whether muscle accumulation of triglyceride is merely a marker of other metabolic abnormalities or plays a causative role in the development of insulin resistance.

A central question in the etiology of IMTG accumulation in insulin-resistant individuals is whether triglycerides accumulate as a result of increased total FFA flux to muscle or of a primary defect in fatty acid oxidation (254). Muscle from obese, insulin-resistant individuals appears to have a reduced capacity for uptake and oxidation of circulating FFAs (294,295), which

might be attributable to defects of fatty acid oxidation at the levels of carnitine palmitoyltransferase-1 (CPT-1) or at a subsequent step or both (296). The CPT-1 enzyme controls the entry of long-chain fatty acyl-CoA (LCFA-CoA) into the mitochondria and is the initial and rate-limiting step in the oxidation of fatty acids. Of note, prolonged pharmacologic inhibition of muscle CPT-1 in rats causes the accumulation of IMTG and the development of insulin resistance (297). Additionally, plasma delivery of FFA itself, as well as glucose delivery and plasma insulin levels, may determine the rate of muscle fatty acid oxidation (298-300) through tissue accumulation of malonyl-CoA. There is increased availability of circulating FFAs in insulin-resistant individuals (254). McGarry et al. (301) first identified malonyl-CoA as a biochemical sensor implicated in the switch from fatty acid to glucose oxidation, because malonyl-CoA is a potent allosteric inhibitor of CPT-1 (302). In the presence of high circulating levels of glucose, insulin, and FFA, the accumulation of malonyl-CoA inhibits CPT-1 and reduces fatty acid oxidation, favoring lipid storage into triglycerides. Experimental evidence suggests that excessive FFA delivery to muscle from the circulation can be a source of triglyceride accumulation in muscle (303,304). An extramuscular defect of fatty acid metabolism could contribute to the intramyocellular triglyceride accumulation and the skeletal muscle lipotoxic effects seen in obesity and type 2 diabetes (254). Together, these findings suggest that impaired muscle fatty acid oxidation and increased FFA delivery have synergistic effects on IMTG accumulation and muscle insulin resistance in patients with obesity and insulin resistance (305)

In studies of the relationship between IMTG and insulin action, many apparent clinical and experimental paradoxes suggest that IMTG may be a marker for other metabolic defects. Triglycerides accumulate in the muscle tissue of highly physically trained athletes (306), who demonstrate enhanced insulin sensitivity. A woman found to be homozygous for a missense mutation in the carnitine palmitoyltransferase II gene had decreased muscle fat oxidation and markedly impaired insulinstimulated glucose uptake yet normal IMTG (307). Thus, it has been suggested that muscle triglyceride may not have adverse metabolic consequences in muscle that has the capacity for efficient lipid utilization (307). The onset of type 2 diabetes is associated with a marked increased accumulation of intramyocellular lipid (IMCL) despite no further worsening in insulin action. Additionally, although there was an initial correlation between IMCL and insulin resistance in individuals with type 2 diabetes, near-normalization of plasma glucose with insulin infusion for ~3 days increased IMCL without changing insulin action, such that postinsulin levels of IMCL were actually positively correlated with insulin sensitivity (308). Furthermore, in several cultured cell models, the accumulation of intracellular triglyceride actually appeared to be protective against toxic cellular effects of fatty acids (309). Whereas oleic acid supplementation promoted triglyceride accumulation and was associated with normal cell viability, excess palmitic acid was poorly incorporated into triglyceride and induced apoptosis. Moreover, in cells lacking the enzyme that catalyzes the final step in mammalian triglyceride synthesis, oleate induced cellular lipotoxicity. Although these studies exonerated intracellular triglyceride from proapoptotic effects of lipid accumulation, they did not specifically examine insulin action or identify a putative effector (or effectors) of lipotoxicity.

Indeed, a more consistent relationship has been demonstrated between insulin stimulation of glucose uptake and suppression of LCFA-CoA in skeletal muscle (310). Whereas improved insulin action and reduced LCFA-CoA resulted from both a bout of exercise and short-term caloric restriction,

436 JOSLIN'S DIABETES MELLITUS

decreased muscle triglyceride was observed only with caloric restriction. There are several potential mechanisms whereby increased LCFA-CoA could inhibit muscle glucose metabolism (310). Increased LCFA-CoA could lead secondarily to increases in the concentration of diacylglycerol, phosphatidic acid, and triglycerides and activation of one or more protein kinase C (PKC) isoforms, which would downregulate insulin signaling. Other proposed mechanisms whereby increases in LCFA-CoA could cause insulin resistance include alterations in membrane fluidity (311,312), direct inhibition of enzymes such as glycogen synthase (313), and acylation of proteins involved in GLUT4 translocation (314). LCFA-CoAs would be expected to accumulate in the cytosol under conditions of increased FFA availability and decreased fatty acid oxidation, as was described above in the context of insulin resistance. States of energy excess, glucose, insulin, and citrate result in increased malonyl-CoA, which is paralleled by a rise in cytosolic LCFA-CoA.

INTRAHEPATOCELLULAR TRIGLYCERIDE ACCUMULATION

Nonalcoholic hepatic steatosis (fat infiltration) is frequently observed in obese subjects (315,316) and can range from mild hepatic steatosis to steatohepatitis, fibrosis, and cirrhosis (317,318). Although liver biopsy is considered the "gold standard" for quantification of liver triglyceride accumulation, localized ¹H magnetic resonance spectroscopy provides a noninvasive and highly specific estimation of hepatic fat *in vivo* (319,320). As with the relationship between IMCL and insulin action, it remains to be determined whether hepatic steatosis causes or develops as a consequence of hepatic and/or peripheral insulin resistance (321). Several recent observations demonstrating correlations between intrahepatocellular triglyceride (IHTG) and both hepatic and peripheral insulin action will be presented here along with proposed theories for how IHTG might impact insulin action.

Hepatic steatosis is associated with decreased requirements for glucose infusion during hyperinsulinemic clamp studies, indicating insulin resistance that could be either hepatic or peripheral (322). Likewise, percent hepatic fat was the obesityassociated parameter best correlated with daily insulin dose in subjects with stable type 2 diabetes (323). Nonobese, nondiabetic subjects with biopsy-proven nonalcoholic fatty liver disease demonstrated both reduced insulin-mediated suppression of hepatic glucose production (approximately a twofold increase relative to nonsteatotic controls) and reduced insulinstimulated glucose disposal (by ~ 50%) and insulin resistance comparable to that of individuals with type 2 diabetes (324). Likewise, stratification of healthy nondiabetic men by IHTG revealed impaired suppression of glucose production by insulin in the men with higher hepatic fat content (325). A small decrease in insulin-stimulated glucose disposal in the higher IHTG group was not significant; however, these subjects were less insulin resistant than those in the previous study. Among individuals with type 2 diabetes, the presence of hepatic steatosis as detected by computed tomography (CT) scanning was associated with reduced insulin-stimulated glucose uptake, whereas only the male subjects demonstrated impaired suppression of glucose production by insulin (326). In a group of healthy nondiabetic subjects, IHTG demonstrated a stronger inverse correlation than IMCL with insulin sensitivity, and this relationship remained significant when corrected for visceral fat content (327).

These intriguing associations between IHTG and peripheral insulin action are consistent with a transgenic mouse model in which decreasing IHTG improved muscle insulin action (328). Liver-specific enhancement of fatty acid oxidation was associated with increased insulin-stimulated peripheral glucose uptake, even though IMCL was actually increased in some muscles (328). Although there is currently no definitive explanation for these observations, it has been proposed that an as yet unidentified liver factor increases glucose uptake into skeletal muscle, because raw liver extracts increased the glucose uptake in isolated rat hindquarter (329). It is conceivable that increased hepatic fat accumulation might interfere with the production or release of this factor, resulting in impaired peripheral insulin action.

"ENVIRONMENTAL" FACTORS CONTRIBUTING TO INSULIN RESISTANCE

Medical Conditions That Result in Insulin Resistance

Insulin resistance has been reported to result from many medical conditions. A discussion of the impaired insulin action that results from many endocrinopathies follows in the next section, and the association of insulin resistance with lipodystrophies is discussed elsewhere in this chapter. One of the first medical causes of insulin resistance to be identified was the presence of antibodies to insulin receptor (type B insulin resistance) (330,331). Although frequently encountered when animal insulin was in wide usage, clinically significant levels of antibodies to insulin receptor have also been described in the presence of various autoimmune disorders, including systemic lupus erythematosus (332). Insulin resistance is also a characteristic feature of renal failure and uremia and improves with dialysis (333,334). The cause of the insulin resistance in renal failure is likely to be multifactorial. Loss of muscle mass and decreased physical fitness, accumulation of uremic toxins, raised levels of growth hormone and glucagon, metabolic acidosis, and dyslipidemia have all been proposed as potential mechanisms (335).

Hepatic cirrhosis is frequently associated with glucose intolerance and insulin resistance (336,337). Although the mechanism (or mechanisms) underlying the insulin insensitivity are unknown, they may include elevation in circulating FFAs and insulin levels, both shown below to inhibit insulin action. Studies of glucose tolerance demonstrated defects in insulin secretion and insulin action, both of which were related to the degree of hepatic iron deposition, in a large kindred with familial hemochromatosis (338). Indeed, iron overload appears to impair both hepatic and peripheral insulin action early in the course of hereditary hemochromatosis (prior to overt hepatic cirrhosis), and phlebotomy may improve insulin action in affected individuals (339,340). In addition, transfusion-induced iron overload in thalassemia major was shown to be associated with insulin resistance, apparently proportional to the degree of liver disease (341).

Insulin resistance has been recognized in patients with any of several types of cancer, particularly malignancies of the gastrointestinal tract and pancreas (342,343). It has been proposed that inflammatory mediators contribute to this insulin resistance, particularly TNF- α and IL-6 (344–346). Potential mechanisms whereby these cytokines inhibit insulin action are discussed below.

Hormonal Mediators of Insulin Action

Insulin resistance has been documented in the presence of many syndromes of abnormal hormone levels, particularly states of hormone excess. These endocrinopathies will be described in some detail, as these disease states shed light on the role of hormones in the pathogenesis of insulin resistance (Fig. 24.3).

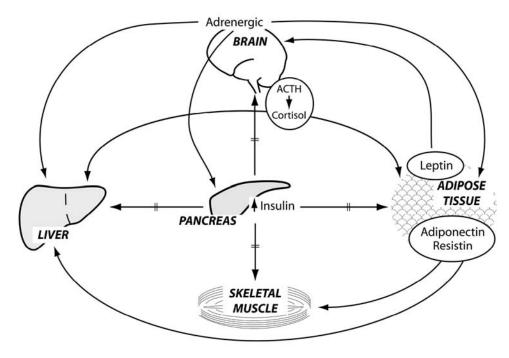

Figure 24.3. The contribution of hormonal hypersecretion to insulin resistance. The diagram identifies hormones whose circulating levels are increased in the metabolic syndrome and shows the tissue-specific effects of hormonal hypersecretion on insulin action, including the effects of hyperinsulinemia per se. ACTH, adrenocorticotropic hormone.

Hyperinsulinemia is the classic indicator of insulin resistance and may itself contribute to the insulin resistance in type 2 diabetes and obesity. Indeed, elevating plasma insulin levels for 7 days in normal rats results in impaired insulin-mediated glucose uptake (347). Additionally, euglycemic, hyperinsulinemic clamp studies have revealed decreased peripheral glucose uptake in patients with insulinoma (348). Moreover, insulin receptor levels are normal or only mildly impaired in type 1 diabetes (349) and are generally increased in animal models of hypoinsulinemic diabetes (350). Amelioration of hyperinsulinemia by streptozotocin treatment in two obese-animal models corrected the decreased levels of insulin receptor expression (351). These data suggest that hyperinsulinemia causes downregulation of the insulin receptor due to increased internalization and degradation after insulin binds to its receptor, leading to secondary insulin resistance (352). Thus chronic hyperinsulinemia in the metabolic syndrome, likely secondary to nutrient excess and insufficient caloric expenditure, in turn contributes to insulin resistance.

Counterregulatory hormones (cortisol, epinephrine, norepinephrine, glucagon, and growth hormone) play significant roles in antagonizing insulin action after hypoglycemia (353). Of note, 24-hour infusions of cortisol impaired insulin-induced suppression of glucose production and stimulation of glucose utilization in normal volunteers (354). Peripheral glucose uptake is also markedly reduced in individuals with Cushing syndrome, even as compared with obese individuals (355). It has been proposed that the metabolic syndrome is associated with hyperactivity of the hypothalamic-pituitary-adrenal axis and that the enhanced cortisol secretion contributes to insulin resistance (356).

It is not clear whether increased sympathetic nervous system activity, which may occur in the metabolic syndrome (357), contributes to decreased insulin signaling. However, in white adipocytes (358), stimulation of the β -adrenergic receptor decreases insulin-stimulated PI 3-kinase activity. Desensitization of β -adrenergic receptors by isoproterenol increases insulin-stimulated glucose uptake in white adipocytes (359). A naturally occurring mutation of the β_3 -adrenergic receptor (W64R) has been associated with increased abdominal obesity and early-onset type 2 diabetes (360), although this remains controversial. In isolated human omental adipocytes, the W64R variant shows decreased β -agonist–induced lipolysis (361), providing a potential mechanism whereby omental adipocity may be increased in patients with this variant. Pheochromocytomaassociated decreases in peripheral insulin action corrected rapidly following surgical resection, suggesting that the insulin resistance was secondary to the pheochromocytoma (362). Among the postulated mechanisms for this insulin resistance are increased levels of norepinephrine (363) or epinephrine or both (364,365).

Growth hormone acts at several levels to block insulin actions, including the inhibition of phosphorylation of the insulin receptor and one of its principal signaling molecules, IRS-1, in response to insulin administration. This leads to reduced sensitivity to insulin both in stimulating peripheral glucose uptake and in suppressing glucose production (366). Furthermore, an excess of growth hormone leads to mobilization of FFAs, which inhibit insulin-stimulated glucose oxidation by acting as a competitive energy source, thus leading to further worsening of insulin resistance. Most patients with acromegaly have some degree of insulin resistance (367). These abnormalities have been reversed by surgical resection of growth hormone-secreting tumors (368) and by administering agents that block growth hormone action (369). Although one study reported that long-term octreotide therapy decreased the secretion of growth hormone, the decrease did not correct the insulin resistance (370). In contrast to growth hormone, IGF-I appears to enhance insulin action and may partially counteract the insulin-opposing effects of growth hormone.

Systemic Effects of Nutrient Excess on Insulin Action

Along with the dramatic lifestyle changes described above, with unprecedented increases in nutrient intake, it is likely that biochemical adaptations that evolved to deal with famine now predispose to nutrient-induced insulin resistance. Teleologically,

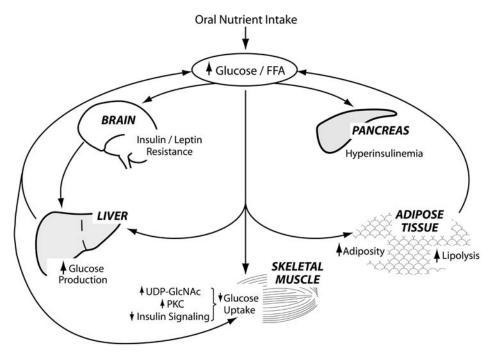

Figure 24.4. Systemic impact of nutrient excess. The diagram shows tissue sources and effects of increased availability of glucose and free fatty acids: FFA, free fatty acids; UDP-GlcNAc, uridine diphosphate-*N*-acetylglucosamine; PKC, protein kinase C.

downregulation of insulin action may have protected cells from potentially toxic effects of further influx of glucose and other nutrients (371). This concept is predicated upon the ability of the cell to "sense" nutrient availability via various mechanisms, which need to be tightly coupled to insulin signaling or glucose transport or both. This review will focus on the effects of increased availability of glucose and FFAs on potential nutrient-sensing pathways and ultimately on insulin action (Fig. 24.4).

GLUCOSE

Glucose toxicity refers to the inhibitory effects of chronic hyperglycemia on insulin secretion and action (372). Hyperglycemiainduced insulin resistance includes downregulation of the glucose transport system by hyperglycemia and a defect in insulin-stimulated glycogen synthesis. Initial clinical evidence of this phenomenon came from the observation that patients with poorly controlled type 1 diabetes are insulin resistant and that this insulin resistance can be ameliorated by tight glycemic control (373,374). Normalization of blood glucose levels with phlorizin treatment completely corrected insulin-mediated glucose metabolism in diabetic rats (375) and restored insulinmediated glucose transport in adipose cells without restoring glucose transporter gene expression (376). Furthermore, in diabetic GK rats, an animal model of lean type 2 diabetes, normalization of glycemia by phlorizin treatment improves glucose tolerance, insulin signaling, and glucose transport in skeletal muscle (377,378).

Following the serendipitous observation that the amino acid glutamine was required for the desensitization by high levels of glucose to insulin in primary cultures of adipocytes, Marshall et al. (379) demonstrated with a series of elegant studies that the flux of glucose through the hexosamine biosynthetic pathway (HBP) is required for glucose-induced insulin resistance. He determined that glucose-induced desensitization of the glucose transport system could be prevented by glutamine analogues that inhibit glutamine:fructose-6-phosphate amidotransferase (GFAT), the initial and rate-limiting enzyme in hexosamine biosynthesis (380,381) (Fig. 24.5). After transport and phosphorylation of glucose to glucose 6-phosphate, the latter is used primarily in the synthesis of glycogen and in glycolysis. A small fraction (1% to 3%) of incoming glucose, after its conversion to fructose 6-phosphate, enters the HBP. The final step in the HBP is the formation of uridine diphosphate (UDP)-*N*acetylglucosamine (GlcNAc), which is a main substrate for protein glycosylation and whose intracellular levels are nutritionally regulated (382–385). The activities of many cytoplasmic and nuclear proteins appear to be regulated by glycosylation on their serine and/or threonine residues, including important enzymes and transcriptional factors (386,387). The HBP could be considered a prime example of a biochemical mechanism of nutrient sensing, in that it becomes activated by increased glucose fluxes (388).

Administration of glucosamine, which enters the HBP at a point distal to enzymatic amidation by GFAT, induced cellular insulin resistance to a degree comparable to that of hyperglycemia, even in the presence of normal glucose levels (389). Glucose-induced insulin resistance is blunted by inhibiting GFAT activity and expression (390), suggesting that the deleterious effects of hyperglycemia are mediated by activation of HBP. In vivo, infusion of glucosamine into conscious rats induced a pattern of impaired insulin-stimulated glucose uptake and glycogen synthesis that was similar to the glucose toxicity model described above (381). Furthermore, the effects of glucosamine infusion and chronic hyperglycemia were not additive in diabetic rats, indicating that it is likely that increased flux through the hexosamine pathway could account for the insulin resistance observed with hyperglycemia. The link between insulin resistance and HBP has been validated in transgenic models in which the overexpression of GFAT in muscle and fat leads to peripheral insulin resistance (391,392). HBP induces insulin resistance by inhibiting multiple sites in the insulin-signaling cascade, particularly activation of PI 3-kinase by insulin (393). Several groups have shown that insulindependent glucose uptake, as well as glycogen synthesis, is downregulated by HBP activation (394,395).

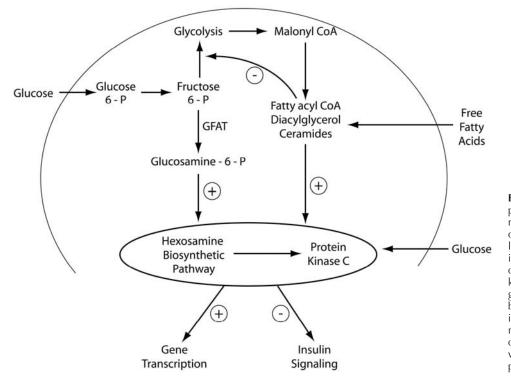

Figure 24.5. The role of nutrient-sensing pathways in the induction of nutrient-mediated insulin resistance. In the presence of increased glucose and insulin, intracellular generation of malonyl-CoA results in increased fatty acyl-CoA. Both the hexosamine biosynthetic pathway and protein kinase C (PKC) are activated by increased glucose and fatty acyl-CoA, and both probably contribute to insulin resistance by impacting gene transcription and insulin signaling. Increased flux through the hexosamine pathway has been shown to activate PKC. GFAT, glutamine:fructose-6-phosphate amidotransferase; P, phosphate.

Another potential mechanism for glucose-induced downregulation of insulin action is activation of the serine kinase PKC, described above. PKC is activated by the intracellular metabolite diacylglycerol, whose intracellular concentration increases in a glucose-dependent manner during exposure of isolated muscles to hyperinsulinemia (396). In NIH3T3 cells overexpressing the insulin receptor, PKC inhibitors blocked insulin desensitization by glucose (397). An intriguing potential link between glucoseinduced activation of the HBP and PKC was provided by the recent observation that both hyperglycemia and glucosamine activate PKC β and PKC δ (398). Indeed, cotransfection of dominant-negative versions of these PKC isoforms prevented the activation of PAI-1 promoter transcription by both sugars, because PAI-1 gene expression is known to be regulated by the HBP via glycosylation of the transcription factor Sp-1 (399). The potential collaborative role of these pathways in mediating insulin resistance is schematically outlined in Fig. 24.5.

INCREASED LEVELS OF CIRCULATING FREE FATTY ACIDS

Chronic elevations in circulating FFA levels are a classic feature of insulin resistance and type 2 diabetes (269,400). Their impact on insulin action in both skeletal muscle and liver will be discussed separately below.

Skeletal Muscle. Inadequate suppression of fatty acid oxidation by insulin is a common feature of various forms of insulin resistance in humans (401), and a strong, inverse correlation between glucose and lipid oxidation has been observed in obese subjects with type 2 diabetes (402). Randle et al. (403) first recognized this relationship between carbohydrate and lipid metabolism in heart and diaphragm muscle. The ensuing hypothesis was that a glucose–fatty acid cycle operates by decreasing the rate of oxidation of the alternate substrate in the presence of increased availability of the other (404). As initially proposed by Randle, an increase in fatty acid availability results in an elevation of the intramitochondrial acetyl CoA/CoA and NADH/ NAD⁺ (reduced form of nicotinamide adenine dinucleotide/ oxidized form of nicotinamide adenine dinucleotide) ratios, with subsequent inactivation of pyruvate dehydrogenase. This in turn causes an increase in citrate concentrations, leading to inhibition of phosphofructokinase. Subsequent increases in intracellular concentrations of glucose-6-phosphate were predicted to inhibit hexokinase II activity, resulting in an increase in intracellular glucose concentration and a decrease in muscle glucose uptake.

Many in vivo studies in both humans and animals have emphasized that, although an increase in circulating FFA levels during insulin-clamp studies promptly decreased the rate of carbohydrate oxidation, defective glucose uptake could be detected only after 3 to 4 hours of lipid infusion (405-408). Recent observations have led to a proposed mechanism whereby increased FFA levels lead to downregulation of insulin signaling in human skeletal muscle (409). Increased FFA levels have been shown to enhance phosphorylation of serine/threonine sites on insulin receptor substrates (IRS-1 and IRS-2), in turn reducing the ability of the insulin receptor substrates to activate PI 3-kinase and glucose transport (410). Moreover, an acute elevation of plasma fatty acids for 5 hours resulted in activation of the serine kinase PKCθ in skeletal muscle, which was associated with decreased tyrosine phosphorylation of IRS-1 (411). Chalkley et al. (412) have reported that lipid infusion for a comparable duration increased muscle levels of triglyceride and LCFA-CoA, which would be expected to cause an increase in diacylglycerol, a known potent activator of PKCθ (413). Activation of other PKC isoforms has recently been shown to be altered in skeletal muscle in FFA-induced insulin resistance. Increasing FFA levels for 2 hours in nondiabetic humans increased membrane-associated PKCβ2 and PKCθ (414). Additionally, fatty acid infusion reduced insulin-stimulated activation of PKC λ/ζ , an atypical PKC isoform required for insulin stimulation of glucose uptake and GLUT4 translocation, in muscle of normal rats (415).

Increased FFA levels may also promote inflammation. It has recently been hypothesized that FFAs may cause skeletal muscle insulin resistance by activating the serine kinase IKK- β , which subsequently leads to increased serine phosphorylation of IRS-1 (416). High-dose salicylate therapy, long known to be effective in lowering blood sugar levels in type 2 diabetes (417), has many antiinflammatory actions, including inhibition of IKK- β . Both high-dose salicylate therapy and targeted disruption of IKK- β prevented fat-induced insulin resistance and inactivation of IRS-1–associated PI 3-kinase in skeletal muscle (416).

The HBP, whose role in glucose-induced insulin resistance was discussed above, may provide a unifying mechanism for the metabolic effects of both glucose and FFAs (418). FFAs can inhibit the entry of fructose-6-phosphate into the glycolytic pathway, thereby causing a shunt of fructose-6-phosphate toward the formation of glucosamine-6-phosphate (419). Increased concentration of acetyl-CoA, derived in the mitochondria from the oxidation of fatty acids, decreases the rate of pyruvate oxidation via inhibition of pyruvate dehydrogenase (420). Furthermore, the entry of fructose-6-phosphate into the glycolytic pathway is also limited by the inhibition of phosphofructokinase, mediated by an increased concentration of citrate (403) or a decreased concentration of xylulose-5-phosphate or both (421). Indeed, sustained elevations in FFA levels in normal rats induced defects in insulin action and accumulation of skeletal muscle UDP-GlcNAc comparable to those observed in the presence of hyperglycemia and glucosamine infusion (382), suggesting that the increased intracellular fructose-6-phosphate provides substrate for the hexosamine pathway. Incubation of human myotubes with the saturated fatty acids palmitate and stearate resulted in a threefold to fourfold increase in expression of the mRNA of GFAT, the rate-limiting enzyme of the hexosamine pathway (422).

Liver. Increased circulating FFA levels also impair the suppressive effects of insulin on hepatic glucose production. Various mechanisms appear to contribute to this phenomenon. FFAs have been shown to stimulate gluconeogenesis in vitro (423), probably due to both increased production of ATP and NADH (424) and increased gluconeogenic gene expression (425). Additionally, chronic high-fat feeding in rats is associated with an increase in the activity ratio of hepatic glucose-6phosphatase/glucokinase, thus favoring increased hepatic glucose output (426). Although this model also demonstrated hyperinsulinemia and other metabolic abnormalities, it has recently been shown that increased FFA levels per se acutely induce the expression of hepatic glucose-6-phosphatase in normal rats (427). Transcriptional regulation of hepatic genes by lipids could potentially be mediated via the PPARs (428). Combined elevations of malonyl-CoA and cytosolic long-chain CoA may contribute to increased hepatic glucose production in obesity and type 2 diabetes (254). Conversely, hyperinsulinemia promotes conditions favoring FFA biosynthesis, thus further aggravating the metabolic conditions. High levels of malonyl-CoA, by suppressing CPT-1, induce a preferential flux away from FFA oxidation and toward esterification, with increased production of triglycerides and very-low-density lipopolysaccharides and an exacerbation of the hyperlipidemia and insulin resistance (254).

Oxidative Stress

Inducing conditions of oxidative stress in *in vitro* models results in reduced responsiveness to insulin (429) and impaired insulin signaling (430). Furthermore, the antioxidant lipoic acid prevents the induction of insulin resistance in the presence of oxidative stress (431). It has been proposed that activation of common stress-activated signaling pathways such as nuclear factor-KB, p38 MAPK, and NH₂-terminal Jun kinases/stress-activated protein kinases by glucose and possibly FFAs leads to both insulin resistance and impaired insulin secretion (432,433). Increased oxidative stress has recently been proposed as a potential unifying mechanism among many nutrient-activated pathways (434). Indeed, increased nutrient availability increases the production of reactive oxygen species and thereby results in activation of PKC isoforms, increased formation of glucosederived advanced glycation end-products, and increased glucose flux through the aldose reductase pathway (434). Although this relationship has been well established in endothelial cell models of diabetic complications, the role of oxidative stress in nutrient-mediated activation of PKC will likely also prove relevant in the pathogenesis of insulin resistance.

Aging

The final "environmental" factor that appears to contribute to insulin resistance is advancing age. An increased incidence of insulin resistance and type 2 diabetes has frequently been observed with both natural aging and progeria syndromes (435,436). Various characteristic features of aging that could predispose to insulin resistance include increased fat mass and particularly increased visceral adiposity (437,438), increased circulating levels of inflammatory proteins, and increased cellular accumulation of triglycerides (439). A consistent observation in multiple experimental models of aging is that chronic restriction of caloric intake markedly improves survival and prevents the onset of insulin resistance (440). It has been hypothesized that the beneficial effects of caloric restriction on the metabolic alterations of aging are largely accounted for by its prevention of visceral fat accumulation (441). Potential support for this theory is provided by the recent obervation that removal of visceral fat prevented insulin resistance and glucose intolerance in aging rat models of obesity and insulin resistance without altering plasma levels of FFAs (442).

It has recently been proposed that an age-associated decline in mitochondrial functions contributes to insulin resistance in the elderly (439). Indeed, mitochondrial oxidative and phosphorylation function as assessed by *in vivo* ¹³C/³¹P NMR spectroscopy was reduced by ~40% in association with increased intramyocellular and intrahepatocellular lipid content and decreased insulin-stimulated glucose uptake. Finally, it has been proposed that aging-induced resistance to the effects of leptin on fat distribution and insulin action contributes to the increased tissue lipid accumulation and insulin resistance (443). Of note, this aging-associated leptin resistance appears to be independent of fat mass, because long-term caloric restriction induced reductions in fat mass yet no improvement in sensitivity to leptin (444).

CONCLUSIONS

Obesity and type 2 diabetes are currently at epidemic levels both in the United States and around the world. Even more sobering is the prediction that, at current growth rates, the global prevalence of type 2 diabetes can be expected to essentially double within the next 20 years. Because the mortality and morbidity currently attributable to type 2 diabetes are already very high, the anticipated increase in the prevalence of type 2 diabetes is likely to bring an enormous healthcare burden. Although accompanying defects in insulin secretion are required for the development of frank diabetes, the significant contribution of insulin resistance to the pathogenesis of both type 2 diabetes and atherosclerotic disease underscores the clinical significance of this defect in hormone action.

As reviewed above, insulin resistance develops from the complex interplay of genes, obesity, and "environment," with the latter including nutritional and hormonal factors, as well as advancing age. Given the stable nature of the human genome, the burgeoning prevalence of insulin resistance is likely due to a rapid and dramatic lifestyle progression from hunting and gathering to farming to sedentary overeating. Indeed, genes that were selected over many millennia to favor energy efficiency and storage now appear to be highly maladaptive in the face of nutrient excess. There are complex and additive mechanisms whereby nutrient excess leads to insulin resistance, including the hormonal and proinflammatory effects of increased fat mass, as well as direct effects of nutrients on insulin action via nutrient-sensing pathways. To prevent toxic accumulation of nutrients in insulinsensitive tissues such as skeletal muscle, activation of nutrientsensing pathways such as the HBP and PKC may be interconnecting mechanisms to detect nutrient excess and inhibit further insulin-mediated glucose uptake.

Averting a global health crisis will require a reckoning of the toxic effects of current lifestyle trends and a radical adjustment in the ratio of calories consumed to calories expended.

SUMMARY 458

Type 2 diabetes mellitus is a worldwide health crisis; the World Health Organization predicts an incidence of 300 million by 2025 (1). The past decade has seen great progress in our understanding of the pathogenesis of type 2 diabetes (Fig. 25.1). The initial event is a genetic predisposition for glucose intolerance. Although specific polymorphisms or mutated genes are not yet known, many that affect the liver, skeletal muscle, adipose, β -cells, or brain physiology will undoubtedly be uncovered. Lifestyle and environmental factors also determine whether glucose intolerance develops (2). An observation from many cross-sectional and longitudinal studies is the presence of insulin resistance (from obesity, a high-fat diet, inactivity, aging, or a genetic basis) early in the course, even predating the hyper-

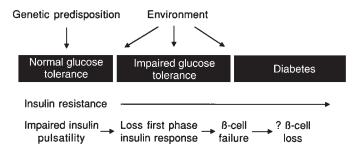

Figure 25.1. Proposed schema for the pathogenesis of type 2 diabetes. Predicted time points for the onset of various aspects of the β -cell dysfunction in this disease that are shown are based on the available literature, as reviewed in the chapter.

glycemia (3–7). This observation is so well known that type 2 diabetes is understood by most students and practicing physicians to be a disease of insulin resistance. However, several lines of investigation, summarized below, have established a crucial role for β -cell dysfunction.

- β-Cell dysfunction is always found in type 2 diabetes. Furthermore, it occurs early and likely predates the hyperglycemia (8–10).
- Insulin resistance changes little during the progression from impaired glucose tolerance (IGT) to diabetes. In contrast, β cell function undergoes substantial change. Cross-sectional and longitudinal studies have shown an increase in fasting insulin level and in insulin response to oral glucose in the early phases of the disease that keep glycemia normal despite the presence of insulin resistance, followed by a decrease when fasting glycemia surpasses 140 mg/dL (11,12). This inverted U-shaped curve of insulin levels (Fig. 25.2) was initially used to support the importance of insulin resistance in the early stages of the disease, as reflected in the increasing insulin output. However, more recent interest has focused on the decline—the so-called β -cell failure—as it coincides with, and is thought to cause, the progression from IGT to overt diabetes (9,10,13–15). Further, prospective study of persons with normal glucose tolerance (16) or IGT (17) showed that those with the lowest insulin response to a meal or to an oral glucose challenge (low insulin responders) carry the highest risk for developing type 2 diabetes later in life. These experimental observations highlight the importance of β-cell function in determining the glycemic status of at-risk persons.

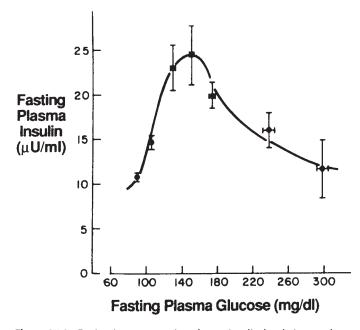

Figure 25.2. Fasting immunoreactive plasma insulin levels in nonobese subjects stratified by the level of glycemia. (From DeFronzo RA, Ferrannini E, Simonson DC. Fasting hyperglycemia in noninsulin-dependent diabetes mellitus: contributions of excessive hepatic glucose production and impaired tissue glucose uptake. *Metabolism* 1989;38:387–395, with permission.)

- Following the onset of diabetes, the β -cell dysfunction is reversible to a large degree by intensive glycemic control (18–20). In one of these studies (20), insulin pumps were used for 21 days in persons with type 2 diabetes. Improvement was observed not only in β -cell function but also in insulinmediated suppression of hepatic glucose production and in some lessening of insulin resistance. These findings established the concept that part of the diabetes phenotype is acquired from metabolic derangements in the prediabetes/IGT phase of the disease through glucotoxicity (21,22), β -cell exhaustion (23), or less well defined mechanisms. Dysmetabolism-induced acquired tissue dysfunction explains why type 2 diabetes presents a relatively uniform clinical syndrome in different ethnic groups and populations despite presumed diverse genetic causes.
- Over time, type 2 diabetes becomes less responsive to oral hypoglycemic therapy in tandem with worsening β-cell function (24,25). The working assumption is that pathogenic elements that lead to a loss in β-cell mass become operative.
- There is little information from human studies regarding the biochemical and molecular basis for the β-cell dysfunction in type 2 diabetes because of the unavailability of pancreatic biopsy. Instead, animals—both rodents and larger animals—have been the major venue of investigation, as their β-cell (dys)function with diabetes closely resembles that of humans. Animal studies have identified a panoply of β-cell abnormalities with diabetes. We do not yet know which mechanisms operate in humans, but it seems certain that the β-cell dysfunction will be multifaceted and will entail multiple mechanisms.

To summarize, there is now general acceptance that β -cell dysfunction plays a crucial and necessary role in type 2 diabetes. Indeed, most investigators in the field consider defective insulin secretion and tissue insulin resistance of equal impor-

tance in the development of this disease; in the vast majority of affected persons, both must be present for the diabetes syndrome to occur (26). Whether defective insulin secretion and tissue resistance to insulin represent pleiotropic tissue effects of a single defect or multiple abnormalities is unknown. Another understanding is that type 2 diabetes is a progressive disease. Loss of β -cell function, and possibly of β -cell mass, is believed to underlie this progression, highlighting the pivotal role of the β -cell in determining the natural history of this disease. Many excellent reviews on β -cell dysfunction in type 2 diabetes are available (27–32).

NORMAL β -CELL FUNCTION

Pancreatic β -cells regulate the storage and metabolism of cellular fuels through their secretion of insulin. This crucial function is accomplished through a feedback loop whereby glycemia upregulates β -cell function—insulin secretion, proinsulin biosynthesis, processing of proinsulin to insulin, and β -cell replication rate—and the secreted insulin in turn lowers glycemia by inhibiting hepatic and renal glucose production and increasing glucose uptake into target organs, primarily skeletal muscle. Glucose regulation of insulin secretion occurs directly (*glucoseinduced insulin secretion*) and also through modulation of the insulin response to insulinotropic hormones, nutrients, and neurotransmitters (*glucose potentiation of nonglucose secretagogues*; Fig. 25.3). These dual aspects of glucose-regulated insulin secretion are a potent modulatory system that ensures that the tissues' needs for insulin are exactly met in the fasting and post-

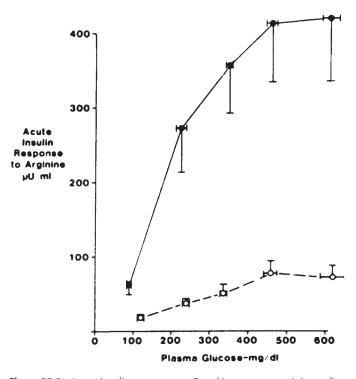

Figure 25.3. Acute insulin responses to 5 g of intravenous arginine at five different glucose levels in eight subjects with type 2 diabetes (*open circles*) and eight control subjects (*closed circles*). Insulin responses at all of the glucose levels are markedly attenuated in the subjects with type 2 diabetes. (From Ward WK, Bolgiano DC, McKnight B, et al. Diminished B cell secretory capacity in patients with noninsulin-dependent diabetes mellitus. *J Clin Invest* 1984;74:1318–1328, with permission from the American Society for Clinical Investigation.)

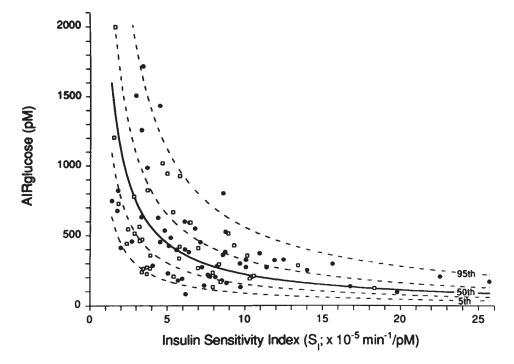

Figure 25.4. Curvilinear relationship between insulin sensitivity (S₁) and the first-phase insulin response (AlRglucose) in 93 normoglycemic subjects: 55 men (*closed circles*) and 38 women (*open squares*). Lines depicting the 5th, 25th, 50th, 75th, and 95th percentiles are shown. (Copyright © 1993 from the American Diabetes Association. From Kahn SE, Prigeon RL, McCulloch DK, et al. Quantification of the relationship between insulin sensitivity and β -cell function in human subjects: evidence for a hyperbolic function. *Diabetes* 1993;42:1663–1672, with permission from the American Diabetes Association.)

prandial states. The need for insulin is for the most part determined by the sensitivity of tissue to insulin—a curvilinear relationship exists with insulin secretion (Fig. 25.4) (33). Thus, even wide variations in insulin sensitivity such as the insulin resistance of puberty (34), pregnancy (35), and aging (36) do not normally affect glycemia. Also, dysfunction of the system can be determined by graphing insulin sensitivity and secretion from the experimental population to see if these values fall on the curvilinear curve (10,37,38). Another *in vivo* approach to testing the glucose-sensing character of β -cells uses a graded glucose infusion to produce a progressive increase in glycemia (39).

It is not only the amount of insulin released that is important. An acute increase in glycemia that can be approximated experimentally with intravenous glucose elicits a large burst of insulin secretion that lasts 5 to 7 minutes (first phase) followed by sustained insulin secretion that lasts for the duration of the hyperglycemia (second phase). Meals also induce a biphasic pattern of insulin secretion, although the phases are less distinct, with the early phase ascribed to the first 30 minutes and the later phase to the remaining postprandial hyperinsulinemia (1 to 2 hours normally). The biphasic pattern is necessary for normal mealtime glucose tolerance, with the concept being that the first phase primes the insulin-sensitive tissues for the coming food. Supporting this notion are studies that experimentally disrupted the early insulin response to a meal in otherwise healthy, normoglycemic subjects, causing impaired insulin-mediated tissue glucose disposal and excessive postprandial glycemia (40,41).

Insulin secretion occurs as oscillatory pulsations with a periodicity of 11 to 14 minutes, thought to be necessary to fully regulate hepatic glucose production (42,43). Also, large bursts of insulin release (*ultradian oscillations*) occur several times a day, particularly with meals (44), increasing the efficiency of nutrient clearance following meals (45).

Thus, the β-cell functions in a highly complex fashion that regulates the timing and overall insulin response to a meal to preserve normoglycemia. Quantitative insulin release and the pulsatile patterns can be tested *in vivo* by means of frequent insulin measurements to an appropriate stimulus. Also, the glucosesensing and pulsatile-secretion characteristics can be jointly tested with an oscillatory glucose infusion that causes small increases and decreases in plasma glucose levels. Insulin secretion normally attains an oscillatory pattern termed entrainment (46,47). Failure of entrainment has been identified as an early defect in insulin secretion that precedes abnormal responses to more traditional tests. In vivo testing has been aided by several technical advances over the last few years. Insulin-specific assays are now widely available that have eliminated the cross-reactivity with proinsulin and its conversion intermediates (which are biologically inactive) that affected earlier assays. Also, insulin is secreted into the portal vein and undergoes a substantial firstpass clearance by the liver (approximately 50%). Thus, insulin levels in the peripheral circulation only approximate insulin secretion. Many investigators now analyze C-peptide valuesthe portion of proinsulin that is removed as it is converted to insulin. C-peptide is secreted with insulin in an equimolar ratio but undergoes minimal hepatic degradation and thus can be used for calculating true rates of insulin secretion (48,49).

β-CELL DYSFUNCTION IN TYPE 2 DIABETES

β-Cell Unresponsiveness to Glucose

The distinctive β -cell defect in type 2 diabetes is the loss of the first phase of glucose-induced insulin secretion (Fig. 25.5). This observation was first made in the late 1960s, when persons with

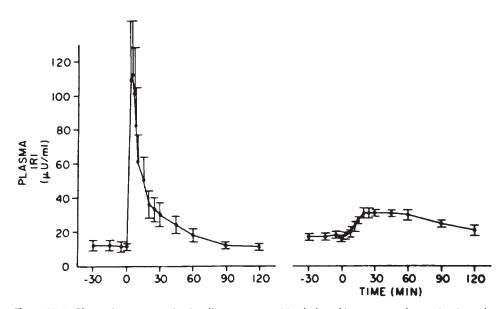

Figure 25.5. Plasma immunoreactive insulin response to 20-g bolus of intravenous glucose in nine subjects with type 2 diabetes (*right*) and nine normoglycemic control subjects (*left*). The first-phase insulin response (from 0 to 10 minutes) is totally lacking in the subjects with type 2 diabetes. In contrast, the second phase (from 10 minutes continuing for the duration of hyperglycemia) is intact in the subjects with diabetes and is greater than in the controls because of the persistent hyperglycemia in the subjects with diabetes following the glucose administration. (Reprinted from Pfeifer MA, Halter JB, Porte D Jr. Insulin secretion in diabetes mellitus. *Am J Med* 1981;70:579–588, with permission from Elsevier Science.)

type 2 diabetes were noted to have a delayed insulin response to intravenous glucose, and later was recognized as loss of the first phase. The second phase is also impaired but to a lesser degree (50,51). Subsequent investigation showed that this defect was fully established by the time the fasting glucose level reached 115 mg/dL (52), clearly predating overt diabetes, but was not present in persons with truly normal glucose levels in whom type 2 diabetes developed later (3,6). Thus, it first appears in the prediabetes state, termed IGT, which is clinically manifest as excess postprandial excursions of glycemia. Given the importance of the first-phase insulin response for normal prandial glucose tolerance (40,41), it follows that this defect is an important cause of the IGT state. Attesting to this idea is a study that simulated a burst of insulin with a short-term insulin infusion at the beginning of a meal in persons with type 2 diabetes, which resulted in a marked improvement in postprandial glycemia (53).

A major advance in our understanding occurred with the demonstration that intensive glycemic control restored the firstphase insulin response in subjects with type 2 diabetes (19). At about the same time, glucose-induced insulin secretion was shown to be impaired in diabetic animals (discussed subsequently). An important observation, made in diabetic rats, is that phloridzin reverses the defect (54). Phloridzin promotes glycosuria; it is used experimentally in diabetic animals to restore normoglycemia without changing insulinemia, thus helping to identify pathogenic effects of hyperglycemia. The understanding that has evolved from these findings is that the defect in glucose-induced insulin secretion occurs when β -cells are exposed to a "toxic" environment of an abnormally high level of glycemia (so-called *glucose toxicity*).

Insulin responses to nonglucose secretagogues are less impaired than those to glucose. When the defective glucoseinduced insulin secretion was first investigated, nonglucose agents were thought to be unaffected, a finding that led to the idea that the glucose response was uniquely deranged (*selective glucose unresponsiveness*). However, later studies that were more

carefully controlled for glycemia in the subjects with and without diabetes made it clear that responses to nonglucose secretogogues also were impaired, although less so than those to glucose. This challenged the concept that glucose unresponsiveness is the prototypical β -cell abnormality in type 2 diabetes; however, subsequent investigation (55) showed that the basis for the defective nonglucose-mediated secretion was impaired glucose potentiation (Fig. 25.3). The time of onset for the glucose potentiation defect is not as well defined as that for glucose-induced insulin secretion, and it is not clear if these dual abnormal effects of glucose on insulin secretion represent a single defect or separate biochemical/molecular defects in glucose sensing by the β -cell. Viewed together, type 2 diabetes entails defective glucose regulation of insulin secretion through both pathways-glucoseinduced insulin secretion (in particular the first phase) and glucose potentiation-emphasizing why fasting and postprandial hyperglycemia are defining characteristics of this disease.

For many years there was confusion about how β -cell dysfunction could be present in the prediabetes/IGT state, in particular the loss of the first-phase response, when countless studies had showed hyperinsulinemia (both fasting and after a glucose challenge or a meal) at that time (Fig. 25.2). Insight into this seeming paradox came with the understanding of the importance of the early insulin response for control of postprandial glycemia (40,41); loss of this early response results in an excessive mealinduced rise in glycemia, and this hyperglycemia causes the late insulin response to exceed that seen normally. Previous studies had generally looked at insulin levels 2 hours after a meal or oral glucose challenge and thus had missed the defect in early insulin secretion. This concept is shown in Figure 25.6, which shows the 30-minute and 2-hour insulin values after oral glucose challenge across a wide range of glycemia (29). Note the disparity as the early insulin response decreases with increasing glycemia at a time when later insulin release is increasing.

Thus, a characteristic feature of type 2 diabetes is loss of the first-phase insulin response to a meal. It occurs early in the

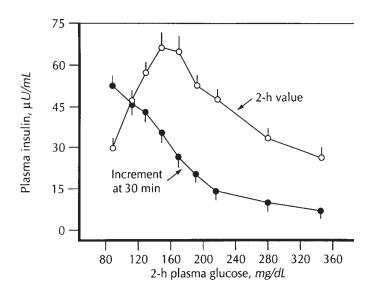

Figure 25.6. Comparison of 30-minute and 2-hour plasma insulin responses during oral glucose tolerance tests as a function of 2-hour plasma glucose values in 294 subjects. (From Gerich J, Van Haeften T. Insulin resistance versus impaired insulin secretion as the genetic basis for type 2 diabetes. *Curr Opin Endocrinol Diabetes* 1998;5:144–148, with permission.)

course of type 2 diabetes, predating fasting hyperglycemia, and is a major cause of the postprandial hyperglycemia that characterizes IGT and overt diabetes. This concept underlies the recent use of drugs for type 2 diabetes (meglitinides and phenylalanine derivatives) that are taken at meals to induce a rapid, short-lived insulin response.

Abnormal Pulsatile Secretion of Insulin

The pattern of orderly oscillations of insulin secretion with an 11- to 14-minute periodicity is lost in type 2 diabetes (56). Relatives of persons with type 2 diabetes show this defect when their glucose tolerance is normal (57,58), showing that it occurs early in the course of the disease. This might imply a genetic etiology. Countering that idea is a recent study showing recovery of oscillations in persons with type 2 diabetes after an overnight infusion of somatostatin, which pharmacologically blocks insulin release—interpreted by the authors as indicating that depletion of a readily releasable pool of insulin granules underlies the oscillation defect (59).

It is now generally accepted that the abnormal insulin pulsatility impairs normal regulatory control of insulin over hepatic glucose production. However, this understanding is relatively recent. The importance of the pulsatility defect was uncertain when first observed, as the magnitude of the pulsations in the normoglycemic control subjects was quite small (56): It was difficult to appreciate that such a minor effect would have any physiologic importance. Those studies used blood from the peripheral circulation. Insulin is secreted into the portal vein and undergoes substantial hepatic extraction. The breakthrough came with the understanding that the pulses are in fact large and are damped by hepatic extraction so that only a small fraction escapes the liver (42,60). Thus, the abnormal peripheral pulsations in type 2 diabetes represent very distorted insulin delivery to the liver, fitting with the idea of major dysregulation to the insulin-hepatic system. Future treatments might target this abnormality. For example, glucagon-like peptide-1 (GLP-1), which is under investigation as a hypoglycemic therapy for type 2 diabetes, increases pulsatile insulin secretion (61).

The ultradian oscillations—the large bursts of insulin that occur every 1 to 2 hours and more frequently with meals—also are disrupted in type 2 diabetes (62,63). This fact is well established, but the impact on glucose homeostasis is not totally clear. Regardless, pulsatile delivery of insulin holds a physiologic advantage, as evidenced by studies that have shown a greater hypoglycemic effect of pulsed versus continuously infused exogenous insulin (64). As such, loss of the pulsatile pattern of insulin secretion in type 2 diabetes disrupts this aspect of the glucose homeostasis system.

Increased Proinsulin-to-Insulin Ratio

The blood levels of insulin precursors (proinsulin and its conversion intermediates, which have only weak biologic activity) are disproportionately increased relative to insulin in type 2 diabetes (65,66). The same observation has been made in patients with diabetes caused by cystic fibrosis (67), a finding that raises the possibility that this disproportionate increase is another manifestation of hyperglycemia-induced β-cell dysfunction. However, the relationship of this increased ratio to hyperglycemia has been confused by seemingly inconsistent data. Most cross-sectional data show that the increased proinsulin/insulin ratio in type 2 diabetes occurs after the onset of hyperglycemia (68,69), with the ratio increasing as glycemia worsens (69,70). In disagreement are reports of an increased proinsulin/insulin ratio in the absence of glucose intolerance in populations at high risk for type 2 diabetes (71,72). Treatment studies to determine how reversal of hyperglycemia affects the proinsulin/insulin ratio also have not clarified its dependence on abnormal glycemia, because both improvement (73) and no effect (74) have been reported. Insight into this conundrum has come from the previously mentioned study that administered an overnight infusion of somatostatin to persons with type 2 diabetes; the proinsulin/insulin ratio was normalized by this pharmacologic inhibition of insulin secretion (59). This observation suggests that excessive insulin secretion, as opposed to hyperglycemia per se, underlies the raised proinsulin/insulin ratio. Another study of type 2 diabetes (75) and a study in diabetic sand rats (76) made a similar conclusion.

Our laboratory has studied diabetic rats in an effort to gain insight into the mechanistic basis for the raised proinsulin/insulin ratio (77-79). We first studied rats that had 90% of their pancreas removed (90% pancreatectomy) and observed an increased abundance of proinsulin-like peptides relative to insulin in pancreatic extracts, suggesting that the underlying defect was the storage, and subsequent secretion, of material enriched in proinsulin (77). We made the same observation in normal rats that received 48hour infusions of glucose (78). That study showed the increased ratio resulted from a decreased insulin content, not from an increased proinsulin content (Fig. 25.7). Also, co-infusion of diazoxide to inhibit insulin secretion blocked the increase in the proinsulin/insulin ratio, results analogous to those seen in humans infused with somatostatin (59). These findings are in accord with the previously stated concept that an ongoing hypersecretion of insulin leading to depletion of the releasable insulin stores is the cause of the enhancement in proinsulin secretion, likely through secretion of immature, proinsulin-enriched granules. Confirmatory evidence was obtained by infusing normal rats for 3 days with large amounts of the insulin secretagogue tolbutamide (plus glucose to keep them euglycemic) and observing a raised percentage of proinsulin in pancreatic extracts (78). Furthermore, this concept implies that there is no biochemical or molecular defect in the proinsulin-processing pathway in diabetes, which we demonstrated to be the case in glucose-infused rats (79).

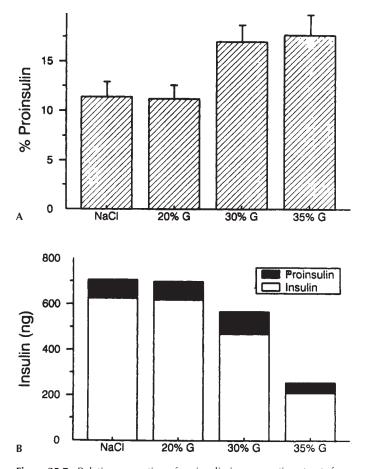

Figure 25.7. Relative proportion of proinsulin in pancreatic extracts from rats that received a 48-hour infusion with glucose. Pancreases underwent extraction, insulin/proinsulin precipitation, and separation of the insulins and proinsulins by high-performance liquid chromatography. Immunoreactive insulin and proinsulin were determined as the areas under the curve of the different peaks measured by insulin radioimmunoassay. **A:** % proinsulin = plasma immunoreactive insulin response (IRI) proinsulin/(IRI insulin + IRI proinsulin). **B:** IRI insulin and proinsulin in chromatography samples. Note that an increase in % proinsulin content. (Copyright © 1993, American Diabetes Association. From Leahy JL. Increased proinsulin/sulin/sulin ratio in pancreas extracts of hyperglycemic rats. *Diabetes* 1993;42:22–27. Reprinted with permission from the American Diabetes Association.)

Thus, the increased proportion of stored and circulating proinsulin in the diabetic rats appears to be secondary to a hypermobilization of granules, which leads to a rapid transit time and thus to incomplete processing to fully mature insulin. This hypersecretion scenario fits perfectly with the findings in patients with type 2 diabetes (59,75). However, enhanced insulin secretion per se is not enough to raise the proinsulin/insulin ratio, as is apparent from studies of nondiabetic obese subjects who are hyperinsulinemic but who have normal to lowered proinsulin/insulin ratios (68,80). Instead, some underlying element of β -cell dysfunction must be present as well.

β -CELL MASS AND STRUCTURE IN TYPE 2 DIABETES

The preceding discussion was of abnormalities that affect β -cell function. A second topic is whether the mass of β cells is lowered in type 2 diabetes and if so why? Relatively little is known about this subject, as investigation has been hampered by the

inability to obtain pancreatic biopsy samples from free-living humans. Further, there is no noninvasive way to assess β -cell mass, although interest in the development of techniques that will allow that goal to be reached is growing. We are thus dependent on autopsy studies that have quantified pancreatic β -cell mass. However, these studies are few and are open to interpretation because of incomplete physiologic/clinical information about the subjects or of inexact matching with controls. Finally, the technical challenge of measuring β -cell mass in humans is substantial, which means that none of the available studies (81-83) are large. As such, they usually are viewed collectively, leading to the conclusion that the β-cell mass is modestly lowered in type 2 diabetes. Illustrating that conclusion is the study by Klöppel et al. (83), which is noteworthy not only because it is one of the largest but also because it controlled for obesity. They observed a doubling of β -cell mass in the obese versus nonobese control subjects (showing why weight matching of subjects is so important for this kind of study) and a 50% reduction in β-cell mass in the obese and nonobese diabetic subjects compared with their weight-matched controls (83).

That β -cell mass is decreased in type 2 diabetes is generally well accepted, but it is not known when it occurs or how it is temporally related to the β -cell failure that leads to the development of hyperglycemia. This early stage of diabetes is characterized by considerable recovery of β-cell function following intensive glycemic control (18-20), which has led some to conclude that abnormalities in β -cell function, not mass, are foremost. In contrast, the United Kingdom Prospective Diabetes Study (UKPDS), a study of intensive treatment in new-onset type 2 diabetes, reported increases in glycemia over time, in tandem with worsening of β -cell function, whether diet, sulfonylurea, metformin, or insulin therapy was used (24,25). This observation has led to speculation that the waning β -cell function in longstanding diabetes stems from a declining β -cell mass. The cause of that effect is not known. It is clearly not immune-mediated and is thus distinct from type 1 diabetes: morphologically, the islets appear relatively normal (except for amyloid infiltration, which is discussed below), and insulitis is never present (84). Also missing is evidence for the hyperactivity that might be expected in response to the hyperglycemia, with few mitotic figures found (84) and only modest degranulation seen (85). A recent finding in some diabetic animals is increased β -cell apoptosis (86–89), although its relevance for human type 2 diabetes is unknown.

Islet Amyloid

The best-studied mechanism that might lead to accelerated β -cell death in type 2 diabetes is the development of islet amyloid (90–93). Islet amyloid deposits were first described nearly 100 years ago by Opie (94). Although these deposits were found commonly in type 2 diabetes, they were thought to hold little significance until the seminal study of Howard that correlated islet morphology with the clinical and metabolic status of *Macaca nigra* monkeys as they went from nondiabetes to diabetes (95). Howard reported that the appearance of islet amyloid coincided with, or immediately preceded, hyperglycemia and concluded that amyloid-induced destruction of islet β -cells caused metabolic progression to diabetes. This relationship, which also was observed in cats (96), spurred substantial interest in islet amyloid.

A breakthrough in this field occurred with the identification and cloning, simultaneously by two groups, of the peptide that makes up the amyloid deposits. This peptide was termed *amylin*; the more common term today is *islet amyloid polypeptide* (IAPP) (97,98). IAPP is a 37-amino-acid peptide normally produced in β -cells that is copackaged with insulin in secretory granules. The 25- to 28-amino acid sequence is conserved in humans, monkeys, and cats [Ala-Ile-Leu-Ser], all of which develop islet amyloid in tandem with diabetes. This amino acid sequence is necessary for the formation of amyloid fibrils, as shown by the lack of fibril formation *in vitro* or *in vivo* of IAPP from animals that lack this sequence (rats, guinea pigs, and mice). This dichotomy has proven useful for studies in transgenic mice that have overexpressed human IAPP in β -cells, as there is no risk of amyloid formation from the mouse's own IAPP (99,100). The normal function of IAPP remains controversial. It slows gastric emptying—whether this effect is physiologic or pharmacologic is debated—and clinical trials are in progress of the ability of an analogue of IAPP to decrease postprandial glucose excursions in persons with diabetes (101).

The effects of IAPP on β -cells have been studied extensively *in vitro* and *in vivo*. When placed in solution, IAPP forms fibrils, and these aggregates have been shown to be cytotoxic to islets *in vitro* (102,103). However, the relevance of this observation *in vivo* is debated. Studies in transgenic mice that have overex-pressed human IAPP have resulted in amyloid deposition and diabetes (99,100). However, a concern is that this requires very high levels of IAPP expression (99) or an accompanying insult, such as insulin resistance from growth hormone or dexamethasone treatment (104), or a high-fat diet (100). Whether this correquirement shows that IAPP is nonpathologic under normal conditions or that physiologically nonrelevant circumstances are required to induce pathogenic outcomes is still not clear.

Crucial questions must be answered before confirmation of a pathogenic role for IAPP and the amyloid deposits. There is no doubt that islets with amyloid deposits have a small β -cell mass with cellular distortion and destruction. The crucial question is which came first? Is the deposition of amyloid an early event that precedes hyperglycemia or does it occur only after mild hyperglycemia (and thus the β -cell functional failure) has developed? Do IAPP aggregates then induce functional and/or β-cell structural damage? Alternatively, is type 2 diabetes associated with β -cell death through an effect that is unrelated to IAPP such that the cellular stores of IAPP are released and form amyloid extracellularly among the cellular debris? Currently, there are no answers to these questions. However, studies of pancreas specimens that have been collected at autopsy from subjects who span the full range from nondiabetes to severe diabetes are in progress. The key information obtained from these studies should help determine the role of islet amyloid in this disease.

MECHANISMS OF β -CELL DYSFUNCTION

Glucose Toxicity

The hypothesis has been advanced that chronic hyperglycemia causes alterations in β -cell function, termed *glucose toxicity*. The idea started with the observation of substantial recovery of β -cell function in type 2 diabetes following treatments that restored normoglycemia (18–20). Also influential was the observation that diabetic animals have β -cell dysfunction similar to that in humans with type 2 diabetes (discussed below), supporting a causative effect of the metabolic environment. Subsequent biochemical and molecular studies of β -cell lines and islet tissue have uncovered plausible mechanisms for hyperglycemia-induced β -cell dysfunction. The term *glucose toxicity* was coined to represent tissue dysfunction from a hyperglycemic environment. Our own usage of the term is focused on the idea of a direct impairment effect of the raised glycemia on

 β -cell function as opposed to *exhaustion*, which is an indirect effect of hyperglycemia acting through a nonsustainable hypersecretion of insulin (23). The difference may seem subtle but becomes clear when reversal studies are performed with inhibitors of insulin secretion, as will be discussed subsequently. Generally, terminology that holds no exact mechanistic meaning is not advised. Regardless, the literature on type 2 diabetes and β -cell dysfunction is replete with these terms, and readers need to be familiar with their meanings.

Multiple rat models of experimental hyperglycemia have been studied for β -cell function, including the administration of streptozotocin during the neonatal period (105-107), partial pancreatectomy (108,109), and in vivo glucose infusions (110,111). Studies have also been carried out in a variety of rodents with spontaneous hyperglycemia, including GK rats (112), Zucker diabetic fatty (ZDF) rats (113), Otsuka Long-Evans Tokushima fatty (OLETF) rats (114), and many others. A universal finding is that secretion in response to glucose is impaired as opposed to secretion in response to nonglucose secretagogues such as arginine, glucagon, or tolbutamide, which are relatively unaffected (Fig. 25.8). This pattern of selective unresponsiveness to glucose closely resembles the pattern in human type 2 diabetes, as described. Just as important in terms of the concept of glucose toxicity is the complete absence of β cell unresponsiveness to glucose with normoglycemia, as determined in studies of animals without a genetic predisposition to diabetes or before the onset of hyperglycemia in animals that later go on to develop diabetes (113,114). This concept is further supported by the finding that glucose-induced insulin secretion *in vitro* or *in vivo* is recovered with therapies that reverse the hyperglycemia (115-117). The most influential of these studies in terms of identifying hyperglycemia as the causative factor was a study of phloridzin. As previously discussed, phloridzin promotes glycosuria and restores normoglycemia without changing plasma insulin or other metabolic factors and thus identifies tissue dysfunction related to hyperglycemia. Rossetti et al. (54) reported correction of the β -cell dysfunction in 90% pancreatectomized diabetic rats after phloridzin treatment.

Many biochemical and molecular mechanisms for the induction of β -cell dysfunction by hyperglycemia have been proposed based on studies of islet tissue from diabetic animals or the use of superphysiologic glucose concentrations in vitro. The proposed mechanisms include excess glycogen storage (118), impaired glucose transport into the β -cell (119), impaired activity of key signaling pathways such as the glycerol phosphate shuttle (120,121) or pyruvate carboxylase (121,122), defective ATP-sensitive channel activity (123-125), reduced expression of voltage-dependent calcium channels (126,127), defective hydrolysis of membrane inositol phospholipids (128), cycling of glucose-6-phosphate back to glucose through increased glucose-6phosphatase activity (129-131), altered Na+-K+-ATPase activity coupled with reduced myoinositol uptake (132), and loss of β cell differentiation (133). That there are so many possible mechanisms clearly demonstrates how "toxic" a hyperglycemic environment is for β -cells. Stated another way, it is almost certain that the β -cell dysfunction in human type 2 diabetes will stem from multiple biochemical/molecular defects.

β-Cell Exhaustion

A related concept is β -cell exhaustion or overwork, which we (23,134) and others (59) view as β -cell dysfunction from a nonsustainable hyperstimulation of insulin secretion. In that case, hyperglycemia is the stimulus for the β -cell dysfunction but is not the operative mechanism. This subtlety is revealed when reversal strategies are undertaken that use inhibitors of insulin

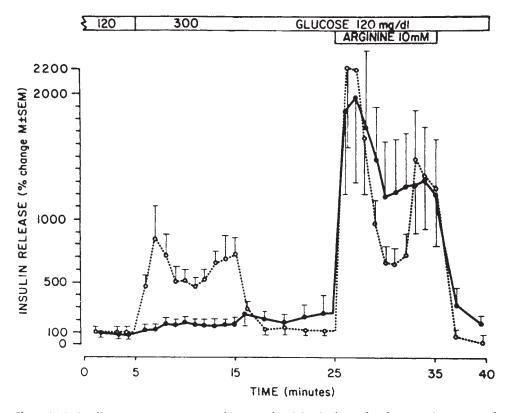

Figure 25.8. Insulin secretory responses to glucose and arginine in the perfused pancreatic remnant of 90% pancreatectomized diabetic rats (*solid line*) and normoglycemic control rats (*dotted line*). Studies were performed 8 to 11 weeks after pancreatectomy or sham surgery. Note the pattern of selective glucose unresponsiveness in the diabetic rats, as reflected in the brisk insulin response to arginine but the absence of response to a high level of glucose. (From Bonner-Weir S, Trent DF, Weir GC. Partial pancreatectomy in the rat and subsequent defect in glucose-induced insulin release. *J Clin Invest* 1983;71:1544–1553, with permission from the American Society for Clinical Investigation.)

secretion. The most studied inhibitor is diazoxide, although somatostatin has also been used. Glycemia is unchanged in these studies, or sometimes worsens, so that detrimental tissue effects of hyperglycemia versus hyperstimulated insulin secretion can be identified separately.

Support for the concept of β -cell exhaustion began with Sako and Grill (135), who reported that diazoxide prevented β -cell dysfunction in normal rats that were made hyperglycemic by a 48-hour glucose infusion in vivo. These investigators also showed a protective effect of diazoxide during long-term in vitro incubation of islets with high glucose and made the additional observation that the diazoxide effect resulted from preventing the insulin content of β -cells from declining below a critical level (136). Glucose-infused rats are markedly hyperinsulinemic, and the hyperglycemia is by necessity short term, so the applicability of the Sako and Grill study to the more usual situation of normal to subnormal plasma insulin levels with long-term diabetes was unclear. We treated rats that were diabetic from a 90% pancreatectomy with diazoxide for 5 days: Glucose-potentiated insulin secretion in response to arginine (a commonly used nonglucose secretagogue) normalized (Fig. 25.9). In contrast, the direct effect of glucose on insulin secretion improved minimally. The recovery of glucose potentiation occurred in tandem with normalization of the insulin content for the β -cell mass (137). A second mode for lowering insulin secretion, a 40-hour fast, produced similar results-a marked improvement in glucose potentiation but no change in glucoseinduced insulin secretion—this time using $\text{GLP-}1^{7\text{--}37}$ as the nonglucose secretagogue (138). GLP-17-37 is a member of the

incretin family of gut-released peptides that potentiate mealinduced insulin secretion (139,140). Both of these studies noted a linear correlation between the insulin content of the pancreas and glucose-potentiated secretion of insulin before and after treatments, findings that agree with those of Grill's laboratory concerning the crucial role of insulin content in the exhaustion concept (136). To further test the exhaustion hypothesis, we investigated the prediction that upregulation of insulin secretion in nondiabetic rats sufficient to lower the insulin content should impair glucose-potentiated secretion of insulin. Normal rats received a 48-hour infusion of high-dose tolbutamide (insulin secretagogue) plus enough glucose to maintain normoglycemia: The insulin content of the pancreas declined 50%, and as predicted, glucose-potentiated insulin secretion in response to arginine declined exactly in parallel (141).

These findings support a causative role for excessive insulin release in the defective glucose-potentiated secretion of insulin with chronic hyperglycemia. The concept is that a substrate, cofactor, cellular fuel, or other required substance is depleted, resulting in a lowered insulin response to meals. Our studies have focused on the potential role of the releasable pool of insulin stores as that factor. As already discussed, the same pathogenic mechanism has been linked to the increased proinsulin to insulin ratio and the abnormal pulsatile insulin secretion in type 2 diabetes (59). It is important to note that results supporting the exhaustion concept have been obtained in studies of human type 2 diabetes. Diazoxide therapy (142), a 4-day fast (143), and overnight infusion of somatostatin (59) all improved insulin secretion as opposed to their normal

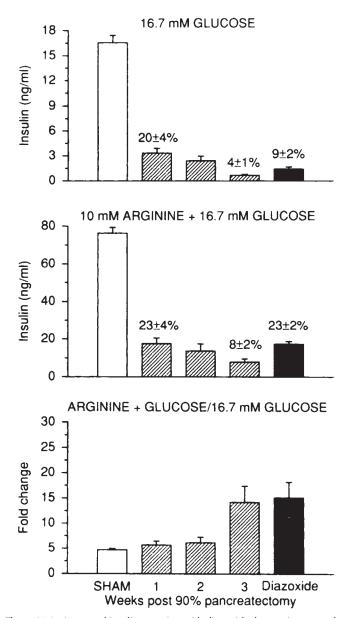

Figure 25.9. Increased insulin secretion with diazoxide therapy in rats made diabetic by 90% pancreatectomy. Insulin secretion in response to 16.7 mM glucose and 16.7 mM glucose/10 mM arginine was assessed with the *in vitro* perfused pancreas at weekly intervals after a 90% pancreatectomy. The percentage values above the bars are fractional output calculated from the results for the sham-operated control rats (*open bars*). Note the decrease in both insulin responses at 3 weeks after surgery, showing the onset of defective glucose responsiveness and glucose potentiation. A 5-day treatment period with diazoxide partially blocked the decrease in glucose-induced insulin secretion and normalized that to glucose/arginine (*solid bars*). (Data from Leahy JL, Bumbalo LM, Chen C. Diazoxide causes recovery of β -cell glucose responsiveness in 90% pancreatectomized diabetic rats. *Diabetes* 1994;43:173–179; and Leahy JL, Bumbalo LM, Chen C. Beta-cell hypersensitivity for glucose precedes loss of glucose-induced insulin secretion in 90% pancreatectomized fraction in 90% pancreatectomized and pance and pan

inhibitory effect, replicating the results in studies of diabetic rats (137,138).

Impaired Proinsulin Biosynthesis

It has been suggested that transcriptional control of proinsulin biosynthesis is impaired by chronic hyperglycemia and that this is a cause of the lowered insulin secretion in type 2 diabetes

25: β -cell dysfunction in type **2** diabetes mellitus 457

(144,145). This idea stems from extensive *in vitro* studies of β cell lines and isolated islets that established that several factors related to a high glucose environment cause defective activation of proinsulin transcription; these factors include lowered expression/binding of the activators PDX-1 (pancreatic duodenum homeobox factor-1; also termed somatostatin transcription factor-1 and islet duodenum homeobox-1) (146) and rat insulin promoter element 3b1-activator (147) and increased expression of the inhibitor C/EBP β (148). Additional support has come from studies in diabetic rats. Zangen et al. (149) reported impaired proinsulin transcription that paralleled lowered expression of PDX-1 in 90% pancreatectomized diabetic rats. Seufert et al. (150) reported similar results in ZDF rats in association with upregulation of C/EBP β expression (150). Harmon et al. (151) prevented hyperglycemia in ZDF rats with troglitazone, thereby eliminating the lowered gene expression of proinsulin, in association with recovery of PDX-1 expression/binding. A recent cross-sectional study of diabetic rats with various levels of hyperglycemia suggested that inhibition of gene expression of proinsulin requires severe hyperglycemia (133). We speculate that this effect plays a role in the β -cell dysfunction of markedly hyperglycemic type 2 diabetes but not in the β-cell failure of new-onset diabetes, in which hyperglycemia is typically mild for most patients.

Lipotoxicity

Other metabolic disruptions beside hyperglycemia make up the diabetic environment, including hypertriglyceridemia and elevated circulating and tissue levels of free fatty acids. A hypothesis about the pathogenesis of β -cell dysfunction secondary to these factors, called lipotoxicity, has evolved based on several experimental findings (152–155). Islets cultured with elevated levels of fatty acids develop β-cell dysfunction reminiscent of that in type 2 diabetes, namely lowered glucose-induced insulin release, impaired proinsulin synthesis, and accelerated β-cell apoptosis (156,157). Plausible biochemical and molecular mechanisms for the β-cell dysfunction were identified soon afterward. Fatty acids were shown to lower expression of IDX-1 (also called PDX-1), which is a key transcription factor for β -cell development, glucose metabolism, and proinsulin synthesis (158). Also, the well-known effect of fatty acids to impair glucose oxidation through lowered activation of pyruvate dehydrogenase, the so-called Randle cycle (159,160), was shown to be operative in fatty acid-cultured islets and was implicated in the lowered glucose-induced secretion of insulin (161). The most influential studies have been the extensive studies of ZDF rats by the Unger laboratory (155,162,163). These rats are obese and hyperlipidemic, and the males have large stores of triglyceride in islets in tandem with the spontaneous development of diabetes. These investigators have identified a well-characterized biochemical sequence of altered islet triglyceride metabolism that was shown to correlate with β -cell dysfunction and apoptosis. Unclear, however, is whether the findings from these studies of ZDF rats can be applied to other hyperlipidemic states, since the genetic abnormality in ZDF rats is a mutated leptin receptor that blocks leptin action and a leptin deficiency plays a central role in their identified pathogenic sequence (164,165).

Despite these findings, there remains uncertainty about the lipotoxicity concept. Of concern are the observations from several studies that used long-term lipid infusions in nondiabetic humans; most found minimal to no detrimental effect on insulin secretion (166–169). This is not surprising, as nondiabetic insulin-resistant states entail supernormal β -cell function/insulin secretion (33) despite the common occurrence of

hypertriglyceridemia (170). Also, reexamination of the biochemical defects that were purported to cause the fatty acid–induced β -cell dysfunction has led to questioning of some of the original findings. We (171) and others (172) observed no Randle cycle–induced impairment of glucose oxidation in fatty acid–cultured islets or β -cells. Also, the reported inhibitory effect of fatty acids on proinsulin biosynthesis (156) was not confirmed by an in-depth analysis (173). Finally, hyperlipidemia or raised islet triglyceride stores are clearly not mandatory for β -cell dysfunction in diabetic rats (174). None of these negative data eliminate the possibility of lipid-induced β -cell dysfunction. However, the concept needs to be investigated further to determine the role of lipid-induced dysfunction (if any) in type 2 diabetes.

SUMMARY

Debate about the importance of β -cell dysfunction in the pathogenesis of type 2 diabetes is over. Prospective studies of the progression to type 2 diabetes have highlighted the crucial role played by β -cell dysfunction. A notable example is the study from Weyer et al. that monitored insulin action, insulin secretion, and endogenous glucose output in 17 Pima Indians as they progressed from normal glucose tolerance to diabetes, compared with 31 Pima Indians who retained normal glucose tolerance over the same time (10). In those in whom diabetes developed, defects in both insulin secretion and insulin action were present when they were normoglycemic, but it was the lowering of the insulin response to intravenous glucose that best correlated with the progression from normoglycemia to diabetes. In addition, there is now a clear understanding that β -cell dysfunction continues to exert a major influence once diabetes develops, with a particular focus on the progression from oral monotherapy, to therapy with a combination of oral agents, to insulin therapy likely reflecting deteriorating β -cell function (24,25).

The past decade has seen considerable progress in our understanding of potential pathogenic mechanisms, and we are optimistic that we are on the threshold of identifying prevention and/or therapeutic strategies that will preserve β -cell function in this disease. However, major challenges remain, the foremost being the determination of the molecular, biochemical, and genetic bases for the β -cell dysfunction. Animal models have been the major investigative tools until now, but their relevance to human disease is still uncertain. Ways must be found to identify the defects that occur in humans and to design experimental systems that reproduce the human pathogenic condition. We must clarify the role of β -cell dysfunction versus loss of β -cell mass in the disease. The identification of ways of imaging β -cells noninvasively for both function and mass is a key requirement. Biochemical and molecular investigation into normal β -cell function and development must continue. Some of the most important recent advances are based on defining how β -cells work normally, for example, how β -cells grow and develop (175,176) and the role of islet neogenesis (177) are important topics of active investigation. Also, a functional role for "the insulin signaling cascade" within β -cells was identified just a few years ago (178–180). It is plausible that future breakthroughs will take advantage of signaling pathways or other aspects of β -cell physiology that are not yet known to exist.

It is almost certain that in the next decade our treatment of type 2 diabetes will change to take advantage of the incredible, and ongoing, scientific advances. Much attention will be focused on prevention. A reasonable prediction is that β -cell–directed therapies will play a crucial role in both endeavors.

CONCLUSION 474

The early clinical descriptions recognized that maturity-onset diabetes of the young (MODY) was a monogenic form of diabetes with a single gene mutation causing diabetes within a family. Our understanding of MODY has been transformed by defining the genes involved in this condition. MODY initially was defined solely by clinical criteria, but now a genetic subclassification is possible based on the description of six genes in which mutations have been described. With the description of the etiologic genes, there have been new clinical insights, and with each gene resulting in the description of discrete clinical and physiologic entities for mutation. The definition of the underlying molecular genetics frequently helps determine the likely clinical course, prognosis, and best treatment options. Recent classifications of diabetes by the American Diabetes Association (ADA) and the World Health Organization (WHO) (1) have recognized this by classifying MODY now as discrete subtypes of diabetes arising from mutations in specific β -cell genes. MODY is probably the first area of diabetes in which molecular genetics has played a clear clinical as well as research role.

EARLY DESCRIPTIONS OF MATURITY-ONSET DIABETES OF THE YOUNG

In the pre-insulin era, it was recognized that some patients with diabetes did not die and that these patients typically had a parent with diabetes. Cammidge noted in 1928 that "a dominant inheritance is almost invariably associated with a good prognosis" (2). It is likely that this is the first recognition of a clinical subgroup that was later known as MODY.

Strongly inherited young-onset familial diabetes subsequently was recognized and studied by Fajans in the 1960s and 1970s (3,4). In 1974, Tattersall recognized that an autosomal dominant inheritance was a feature of this condition (5). The term *MODY* was coined in 1975, although initially this stood for maturity-onset type diabetes of young people (6). Subsequently, a large number of families with variable phenotypes were described throughout the world. Although some of the phenotypic variation resulted in the use of different definitions, it became apparent that there was clinical heterogeneity in MODY, even if only white families with an age of onset of 25 years were considered (4,7). This clinical heterogeneity is now explicable in terms of genetic heterogeneity (8).

CLINICAL DEFINITION OF MATURITY-ONSET DIABETES OF THE YOUNG

In the vast majority of patients, it is now possible to define MODY as diabetes associated with β -cell dysfunction resulting from a specific mutation in a MODY-related gene. However, it is clearly not feasible to perform genetic studies on all subjects, and hence clinical criteria still are necessary to identify those patients in whom a mutation is likely. In addition, some subjects have MODY but the etiologic genes have not yet been defined. Criteria we propose are those used in genetic studies in the United Kingdom and France (8).

Early Onset Non–Insulin-Dependent Diabetes

By definition, a family is considered to have early onset diabetes if at least one and ideally two members of the family are diagnosed with diabetes before the age of 25 years, although it is recognized that other family members, particularly in older generations, may be diagnosed later.

Patients are considered non–insulin-dependent if 5 years after diagnosis they either are not receiving insulin treatment or are insulin treated but have significant levels of circulating C-peptide. Family members are considered to be affected either if they had diabetes by WHO criteria or, particularly in the case of glucokinase mutations, if they had fasting hyperglycemia (>6 mmol/L or >108 mg/dL) (9,10).

Autosomal Dominant Inheritance

The minimal criterion for autosomal dominant inheritance is the occurrence of diabetes in two generations, although most MODY families have at least three or more generations affected. In an autosomal dominant condition, only one of the two parents of an affected child should be affected. Therefore, considerable caution should be taken before defining a family in which both parents have diabetes as a MODY family, especially because children who inherit a "double gene dose" of type 2 diabetes from both parents also may have an earlier onset of diabetes (11).

Other Features

While early-onset, non–insulin-dependent diabetes and an autosomal dominant inheritance have typically been used for the definition of MODY, other features can help in identifying whether a particular family has MODY. The most important features follow:

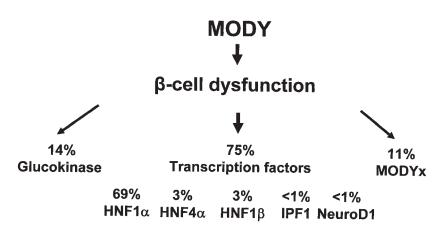

- β-cell dysfunction: β-cell dysfunction rather than insulin resistance is a characteristic of MODY. A young subject with acanthosis nigricans, the cutaneous marker of marked insulin resistance, is very unlikely to have MODY.
- Lean-body habitus: Subjects with MODY mutations do not need to be obese to develop diabetes, in marked contrast to most subjects with childhood or early onset type 2 diabetes (12). However, MODY cannot be excluded if a subject is obese, as most series suggest that obesity is similar to that seen in the normal population. However, it is unlikely to be a consistent feature of diabetes throughout a family.

DEFINITION OF THE GENETIC BASIS OF MATURITY-ONSET DIABETES OF THE YOUNG

The development of modern genetic techniques centered on the use of the polymerase chain reaction in the early 1990s has considerably helped in defining the genes in MODY. The definition of genes in monogenic MODY families was always likely to be considerably easier than defining genes in polygenic type 1 and type 2 diabetes, in which there are multiple genes and a large environmental component. The early onset favored the collection of large, multigeneration pedigrees that greatly facilitated analysis and gave a single family sufficient power to define a new locus or gene (9,13,14). Candidate genes were also relatively easy to define, as all families had a β -cell defect.

The breakthroughs in defining the genetic etiology came through the use of linkage methods. A candidate-gene approach was used in defining the role of the glucokinase gene in French and English MODY pedigrees (9,10). The major breakthrough, however, was the use of linkage to localize etiologic genes with a positional mapping approach that identified susceptibility loci on chromosome 20q (MODY1) and 12q (MODY3) (13,15). The MODY gene on 12q was defined as being hepatic nuclear factor (HNF) 1α (16). This was a seminal finding that led to the rapid recognition that HNF4 α was the MODY1 gene (17). It also clearly indicated that HNF1β (MODY5), which forms heterodimers with HNF1 α , was also an excellent candidate gene. The role of the HNF in β -cell function had previously been unsuspected. The description of insulinpromoter factor (IPF) 1 (also known as PDX1) as the MODY4 gene arose from observations in a family initially investigated because the proband had pancreatic agenesis, a condition seen in the IPF1 knockout mouse (14,18). It was shown that heterogeneity for a severe mutation caused MODY, while homozygosity for this mutation caused pancreatic agenesis.

A variety of approaches have therefore led to the identification of the genes involved in MODY. These observations opened new areas of understanding and research on β -cell physiology, pathophysiology, and genetics.

RELATIVE PREVALENCE OF THE DIFFERENT SUBGROUPS OF MATURITY-ONSET DIABETES OF THE YOUNG

Large national collections, particularly in the United Kingdom and France, allow assessment of the relative prevalence of the different subgroups of MODY. Figure 26.1 shows the relative contribution of the six known genes in United Kingdom pedigrees that have been collected principally from adult hospital clinics (19).

Although the prevalence of the mutations varies, $HNF1\alpha$ (MODY3) is the commonest cause in most MODY series. This depends on the strictness of the criteria for MODY used when recruiting families, the predominant method of recruiting families, and racial origin. In two large collections from France and Italy, glucokinase (MODY2) is the most prevalent subtype (20,21). This probably represents the detection of asymptomatic,

Figure 26.1. Distribution of MODY in the United Kingdom MODY collection. (Data from 131 families from Frayling TM, Evans JC, Bulman MP, et al. Beta-cell genes and diabetes: molecular and clinical characterization of mutations in transcription factors. *Diabetes* 2001;50[Suppl 1]: S94–S100; and A. T. Hattersley and S. Ellard, unpublished.)

mild fasting hyperglycemia in children based on recruitment from pediatric clinics or by screening young children in family studies (22). In contrast, the majority of other MODY series are recruited from adult diabetes clinics, where the majority of patients have symptomatic diabetes, so MODY3, with more marked hyperglycemia, is more common. It does appear that, even allowing for differences in diagnostic criteria and ascertainment, the prevalence of the known MODY genes is considerably lower in Japanese and Chinese series than in series of European whites.

As the different genetic subgroups of MODY have clear differences in clinical and physiologic phenotypes, they are discussed separately below and summarized in Table 26.1. A genetic classification is clinically useful, as the phenotypic differences between MODY2 and MODY3 are as marked as the differences between type 2 diabetes and either MODY2 or MODY3.

TABLE 26.1. Comparison of the Different Subtypes of Maturity-Onset Diabetes of the Young						
Characteristic	HNF4α (MODY1)	Glucokinase (MODY2)	HNF1α (MODY3)	IPF1 (MODY4)	HNF1β (MODY5)	MODYx
Chromosomal location Frequency in U.K. Mutations	20q 3% No evidence of a common mutation	7p 14% No evidence of a common mutation	12q 69% C insertion in the exon 4 C tract (codon 291) in 10%–15% of families with mutations	13q <1% D76N found in many populations but type 2 not MODY	17q 4% No evidence of a common mutation	Unknown 12% Not known
Penetrance of mutations at age 40 y	>90%	45% (>90% FPG >6 mmol/L)	>95%	?>80%	>95%	Not known
Onset of hyperglycemia	Adolescence Early adulthood	Early childhood (from birth)	Adolescence Early adulthood	?Early adulthood	?Similar to HNF1α	Uncertain
Severity of hyperglycemia	Progressive May become severe	Mild with minor deterioration with age	Progressive May be severe	Limited data: ?less penetrant than HNF1α	May be severe	Variable
Microvascular complications	Frequent	Rare	Frequent	Limited data	Frequent	Variable
Pathophysiology	β-cell dysfunction	β-cell dysfunction Glucose sensing disorder	β-cell dysfunction	β-cell dysfunction	β-cell dysfunction and insulin resistance	β-cell dysfunction
Non-diabetes- related features	Low plasma triglycerides	Reduced birth weight	Low renal threshold for glucose	Pancreatic agenesis in homozygotes	Renal cysts Renal failure	

HNF4α MUTATIONS (MATURITY-ONSET DIABETES OF THE YOUNG-1)

Molecular Genetics

MODY1 was the first genetic locus to be defined in MODY (13). The localization of the gene to the long arm of chromosome 20 by Bell et al. (13) was possible because of the collection of DNA samples and careful longitudinal study of the extensive RW pedigree by Fajans (23). Fine mapping of this gene was difficult, as linkage to MODY1 was rare (10). The major breakthrough in defining the MODY1 gene was the identification of the MODY3 gene as HNF1 α (16). This led to the rapid recognition that HNF4 α was the MODY1 gene and to the identification of a non-sense mutation Q268X that co-segregated with MODY in the RX pedigree (17) (see below).

Mutations in HNF4 α are considerably less common than mutations in HNF1 α , with fewer than 20 mutations being described during the first 5 years following the description of the gene [reviewed in reference (24)]. These mutations are distributed throughout the gene and consist of nonsense, frameshift, and missense mutations. Recently, it has been shown that the main HNF4 α isomer in the β -cell uses a farupstream promoter and alternative exon 1 (25). This P2 promoter has HNF1 and IPF1 binding sites. The critical regulatory role of these binding sites in the β -cell has been established by studies in HNF1 α knockout animals and the finding of a mutation that causes MODY in the IPF1 binding site (25,26).

Phenotype of Patients with HNF4 α Mutations

CLINICAL CHARACTERISTICS

The clinical phenotype of HNF4 α mutations is far more similar to the phenotype seen with HNF1 α mutations than the phenotype seen with the glucokinase mutations (Table 26.1). Children younger than 10 years of age who have HNF4 α mutations usually have normal glucose tolerance and develop diabetes in adolescence or early adulthood. In some families, the age at diagnosis is older than that in HNF1 α families, but this is not a consistent finding (27). Patients show worsening glycemia with increasing age as the result of progressive β -cell dysfunction.

HNF4 α is expressed in a wide range of cell types and tissues. Secretion of both glucagon from the α -cells and the pancreatic polypeptide (PP) cells is also reduced in patients with MODY1 (28).

PENETRANCE OF MUTATIONS

HNF4 α generally has a high penetrance, with the majority of subjects with a diagnosis of diabetes by the age of 25 years. Teenagers and young adults who have carried the mutation but who had not developed diabetes on repeated glucose tolerance testing have been described. In some families, the older age of diagnosis probably reflects reduced penetrance of specific mutations (27,29).

TREATMENT

As in patients with HNF1 α mutations, those with HNF4 α mutations show a progressive deterioration in glycemia and frequently require oral agents and insulin. Some patients have been successfully maintained for decades on sulfonylureas (30) and, like patients with MODY3, may be sensitive to the hypoglycemic effects of sulfonylurea therapy.

COMPLICATIONS

Both microvascular and macrovascular complications are frequent. The frequency is thought to be similar to that in subjects with type 1 or type 2 diabetes (4).

EXTRAPANCREATIC FEATURES

The main extrapancreatic manifestations described result from reduced transcription of hepatic target genes of HNF4 α . Reduced concentrations of the apolipoproteins apoA_{II}, apoC_{III}, and possibly apoB are found in patients with MODY1 but not in patients with type 2 diabetes (31,32). Triglyceride levels are decreased in patients with MODY1 in contrast to patients with type 2 diabetes, in whom levels are usually increased. This elevation probably reflects decreased lipoprotein lipase activity resulting from the reduction in apolipoproteins (31). In contrast to patients with mutations in HNF1 α , low renal threshold for glucose has not been reported in patients with MODY1.

PATHOPHYSIOLOGY

Patients with HNF4 α mutations have progressive β -cell dysfunction. This β -cell dysfunction is characterized by an inability to increase insulin secretion when blood glucose levels are high (33). In contrast to HNF1 α , prolonged hyperglycemia (18 hours) does not prime the β -cell in nondiabetic individuals (33).

CLASSIFICATION

The separation of patients with HNF4 α mutations from patients with mutations in other transcription factors would normally require molecular genetic diagnosis. The ADA classification proposes that an etiologic diagnosis be used, for example, genetic defect in β -cell function; chromosome 20 HNF4 α .

PREVALENCE

Mutations in HNF4 α are far less common than mutations in HNF1 α . In the United Kingdom, families with HNF4 α mutations represent 2% to 4% of MODY families (Fig. 26.1).

Disease Mechanisms in Maturity-Onset Diabetes of the Young-1

FUNCTIONAL CHARACTERISTICS OF MATURITY-ONSET DIABETES OF THE YOUNG-1 MUTATIONS

The functional characteristics of HNF4 α mutations associated with MODY1 have been studied extensively [reviewed in reference (24)]. The principal mutation mechanism is haploinsufficency, with the majority of mutations showing a considerable reduction of transcription activity *in vitro*: They are not "dominant-negative" mutations, because they do not significantly interfere with the activity of wild-type HNF4 α . The HNF4 α mutation associated with later-onset type 2 diabetes shows intermediate activity *in vitro* between wild-type and the mutations causing MODY (27).

Mechanisms Involved in Development of Diabetes in Maturity-Onset Diabetes of the Young

The mechanisms resulting in heterozygous mutations in the HNF4 α gene that cause β -cell dysfunction are not fully established. Studies by Stoffel and Duncan (34) using embryonic stem cells have established that HNF4 α regulates the expression of genes encoding components of the glucose-dependent insulin-secretion pathway, including glucose transporter 2; the glycolytic enzymes aldolase B and glyceraldehyde 3-phosphate dehydrogenase; and liver pyruvate kinase. The progressive loss

GLUCOKINASE MUTATIONS (MATURITY-ONSET DIABETES OF THE YOUNG-2)

Molecular Genetics

GLUCOKINASE AS A CANDIDATE GENE FOR MATURITY-ONSET DIABETES OF THE YOUNG

Glucokinase was the first MODY gene identified. The role of glucokinase in insulin secretion made it an ideal candidate gene for MODY. Glucokinase is one of four isoforms of hexokinase, enzymes that catalyze the first step in the metabolism of glucose: its phosphorylation to glucose-6-phosphate. Glucokinase is expressed principally in pancreatic β -cells and in hepatocytes. In β -cells, glucose phosphorylation is closely linked with the initiation of insulin secretion (35,36). Unlike the other hexokinases, glucokinase has a low affinity for glucose (K_m of 5.5 mmol/L or 99 mg/dL plasma glucose concentration) and is not inhibited by its product. These features allow β -cells and hepatocytes to change rates of glucose phosphorylation at physiologic glucose concentrations (4–15 mmol/L or 72–270 mg/dL). Glucokinase had consequently been termed the *pancreatic glucose sensor* (36).

MUTATIONS OF THE GLUCOKINASE GENE CAUSE MATURITY-ONSET DIABETES OF THE YOUNG

The characteristic of glucokinase strongly suggested that this might be an important candidate gene in type 2 diabetes. Tanizawa and colleagues in Permutt's laboratory at Washington University in St. Louis cloned the human gene and showed that it had a structure similar to that of the rat gene, with 12 exons and discrete pancreatic and hepatic promoters (37). The identification of two microsatellite polymorphisms flanking the glucokinase gene led to the description in early 1992 of linkage in French and English MODY pedigrees (9,10).

MOLECULAR GENETICS OF THE GLUCOKINASE GENE

The demonstration of linkage between MODY and the glucokinase gene was quickly followed by the characterization of the human gene and the detection of mutations (38–40). The first mutation was reported in 1992 (38), and more than 100 mutations of the glucokinase gene have now been described in many populations, with the majority found in France and Italy (20,21, 38–43). All these mutations have been associated with mild to moderate hyperglycemia.

It is interesting that one mutation is associated with the opposite phenotype, that is, hypoglycemia associated with hyperinsulinemia (44). This is due to a gain-of-function mutation that results in overproduction of insulin. Homozygous loss-of-function mutations in the glucokinase gene have recently been shown to result in permanent neonatal diabetes that is severe and requires insulin treatment from birth (45).

Mutations associated with hyperglycemia are distributed throughout the gene, and different mutation mechanisms, with nonsense, missense, frameshift, and splice-site mutations, having all been described. The mutations associated with MODY2 have been shown to have reduced activity when expressed *in vitro*. Many mutations alter the maximal activity of the enzyme for glucose phosphorylation or alter its affinity for glucose (46). Other mutations, distant from the glucose binding cleft of the enzyme (encoded by exons 5, 6, 7, and 8), either can alter the structure by a major alteration in protein structure as a result of nonconservative changes in amino acid or can alter adenosine triphosphate phosphorylation (47,48).

Phenotype of Patients with Glucokinase Mutations

CLINICAL CHARACTERISTICS

Despite the wide variety of mutations (49), alterations in the glucokinase gene result in a discrete phenotype, summarized in Table 26.1. An increased fasting blood glucose is a consistent feature, and the majority of patients have blood glucose values within a tight range of 6 to 8 mmol/L or 108 to 144 mg/dL (Fig. 26.2). A fasting glucose level below 5.5 mmol/L is extremely rare in MODY2 patients, and no patients with mutations have had fasting glucose values consistently below 5.5 mmol/L (50). There is a mild deterioration in fasting blood glucose levels with age, but blood glucose levels in patients in their eighth and ninth decades still rarely exceeded 9 mmol/L (50–52). This mild hyperglycemia is present very early in life, and patients have been described who have hyperglycemia in the first weeks of life (53). Recent observations showing altered birth weight and fetal growth support the concept that these changes in the β -cell function are present before birth (43).

Patients with glucokinase mutations are usually asymptomatic throughout their life and rarely have symptoms of hyperglycemia. The vast majority will be detected by screening either for routine medical examinations, during pregnancy, or family screening when MODY is suspected (9,54). In most patients, the age of diagnosis is the age at which they are first tested. While being diagnosed young is supportive of a glucokinase mutation, the fact that a patient is diagnosed only in old age should not be used to exclude the diagnosis. More than in any other type of diabetes, MODY2 may be diagnosed decades after the age of onset.

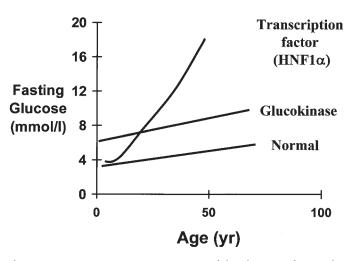

Figure 26.2. Diagrammatic representation of the change in fasting glucose with age in untreated patients with HNF1 α and glucokinase mutations. (Based on data from Hattersley AT. Maturity-onset diabetes of the young: clinical heterogeneity explained by genetic heterogeneity. *Diabet Med* 1998;15:15–24; Stride A, Vaxillaire M, Tuomi T, et al. The genetic abnormality in the beta cell determines the response to an oral glucose load. *Diabetologia* 2002;45:427–435; and Pearson ER, Velho G, Clark P, et al. Beta-cell genes and diabetes: quantitative and qualitative differences in the pathophysiology of hepatic nuclear factor-1alpha and glucokinase mutations. *Diabetes* 2001;50[Suppl 1]:S101–S107.)

TREATMENT

Patients with glucokinase mutations rarely need any pharmacologic treatment (51,52). The majority of patients with glucokinase mutations (>85%) are treated with diet alone. Avoiding unrefined carbohydrate may not be as important as in patients with type 2 diabetes, because most patients with glucokinase mutations show little increment in their blood glucose on receiving 75 g of glucose in an oral glucose tolerance test (50,52,55). Another interesting observation is that body mass index makes little difference to the level of glycemia in patients with glucokinase mutations (50,51). This is in marked contrast to patients with type 2 diabetes, in whom weight loss can very effectively reduce glycemia. In patients with glucokinase mutations, this is probably because the fasting hyperglycemia is due to a defect in glucose sensing; thus, as in the healthy subject, increased insulin resistance as a result of obesity results in compensatory hyperinsulinemia rather than hyperglycemia. The only time that patients with glucokinase mutations are likely to consistently receive treatment is during pregnancy (see below).

COMPLICATIONS

Patients with MODY2 rarely suffer from microvascular complications (42,51), probably because their hyperglycemia is mild. The rare cases of proliferative retinopathy and diabetic retinopathy reported in the French series may represent coincidental conventional type 2 diabetes in patients who also have a glucokinase mutation. It is hard to assess whether patients with MODY2 have significant macrovascular complications, because only 500 patients have been described in the literature. An increased risk of macrovascular disease is seen in patients with impaired glucose tolerance, so an increased risk might be expected in subjects with glucokinase mutations (56). However, in contrast to patients with impaired glucose tolerance, patients with glucokinase mutations have normal fasting lipid concentrations (51), are not significantly insulin resistant (9), and have less postprandial hyperglycemia (50,52,55). These factors are all likely to reduce the macrovascular risk in patients with glucokinase mutations.

PATHOPHYSIOLOGY

In keeping with our understanding of the biochemistry of glucokinase, patients with glucokinase mutations have been shown to have β -cell dysfunction characterized as a defect in glucose sensing (9,51,57,58). First-phase insulin response to an intravenous glucose bolus is well preserved (57).

Patients with glucokinase mutations do not show the features of insulin resistance seen in type 2 diabetes. Insulin concentrations and plasma lipids are normal, and in most series there is no increase in insulin resistance (9,51). In a large series of French patients, a small but statistically significant increase in insulin resistance was found in patients with glucokinase mutations with diabetes compared both with patients with glucokinase mutations who have only fasting hyperglycemia and with normal controls (59). There are many possible explanations of this result: severe glucokinase mutations may affect both β -cell function and insulin sensitivity, the insulin resistance was secondary to glucose toxicity, or these patients had other genetic or environmental influences that predispose to type 2 diabetes resulting in their reduced glucose tolerance and insulin resistance. It has clearly been demonstrated that patients with glucokinase mutations do have reduced hepatic glycogen synthesis, confirming that glucokinase is a ratedetermining step in the liver as well as in the pancreatic β -cell (60).

CLASSIFICATION

The same glucokinase mutation has been identified in patients who were defined as having MODY, type 2 diabetes, or gestational diabetes (40,61), depending on when the diagnosis was made. There was no evidence of a different phenotype in these three groups (62). This shows the difficulties of a clinical classification for which the time of diagnosis determines the classification of the type of diabetes. Patients with a glucokinase mutation appeared to have a discrete phenotype, and hence a classification based on etiology had been proposed (62,63) and supported by the ADA as "genetic defects of β -cell function; chromosome 7, glucokinase" (64).

PREVALENCE

The prevalence of glucokinase mutations is difficult to assess, because the mild hyperglycemia and absence of symptoms means patients frequently do not receive a diagnosis. No large-scale population studies to assess the prevalence of glucokinase mutations have been done. In the white population, approximately 2% of the population will be diagnosed as having gestational diabetes, and of these, approximately 2% to 5% (65) will have a glucokinase mutation. This would suggest a population prevalence of 0.04% to 0.1%.

The prevalence of patients with MODY who have glucokinase mutations ranges from as high as 56% in France (20), to 12.5% in the United Kingdom (43), and to less than 1% in Japan (66). This probably reflects differences in ascertainment (see previous section), as well as a genuinely lower prevalence in Japan than in Europe.

Glucokinase Mutations and Pregnancy

DIAGNOSIS OF GLUCOKINASE MUTATIONS AS GESTATIONAL DIABETES

Patients with glucokinase mutations are frequently diagnosed during screening in pregnancy. In the series of European whites, the prevalence of glucokinase mutations ranged from 0% to 6% (65). The recognition of subjects with glucokinase mutations is important, because they have a different clinical course both within and outside pregnancy compared with most other subjects with gestational diabetes. Patients' clinical characteristics can be used to detect those who are most likely to have a glucokinase mutation. Specific criteria favoring a diagnosis of a glucokinase mutation have been shown to be persistent fasting hyperglycemia, a small increment on the oral glucose tolerance test (<3 mmol/L or <54 mg/dL), and a family history of mild hyperglycemia (65).

FETAL GROWTH IN PREGNANCIES OF WOMEN WITH GLUCOKINASE MUTATIONS

Fetal growth in pregnant patients with MODY2 has been shown to be dependent on whether the fetus has inherited the mutation from its mother (43). Fetal insulin secretion is a key determinant of fetal growth, acting mainly during the third trimester when the weight of the fetus increases markedly. Macrosomic children born to mothers with diabetes in pregnancy have increased fetal insulin secretion in response to fetal pancreatic sensing of maternal hyperglycemia. Factors that alter fetal insulin secretion will therefore alter intrauterine growth by altering fetal insulin-mediated growth.

A glucokinase mutation in a pregnant mother will result in maternal hyperglycemia, hence increasing fetal insulin secretion and fetal growth. Inheritance of the mutation by the fetus will result in reduced sensing of the maternal glucose by the fetal pancreas and hence reduced fetal insulin secretion and

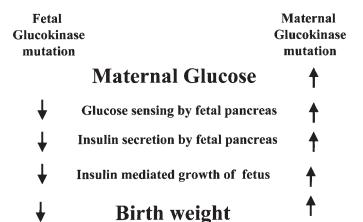

Figure 26.3. The contradictory effects of a fetal and maternal glucokinase mutation on birth weight are mediated by the fetal mutation resulting in reduced fetal insulin secretion and a maternal glucokinase mutation resulting in maternal hyperglycemia and hence in increased fetal insulin secretion.

reduced intrauterine growth. The two contradictory effects of glucokinase mutations are shown in Figure 26.3. The effects of inheriting a glucokinase mutation by either mother or fetus are considerable. Children born to mothers with a glucokinase mutation were 601 g heavier at birth than children born to mothers without a glucokinase mutation, and children who inherited a glucokinase mutation weighed 521 g less than children without a glucokinase mutation. Figure 26.4 shows the effects of fetal and maternal mutations on mean birth weight centiles, showing that the two effects are additive. When both mother and fetus had the glucokinase mutation, two opposing effects canceled out and the baby was of normal weight.

These observations have important theoretical implications. They establish that glucokinase plays a key role in the sensing of glucose by the fetus in utero. It also led to a more wide-ranging hypothesis described as the "fetal insulin hypothesis" (67). This proposes that genetic defects that alter either fetal insulin secretion or fetal insulin action could, by reducing insulin-mediated growth, reduce birth weight. This therefore provides a potential explanation of the association seen between low birth weight and diabetes in adult life. This association had previously been attributed to intrauterine programming as the result of intrauterine malnutrition. The relative importance of these two factors may vary between populations and requires further study. It is likely that both the intrauterine environment and fetal genetics are important in explaining the association.

MANAGEMENT OF PREGNANCIES INVOLVING GLUCOKINASE MUTATIONS

The observations of the impact of glucokinase mutations on fetal growth are important for the management of the pregnancies of mothers who have glucokinase mutations. These mothers will have fasting hyperglycemia that will not respond to dietary measures. Most modern recommendations suggest that such patients are treated with insulin, achieving normoglycemia, and many subjects with glucokinase mutations therefore are treated with insulin during pregnancy. However, recent observations have suggested that the fetal genotype is a far greater determinant of pregnancy outcome than is treatment of the mother with insulin. In addition, it is debatable whether the achievement of maternal euglycemia is desirable if the baby has a mutation, because this may result in a small baby (68). The baby is small if the fetus inherits a mutation from the father and is born in a normal mother (67,69). Treatment decisions in glucokinase gestational diabetes should therefore be related to fetal growth as shown by scans rather than to maternal glycemia levels alone, as has been proposed in other types of gestational diabetes. Fetal hypoglycemia is not seen when the fetus has inherited the mutation, and the newborn child will have mild fasting hyperglycemia that is unlikely to progress [reference (53); and G. Spyer and A. T. Hattersley, unpublished data].

The recognition that a patient has a glucokinase mutation is also important for the subsequent treatment of the mother. It is likely that, even if she has been receiving very large doses of insulin, she will not require pharmacologic therapy after the pregnancy. In contrast, in subjects with gestational diabetes that is not due to a glucokinase mutation, deterioration to type 2 diabetes over the following 10 years is unlikely.

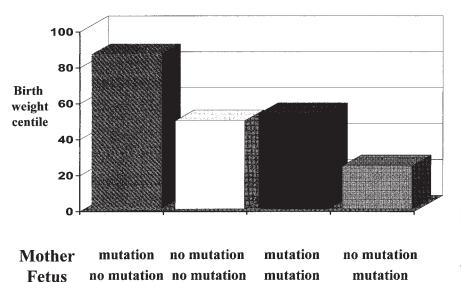

Figure 26.4. Birth weight centile according to maternal and fetal mutation status in families with glucokinase mutations. (Data from Hattersley AT, Beards F, Ballantyne E, et al. Mutations in the glucokinase gene of the fetus result in reduced birth weight. *Nat Genet* 1998;19:268–270.)

HNF1α MUTATIONS (MATURITY-ONSET DIABETES OF THE YOUNG-3)

Molecular Genetics

Graeme Bell's group in Chicago and collaborators from France, the United Kingdom, Japan, Denmark, and the United States were first to show that the transcription factor HNF1 α encoded the MODY3 gene (16). Studies of MODY pedigrees in United Kingdom (70), Germany (71), France (72), Denmark (73), Italy (74), Finland (75), North America (75), and Japan (76) confirmed that HNF1 α mutations are the most common known cause of MODY. Although many different mutations occur, approximately 15% of the families with an HNF1α mutation have an insertion of an extra nucleotide (C) in the C tract in exon 4, leading to a frameshift (mutation P291fsinsC). This common mutation is thought to result from a hotspot for spontaneous mutations rather than representing a single distantly related family (71,75,77). More than 100 other mutations have been found scattered throughout the gene and consist of frameshift, missense, nonsense, and splice-site mutations.

Phenotype of Patients with HNF1α Mutations

CLINICAL CHARACTERISTICS

The phenotype associated with HNF1 α mutations is markedly different from that found in patients with glucokinase mutations (Table 26.1 and Fig. 26.2). Most subjects under the age of 10 years have a normal fasting blood glucose level and normal glucose tolerance. In adolescence and early adulthood, subjects with HNF1 α mutations may show no, or only minimal, elevation of fasting blood glucose level but are frequently diabetic on the 2-hour value in an oral glucose tolerance test (50). The mean age for the clinical diagnosis of diabetes is 23 years. Most subjects present with symptoms related to hyperglycemia (54). Glycosuria is an early marker as a result of the reduced renal threshold in these patients (78,79).

PENETRANCE OF MUTATIONS

HNF1 α mutations have a high penetrance, with the majority of subjects having diabetes by the age of 25 years (52,70). However, diabetes was not diagnosed until middle or old age in some subjects found to carry HNF1 α mutations; it is difficult to determine whether this is due to a delayed diagnosis, a later onset of diabetes, or both. Frequently, the subjects with HNF1 α mutations who do not have diabetes on testing are young and diabetes is likely to develop later in life (70). Some individuals reach early middle age without having diabetes, and these unusual cases probably represent reduced penetrance of the gene mutation (80). These subjects may compensate for their β -cell defect by being sensitive to the insulin or may have a less severe β -cell defect.

TREATMENT

In contrast to the relatively stable mild hyperglycemia seen in patients with glucokinase mutations, once diabetes develops in patients with HNF1 α mutations, they show progressive deterioration in their glucose tolerance (Fig. 26.2). Their treatment requirements are also likely to increase as they get older. Approximately one third of subjects with diabetes who have HNF1 α mutations are treated by diet; one third, with oral agents; and one third, with insulin. The patients receiving insulin tend to be older and more obese than those treated with diet or oral agents. Some patients are misdiagnosed as having

type 1 diabetes because they present with osmotic symptoms in their late teens or early twenties with a random blood glucose in the region of 15 to 20 mmol/L and are started immediately on insulin treatment. Such patients may be recognized by their autosomal dominant family history, the absence of typical type 1 diabetes human leukocyte antigen markers, excellent glycemic control despite relatively low doses of insulin (usually <0.5 U/kg), and an absence of ketoacidosis even when insulin is omitted.

Patients with HNF1 mutations may show marked sensitivity to the hypoglycemic action of sulfonylureas (81,82). This is particularly marked at diagnosis and during the first 10 years of disease. This may result in marked symptomatic hypoglycemia while starting therapy. In patients with type 2 diabetes, metformin and sulfonylureas are equally effective in reducing hyperglycemia, but in patients with HNF1 α mutations, there have been reports of marked deterioration in glycemic control on transferring from sulfonylureas to metformin, with a subsequent decrease in glycosylated hemoglobin A1c (HbA1c) of 4% to 5% when they return to sulfonylureas (82). Therefore, low-dose sulfonylureas are the appropriate first-line medication for patients with HNF1α mutations, although they must be introduced with caution. This is an example of pharmacogenetics and is a clear reason for establishing the cause of early onset non-insulin-dependent diabetes.

COMPLICATIONS

Microvascular complications, particularly retinopathy, can develop, especially if treatment of hyperglycemia is inadequate (60,83). This means that it is important to strive for excellent glycemic control. The pattern of complications and also of vascular dysfunction is similar to that seen in type 1 diabetes (84). In both of these subgroups of diabetes, the primary pathophysiology is in the β -cell, with insulin resistance and dyslipidemia less frequently seen than in type 2 diabetes.

PATHOPHYSIOLOGY

The pathophysiology in patients with HNF1 α mutations is a progressive β -cell defect (8,52,85). Physiologic experiments have shown that the patients who have inherited the HNF1 α mutation but are not yet diabetic show adequate insulin when fasting but are unable to increase their insulin secretion as glucose levels rise. Once patients have established diabetes, insulin secretion is reduced at all glucose values (85). Prolonged hyperglycemia (18 hours) primes the β -cell in nondiabetic but not in diabetic mutation carriers (85). Increased sensitivity to insulin is seen in mutation carriers, and the mechanism for this is unknown (52)

CLASSIFICATION

Most subjects with HNF1 α mutations present with symptomatic diabetes and have hyperglycemia in the diabetic range by adolescence or early adulthood. The recent ADA classification now suggests an etiologic diagnosis be used, for example, genetic defect in β -cell function; chromosome 12 HNF1 α .

PREVALENCE

Mutations in HNF1 α are the commonest cause of diabetes in European white patients with MODY. If strict criteria are used, then a prevalence of this form of MODY among patients with MODY is 50% to 90%, but the prevalence is lower when less stringent criteria are used. We estimate that these patients account for approximately 1% to 2% of white patients in a diabetes clinic, although many of these cases may not be formally

recognized as MODY (86). This would result in a population frequency of approximately 0.02% to 0.04%.

Extrapancreatic Manifestations: Low Renal Threshold for Glucose

The early descriptions of MODY described a discrete subgroup of MODY families who had a low renal threshold before diabetes develops (5,87). It has now been shown that these patients had a mutation in HNF1 α (65) and that a low renal threshold is a feature of other patients with MODY3 (78,79). This is probably due to reduced expression of the high-capacity/low-affinity sodium-glucose transporter-2 (SGLT-2), reducing glucose reabsorption in the proximal tubule (88).

Disease Mechanisms with HNF1 α **Mutations**

The disease mechanisms that result in HNF1 α mutations causing β -cell dysfunction are complex. There is evidence that dominant-negative mutations in cell lines reduce many critical components of carbohydrate metabolism, resulting in reduced GLUT2 transporter expression and mitochondrial dysfunction (89–91). In addition, there is evidence of increased apoptosis and reduced β -cell proliferation (91–94).

One fascinating feature is that mutations in the different transcription factors result in a very similar pattern of β -cell dysfunction even though there is considerable variation in the extrapancreatic features (see previous section). This would suggest a common mechanism or common pathway resulting in β -cell dysfunction. There is increasing evidence that the MODY transcription factors show considerable interaction and form a regulatory network that maintains β -cell function and hence normal glucose homeostasis (95) (Fig. 26.5). It has recently been established that much of the interaction occurs at the β -cell alternative upstream (P2) promoter in HNF4 α (25,26). Through binding sites in this alternative promoter, HNF1 α , HNF1 β , and IPF1 can increase HNF4 α expression and, conversely, HNF4α can increase expression of HNFα through a binding site in the HNF1 α promoter. This would suggest not only that HNF4 α regulates HNF1 α expression but that HNF1 α regulates HNF4 α expression in β -cells. The critical role of this network is shown, as both mutations in the HNF4a P2 promoter and the HNF1 α promoter are sufficient to result in MODY (25,74).

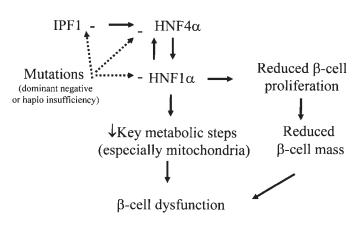

Figure 26.5. Possible mechanisms by which transcription factor mutations in MODY result in cell dysfunction. Note that IPF1, HNF4 α , and HNF1 α form a regulatory network and may result in β -cell dysfunction by common pathways.

INSULIN PROMOTER FACTOR 1 MUTATIONS (MATURITY-ONSET DIABETES OF THE YOUNG-4)

Molecular Genetics

Elegant clinical science led to the identification of the IPF1, also known as PDX1, as a cause of MODY. The key role of IPF1 in the development of the pancreas was illustrated by the presence of pancreatic agenesis in mice with a homozygous knockout of IPF1. Stoffers and colleagues (18) studied a child with pancreatic agenesis and found a homozygous frameshift mutation that had dominant-negative characteristics *in vitro* (96). They noticed that there were multiple generations with diabetes on both sides of the family and went on to show that the heterozygous frameshift mutation co-segregated with non–insulindependent diabetes in both parents' families, with a significant total LOD (logarithm of the odds) score of 3.43 (14). No other IPF1 mutations causing MODY have been described.

Phenotype of Patients with Mutations in Insulin Promoter Factor 1

CLINICAL PHENOTYPE

Defining the clinical phenotype is difficult, because there is only one published family to date. This family met standard criteria for MODY, but there is evidence that this gene was less penetrant than a typical HNF1 α mutation (14). Two individuals who inherited the mutation had apparently had normal glucose levels at 22 and 23 years, and the mean age at diagnosis was 35 years (range, 17–68), which is considerably older than the 23 years seen with HNF1 α mutations.

PREVALENCE

In France, Japan (97), and the United Kingdom (98), no IPF1 mutations that cause MODY have been found. However, in French families, perfect co-segregation with early onset type 2 diabetes has been shown with moderately severe missense mutations, suggesting IPF1 mutations can result in a monogenic form of type 2 diabetes. Other milder missense mutations were shown to predispose but not to cause early onset type 2 diabetes in the United Kingdom, French, and Swedish pedigrees (98–100).

PHYSIOLOGY

Physiologic studies have shown that carriers of IPF1 mutations that cause MODY have severe β -cell dysfunction, particularly in response to glucose, but, like patients with MODY3, are insulin sensitive (101). Less severe mutations that predispose to type 2 diabetes also resulted in reduced insulin secretion, particularly first-phase insulin secretion (99). It is likely that variation of the severity of the mutation seen *in vitro* explains the variation in phenotype. The less severe missense IPF1 mutations are likely to be part of a polygenic predisposition to type 2 diabetes rather than to a simple monogenic etiology seen in MODY, and hence the pathophysiology is less clear-cut.

HNF1 β MUTATIONS (MATURITY-ONSET DIABETES OF THE YOUNG-5)

Molecular Genetics

HNF1 β forms heterodimers with HNF1 α and was therefore a clear candidate gene for MODY. The first description of an

HNF1 β mutation was in a Japanese subject with MODY (102). HNF1 β mutations are rare causes of MODY both in Japan and the United Kingdom (102,103). With the recognition that these patients usually present with nondiabetic renal disease before diabetes, many more families have been identified from renal clinics. The majority of the 15 HNF1 β mutations described to date have presented with kidney disease in children or young adults (104) and are nonsense or frameshift mutations in early exons [reviewed in reference (24)].

Phenotype of Patients with HNF1β **Mutations**

The striking feature of MODY5 has been that these subjects, in addition to having early onset diabetes, have all had nondiabetic renal disease. We therefore recently proposed the term *renal cysts and diabetes* (RCAD) for the clinical syndrome associated with HNF1 β mutations (105).

DIABETES PHENOTYPE

HNF1 β mutations result in early onset non–insulin-dependent diabetes of a severity similar to that in patients with mutations in HNF1 α . Children and young adults have been described who have normal or impaired glucose tolerance, suggesting that there is a progressive deterioration in β -cell function. The mean age at diagnosis is the early 20s. Physiologic studies in a single subject showed a clear β -cell defect (106), and it is likely that this is the pathophysiology in all subjects, although, in contrast to HNF1 α , preliminary studies suggest that subjects with HNF1 β mutations are insulin resistant (E. R. Pearson, C. Bingham, and A. T. Hattersley, unpublished observations).

COMPLICATIONS

Subjects have been described who have proliferative retinopathy, suggesting that these patients, like carriers of HNF1 α mutation, are at risk of microvascular complications (102).

RENAL PHENOTYPE

In the initial description of HNF1 β mutations, patients with mutations had end-stage renal failure and proteinuria (102). Subsequent study of these patients (107) and other publications have shown that these features represent a non–diabetes-related renal phenotype of HNF1 β mutations. In a second Japanese family, all members of a family who had an HNF1 β mutation had at least one renal manifestation (108). These included cysts in the kidney on ultrasound, end-stage renal failure, and proteinuria. These renal manifestations were seen in young children with mutations at a time when they were not diabetic (108). Nondiabetic renal disease has been a consistent feature of all families with HNF1 β mutations [for a review, see reference (104)].

The renal manifestations of MODY5 are the result of abnormal development of the kidney, and abnormal renal morphology may be observed on scans as early as 17 weeks of pregnancy (106,108). The renal disease varies, with three discrete renal histologic manifestations having been described: oligomeganephronia (109), cystic dysplasia (106), and familial hypoplastic glomerulocystic kidney disease (105). It is uncertain what determines the morphology of the renal defect, but it probably reflects the functional characteristics of the mutation (24). Additional families will be needed to establish if there is a reproducible association between the phenotypes and the functional characteristics of the mutation.

Renal cysts have been seen in some members of all families with $HNF1\beta$ mutations. Equally, there is considerable variation

Causing Kenai Cysis and Diabeles (KCAD)				
Clinical feature	Percent of subjects with HNF1 β mutations and details			
Renal cysts	70%			
Renal impairment	73%			
Renal histology (includes)	Glomerulocystic kidney disease			
0,	Renal dysplasia

Causing Renal Cysts and Diabetes (RCAD)

in the severity of renal dysfunction associated with a single mutation. End-stage renal disease will develop in approximately 50% of subjects before the age of 45 years. Other developmental disorders have been seen in association with HNF1 β mutations, including uterine abnormalities (104,109), a lantern jaw, and pyloric stenosis (106). The salient clinical features of the RCAD syndrome in patients with MODY5 are summarized in Table 26.2.

Pathophysiology of HNF1β **Mutations**

The common feature of all the renal lesions is that they likely result from abnormal development of the kidney, and the vast majority result from abnormal development of the nephron. HNF1 β has been shown to be expressed in very early stages of embryologic development of the kidney. A critical role in the development of the kidney was not apparent from transgenic mice, as the HNF1 β heterozygous mouse has no phenotype and HNF1 β homozygosity is lethal to the embryo. It is uncertain if the pancreatic β -cell lesion that results in diabetes in later life is the result of abnormal pancreatic development.

NEUROD1 AND ISLET-BRAIN-1 MUTATIONS (MATURITY-ONSET DIABETES OF THE YOUNG-6)

Mutations in NeuroD1 (110) and Islet-Brain-1 (111) have been described in early onset familial type 2 diabetes. One NeuroD1 family met the clinical criteria for MODY, although in this family there was not perfect co-segregation with diabetes (110). NeuroD1 mutations were not detected in United Kingdom, French, or Japanese MODY series. However, recently a missense mutation was described in a MODY family from Iceland that showed complete co-segregation with diabetes, strengthening the case that NeuroD1 should be considered MODY6. No detailed descriptions of clinical characteristics or pathophysiology are available for the NeuroD1 MODY families.

NO GENE DEFINED MATURITY-ONSET DIABETES OF THE YOUNG-X

Key candidate genes are likely to be involved in gene transcription, development, or glucose sensing in the pancreatic islet.

The genes are still undefined for a significant proportion of MODY families. In the United Kingdom and France, this accounts for approximately 15% of MODY cases, but the proportion is considerably higher in Japan.

One interesting subgroup of MODY for which the underlying molecular genetics have not be defined is a subgroup of youth-onset diabetes in black patients termed atypical diabetes mellitus (ADM) (112,113). ADM represent 10% of youth-onset diabetes in blacks. These young people present acutely with weight loss and frequently with ketoacidosis, but months to years after diagnosis, atypical diabetes mellitus reverts to a non–insulin-requiring course similar to MODY in whites. ADM was found in at least two generations in 75% of the families; there was no evidence of pancreatic autoimmunity, and insulin secretion was intermediate between secretion in nondiabetic controls and patients with classic type 1 diabetes (112).

In the absence of an underlying genetic defect, it is difficult to make precise statements on the phenotype of MODYx. Some families who do not have a mutation in the known MODY genes have been defined by less rigorous criteria. In such families, diabetes may result from a high concentration of polygenic influences rather than a single gene. In those families in which there is likely to be a single gene mutation segregating, there still appears to be some heterogeneity. In the French and United Kingdom series, the phenotype in MODYx families was intermediate between the phenotypes in MODY2 and MODY3. Genetic analysis using a combination of reverse genetics and candidate gene studies will help define these families further.

USING MOLECULAR GENETIC INFORMATION IN THE MANAGEMENT OF PATIENTS WITH MATURITY-ONSET DIABETES OF THE YOUNG

We have reached a level of scientific understanding such that molecular genetic information can help in the clinical management of patients. The potential advantages and disadvantages of diagnostic and predictive genetic testing are outlined in Table 26.3. For patients with diabetes, a molecular genetic diagnosis will allow a definitive diagnosis of MODY to be made and the subtype to be classified and hence will help with treatment and prediction of the likely prognosis and clinical course. A young child with a slightly increased fasting glucose level can be predicted to have a very different clinical course and treatment if he or she has a glucokinase mutation, a mutation in HNF1 α , or neither of these and a high level of islet cell antibodies. For this reason, the United Kingdom, France, and other European countries have introduced diagnostic molecular genetic testing. Details of diagnostic testing for patients and their physicians are available on the website: www.diabetesgene.org. An area of uncertainty is the degree of medical supervision necessary for patients with glucokinase gene mutations. Certainly, close follow-up of children who have only mildly increased fasting glucose levels is not warranted, and repeated contact with a diabetes clinic dealing predominantly with type 1 diabetes may be detrimental. We cannot assume that older patients will not have diabetic complications, particularly as there is no evidence that these patients are

TABLE 26.3. Advantages and Disadvantages ofDiagnostic and Predictive Testing in MODY					
Diagnostic testing					
Possible advantages	Possible disadvantages				
Confirm diagnosis of MODY: Not type 1 or type 2 Diagnosis in other family members	Implications for family: Awareness of 50% risk to child				
Identification of subtype: Extrapancreatic features Specific treatment Pregnancy outcome Clinical care: Targeted follow-up Advice re: clinical course Complication screening	Cost implications: Full sequencing of gene required as only 15% have common mutation—expensive				
Predictive testing					
Possible advantages	Possible disadvantages				
Reduced uncertainty	Relationships and emotions: Effect on family relationships Feelings of guilt and blame				
Positive result: Adaptation Reduced delay in diagnosis of diabetes Misdiagnosis of type 1 or type 2 diabetes unlikely Negative result: No screening required	Positive result: Uncertainty of when diabetes will develop Confirms 50% risk to each child Insurance implications				

protected from developing polygenic type 2 diabetes. Annual follow-up of adults, including measurement of HbA1c, is probably all that is required. Only the few patients with an elevated HbA_{1c} will require more careful follow-up or treatment.

Mutation-based genetic testing can predict, with a high degree of accuracy, whether MODY is likely to develop in an unaffected first-degree relative. Full genetic counseling should be provided for individuals who seek predictive genetic testing. The child of a patient with MODY may find it helpful to know whether or not they have inherited a mutation, especially if they reach the age of 25 and are apparently unaffected. If they do not have the mutation, then the risk of diabetes would be the same as that of the population and hence screening on an annual basis would no longer be necessary. Testing of young children may also be beneficial, but this is considerably more controversial (114,115). This area of clinical practice needs to be studied carefully before its widespread introduction into clinical use.

CONCLUSION

The definition of the underlying genes in MODY has developed from the early clinical description. Mutations in six discrete genes have been shown to cause MODY: glucokinase, hepatocyte nuclear factor 1 α (HNF1 α), hepatocyte nuclear factor 4 α (HNF4 α), hepatocyte nuclear factor 1 β (HNF1 β), insulin-promoter factor 1 (IPF1), and NeuroD1. The description of these genes has allowed us to understand much of the clinical and physiologic heterogeneity seen in MODY. Molecular genetic testing provides new possibilities for the classification of MODY and possibly for the prediction and eventually the prevention of diabetes within these families.

Acknowledgments

I am very grateful to Diabetes UK, the Wellcome Trust, the European Union, the Medical Research Council, Northcott Devon Medical Foundation, DIRECT, PPP Healthcare Trust, The Darlington Trust, The Royal Devon and Exeter NHS Trust, Perkin Elmer Biosystems, and the University of Exeter for supporting our work on MODY.

Many outstanding colleagues in Exeter, Birmingham, and Oxford and our collaborators throughout the world have contributed to the ideas in this chapter and are gratefully acknowledged.

GENETIC SYNDROMES 488

CHRONIC COMPLICATIONS IN SECONDARY FORMS OF DIABETES 488

The term secondary diabetes generally refers to diabetes or glucose intolerance that develops in association with disorders (or factors) other than those currently defined as type 1 or type 2 diabetes mellitus or gestational diabetes mellitus. According to the classification system developed by the Expert Committee on the Diagnosis and Classification of Diabetes Mellitus (1), the subclass "secondary diabetes" contains a variety of types of diabetes, in some of which the etiologic relationship is known (e.g., diabetes secondary to pancreatic disease, endocrine disease, or administration of certain drugs). In others, an etiologic relationship is suspected because of a higher frequency of association of diabetes with a syndrome or condition (e.g., a number of genetic syndromes). The extent of glucose intolerance in patients with secondary forms of diabetes varies widely, presenting as insulin-requiring or non-insulin-requiring overt diabetes, simulating type 1 (insulin-dependent diabetes mellitus) or type 2 diabetes (non-insulin-dependent diabetes mellitus) or as milder forms such as impaired fasting glucose (IFG), impaired glucose tolerance (IGT), or minimally abnormal glucose tolerance, considered nondiagnostic. Another complexity in the evolution of secondary diabetes is that an underlying

coexisting predisposition to primary diabetes might be unmasked, a not uncommon occurrence, considering the prevalence of diabetes and the presumed genetic underpinnings of diabetes in the population.

Table 27.1 presents a classification of various forms of secondary diabetes. When diabetes is secondary to pancreatic disorders, particularly when β -cell mass is greatly reduced, e.g., by malignancy or pancreatectomy, or when diabetes is due to chemical agents toxic to the β -cell, e.g., pentamidine or pyriminil (Vacor), overt diabetes with or without ketoacidosis often will result, depending on the extent of β -cell loss. On the other hand, when diabetes is secondary to endocrinopathies leading to counterregulatory hormone production (e.g., acromegaly, Cushing syndrome, hyperthyroidism), overt diabetes, or ketoacidosis are unusual, thanks to the capacity of the β -cell reserve (2,3). Thus, the net metabolic outcome in patients with secondary diabetes depends on the direct or indirect impact of the underlying disorders on (a) insulin secretion, i.e., inhibition or compensatory hyperinsulinemia; (b) insulin sensitivity, i.e., glucose utilization; and (c) hepatic glucose output.

- A. Pancreatic disorders
 - a. Pancreatectomy
 - b. Pancreatitis
 - c. Cystic fibrosis
 - d. Pancreatic cancer
- e. Hemochromatosis
- B. Endocrinopathies
 - a. Disorders of growth hormone secretion 1. Acromegaly
 - 2. Growth hormone deficiency states b. Hyperprolactinemic states
 - c. Glucocorticoid excess (Cushing syndrome)
 d. Catecholamine excess (pheochromocytoma)
 - e. Primary hyperaldosteronism
 - f. Hyperthyroidism

 - g. Disorders of calcium and phosphorus metabolism h. Tumors of endocrine pancreas or gut (see Chapter 70)
 - 1. Glucagonoma
 - 2. Somatostatinoma
 - 3. Pancreatic cholera syndrome
 - 4. Carcinoid syndrome
 - 5. Multiple endocrine neoplasia (MEN) syndromes i. Polyglandular deficiency syndromes (see Chapter 69)
 - Polyneuropathy, organomegaly, endocrinopathy, monoclonal gammopathy, skin changes (POEMS) syndrome
- C. Drugs, chemical agents, and toxins
 - a. Diuretics and antihypertensive agents: Thiazides; chlorthalidone; loop diuretics (furosemide, ethacrynic acid, metolazone); diazoxide;
 - clonidine; β-adrenergic antagonists
 - b. Hormones: Glucocorticoids, adrenocorticotropic hormone, α -adrenergic agonists, growth hormone, glucagon, oral contraceptives,
 - progestational agents Psychoactive agents: Lithium, opiates, ethanol, phenothiazines, atypical antipsychotics
 - d. Anticonvulsants: Diphenylhydantoins (Dilantin)
 - e. Antineoplastic agents: Streptozotocin, L-asparaginase, mithramycin

PANCREATIC DIABETES

Pancreatectomy

Diabetes that results from pancreatectomy is, in a mechanistic sense, the prototype of insulin-deficient secondary diabetes. The amount of human pancreas that must be surgically removed or pathologically destroyed before the development of fasting hyperglycemia is a matter of some debate. Of interest, elegant studies in baboons revealed that after induction of diabetes with streptozotocin, the animals developed fasting hyperglycemia and a reduction in β -cell function *in vivo* when 40% to 50% of the β-cell mass was still detectable by islet morphometric assessment (4). Furthermore, of 28 healthy human donors who underwent 50% pancreatectomy, 7 (25%) developed glucose intolerance and a deterioration in insulin secretion after 8 to 15 months (5) (Fig. 27.1). However, none of these individuals developed overt diabetes during this time. It has been suggested that development of diabetes in partially pancreatectomized humans depends on several additional factors, such as rate of regeneration of β -cells, changes in nutritional status caused by weight loss and concomitant exocrine insufficiency, and the glucagon deficiency resulting from loss of α -cells (6).

Subtotal or total pancreatectomy theoretically provides a model for diabetes with "pure" insulin deficiency, because glucagon also should be absent (7). However, there are many reports of normal or elevated levels of immunoreactive glucagon (IRG) originating from extrapancreatic sources (gastrointestinal) in such patients (8–10). In most studies, the majority of this IRG comprised larger-molecular-weight material, which does not have biologic activity, but small quantities of 3500-kDa pancreatic glucagon may also be detectable (8). The biologic significance of extrapancreatic glucagon in these patients is not known, and their levels of IRG do not respond to arginine administration, although paradoxical stimulation in response to oral glucose or mixed meals has been reported (8,10).

The clinical presentation of diabetes in pancreatectomized humans differs from that of type 1 diabetes in several respects:

- Because of coexisting exocrine deficiency, pancreatectomized individuals present a nutritional challenge. They tend to be leaner than patients with type 1 diabetes and present with various degrees of malabsorption despite treatment with pancreatic enzyme supplements. Consequently, their insulin requirements are lower than those of weight-matched patients with type 1 diabetes (11).
- Pancreatectomized patients are more prone to hypoglycemia and may have a more sluggish and delayed recovery from hypoglycemia. The reasons for these differences are multiple. Glucose turnover and gluconeogenesis are considerably diminished, and levels of gluconeogenic precursors (alanine, lactate, pyruvate) are markedly increased owing to lack of glucagon (12,13); these changes are reversible by physiologic replacement of glucagon. Furthermore, epinephrine release in response to hypoglycemia may be markedly blunted (14), possibly due to recurrent episodes

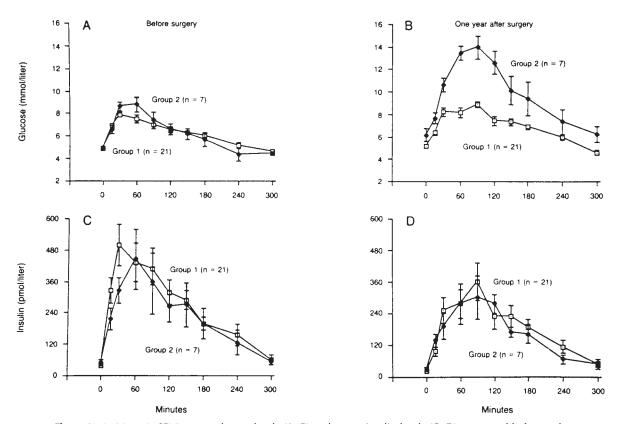

Figure 27.1. Mean (\pm SEM) serum glucose levels (**A**, **B**) and serum insulin levels (**C**, **D**), measured before and 1 year after hemipancreatectomy during 5-hour oral glucose tolerance tests in 21 transplant donors with normal glucose tolerance at 1 year (*group 1; open squares*) and 7 donors with abnormal glucose tolerance at 1 year (*group 2; closed circles*). (From Kendall DM, Sutherland DER, Najarian JS, et al. Effects of hemipancreatectomy on insulin secretion and glucose tolerance in healthy humans. *N Engl J Med* 1990;322:898–903, with permission. Figure 27.2. Changes in blood concentrations (mean \pm SEM) of glucose and 3-hydroxybutyrate in patients with type 1 diabetes (n = 6) and pancreatectomized subjects (n = 4) after withdrawal of insulin. *P < 0.05; **P < 0.02. (From Barnes AJ, Bloom SR, Alberti KGMM, et al. Ketoacidosis in pancreatectomized man. N Engl J Med 1977;296:1250–1253, with permission. Copyright © 1977 Massachusetts Medical Society. All rights reserved.)

of hypoglycemia. Thus, combined defects in glucagon and epinephrine may underlie prolonged and delayed recovery from hypoglycemia in such patients.

- Ketonemia and ketoacidosis are less severe in pancreatectomized patients despite comparable stimulation of lipolysis. As shown in Figure 27.2, withdrawal of insulin for 12 hours from totally pancreatectomized subjects (n = 4) and age- and weight-matched patients with type 1 diabetes (n =6) resulted in about a 50% reduction in the magnitude of hyperglycemia and hyperketonemia in the former (15). There were no significant differences in levels of free fatty acids and glycerol. Glucagon was undetectable before and after insulin withdrawal in pancreatectomized subjects (7,15). These studies strongly support the important role of glucagon in the promotion of ketogenesis but also argue against a primary role of glucagon in the induction of ketoacidosis.
- The issue of insulin sensitivity and peripheral glucose utilization following pancreatectomy is controversial. Although some investigators reported increased cellular insulin binding and enhanced hepatic and extrahepatic insulin sensitivity (16), others observed a state of peripheral insulin resistance (17) that was further impaired by glucagon replacement (18). Some of these discrepancies may be explained by differences in patient characteristics and alcohol intake and by the lack of consistent control for the induction of insulin resistance by antecedent hyperglycemia per se.

Pancreatitis

Diabetes secondary to pancreatitis accounts for fewer than 1% of cases of diabetes in the United States and other Western countries. However, in many parts of the world (especially tropical countries), the proportion is much higher.

Transient hyperglycemia may be seen in up to 50% of patients with acute pancreatitis in the absence of further attacks, but persistent diabetes develops-presumably as a result of ongoing chronic, painless pancreatitis-in fewer than 5% of such individuals during long-term follow-up in the absence of further attacks (19). On the other hand, in patients with chronic, relapsing pancreatitis, the incidence of diabetes increases over the years, being present in about 40% to 50% of patients after 20 years, with an additional 25% to 30% having IGT (19,20). Among patients with fibrocalcific pancreatitis, up to 80% to 90% have overt diabetes or IGT (19,20). In Western societies, the etiology of chronic pancreatitis is largely alcohol related in both patients with and without biliary disease. The precise mechanisms by which chronic pancreatic inflammation leads to glucose intolerance are not established, but compromised blood flow to islets from fibrotic scarring of exocrine pancreas may play a role. Insulin and C-peptide secretory responses to various secretagogues, including orally and intravenously administered glucose, sulfonylureas, glucagon, and amino acids, are impaired, and these abnormalities are correlated with the magnitude of exocrine pancreatic dysfunction (19,21,22). Glucagon levels are markedly increased in acute pancreatitis, both in the basal state and following stimulation with alanine. This increase may contribute to the transient hyperglycemia frequently seen in this situation (23). In chronic pancreatitis, the basal glucagon levels are normal or elevated, but the responses to amino acids (9,23) or to insulin-induced hypoglycemia (24,25) usually are found to be blunted. In some studies, however, levels of glucagon-like immunoreactivity were increased after stimulation (20,26), perhaps due to glucagon derived from extrapancreatic sources, but the significance of this observation is uncertain. Finally, in a small series of patients with chronic pancreatitis, a partial hepatic insulin resistance was shown in the presence of pancreatic polypeptide (PP) deficiency, which was reversible by PP infusion (27).

Patients with diabetes secondary to chronic pancreatitis may show a delayed recovery from hypoglycemia, a situation similar to that seen in pancreatectomized subjects. However, the incidence and severity of hypoglycemia in these patients are influenced by a number of other factors, e.g., alcohol intake, nutritional status, and state of malabsorption.

Subtle abnormalities of pancreatic exocrine function may sometimes be seen in patients with type 1 or type 2 diabetes (28,29), a finding that suggests the loss of a trophic effect of islet cell secretion on acinar cell function. These abnormalities, usually asymptomatic, may occasionally be difficult to differentiate from chronic, painless pancreatitis and may make additional diagnostic workup necessary.

Cystic Fibrosis

Cystic fibrosis (CF), one of the most common autosomal recessive disorders in the white population, leads to chronic progressive pulmonary disease and pancreatic insufficiency. With the increasing life expectancy of patients with CF, the incidence of diabetes due to CF has been increasing as a comorbidity. IGT or diabetes has been reported in up to 50% of adult patients with CF (30-32). Progressive insulin deficiency develops because of fibrotic destruction of islets and a marked decrease in β -cell mass (31). In addition, islet amyloid deposition was detected in 69% of 41 diabetic cases in one series (33). The extent of glucose intolerance depends also on additional factors, e.g., malnutrition, infections, and liver dysfunction. Recently, an increased prevalence of mutations in the cystic fibrosis transmembrane conductance regulator (CFTR) gene was reported in patients with "idiopathic" chronic pancreatitis as well as "alcoholic" chronic pancreatitis in the absence of any diagnostic features of CF (34,35). In most of these patients, one abnormal allele was detected. Thus, heterozygosity for CFTR mutation might be an underlying defect in many adult patients presenting with chronic pancreatitis.

Pancreatic Cancer

Pancreatic malignancy, leading to loss of β -cell mass, is a wellknown cause of diabetes. However, whether diabetes is a risk factor for pancreatic malignancy remains controversial. In some case-control studies, diabetes could not be shown to be a risk factor, after excluding patients with recent onset (<3 years) of hyperglycemia (36). However, in a large meta-analysis of 20 casecontrol or cohort studies, a twofold relative risk of pancreatic cancer was found, even after excluding those with diabetes of up to 5 years of duration (37). Furthermore, in a large, prospective cohort study, with a 25-year duration of follow-up, a progressive increase in the risk of pancreatic cancer was seen with increasing glucose levels following a glucose load at baseline (38). Whether hyperglycemia itself or the associated metabolic abnormalities, e.g., hyperinsulinemia or abnormalities in the insulin-like growth factor (IGF) axis, are involved in pancreatic carcinogenesis is unclear. In a series of patients with pancreatic cancer, with or without diabetes, levels of islet amyloid polypeptide (IAPP) were more than twice as high in those with diabetes compared with those with normal glucose tolerance (39).

HEMOCHROMATOSIS

Prevalence and Clinical Features

Hemochromatosis is the most common autosomal recessive disorder; the gene frequency is 7% to 10% among white populations, and the disease prevalence is 2 to 4 per 1,000 population (40–44). The disease is expressed three to five times more frequently in men than in women, since about 60% to 80% of homozygous women do not accumulate iron significantly because of menstrual blood loss and pregnancies.

The hemochromatosis gene (HFE) has been localized to chromosome 6, and two missense point mutations, C282Y and H63D, account for 65% to 100% of all patients of European descent (41,44). H63D is not deleterious by itself but probably acts synergistically in persons who are also heterozygotes for C282Y. In large series of participants, gene frequencies for C282Y and H63D mutations were 5% to 6% and 13% to 15%, respectively, whereas about 2% were compound heterozygotes. However, only about 50% of homozygotes for C282Y express clinical features of hemochromatosis, more commonly men than women (45,46).

Iron deposition occurs primarily in parenchymal cells of liver, pancreas, adrenals, anterior pituitary, myocardium, and skeletal muscle. The classic triad of hepatomegaly, diabetes, and skin pigmentation ("bronze diabetes"), once considered common, is in fact not a frequent association, considering the changing clinical presentation associated with early diagnosis and earlier treatment (41,45). Some of the common presenting symptoms are hepatomegaly with or without abdominal pain, arthralgias, fatigue, and impotence. Presence of symptoms usually correlates with the severity of iron accumulation as documented by liver biopsy and with the presence of cirrhosis. Cirrhosis was present at diagnosis in about 70% of patients prior to the availability of genetic tests (47). Hepatocellular carcinoma develops in about 15% to 30% of patients, depending on patients' longevity, despite the successful removal of iron.

Hemochromatosis may have a number of secondary causes, including sideroblastic anemias (chiefly thalassemia major), chronic hemolytic anemias, multiple blood transfusions, porphyria cutanea tarda, and dietary or medical iron overload, e.g., consumption of iron-rich beer among the Bantus (40,41). None of these conditions is linked with HFE gene mutations (41). The severity of total-body iron load produced by these states is variable but is usually less than the loads of 30 g or more seen in primary (idiopathic) hemochromatosis. Alcohol promotes iron absorption but does not, by itself, result in hemochromatosis.

Diabetes in Hemochromatosis

Abnormal glucose tolerance occurs in up to 75% to 80% of patients with hemochromatosis; of these, 50% to 60% have overt diabetes (45,47,48). Similarly, glucose intolerance was present in about 50% of patients with thalassemia major following chronic transfusion therapy (49,50). In a large series of patients with hemochromatosis, 25% had first-degree relatives with diabetes (48).

Conversely, hemochromatosis was diagnosed in 1.3% of 894 patients with diabetes by the old criteria in Italy, where the gene frequency is lower (51). The prevalence in age- and sex-matched controls was 0.2%. The pathogenesis of glucose intolerance in iron-overload states remains controversial, because multiple factors, including cirrhosis, pancreatic iron deposition, and underlying primary diabetes, can be involved. However, the severity of cirrhosis and iron load is correlated with the degree of glucose intolerance, and the control of diabetes improves in 35% to 45% of all patients following iron depletion (40,47).

Studies of β -cell and α -cell function in the presence of iron overload have revealed several interesting features. Patients who develop overt diabetes usually have impaired β -cell function (48,49), and about 40% to 50% of them require insulin therapy. However, in patients studied in a precirrhotic stage

and in those who have not developed overt diabetes, significant hyperinsulinemia was observed in response to oral glucose (52,53) and during a hyperglycemic clamp (53). Furthermore, rates of insulin-mediated glucose disposal were impaired in patients with transfusion-induced iron overload in the latter study (53). These observations suggest that insulin resistance secondary to hepatic or extrahepatic (muscle?) iron deposition precedes the β-cell dysfunction and overt diabetes that eventually develop. However, the mechanism of insulin resistance produced by iron overload remains unknown. In histopathologic studies, an increase in β -cell mass was demonstrated in a small number of nondiabetic or mildly diabetic patients with iron overload (54). However, whether iron infiltration of pancreatic islets explains the later β-cell dysfunction remains controversial. In patients with hemochromatosis, glucagon secretion was augmented by arginine and was not suppressed by oral glucose (55,56), responses similar to those seen in primary diabetes. In this respect, the α -cell responses seem to differ from those seen in patients with chronic pancreatitis (21,22) and are in keeping with the observation that iron deposition in islets, albeit variable, is restricted to β -cells (54).

In making the diagnosis of hemochromatosis, it should be noted that biochemical tests of iron metabolism, i.e., determinations of serum iron, transferrin saturation, and ferritin levels, are helpful but are not as specific for the diagnosis as is the hepatic histology (41). The availability of genetic tests helps diagnosis in relatives at early stages (45). Recently, attention was drawn to the presence of hyperferritinemia in 10% to 30% of unselected patients with type 2 diabetes (57). In most cases, the hyperferritinemia in such patients resolved spontaneously or proved to be due to other causes when follow-up studies were done (58). An underlying chronic inflammatory state also may result in a nonspecific increase in iron stores in patients with insulin resistance; the relevance of this to development of diabetes and its complications needs further study (59). Such studies underscore the need for confirmation of results, particularly when patients with diabetes are being screened for hemochromatosis.

Management and Prognosis

Regular phlebotomy treatment, often lifelong, remains the treatment of choice for hemochromatosis. Successful iron depletion, initiated early in the course of disease, clearly reduces the incidence and progression of cirrhosis, improves diabetes control, and frequently reduces damage to other target organs and overall morbidity and mortality (41,47). In a large prospective study of 163 patients, with a mean follow-up period of 10.5 ± 5.6 years, the major determinants of reduced survival included the presence of cirrhosis, diabetes, and failure of iron depletion (47) (Fig. 27.3). Mortality ratios (observed/expected) for liver cancer, cardiomyopathy, cirrhosis, and diabetes were 219, 306, 13, and 7, respectively, for patients with hematochromatosis as compared with those for the general population in this study. Successful iron depletion, however, did not protect from the development of liver cancer.

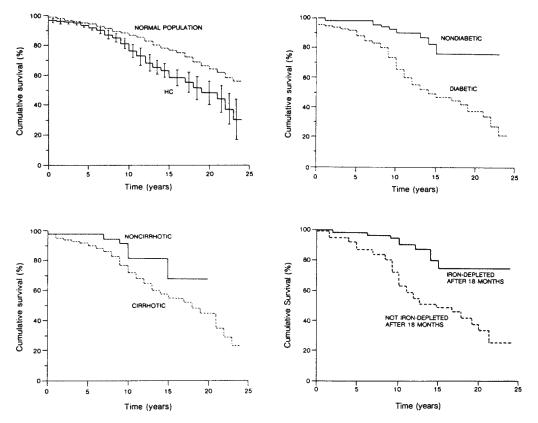

Figure 27.3. Cumulative survival in 163 patients with hemochromatosis compared with normal population and in the same patients with (n = 112) or without (n = 51) cirrhosis; with (n = 89) or without (n = 74) diabetes; and depleted (n = 77) or not depleted (n = 75) of iron during the first 18 months of venesection (see text for details). All differences were statistically significant (P < 0.05 to < 0.002 by log-rank test). (From Niederau C, Fischer R, Sonnenberg A, et al. Survival and causes of death in cirrhotic and noncirrhotic patients with primary hemochromatosis. *N Engl J Med* 1985;313:1256–1262, with permission. Copyright © 1985 Massachusetts Medical Society. In patients unable to undergo phlebotomy, such as those with thalassemia or other forms of anemia, chelation therapy with deferoxamine is an alternative for which the outcome is often successful (41,60,61), although the effects of this regimen on diabetes control have not been studied.

ENDOCRINOPATHIES

The major sites of action of various counterregulatory hormones on target organs and the principal mechanisms of their diabetogenic effects are listed in Table 27.2.

Disorders of Growth Hormone Secretion

Classic experiments, using crude pituitary extracts, performed more than 60 years ago demonstrated a relationship between the anterior pituitary and diabetes (62). In rat pancreatic monolayer cultures derived from an islet tumor cell line (63) or neonatal pancreas (64), growth hormone (GH) stimulated β -cell replication, an effect that was claimed to be independent of GH-induced insulin-like growth factors (64). However, chronic administration of GH in experimental animals over prolonged periods has been shown to result in hypersecretion of insulin followed by eventual loss of β -cells and permanent diabetes (65).

SECRETION AND METABOLIC EFFECTS OF GROWTH HORMONE

The physiology of GH secretion and its diverse metabolic effects on carbohydrate, protein, and lipid metabolism in humans have been studied extensively (66-68). In healthy subjects, GH release is stimulated by hypoglycemia, sleep, exercise, stress, and amino acids and is inhibited by hyperglycemia. Recently, a 28-amino-acid gastric hormone, ghrelin, has been identified as a potent ligand for GH secretagogue receptor (GHS-R), probably mediating GH secretion in response to various stimuli via neurons in the hypothalamus secreting growth hormone-releasing hormone (GHRH) (69). Infusions of GH in healthy subjects that produce increments in plasma GH levels within the supraphysiologic range (up to 30 to 50 ng/mL) initially result in acute but transient (2 to 4 hours) insulin-like effects, i.e., suppression of hepatic glucose production and enhancement of peripheral glucose clearance (69–72). In fact, insulin levels increase over this period, offering an explanation for some portion of these effects. Subsequently, over a 2- to 12-hour period, similar increments or

increments closer to the physiologic range (73) are associated with the "delayed" insulin-antagonistic effects. The primary site of GH-induced insulin resistance resides at the level of peripheral tissues (72,73), as first suggested by the elegant studies of forearm perfusion by Zierler and Rabinowitz (74). Although an effect of GH on inhibition of peripheral glucose uptake is well established, the lipolytic effect has not always been confirmed (67,75).

The understanding of the cellular site of insulin resistance induced by GH is complicated; multiple coexisting factors are involved, including GH concentrations, GH-binding proteins, presence or absence of hyperinsulinemia, and glucose intolerance. In most studies of healthy subjects given GH infusions or of patients with acromegaly, binding of insulin to receptors on circulating monocytes or hepatocytes was found to be little affected as a result of reciprocal effects on receptor number and affinity (72,73,66,76). However, in acromegalic patients with fasting hyperglycemia, the compensatory increase in receptor affinity that occurs in such patients with normoglycemia may fail to occur, a factor contributing to glucose intolerance (77). In cultured adipocytes, GH was shown to inhibit the expression of the gene for the glucose transporter GLUT1 but not that for the transporter GLUT4 (78). Thus, probably both postreceptor and receptor defects in insulin action underlie the diabetogenic effects of GH excess, although the precise nature of these defects remains unknown.

DIABETES IN ACROMEGALY

Anterior pituitary adenomas that hypersecrete GH account for more than 90% of cases of acromegaly (79). Other causes include ectopic (nonpituitary) sources of GH or GHRH, e.g., pancreatic islet cell tumors, carcinoid tumors, and hypothalamic hamartomas.

Glucose intolerance is prevalent in patients with acromegaly, affecting about 60% to 70%. However, overt diabetes requiring treatment occurs in only 10% to 30% of patients (80–83). Even more frequent than glucose intolerance is evidence for insulin resistance, which is manifested by a striking hyperinsulinemia in response to orally or intravenously administered glucose and other secretagogues, as well as markedly attenuated responses to exogenous insulin (67,68,84). Defects in both hepatic action and peripheral glucose disposal have been described in studies using insulin clamp techniques (70,73). Overall, GH levels in individual patients correlate poorly with both hyperinsulinemia and the severity of glucose intolerance. A better correlation of disease activity and glucose intolerance is found with serum levels of insulin-like growth factor 1 (IGF-1) (67,68) or

IGF-binding protein 3 (IGFBP-3) (85). In contrast to patients with acromegaly with normal or impaired glucose tolerance, insulin secretion is quite blunted by the time overt diabetes develops, with or without ketosis (68,84), a finding reminiscent of that in animal models of metasomatotrophic diabetes (65). However, coexistent primary diabetes (type 1 or type 2) may also be present, particularly if diabetes persists after successful treatment of acromegaly in such patients. Considerable evidence exists from studies of somatostatin infusion that lipolytic and ketogenic effects of GH supervene only after significant insulinopenia (71,86). Successful treatment of acromegaly, with normalization of GH and IGF-1, is usually accompanied by striking improvements in glucose tolerance and a reversal of hyperinsulinemia, as well as by normalization of insulin sensitivity (68,82-84). However, the results are unpredictable in those with overt, symptomatic diabetes (84,87). Lack of a complete remission in many patients may be due to incomplete cure of acromegaly, defined as suppression of GH to less than 2.5 ng/mL or to less than 1 ng/mL after oral glucose, using newer, ultrasensitive assays (88). Some have argued that this cut-off should be even lower, i.e., less than 0.5 ng/mL (89). The increase in mortality rate in acromegaly may persist unless GH levels are suppressed to the near-normal range (90,91). Moreover, glucose intolerance and hypertension are independent determinants of acromegalic cardiomyopathy (92).

The long-acting somatostatin analogue octreotide has been shown to be a useful adjunct in the treatment of acromegaly. In large, multicenter trials lasting up to 30 months of 58 and 103 patients, most of whom had previously been treated with surgery or radiotherapy (93,94), treatment with octreotide for 6 months or more resulted in substantial improvement in about 65% of patients. However, biochemical cure, defined by GH less than 5 ng/mL and normal IGF-1, occurred in about 50% of patients, and only approximately 2% to 40% of patients fulfilled the more stringent criterion of GH suppression to less than 2 ng/mL in both of these large series of patients (93,94).

Regarding the effects of octreotide therapy on glucose tolerance, the results from various reports indicate a mixed outcome, depending on the baseline metabolic status (68). On the one hand, in patients with overt diabetes or IGT, significant improvement in glucose tolerance or normalization of diabetes may result after several weeks of treatment. Impressive decreases in insulin requirements among the diabetic subjects within the largest randomized multicenter trial were observed (94). Normalization of GH and IGF-1 was associated with improvements in insulin sensitivity and greater suppression of hepatic glucose output as determined by the euglycemic-hyperinsulinemic clamp technique, whereas peripheral glucose disposal was not affected (95). On the other hand, in patients with normal or minimally impaired glucose tolerance, treatment with octreotide resulted in slight improvement, no change, or even a worsening of glucose tolerance, despite improvements in GH and IGF-1 levels (68,93,96). Thus, an adverse outcome in glucose homeostasis may be seen in some nondiabetic acromegalic patients following treatment with octreotide, depending on baseline characteristics such as β-cell reserve and degree of insulin resistance. Finally, long-term octreotide therapy may result in other side effects, the most important of which is the 40% to 50% incidence of cholelithiasis and/or biliary sludge (94).

Recently, results with longer-acting somatostatin analogues (octreotide LAR and lanreotide) have shown comparable decreases in GH and IGF-1 levels, but the long-term effects on glucose homeostasis with these agents are awaited. Similarly, impressive data on short-term clinical outcome with the growth hormone receptor antagonist, pegvisomant, in a large series of patients with acromegaly were reported recently (97). A 50% decrease in the insulin levels with a modest decrease in glucose levels was reported in that study after 12 to 18 months of follow-up. The long-term effects of this novel approach on glucose intolerance will be of interest.

DIABETES ASSOCIATED WITH ISOLATED GROWTH HORMONE DEFICIENCY

The presence of diabetes in GH-deficient dwarfs presents an interesting paradox. However, it has been known for a number of years that exogenous administration of GH to both normal and hypopituitary subjects augments the insulin response to a variety of secretagogues before a significant change in blood glucose occurs (98). Martin and Gagliardino (99) showed a β -cytotropic effect of GH on isolated pancreatic islets of rats *in vitro*. Similarly, some workers have shown direct effects of GH on islet β -cell replication in neonatal rat-islet monolayer cultures (63,65).

The majority of adult sexual ateliotic dwarfs with monotropic GH deficiency, studied by Merimee and coworkers (100), showed evidence of a mild to moderately severe glucose intolerance and insulin deficiency. It is interesting that after 10 years of follow-up, there was no evidence of diabetic microangiopathy in these dwarfs, despite worsening of glucose intolerance (101). On the one hand, these observations support the concept of a permissive role of GH in the pathogenesis of diabetic vascular disease. On the other hand, the incidence and severity of microangiopathy in patients with acromegaly with a striking increase of ambient GH concentrations do not appear to be increased and may indeed be significantly lower than in patients with genetic diabetes. Further studies on groups of patients well matched for the degree and duration of hyperglycemia are required to settle this question.

A number of long-term follow-up studies in adult patients with hypopituitarism have suggested an increased cardiovascular mortality even after replacement of other hormones (102). This has been ascribed partly to an atherogenic lipid profile, visceral adiposity, and insulin resistance in such patients. Administration of GH in such patients may restore, although not normalize, the cardiovascular risk profile (103). On the other hand, short-term studies with GH therapy over 12 to 30 months also have reported adverse effects on glucose tolerance and insulin sensitivity in hypopituitary adults (104,105). Retinal changes, mimicking diabetic retinopathy, were reported in two nondiabetic patients after 14 to 17 months of treatment with GH (106). However, only 12 cases of overt diabetes were reported among 8,136 GH-treated children (107).

GH is currently being proposed by some as a therapeutic agent for several indications e.g., preservation of lean body mass during aging, human immunodeficiency virus (HIV)–related disorders, prolonged illness, osteoporosis, enhancing tissue repair following surgery or trauma, and stimulation of muscle mass in athletes. Besides its potential for diabetogenic effects, other long-term risks of GH therapy need to be studied before specific recommendations can be made (108).

Hyperprolactinemia

The human prolactin molecule shares considerable homology with the human GH molecule, and an even greater homology exists between their respective mRNAs (79), similarities that suggest a common evolutionary origin. The precise role of prolactin in human physiology is poorly understood (109). A diabetogenic effect of prolactin has been suggested but has not been established in humans. Hyperprolactinemic states are sometimes associated with mild glucose intolerance; however, the difference is of only marginal statistical significance when levels are compared

with those for controls (110,111). In one study of 26 patients with prolactinomas, basal levels of glucose and insulin were comparable to those for controls, despite the presence of chronic endogenous hyperprolactinemia in these patients (110). However, oral glucose tolerance was significantly impaired and associated with insulin insensitivity, as reflected by hyperinsulinemia. It is interesting that both glucose intolerance and hyperinsulinism improved after treatment with bromocriptine, which reduced levels of prolactin. Similarly, in a group of nine patients with hyperprolactinemia and the amenorrhea-galactorrhea syndrome, four of whom had pituitary tumors, mild impairment in glucose tolerance associated with elevated basal levels and postglucose insulin levels was found in comparisons with matched controls (111). These changes were similar in some ways to those normally seen in late pregnancy. Whether prolactin causes insulin resistance leading to hyperinsulinemia or exerts direct effects on the β -cell, or both, is not known.

Cushing Syndrome

METABOLIC EFFECTS OF GLUCOCORTICOIDS

Glucocorticoids, like GH, are the principal insulin-antagonistic hormones. They have diverse metabolic effects on liver, adipose tissue, and muscle (112,113). In the liver, glucocorticoids serve as the key promoters of gluconeogenesis by accelerating the biochemical events at every rate-limiting step. Specifically, glucocorticoids stimulate (a) hepatic uptake of amino acids; (b) activation of pyruvate carboxylase in generating pyruvate from amino acids; and (c) activation of phosphoenolpyruvate carboxykinase (PEPCK), the unidirectional rate-limiting enzyme in the initiation of the cascade of gluconeogenesis from pyruvate. Insulin antagonizes the response of PEPCK gene transcription to glucocorticoids and cyclic adenosine monophosphate (cAMP) (114). Paradoxically, glucocorticoids enhance glycogen deposition, an insulin-like effect. It has been proposed that glycogenesis in response to glucocorticoids may be mediated by insulin (112). However, this effect may well be a direct consequence of activation of glycogen synthase by glucocorticoids (113).

At the level of adipose tissue and muscle, glucocorticoids antagonize insulin-mediated uptake and utilization of glucose (115,116). This effect is mediated at the cellular level by multiple mechanisms, including a decrease in insulin receptor affinity (76,117) and defects in insulin receptor signaling (115-117). Dexamethasone was shown to inhibit glucose transport by causing translocation of glucose transporters from the plasma membrane, an effect reversible by insulin (116). Glucocorticoids also exert a permissive effect on lipolysis by promoting the activation of cAMP-dependent hormone-sensitive lipase, a key enzyme inhibited by insulin (112). The net clinical effect of glucocorticoid excess in humans is a relocation of fat depots, which results in the typical truncal obesity of Cushing syndrome. The precise mechanism by which this unique pattern of fat redistribution develops remains unexplained. However, adipose tissues from various sites do show metabolic differences. Lipoprotein lipase activity is increased and lipolytic activity is decreased in abdominal adipose tissue in comparison to that in femoral adipose tissue in patients with Cushing syndrome (118). Glucocorticoids also augment proteolysis in skeletal muscle (112,113), and the relative distribution of types of muscle fibers may be altered (118). Finally, glucocorticoids may have a direct inhibitory effect on insulin release at the level of Ca²⁺-induced exocytosis (119).

GLUCOCORTICOID-INDUCED DIABETES

In healthy humans, short-term increments in plasma cortisol levels within the range seen in moderate stress situations (~40 μ g/dL) result in a slight increase in levels of glucose, which

is mediated by both hepatic and extrahepatic effects (120,121), as well as in a significant increase in levels of ketones and branchedchain amino acids (121). However, the effects of chronic administration of moderate doses of glucocorticoids to healthy humans are usually compensated for by increased insulin release, which results in minimal changes in glucose levels. Thus, the spectrum of glucose intolerance in patients with Cushing syndrome or exogenous steroid use depends in large part on endogenous β -cell reserve, a situation similar to that in acromegaly. Glucose intolerance occurs in 75% to 80% of patients with Cushing syndrome, but only 10% to 15% of patients develop overt diabetes (122,123). Almost all patients, however, manifest basal and stimulated hyperinsulinemia and insulin resistance.

A contributory diabetogenic effect of glucocorticoid excess is stimulation of glucagon secretion. Glucocorticoid administration over 3 to 4 days in healthy subjects induced an augmented α -cell responsiveness both during the basal state and following protein ingestion or amino acid infusion (124,125). This effect may be mediated by hyperaminoacidemia brought about by augmented proteolysis and perhaps by decreased glucose utilization by α -cells or some other direct effect of corticosteroids on α -cells.

Pheochromocytoma

METABOLIC EFFECTS OF CATECHOLAMINES

Catecholamines influence insulin secretion directly and produce anti-insulin effects at several loci in intermediary metabolism (126,127). In the human, basal insulin secretion is inhibited by α_2 -adrenergic and augmented by β_2 -adrenergic stimulation (127,128). The net effect on insulin secretion is governed by the relative local concentrations of epinephrine, norepinephrine, and various other secretagogues. However, the inhibitory effects on the α -receptor generally predominate over the stimulatory effects on the β -receptor. Stimulation of the α -receptor also may promote glucagon secretion. The role of catecholamines in the physiologic regulation of insulin secretion is still uncertain. A 29amino-acid polypeptide, galanin, was shown to be contained in sympathetic nerve endings in the islets and is proposed to be an additional mediator of insulin inhibition by sympathetic activation (129). In patients with preexisting glucose intolerance, the acute effects of physiologic increments in epinephrine levels on β-cell inhibition are exaggerated, producing greater hyperglycemia than in controls (130).

Catecholamines stimulate hepatic glucose output by promoting glycogenolysis and gluconeogenesis, the former being the predominant immediate effect (127). Glycogenolysis results from the β -adrenergic stimulation of adenyl cyclase, which leads to the release of cAMP. In addition, epinephrine also stimulates hepatic glycogenolysis via a cAMP-independent, Ca²⁺dependent pathway involving the α -adrenergic pathway (131). The effects of catecholamines (mainly epinephrine) on adipose tissue (lipolysis) and muscle (glycogenolysis) are mediated primarily via β -adrenergic receptors. In response to β -adrenergic agonists, proteolysis is inhibited (132), but oxidation of branched-chain amino acids is enhanced (133). However, the significance of these effects of catecholamines on muscle nitrogen balance requires further elucidation.

DIABETES IN PHEOCHROMOCYTOMA

Glucose intolerance occurs in about 30% of patients with pheochromocytoma (126,127,134). Multiple mechanisms may contribute to this intolerance, including (a) the α_2 -adrenergic inhibition of insulin secretion, (b) β -adrenergic stimulation of hepatic glycogenolysis and gluconeogenesis, and (c) enhanced lipolysis. Overt diabetes and ketoacidosis are distinctly unusual. Administration of α -adrenergic blocking agents, e.g., phento-

lamine or phenoxybenzamine, characteristically improves insulin secretion and glucose tolerance (126,135,136). Glucagon levels were surprisingly normal in the basal state (135,136) and markedly suppressed in response to arginine (137) or hypoglycemia (138), findings suggesting normal regulation by hyperglycemia despite an enormous increase in circulating catecholamine levels. However, others have reported a normal increase with arginine (126). Surgical removal of the tumor usually restores or improves glucose tolerance within several weeks (134,137); however, in some cases, it may take up to several months.

Primary Hyperaldosteronism

The triad of hypertension, hypokalemia, and glucose intolerance (Conn syndrome) was described in 1955 (139). Contrary to previous estimates, this syndrome accounts for no more than 2% of cases of hypertension (140,141). Glucose intolerance, previously thought to be present in about 50% of patients with Conn syndrome, is somewhat less common and is usually mild. It probably is the result, to a variable degree, of K⁺ depletion, which may be responsible for blunted insulin secretion (139,142) and perhaps for increased glycogenolysis. In healthy men, K⁺ depletion of 200 to 500 mEq (110% of total body K⁺) during 5- to 14-day periods was shown to result in mild glucose intolerance, whereas insulin sensitivity remained essentially unchanged (143). However, it is not certain if the glucose intolerance seen in Conn syndrome is completely explained by K⁺ depletion (144).

Hyperthyroidism

Hyperthyroidism is associated with significant aberrations of carbohydrate, lipid, and protein metabolism (145). This state is characterized by increased oxygen consumption, rapid gastric emptying, enhanced gluconeogenesis and glycogenolysis, increased lipolysis and ketogenesis, and increased proteolysis. Many of these effects are reproducible in experimental hyperthyroidism induced in nondiabetic (146) or diabetic (147) individuals. The insulin clearance rate was found to be increased by about 40% (148). The data on peripheral glucose disposal and insulin sensitivity are controversial, perhaps because of differences in the methods used. Some studies reported a decreased peripheral insulin sensitivity (149), whereas most others found it to be normal (148) or increased (146,150) compared with that in controls, primarily because of enhanced rates of glucose oxidation as determined by indirect calorimetry.

An increased incidence of glucose intolerance, usually of mild-to-moderate severity, was documented in 30% to 50% of patients with hyperthyroidism (145,151). Increased sympathetic sensitivity mediated via a β-adrenergic mechanism (126) probably contributes to the increased propensity to lipolysis and ketogenesis in such patients (146,152). Elevated levels of free fatty acids might also contribute to glucose intolerance. In patients with preexisting diabetes, the metabolic consequences of untreated hyperthyroidism on hepatic glucose production, lipolysis, and insulin clearance would facilitate the deterioration of glycemic control and even the development of recurrent ketoacidosis (153). In previously nondiabetic individuals, glucose intolerance persisted in 32% (7 of 22) of patients with hyperthyroidism after 12 years of posttreatment follow-up (151). This may be explained, at least in part, on the basis of common autoimmune mechanisms underlying Graves disease and type 1 diabetes.

Disorders of Calcium and Phosphorus Metabolism

Disorders of calcium and phosphorus metabolism may occasionally be associated with significant changes in insulin secretion or sensitivity or both. Hyperinsulinemia in primary hyperparathyroidism has been reported (154,155) and found to correlate with calcium levels (155), whereas glucose tolerance was preserved. Glucose intolerance has been reported in up to 40% of patients with primary hyperparathyroidism (156), suggesting a state of insulin insensitivity due to raised levels of intracellular calcium. On the other hand, experimental hypophosphatemia was shown to produce insulin insensitivity in dogs (157) and humans (158) and may thus be a possible mediator of insulin resistance in primary hyperparathyroidism. In secondary hyperparathyroidism induced by diet in dogs (157) or in patients with renal insufficiency who had undergone parathyroidectomy (159), no evidence was noted of any direct effects of parathyroid hormone itself on glucose disposal or insulin secretion. However, some patients with diabetes who underwent parathyroidectomy for primary hyperparathyroidism showed an increased sensitivity to endogenous and exogenous insulin postoperatively (156). The α -cell responses to arginine, to a protein meal, and to glucose were found to be normal before and after removal of the parathyroid adenoma (156). For discussions of tumors of the endocrine pancreas or gut and of polyglandular deficiency syndromes see Chapters 69 and 70.

POEMS Syndrome (Polyneuropathy, Organomegaly, Endocrinopathy, Monoclonal Gammopathy, Skin Changes)

POEMS syndrome is a rare form of plasma cell disorder associated with an osteosclerotic type of myeloma and several systemic features. About 100 cases have been reported (160,161). Other eponyms of this entity include Takatsuki syndrome and Crow-Fukase syndrome. In most cases (>90%), the M-component is of the γ -light-chain type. A relationship of this syndrome to multicentric angiofollicular lymph node hyperplasia (Castleman disease) has also been suggested (162). The etiology of these entities is obscure, but they appear to be secondary to a defect in immunoglobulin synthesis.

Glucose intolerance has been reported in 30% to 50% of cases (140,141). Other endocrine features include hypogonadism, hypothyroidism, hyperprolactinemia, and adrenal insufficiency.

DRUGS, CHEMICAL AGENTS, AND TOXINS

Administration of a variety of drugs or chemical agents (Table 27.1) is known to induce glucose intolerance or diabetes in previously nondiabetic subjects or to exacerbate hyperglycemia in patients with previously diagnosed diabetes. The diabetogenic effects may be brought about by effects on islet cell function, either directly or indirectly, or on insulin action at hepatic or extrahepatic sites or may be due to variable combinations of these factors. Table 27.3 presents the principal mechanisms of effects of certain therapeutic agents more commonly associated with glucose intolerance or diabetes.

Diuretics and β-Adrenergic Antagonists

The diabetogenic effects of diuretics, particularly high-dose thiazides and chlorthalidone, and β -adrenergic antagonists have been well recognized in clinical practice (163). A 12-year followup epidemiologic study revealed that the risk of developing diabetes over the risk in controls was increased 3- to 4-fold in subjects receiving thiazides, 5- to 6-fold in those receiving β -adrenergic blockers, and 11-fold in subjects receiving both drugs (164). Other large surveys have reported a 40% to 80% increased risk for initiation of treatment for diabetes with

	Impaired insulin secretion	Impaired insulin action	Comments
Diuretics			
Thiazide	+	±	Effects primarily mediated by K ⁺ depletion
Loop diuretics	+	0	
Diphenylhydantoin	+	0	Direct β-cell effects

TABLE 27.3. Sites of Action of Drugs or Agents More Commonly Associated with Diabetes or Glucose Intolerance

thiazides and with use of multiple antihypertensive agents with or without thiazides (165). For thiazides, most studies have indicated that the mechanism involved in this increased risk is an insulin secretory defect caused by hypokalemia and that the defect can be corrected by K⁺ replacement (144,166). Diazoxide, a nondiuretic thiazide, has pronounced inhibitory effects on the β -cell as well as peripheral effects (167).

For β -blockers, an inhibitory effect on β -cell secretion would be anticipated. Indeed, in some cases, drugs such as propranolol precipitated hyperglycemic, hyperosmolar, nonketotic coma (168). Moreover, evidence of peripheral effects of propranolol resulting in insulin resistance has also been reported (163).

In a large prospective study of subjects with hypertension, β -blocker use over 3 to 6 years was associated with a 28% increased risk for developing diabetes after adjustment of other risk factors (169). However, the relationship with the type of β blocker was not studied. The diabetogenic effects of β -blockers should not negate the proven benefits of these agents in reducing mortality in patients with known coronary heart disease.

Diphenylhydantoins

Phenytoin (Dilantin) has direct inhibitory effects on β -cell secretion (170). This effect appears to be dose related, and hyperglycemic, nonketotic coma precipitated by phenytoin toxicity has been reported (163,170).

Glucocorticoids

Glucocorticoid-induced glucose intolerance is characterized by insulin resistance and hyperinsulinemia. As discussed earlier, as in patients with Cushing syndrome, chronic administration of glucocorticoids induces distinct effects on hepatic and extrahepatic sites.

Pentamidine and Pyriminil

Pentamidine, an antiprotozoal agent, and pyriminil (Vacor), a nitrosourea-derived rodenticide, resemble streptozotocin and alloxan chemically. Pentamidine is used in prophylaxis and treatment of *Pneumocystis carinii* infection in patients with acquired immunodeficiency syndrome (AIDS), and an increase in the incidence of insulin-dependent diabetes following its use has been reported (171,172). Use of aerosolized pentamidine, the currently preferred route, has minimized the effects of this agent on carbohydrate metabolism. Similarly, accidental or intentional ingestion of pyriminil may result in the development of insulin-dependent diabetes with or without ketoacidosis as a result of β -cell destruction (173,174). The sequence of events leading to diabetes following use of these agents is similar to that seen with streptozotocin and initially involves a release of insulin from lysed β -cells that lasts for hours and frequently is associated with hypoglycemia and a delayed persistent hyperglycemia caused by β -cell loss after days to weeks (172–174).

Nicotinic Acid

Nicotinic acid in higher dosage causes glucose intolerance by inducing peripheral insulin insensitivity (175). In healthy individuals this is accompanied by minimal changes in glucose tolerance because of adaptive hyperinsulinemia. However, significant hyperglycemia or deterioration in glucose tolerance may result in some patients with a limited β -cell reserve or preexisting diabetes (176,177).

Immunosuppressants

An increased incidence of diabetes in transplant recipients receiving cyclosporine has been reported (163,178). This increase is probably independent of the concomitant diabetogenic effects of corticosteroids in these patients (178,179). Direct inhibitory effects of cyclosporine on β -cells, as well as peripheral effects on glucose transport, have been implicated (163,178). The diabetogenic effects may be more pronounced in African Americans (180). Tacrolimus (FK-506) has also been reported to be associated with an increased incidence of diabetes or worsening of preexisting glucose intolerance (179,181).

Opiates

A hyperglycemic effect of morphine and other opiates has been recognized. Human islets produce β -endorphins and enkephalins. In healthy and diabetic subjects, infusions of β -endorphin resulted in hyperglycemia accompanied by hyperglucagonemia (182). These results are in keeping with the observation of impaired β -cell responsiveness to glucose in subjects addicted to narcotics (183).

Alcohol

Light-to-moderate consumption of alcohol (one to three drinks daily) has been associated with enhanced insulin sensitivity, compared with that in nondrinkers (184). In an epidemiologic survey of a more than 12,000 participants followed up over a period of 3 to 6 years, an intake of more than three drinks of alcohol per day was associated with a 50% increased risk of diabetes in men, whereas no increase in men or women was seen with more moderate intake (185).

Protease Inhibitors

Several recent studies have reported an association between the use of highly active antiretroviral therapy, particularly protease inhibitors, in patients with HIV-related illness and a dysmetabolic syndrome characterized by lipodystrophy, insulin resistance, dyslipidemia, and hyperglycemia (186–188). Many such patients have IGT with variable rates of progression to overt diabetes. In a 5-year study of 221 HIV-infected patients, 5% developed hyperglycemia after the initiation of protease inhibitors (187). IGT was reported in 16% in another series (186). Drugs known to improve insulin sensitivity, e.g., metformin and thiazolidinediones, are undergoing trials in this syndrome and appear to be reasonable choices; long-term results are awaited (189,190).

Atypical Antipsychotics

A number of anecdotal reports have recently pointed to a potential diabetogenic effect of atypical antipsychotic agents, particularly clozapine and olanzapine (191–194). In one series of 82 patients treated with clozapine over a period of 5 years, 30% were diagnosed with diabetes, most requiring treatment (192). Although some of the adverse effects of these agents may be secondary to the weight gain seen with these agents, other mechanisms, including their direct effects on insulin action and islet cell function, need to be explored (194,194a). Severe mental illness and its associated lifestyle changes, by themselves, are known to be associated with increased risk for obesity and diabetes. Therefore, controlled trials with these agents are needed, as outlined by several national organizations (194a).

GENETIC SYNDROMES

More than 50 distinct rare genetic syndromes are associated with glucose intolerance (195). Some of these represent chromosomal defects such as Down syndrome (trisomy 21), Klinefelter syndrome, and Turner syndrome, whereas many others are single-gene defects (Table 27.1). In addition to congenital pancreatic disorders and certain inborn errors of metabolism, a variety of disorders characterized by severe or extreme insulin resistance caused by structural or functional abnormalities of the insulin receptor may produce glucose intolerance or non-insulin-dependent diabetes (see Chapter 28). Examples of genetic disorders linked to obesity-associated insulin resistance include Prader-Willi syndrome (196), Laurence-Moon-Biedl syndrome, and its variant, Bardet-Biedl syndrome (BBS) (197). About 45% of patients with the BBS are glucose intolerant. This disorder, previously thought to be a single-gene recessive disease, has recently been proposed to be a more complex genetic disorder requiring three mutant alleles (198).

In some of the genetic syndromes, a striking incidence of insulin-dependent diabetes, simulating typical autoimmune type

1 diabetes, is an integral feature. Examples include stiff-man syndrome, an autoimmune disorder (see Chapter 23), and several other hereditary neurologic disorders, including Friedreich ataxia (199); DIDMOAD (diabetes insipidus, diabetes mellitus, optic atrophy, sensorineural deafness), also known as Wolfram syndrome, and its variants (200); and maternally inherited diabetes and deafness due to mitochondrial gene mutations (201). In Friedreich ataxia, up to 20% of patients have diabetes, although some may be non-insulin-dependent for variable periods. In contrast, in Wolfram syndrome, autopsy studies have shown a selective loss of islet β -cells (202), a finding explaining the onset of diabetes in early childhood and the absolute insulin requirement in these patients. Urinary tract abnormalities and renal failure, in the absence of diabetic nephropathy, are very common in Wolfram syndrome, and 60% mortality by age 35 was reported in a series of 68 patients (203).

The maternally inherited diabetes and deafness (MIDD) syndrome is due to an A-to-G point mutation at position 3243 of mitochondrial DNA, encoding leucine transfer RNA. Mitochondrial gene mutations are characterized by oxidative phosphorylation defects leading to a variety of clinical syndromes, including a group of myopathies, such as Kearns-Sayre syndrome, Leber hereditary optic neuropathy, myoclonic epilepsy with ragged red fibers (MERRF), and a syndrome of myopathy, encephalopathy, lactic acidosis, and stroke-like episodes (MELAS) (204). In a series of 54 patients from France, MIDD was characterized by lack of obesity and by mild diabetes at onset but progressing to insulin dependency in about 50% of patients by 10 years (201). Myopathy, including cardiomyopathy and neuropsychiatric features, was commonly observed, and a specific retinal lesion, macular-pattern dystrophy, was much more common than diabetic retinopathy. Neurosensory deafness was present in virtually all patients.

CHRONIC COMPLICATIONS IN SECONDARY FORMS OF DIABETES

Whether chronic complications of diabetes (microangiopathy, neuropathy, and macroangiopathy) are a consequence of longterm hyperglycemia per se or require additional metabolic, hormonal, or genetic factors is a controversial issue. If hyperglycemia per se is the most important factor, one would expect an equivalent incidence and prevalence of these complications in secondary forms of diabetes. However, in practical terms, such comparisons of complications in primary versus secondary diabetes are difficult in view of (a) the milder severity of hyperglycemia in most patients with secondary diabetes, (b) the relatively shorter durations of follow-up in patients with secondary diabetes either because of poor prognosis of underlying disease or because of adequate treatment of the disorder with amelioration of hyperglycemia, and (c) lack of genetic markers for the detection of primary diabetes in association with secondary diabetes.

Despite these limitations, there is evidence that diabetic microvascular disease and neuropathy are mainly a function of severity and duration of hyperglycemia, and this view is strengthened by the demonstration of microangiopathic lesions in animal models of diabetes induced by alloxan or streptozotocin and of amelioration of these lesions by insulin treatment. In diabetes secondary to chronic pancreatitis or pancreatectomy, careful comparisons with patients with type 1 diabetes matched for age, sex, and duration and treatment of diabetes revealed a similar prevalence of retinopathy in the two groups (205,206). In another human model, that of pyriminil-induced insulin-dependent diabetes (173,174), a striking

prevalence of diabetic retinopathy, overt proteinuria, and thickened muscle capillary basement membranes was observed that was equal to or even greater than that in matched patients with type 1 diabetes (207) (Table 27.4). This form of diabetes is akin to chemically induced diabetes in animals and excludes the potentially confounding variable of a genetic factor or factors.

In one respect, however, the type of retinopathy in secondary forms of diabetes differs from that in genetic diabetes-i.e., severe or proliferative retinopathy is rare or quite infrequent. This difference may be due in part to a lack of the concomitant increase in GH or related growth factors that may be involved in the progression of proliferative retinopathy in patients with genetic diabetes (208,209). GH at physiologic concentrations was shown to enhance proliferation of human retinal microvascular endothelial cells in cultures (210). Dwarfs with isolated growth hormone deficiency and glucose intolerance do not develop retinopathy (or macrovascular disease) (211), and pituitary ablation was shown to arrest or retard the progression of proliferative retinopathy (212). Similarly, in patients with hemochromatosis, a blunted GH responsiveness was associated with only a mild background retinopathy (213). On the other hand, background retinopathy was reported in the absence of GH in a patient with diabetes following pancreatectomy (214). However, no proliferative retinopathy was observed in this patient despite 24 years of diabetes and the presence of severe nephropathy and neuropathy. Proliferative retinopathy is also rare in patients with acromegaly, despite their having marked elevations in levels of GH for many years. Overall, the available evidence supports the concept that GH is involved in the progression, but not in the initiation, of at least some of the long-term diabetic vascular complications.

Glucose homeostasis depends on a balance between the production of glucose predominantly by the liver and the utilization of glucose by insulin-dependent tissues (muscle and fat) and insulin-independent tissues (brain and kidney). Insulin controls glucose homeostasis primarily through the suppression of hepatic glucose production and stimulation of peripheral (and to a lesser degree, splanchnic) glucose uptake. Insulin resistance occurs when the ability of endogenous or exogenous insulin to promote glucose clearance is impaired (1). Several pathophysiologic conditions are associated with insulin resistance of varying severity (Table 28.1). Medical treatment of patients with these conditions may be difficult but often leads to improved insulin action.

Syndromes of extreme insulin resistance represent the far end of the spectrum of insulin resistance. In general, the syndromes of extreme insulin resistance are caused by genetic defects in the insulin action pathway or in pathways that intersect with the insulin action pathway, or by the presence of autoantibodies to the insulin receptor that affect receptor function, or by autoantibodies to insulin itself (Table 28.2).

DEFINITION OF SEVERE INSULIN RESISTANCE

Patients with severe insulin resistance may be euglycemic if their β -cells are able to produce sufficient insulin to compensate for the defect in signaling, or they may have only impaired

postprandial glucose tolerance, or they may have overt diabetes. Thus, the characterization of these patients differs, depending on the level of glycemia. For individuals with normal glucose levels, serum insulin levels are a good index of the severity of insulin resistance, because the ability of the β -cell to produce insulin, together with the magnitude of the peripheral insulin resistance, will determine the overall degree of hyperinsulinemia. Although there is no established value above which a fasting insulin level reflects severe insulin resistance, in the absence of obesity a fasting insulin value greater than 30 to 50 μ U/mL and/or a postprandial insulin level or an insulin level following glucose challenge that is greater than 200 μ U/mL should warrant further evaluation. However, identifiable genetic defects are less likely to be found when stimulated insulin levels are less than 1,000 μ U/mL.

As patients progress to impaired glucose tolerance or overt hyperglycemia, the β -cell defect may progress and insulin levels may decline. For patients receiving insulin therapy, insulin resistance may be defined according to the insulin dose required to achieve glucose control. Because the normal adult secretes an average of 25 to 40 units of insulin daily (0.3 to 0.5 U/kg per day) and about 70% of exogenous insulin is bioavailable, any patient requiring more than 60 to 100 units of insulin every 24 hours has some degree of insulin resistance. However, for clinical purposes, the requirement of more than 1.5 to 2.0 U/kg body weight suggests more severe insulin resistance and the need for further evaluation. Behavioral problems or improper diabetes management

TABLE 28.1. Conditions Frequently Associated with Clinical Insulin Resistance

should be rigorously excluded as the cause of "insulin resistance." The exclusion of these causes may require careful evaluation of the patient's dietary and drug history and understanding of insulin therapy. Often hospitalization may be necessary to reveal a behavioral problem.

CLINICAL FINDINGS ASSOCIATED WITH EXTREME INSULIN RESISTANCE

The most common clinical features associated with severe insulin resistance include acanthosis nigricans, ovarian dysfunction with hyperandrogenism and hirsutism, and lipoatrophy.

Acanthosis Nigricans

Acanthosis nigricans is characterized by a velvety rash with papillomatosis, hyperkeratosis, and hyperpigmentation in the epidermis (Fig. 28.1). Lesions are commonly found at the neck and axillae and occasionally in the antecubital fossae and other areas. When severe, acanthosis nigricans can involve the entire face and much of the truncal skin. Acanthosis nigricans has been observed in a variety of clinical settings, including several endocrinopathies and internal malignancies, particularly gastrointestinal cancer (2). However, when present, acanthosis

nigricans typically indicates at least a moderate degree of underlying insulin resistance.

When specifically searched for, the frequency of acanthosis nigricans may be higher than previously thought. In an unselected population of 1,412 schoolchildren in Texas, acanthosis nigricans was present equally among boys and girls, with a prevalence of 7.1% (3). The acanthosis nigricans was more frequently noted in obese children, and its severity was correlated with the fasting plasma insulin level. Acanthosis nigricans is even more common in selected groups of patients and was shown to affect up to 29% of women with hyperandrogenism referred to a subspecialty clinic and up to 50% of obese women with polycystic ovarian disease (4). Many of these patients have variants of the type A syndrome with moderate insulin resistance that at least partially reverts with weight loss (see below).

Pseudoacromegaly

Pseudoacromegaly, including frontal bossing, prominence of the jaw and malocclusion of the teeth, macroglossia, increased hand and foot size, skin tags, increased skin thickness, and median nerve entrapment at the carpal tunnel, has been described in some patients with severe insulin resistance (Fig. 28.2). The development of either acanthosis nigricans or an acromegalic appearance has been attributed to direct effects of hyperinsulinemia on skin tissue that result in epidermal hypertrophy. The presence of marked hyperinsulinemia in some patients is sufficient to bind to and activate the insulin-like growth factor 1 (IGF-1) receptor. IGF-1 receptors have a substantially lower affinity for insulin than do insulin receptors themselves, but when the ambient concentration of insulin is sufficiently high, IGF-1 receptors may become activated by a mechanism that has been called "specificity spillover" (5,6). Thus, increased stimulation of the IGF-1 receptor by hyperinsulinemia may be an important mechanism for the stimulation of epidermal growth in acanthosis nigricans. In addition, these mechanisms also may play an important role in the increased production of ovarian androgens in insulin-resistant states. In some patients, it is likely that insulin resistance is limited to insulin-receptor pathways involved in acute metabolic effects such as glucose transport or amino acid uptake and that "growth" effects of insulin are unrestrained and, in fact, accentuated by the hyperinsulinemia.

Hyperandrogenism-Ovarian Dysfunction

Hyperandrogenism-ovarian dysfunction, presenting with primary or secondary amenorrhea or irregular menstrual cycles, is very common in female patients with syndromes of severe insulin resistance, with amenorrhea being more common in those with more severe resistance (7). The menstrual irregularity is associated with an increased production of ovarian androgens, leading to moderately elevated serum testosterone levels and various degrees of hirsutism and virilization (8). Moreover, free or bioavailable testosterone levels may be increased disproportionately in these patients owing to a decrease in sex hormonebinding globulin. The ovaries are typically polycystic and hyperthecotic. Although the exact pathophysiology of such ovarian dysfunction is not known, insulin may cause ovarian hyperstimulation via its own receptor or by cross-reacting with the receptors for IGF-1, which also are present in the ovary. Luteinizing hormone has also been shown to act synergistically with insulin to promote the production of androgen by the ovaries (9).

HIRSUTISM AND VIRILIZATION

Hirsutism, the development of excessive androgen-stimulated terminal hair in a female, may occur with severe insulin resistance. Virilization, including defeminizing signs such as loss of the female body contour or frank masculinization with clitoromegaly and deepening of the voice, increased muscle mass, temporal balding, and increased libido, is less common.

Lipoatrophy or Lipodystrophy

Lipoatrophy or lipodystrophy, a marked reduction in subcutaneous adipose tissue that occurs in a segmental or generalized distribution (Fig. 28.3), is an additional clinical sign associated with the insulin resistance syndromes of leprechaunism and lipoatrophic diabetes. Lipoatrophy can be classified as focal or generalized and congenital or acquired. If lipoatrophy is localized to sites of insulin injection, it can be the result of a form of insulin allergy in individuals without marked insulin resistance. Descriptions of various forms of lipodystrophy are provided later in this chapter.

CHARACTERIZATION OF INSULIN RESISTANCE

Patients suspected of having a syndrome of severe insulin resistance and who are not receiving exogenous insulin may be characterized by fasting and postprandial or post-glucose challenge serum insulin levels. The standard oral glucose tolerance test with both insulin and glucose levels is a rapid and reliable initial diagnostic evaluation. The more markedly elevated these levels, the more severe the resistance and the more likely that the evaluation will reveal an identifiable underlying defect, such as when the fasting insulin level is above 50 mIU/L and the postprandial levels are above 200 to 500 mIU/L, although in some affected patients they may exceed 1,000 mIU/L (with normal values between 2 and 20 mIU/L). The hyperinsulinemia commonly observed in these patients develops by two complementary mechanisms. One is an increase in insulin secretion by the pancreatic β -cell in response to persistent elevations in fasting or postprandial glucose levels, and the other results from defects in the peripheral action of insulin associated with a striking reduction in the metabolic clearance of circulating insulin (10).

Several additional procedures are used clinically to evaluate the severity of insulin resistance. These tests vary in their complexity both in performance and in interpretation. They

share the common element of administering exogenous insulin to rule out the unlikely possibility of an abnormal endogenous insulin molecule (insulin mutation) as the cause of hyperinsulinemia. The insulin tolerance test (ITT) assesses the glucose-lowering effect of an intravenous insulin bolus (6). After an overnight fast, in a normal individual, an intravenous bolus injection of a dose of regular insulin of 0.1 U/kg of body weight will reduce the blood glucose level to a value 50% or less of the initial value or may provoke frank hypoglycemia. A patient with peripheral insulin resistance will require a higher dose of injected insulin $(\geq 0.2 \text{ U/kg})$ to produce this reduction in the fasting glucose level. If the patient requires an insulin bolus of 0.3 U/kg or more to induce hypoglycemia, the diagnosis of extreme insulin resistance is certain. Given the importance of the diagnosis, a serum insulin level should be obtained 10 minutes after insulin injection to confirm that insulin entered the vascular compartment.

In the *steady-state plasma glucose test* (SSPG), also known as the triple-infusion test, somatostatin is infused to suppress endogenous insulin production, and fixed doses of insulin and glucose are co-infused. At steady state, the higher the glucose level for a given insulin dose administered, the more insulin resistant the subject. The *frequently sampled intravenous glucose tolerance test* (FSIVGTT) provides a standardized method to assess both the pancreatic β -cell secretory capacity and periph-

А

Copyright 1993. The Endocrine Society.)

eral glucose uptake in response to a bolus intravenous administration of glucose (0.3 g/kg). Additional information on insulin sensitivity is gained by the administration of insulin (0.03 to 0.05 U/kg) 20 minutes after the glucose load. Euglycemichyperinsulinemic clamp studies are considered the gold standard for measurement of insulin action but are more difficult to perform. A dose-response curve to exogenous insulin is generated by measuring the variable infusion rate of glucose required to maintain euglycemia. The steady-state rate of peripheral glucose utilization (M value) is measured as milligrams of glucose used per kilogram of body weight per minute. Studies have demonstrated total-body glucose clearance to be reduced by 35% to 40% in subjects with type 2 diabetes as compared with that of age- and weight-matched healthy controls, with similar or more modest reduction in insulin sensitivity in persons with obesity, hypertension, and hyperlipidemia (1). More severe reductions are seen in persons with syndromes of extreme insulin resistance. In type 2 diabetes, the primary site of reduced insulin-mediated glucose uptake appears to be located in the peripheral (muscle) tissue (11), and both oxidative and nonoxidative (glycogen storage) components of glucose metabolism may be impaired (12).

INSULIN RESISTANCE DUE TO MUTATIONS IN THE INSULIN-RECEPTOR GENE

Although more than 60 naturally occurring mutations in the insulin-receptor gene have been characterized, three distinct clinical syndromes are associated with mutations in this receptor. All share the clinical features of acanthosis nigricans and hyperandrogenism.

Leprechaunism

Leprechaunism (also known as Donohue syndrome), the most severe of the conditions associated with mutations in the insulin-receptor gene, is characterized additionally by intrauterine growth retardation, a characteristic bird-like facies, fasting hypoglycemia, and glucose intolerance despite insulin levels that may be more than 100 times the normal values (Fig. 28.4). Most patients die within the first year of life. The condition is associated with homozygous mutations in either the coding sequence or the regulatory domains of both alleles of the insulinreceptor gene. Rare patients have two null alleles and totally lack functional insulin receptors.

B

Rabson-Mendenhall Syndrome

Patients with Rabson-Mendenhall syndrome demonstrate abnormalities in the teeth and nails and pineal gland hyperplasia. These patients may survive until adolescence, and many have compound heterozygous mutations in the insulin receptor, producing severe impairment of receptor function.

Type A Syndrome

The type A syndrome of insulin resistance is the least severe of the receptor mutation disorders. Affected females generally also demonstrate significant hyperandrogenism. Patients are neither obese nor lipoatrophic. Although many use the term type A syndrome to identify patients with mutations in one allele of the insulin receptor, many use the term to describe patients who demonstrate the triad of hyperandrogenism, insulin resistance, and acanthosis nigricans (HAIR-AN). Because only a minority of the patients who manifest this triad have heterozygous mutations in the insulin receptor, it is likely that mutations exist in postreceptor insulin-signaling transduction proteins. Likewise, when this triad is seen in the setting of obesity, it is less likely to be associated with a mutation in the insulin receptor than with additional polygenic factors rendering the patient susceptible to the clinical syndrome.

Mutations of the insulin receptor have been described in the insulin-binding domain, the transmembrane domain, and at or near phosphotyrosine sites; not all of these defects are associated with severe insulin resistance and the acromegaloid and hyperandrogenic features. In addition, specific mutations in the insulin receptor are found in only a minority of patients with a severe insulin resistance syndrome.

Insulin action at the cellular level is complex (reviewed in Chapter 6). Postreceptor insulin signaling proteins have been assessed carefully in patients with severe insulin resistance in whom no receptor defect could be identified. There is a small increase in frequency in variations in the insulin-receptor substrate 1 (IRS-1) sequence in subjects with type 2 diabetes as compared with controls (~15% vs. 5%, respectively), and some studies suggest that these may have some functional significance (13,14). IRS-1 variants may be more common among patients with severe insulin resistance; however, as these variants are also present in unaffected persons, they are not likely to account fully for the severe insulin resistance (15,16). Phosphatidylinositol 3-kinase (PI 3-kinase) is central in insulin-mediated glucose disposal and consists of a regulatory domain splice variants p85 α and p85 β and a catalytic domain p110. Variants of p85 α , Met³²⁶Ile, have been described in humans and do not appear to be associated with decreased activity; however, an Arg⁴⁰⁹Gln mutation has been identified in a patient with severe insulin resistance and is associated with lower activity in vitro and higher fasting glucose levels in the carriers within the proband's family (17). In addition, impaired insulin activation of PI 3kinase has been demonstrated in fibroblasts from severely insulin-resistant patients (18,19). Expression levels of genes for other proteins appear altered in some patients with type 2 diabetes, such as the gene belonging to the Ras-guanosine triphosphate superfamily, RAD (ras-associated with diabetes), which has been found to be overexpressed in muscle tissue of patients with type 2 diabetes (20), although the clinical significance of this finding remains uncertain and has not been demonstrated in conditions of extreme resistance.

The role of peroxisome proliferator-activated receptors (PPARs) in modulating insulin sensitivity has only recently been appreciated with the discovery of the thiazolidinedione class of drugs. These agents have been demonstrated to be potent insulin sensitizers, although the molecular mechanisms of action are only partially understood (see Chapter 41). The drugs bind to and activate an orphan nuclear receptor PPAR γ and regulate the transcription of a number of insulin-responsive genes, including glucose transporters, critical for the control of glucose metabolism. PPARs exist as heterodimers with another nuclear receptor, RXR, and effects are dependent on the presence of separate insulin-regulated transcription factors. Two dominant negative heterozygote mutations in the ligand-binding domain of the PPAR γ receptor have been identified in severely insulin-resistant, hypertensive patients with overt diabetes (21).

At the molecular level, multiple alterations in the insulin action cascade have been shown to be present and to contribute to the insulin resistance of type 2 diabetes and the insulin resistance syndromes; however, the relative importance of these alterations remains controversial. These changes are regulatory and include downregulation of the insulin receptor, decreased receptor kinase activity, decreased phosphorylation of receptor substrates, and defects in glucose transporter translocation (22–26). In addition to these signaling defects, several inhibitors of insulin action, such as cytokines, may be involved in the pathophysiology of diabetes. For example, tumor necrosis factor- α (TNF- α), which is expressed by adipose tissue and increased in human obesity, inhibits insulin-receptor kinase activity, and neutralization of TNF- α improves muscle insulin sensitivity in insulin-resistant rats (27). Similarly, the transmembrane glycoprotein PC-1, a threonine-specific protein kinase, nonspecifically inhibits the activity of insulin-receptor tyrosine kinase and has been isolated from fibroblasts of a patient with severe insulin resistance (28), although a primary role for this kinase in the etiology of insulin resistance remains unproven. Although such regulatory involvement may be present in or contribute to syndromes of severe insulin resistance, none has been clearly demonstrated to date.

LIPOATROPHIC DIABETES

Lipoatrophic diabetes encompasses a genetically heterogeneous group of rare syndromes characterized by insulin-resistant diabetes associated with a regional or complete absence of subcutaneous adipose tissue and presence of hypertriglyceridemia. Several forms of this condition have been reported according to mode of inheritance and extent and regional distribution of the lipoatrophy (29). These include congenital types of generalized lipoatrophic diabetes, which may exhibit either dominant inheritance (Köbberling-Dunnigan syndrome) or recessive inheritance (Berardinelli-Seip syndrome). In addition, syndromes of acquired total lipoatrophy (Lawrence syndrome) and various types of acquired partial lipoatrophy have been described.

Congenital Lipoatrophy

DOMINANT INHERITANCE (KÖBBERLING-DUNNIGAN VARIETY)

By studying pedigrees of congenital lipoatrophy with dominant inheritance in Scotland and Germany, Köbberling and Dunnigan delineated two clinical subtypes with characteristic distributions of subcutaneous fat that appear to be consistent within each pedigree (30-32). In type 1 familial lipodystrophy, the loss of subcutaneous fat is confined to the limbs, with sparing of the face and trunk, and intracavity fat deposits. In type 2 congenital lipoatrophy syndrome, the trunk, with the exception of the vulva, also is affected, giving the impression of labial hypertrophy. Associated clinical features variably expressed in the pedigrees include severe hyperlipidemia, acanthosis nigricans, hepatosplenomegaly, tuberoeruptive xanthomata, elevated basal metabolic rate, and insulin-resistant diabetes without ketoacidosis. Genetic characterization of at least 10 kindreds with this condition demonstrates linkage to chromosome 1q, with evidence of a common founder haplotype (33,34). At least five different missense mutations have been identified in the LMNA gene associated with this condition. The protein product of the gene is lamin A/C, a component of the nuclear envelope. Lamins A and C are two alternatively transcribed products of the LMNA gene and are members of the intermediate filament family of proteins that form components of the nuclear lamina, a protein-rich fibrous area below the inner nuclear membrane. The defects in nuclear lamin A/C have been confirmed in additional affected kindreds, but not all patients with the phenotypic characteristics of the syndrome manifest mutations in this gene (35). The lipoatrophic disorder may be caused by a gene tightly linked to this site; however, evidence supports a direct involvement of the LMNA mutation in the disease, and there may be a series of genetic mutations responsible for the phenotype. Heterozygous mutations in *LMNA*, which are more extensive and involve several exons, have been associated with an autosomal dominant form of muscular dystrophy, the Emery-Dreifuss variant (36), characterized by muscle contractures and a cardiac conduction defect and with an age-related dilated cardiomyopathy and conduction system disease, CMD1A (37). Rodent models with a targeted deletion of this gene develop postnatal cardiac and skeletal muscle dystrophy and a loss of white adipose tissue (38). *LMNA* is expressed ubiquitously in cells; thus, the sitespecific amino acid substitutions associated with these three distinct clinical syndromes reveal distinct functional domains of the lamin A/C protein to the different cell types. Further studies may reveal the role of lamin A/C in adipocyte function and insulin action.

RECESSIVE INHERITANCE (BERARDINELLI-SEIP SYNDROME)

The autosomal recessive form of congenital generalized lipoatrophy has been reported to occur more widely (39) than the dominant variety (40). Parental consanguinity is frequent, and cases are equally distributed among males and females. The absence of subcutaneous fat and muscular hypertrophy is noted in early infancy, although the diabetes typically appears during or after puberty. Imaging studies and autopsy demonstrate a near-complete absence of metabolically active adipose tissue from the subcutaneous area, from the intraabdominal, retroperitoneal, and epicardial regions, as well as from the bone marrow. Unlike with the dominantly inherited Köbberling-Dunnigan syndromes, both facial fat and buccal fat are affected. In contrast, mammary fat tissue may be spared, and mechanical adipose tissue is present in the palms, soles, scalp, and perineal areas. Loss of subcutaneous adipose tissue causes the thyroid, peripheral veins, and skeletal muscles to appear more prominent, and actual muscular hypertrophy may occur.

Growth and maturation of bone during the first 4 to 5 years of life are frequently accelerated. Acromegalic facies, along with thick skin and large hands and feet, may be present. Acanthosis nigricans is often a later development. Umbilical herniation is common. Hepatomegaly, resulting from increased stores of lipid and glycogen, is frequently observed and can be massive. Hypertriglyceridemia with eruptive xanthomas, lipemia retinalis, and episodic pancreatitis also may occur. Polycystic ovaries and menstrual irregularity are common in affected females. Mental retardation, psychiatric disturbances, and intracerebral disorders localized to the region of the third ventricle have also been associated with congenital lipoatrophy.

Laboratory studies of patients with recessive, congenital lipoatrophic diabetes have demonstrated a striking elevation of the basal metabolic rate with normal thyroid function. Despite the acromegaloid appearance, circulating levels of growth hormone are normal. A striking type IV or type V hyperlipoproteinemia typically is present and appears to be due to increased synthesis and decreased clearance of lipoproteins (41). When diabetes has been present for years, long-term diabetic complications have been described, including nephropathy with proteinuria and hypertension, peripheral neuropathy, and diabetic retinopathy. The hepatomegaly often leads to portal hypertension and irreversible cirrhosis, which is commonly the cause of death in patients with this disorder.

Previous studies of candidate genes involved in insulin action and lipid metabolism have not identified the molecular basis of this form of lipodystrophy; however, two chromosomal loci have been identified in association with this disorder. Genetic characterization of 17 carefully ascertained patients with the syndrome demonstrated linkage with the chromosomal locus 9q34. Initially termed BSL1, the gene responsible was revealed to encode

500 JOSLIN'S DIABETES MELLITUS

1-acylglycerol-3-phosphate O-acyltransferase 2 (AGPAT2) (42). AGPAT2 is abundantly expressed in adipose tissue and catalyzes the acylation of lysophosphatidic acid to form phosphatidic acid, an intermediate in the biosynthesis of triacylglycerol and glycerophospholipids; mutations in this gene thereby inhibit triacylglycerol synthesis and storage in adipocytes. The second locus, identified as BSCL2 and located on chromosome 11q13, is found in cohorts from Norway and Lebanon (43a). The defect has been identified within the gene that encodes a protein termed seipin, of unknown function and with little homology to known proteins. Seipin is widely expressed, with particularly high levels in the brain. Several variants of this locus are found with the syndrome; most are null mutations and probably result in a severe disruption of the protein. As subsets of patients do not have mutations in either of these genes, additional loci will likely be identified (43b). Other candidate genes include a series of proteins involved in adipocyte differentiation. Transgenic mice with altered expression of the transcription factors sterol responsive element binding protein 1 (SREBP1c) (44) and CCAAT/enhancer binding protein (C/EBP) (45) demonstrate features similar to those of congenital generalized lipodystrophy and support a role for transcription factor involvement in the syndrome. Although no mutations in PPARy have been identified to date in patients with Berardinelli-Seip lipoatrophic syndromes (46,47), evidence is beginning to suggest a role for these nuclear regulatory proteins in the disease, and a heterozygous mutation in the PPARy coding region in exon 6 at a highly conserved residue in one patient with a familial partial lipodystrophy (48) suggests a role for this gene in some forms of the disorder.

Acquired Lipoatrophy

GENERALIZED FORM

Acquired, generalized lipoatrophy was first described by Lawrence in 1946 (49). Affected patients exhibit a generalized absence of body fat, insulin-resistant nonketotic diabetes mellitus, an elevated basal metabolic rate with hyperhidrosis, and hyperlipidemia with hepatosplenomegaly. The occurrence of this condition is sporadic, without familial inheritance. In many cases, a viral illness precedes the development of lipoatrophy, but a direct viral etiology has not been demonstrated. The onset is usually in childhood or shortly after puberty, and this condition has a 2:1 preponderance in females. Clinical diabetes typically follows the onset of lipoatrophy by an average of 4 years. In the Lawrence syndrome, as in the congenital form of lipoatrophic diabetes, hepatomegaly can lead to cirrhosis, which may be the ultimate cause of death. Accelerated atherosclerosis also may occur and contribute to premature coronary artery disease.

PARTIAL LIPOATROPHY

Several forms of acquired, partial loss of subcutaneous adipose tissue have been described (50). In partial lipoatrophy, the most common pattern is loss of fat from the face and trunk with normal or actually increased fat deposition below the waist. Occasionally, only the lower half of the body is affected or lipodystrophy is segmental in a dermatomal distribution.

Familial occurrence of partial lipoatrophy has also been described, although the mode of inheritance is not clearly Mendelian. Acquired partial lipoatrophy may represent a less severe variant of the generalized disorder (Lawrence syndrome), and families have been described in which both forms of the disease occur. In rare cases, the partial form may develop into generalized total lipoatrophy. Like acquired generalized lipoatrophy, females are affected predominantly, the onset of partial lipoatrophy usually occurs in childhood, and in some cases onset has been preceded by an infectious illness.

Patients with partial lipoatrophy frequently have hypocomplementemia, which also has been associated with membranoproliferative (mesangiocapillary) glomerulonephritis in some individuals (51,52). These alterations have not been observed in the congenital lipoatrophic disorders. The reduction in levels of serum complement is due to the presence of an IgG autoantibody that binds to and stabilizes the C3 convertase enzyme. The result of this antibody action is an increase in the splitting of complement factor C3 and the activation of the alternative pathway of complement. This autoantibody is indistinguishable from the C3 nephritic factor observed in patients with membranoproliferative glomerulonephritis who do not have partial lipodystrophy, and the relationship between the complement system defect and the clinical lipodystrophy remains obscure.

Pathogenesis

As described above, multiple molecular and genetic mechanisms underlie the lipoatrophic syndromes. A direct role for the insulin receptor has not been demonstrated in these disorders. Studies on several siblings in a pedigree with recessive congenital lipodystrophy revealed heterogeneity in the function and expression of the insulin receptor in cultured cells, as well as a variant sequence of the insulin-receptor gene in the family members (53). The abnormalities were not fully linked to the clinical expression of the lipodystrophy, a finding that supports a complex nature of the genetic and metabolic defects in this syndrome that may lead to secondary effects on the insulin receptor. No circulating insulin inhibitors or antibodies directed at insulin or the insulin receptor have been found that account for the insulin resistance in patients with lipoatrophic diabetes. However, one case of total acquired lipodystrophy with diabetes but normal circulating insulin levels was associated with increased clearance of circulating insulin or accelerated degradation of insulin at target tissues (54).

Direct examination of cultured fibroblasts from several patients with generalized lipodystrophy has suggested that the severe insulin resistance in this syndrome may actually be due to a postbinding defect in insulin action that affects primarily glucose uptake or glucose metabolism (55). Furthermore, both insulin and IGF-1 receptors from these fibroblasts were found to have defects in their tyrosine kinase activity, suggesting that a signaling abnormality common to these related receptors may play a role in the pathogenesis of the insulin resistance (56).

Other mechanisms have been suggested to play a role in the development of lipoatrophic syndromes but have not been clearly established. A potential association between the immune system and disorders of adiposity and energy balance may ultimately be found in a serum protein named adipsin, which is secreted by adipocytes into the bloodstream. Adipsin has been shown to have serine protease activity identical to that of complement factor D, a process that is the initial step in the activation of the alternative pathway (57). It is interesting that both factor D activity and levels of adipsin mRNA are dramatically reduced in several models of genetic obesity in mice, a finding suggesting a possible role for adipsin in the energy balance of certain states of obesity (58). Some years ago the presence of a circulating lipid-mobilizing factor was thought to be causally associated with lipoatrophic diabetes, but this component remains poorly characterized. This factor was initially isolated from the urine of lipoatrophic patients and, when injected into animals, produced insulin resistance and lipolysis of fat stores (59). The factor was not specific for this syndrome, because it was later found in the urine of diabetic patients with proteinuria (60). However, clinical data on both of these mechanisms remain inconclusive.

The presence of elevated metabolic rate, hyperlipidemia, and insulin resistance suggests hyperactivity of the sympathetic nervous system, but plasma and urinary levels of catecholamine have not been consistently elevated in the patients studied (61,62). However, segmental dysfunction of the adrenergic nervous system or regional differences in the response of adipose tissue to circulating hormones may be etiologic factors in the unique distribution of affected adipose tissue in partial lipodystrophy (63,64).

The association of increased hypothalamic releasing factors in the circulation of lipoatrophic patients has raised the possibility of a hypothalamic role in the etiology of these conditions. Because an accumulation of dopamine within the hypothalamus might lead to accelerated release of hypothalamic hormones, drugs that affect dopamine synthesis or action were tested in lipoatrophic patients. The neuroleptic agent pimozide, which reduces levels of hypothalamic dopamine, was initially described as producing dramatic clinical improvement in several prepubertal or peripubertal patients with lipoatrophy (65). However, subsequent reports demonstrated no clinical benefit from pimozide and diminish the practical therapeutic value of this drug (66,67). Fenfluramine, a dopamine-blocking agent that also lowers serotonin levels, has also been used in a few patients with lipoatrophic diabetes. This agent was initially found to increase the sensitivity of a few patients to exogenous insulin and to improve the hyperhidrosis and hyperlipidemia; however, no consistent long-term beneficial effect has been observed in other studies (68), and the agent is no longer available in the United States (69,70).

The possibility that a hypothalamic lesion might play a role in these disorders is suggested by the frequent occurrence of tumors of the third ventricle in patients with congenital lipoatrophic diabetes (71). It is of interest that, in the diencephalic syndrome of infancy, anterior hypothalamic tumors have also been found to occur in association with diminished body fat, elevated metabolic rate, and accelerated growth. A boy with acquired lipoatrophic diabetes associated with stenosis of the aqueduct of Sylvius demonstrated dramatic clinical improvement after placement of a ventriculocisternal shunt, providing further evidence that hypothalamic dysfunction may contribute to the perturbed metabolic state (67).

Management

Because the etiology of insulin-resistant diabetes in the lipoatrophic syndromes is enigmatic, therapy has consisted of attempts at maintaining the blood glucose level within a reasonable range. Caloric restriction may improve the hyperlipemia and carbohydrate tolerance in patients with lipoatrophic diabetes (70,72). Good control of blood glucose levels may be difficult to achieve in patients with lipodystrophy because of the fixed nature of the underlying abnormalities in peripheral insulin action or glucose uptake found in many of these patients. Some benefit has been demonstrated with the insulin-sensitizing agents, including the biguanide agent metformin and the thiazolidinedione compound troglitazone. In addition to the improvements in insulin sensitivity, thiazolidinedione compounds have been associated with increased adipocyte development (73) and thus seem particularly suited to treat this condition. In a cohort of 13 patients treated over 6 months, troglitazone substantially lowered levels of glycosylated hemoglobin, fasting triglycerides, and free fatty acids and lowered the respiratory quotient, suggesting increased oxidation of fat, while body fat increased (74). However, this agent

has been associated with impaired liver function, the rate of which may be increased in patients with the underlying fatty liver seen in severe insulin resistance, and has been removed from the market. A few patients currently are being treated with other thiazolidinedione compounds, but it is too early to identify any as a superior product for this condition.

The adipocyte hormone leptin is important in regulating energy balance, and lipoatrophic patients are deficient in leptin. Genetically engineered rodent models of lipoatrophic diabetes demonstrate that the metabolic abnormalities improve with surgical fat transplantation (75), and leptin replacement can reverse insulin resistance and diabetes (76). Treatment with recombinant leptin for 4 months has been studied in a small cohort of humans with lipoatrophic conditions (77), demonstrating improved glycosylated hemoglobin, decreased triglycerides and liver volume, and reduced need for other antidiabetic agents.

Attempts at dietary therapy for lipoatrophic diabetes with omega-3 fatty acids resulted in a reduction in serum triglyceride levels and an amelioration of pancreatitis in at least one patient but at the expense of more severe glucose intolerance caused by an inhibition of insulin secretion (78). Limited studies have been conducted using recombinant human IGF-1 in insulin-resistant and lipoatrophic patients, with some suggestion of metabolic improvement (79). As described above, neuroleptic agents have been used in the treatment of lipoatrophic diabetes, with transient or no improvement noted in most cases.

Medical or dietary therapy has not accomplished a reversal of the lipoatrophy with the reappearance of subcutaneous fat tissue. In a case of acquired partial lipodystrophy, however, transplantation of autologous adipose tissue to the face was recently reported to provide a favorable cosmetic improvement (80).

IMMUNOLOGIC INSULIN RESISTANCE

In several syndromes of extreme insulin resistance, the insulin action pathway in target cells is intact but the effectiveness of circulating insulin is blocked by the presence of antibodies that react with the insulin receptor or the insulin molecule itself.

Antibodies to Insulin

Antibodies to insulin are less common today than previously as treatment has shifted from relatively impure preparations of animal insulins to more purified human insulin of recombinant origin. Intermittent exposure is more likely to generate an immune response than is continuous treatment. Insulin resistance due to high-titer immunoglobulin G (IgG) antibodies is extremely uncommon and occurs in well under 0.01% of insulin-treated patients with diabetes. In rare situations the high circulating levels of antibodies to insulin can serve as a reservoir for insulin and contribute to episodes of spontaneous or fasting severe or prolonged hypoglycemia. Most patients receiving insulin therapy, including the human insulins, develop measurable antibodies to insulin; thus, a quantitative measurement of competitive protein binding is necessary to confirm that these antibodies are clinically relevant to the resistance. In insulin-resistant patients, the concentration of antibody measured by binding capacity usually exceeds 5 units of insulin per liter of plasma. In rare cases, switching to an insulin analogue may be an effective form of treatment. Immunosuppression or plasmapheresis also may be effective. Rarely, endogenous high-titer antibodies to insulin appear in the absence of insulin therapy and are associated with autoimmune disease.

Type B Syndrome of Insulin Resistance: Autoantibodies to Insulin Receptor

The type B syndrome of severe insulin resistance is an autoimmune syndrome of circulating antibodies directed at the insulin receptor (81–83) that causes both target-cell insulin resistance and endogenous hyperinsulinemia and most often presents in the fourth to sixth decade of life. Like other autoimmune disorders, this condition has a female preponderance (female-tomale ratio, 2:1) and is often associated with other autoimmune phenomena, such as an increased erythrocyte sedimentation rate, elevated levels of γ -globulins, and autoantibodies to nuclear antigens or DNA. In fact, up to one third of the patients satisfy criteria for the diagnosis of systemic lupus erythematosus or Sjögren syndrome (84). Some of the clinical features of this disorder, such as the severity of the acanthosis nigricans, tend to follow the severity of the underlying insulin resistance.

PATHOGENESIS

Laboratory studies of antibodies to the insulin receptor isolated from patients with type B insulin resistance have demonstrated that these polyclonal antibodies can affect any of several vital aspects of the insulin action pathway. Most often, the antibodies to the insulin receptor cause a decrease in the affinity of the insulin receptor for insulin and lead to peripheral insulin resistance by acting as competitive antagonists of insulin binding. Other receptor antibodies that do not affect hormone binding can interfere with signal transduction by the insulin receptor, accelerate turnover of the insulin receptor, or lead to postreceptor desensitization of the insulin action pathway. Because the antibodies are typically polyclonal, several types of biochemical effects may be elicited by different classes of antibodies to the receptor even in an individual patient (85).

Further clinical heterogeneity of the type B syndrome has been observed in several patients who have developed or have presented with fasting hypoglycemia in association with the presence of circulating antibodies to the insulin receptor (86). In contrast to the patients with severe insulin resistance, these patients exhibit antibodies to the insulin receptor that can interact with the insulin-binding domain of the receptor in a positive manner and actually mimic the actions of insulin. In these individuals, the insulin-like activity of the antibodies is clinically manifest as an erratic hypoglycemic syndrome that may be confused with an islet cell tumor.

As with other autoimmune disorders, the symptoms may wax and wane over time, with the clinical severity dependent on both variation in titer and properties of the circulating autoantibodies. Remarkable clinical heterogeneity has been observed in some patients with type B syndrome, whose condition has actually evolved from one of severe insulin resistance to a hypoglycemic state. This development may occur because of changes in the abundance or activity of free autoantibodies in the circulation, which can have variable effects on insulin action in target tissues. These combined effects obviously can complicate the precise management of blood glucose control in these patients. A fraction of patients experience spontaneous remission of the disorder over a 2- to 3-year period.

In laboratory studies, the chronicity of exposure also has been shown to play an important role in the cellular effects of particular antibodies to the receptor (87). Thus, acute exposure of cultured cells to receptor antibodies may have insulinomimetic effects, whereas exposure for several hours may result in insulin resistance as a consequence of accelerated internalization and degradation of the receptors in the target cells (88). As in other autoimmune disorders, the type B syndrome arises from a defect in the regulation of the immune system rather than from an abnormality of the tissue insulin receptors. This conclusion is supported by the observation that insulin sensitivity appears to be normal in patients with the type B syndrome during periods of antibody remission. Furthermore, normal function of insulin receptors has been demonstrated in cultured cells from patients with type B syndrome, and insulin resistance can be mimicked by incubating the patient's cells with serum containing the receptor antibodies.

Several methods are used by specialized clinical laboratories to detect the presence of antibodies to the insulin receptor, which are typically polyclonal and of the IgG class (89,90). These include the binding-inhibition assay, the immunoprecipitation assay, and an assay of insulin-like activity in the γ -globulin fraction of the patient's serum (Table 28.3). The first method, which depends on the ability of the antibody to inhibit the binding of insulin to its receptor on cultured human lymphoblastoid cells, is the method most commonly used. However, the specificity of this technique may be affected by the presence of nonspecific inhibitors of insulin binding that may be found in the plasma of individuals without receptor antibodies.

The immunoprecipitation assay is performed by incubating the patient's serum with affinity-labeled insulin receptors and isolating the immune complexes that result in a positive test (90). This assay is somewhat more difficult to perform but is more sensitive than the binding-inhibition assay and can detect antibodies directed at sites other than the insulin-binding domain of the receptor. Flow cytometry has also been used to demonstrate the presence of antibodies to insulin receptor in the serum of patients with the type B syndrome (91). Assays based on the insulin-like activity of the antibodies are sensitive but are not specific for antibodies to insulin receptor and may give a positive response to other factors in the patient's circulation.

It is interesting that, in addition to immunosuppressive and plasmapheresis approaches, administration of recombinant human IGF-1 has improved both insulin sensitivity and glycemic control in some patients (92).

Ataxia-telangiectasia

Low-molecular-weight IgM antibodies to insulin receptors have been described in several patients with ataxia-telangiectasia (93). Ataxia-telangiectasia is a rare recessive syndrome characterized by progressive cerebellar ataxia, oculocutaneous telangiectasia, recurrent upper and lower respiratory tract infections,

TABLE 28.3. Evaluation of Pathogenetic Mechanism in Patients with Extreme Insulin Resistance

Assay of postreceptor defect in cultured cells

and a variety of immunologic abnormalities. About 60% of patients with this syndrome have glucose intolerance, hyperinsulinemia, and a decreased sensitivity to exogenous insulin. As in the typical type B syndrome, the insulin receptors on cultured fibroblasts are normal, indicating that there is no underlying defect in the insulin receptor itself.

PREVENTION OF DIABETES IN MINORITY GROUPS 519

SUMMARY 520

As human beings, we all share innumerable biologic, psychological, spiritual, and social elements. At the same time, we are each different enough in some or all these elements to make us unique. An evident and closer share of genetically transmitted physical characteristics, history, nationality, religion, language, traditions, and cultural heritage provides the basis to our integration into races or ethnic groups. Race is defined primarily by genetically transmitted physical characteristics, whereas ethnicity is a broader concept that refers to the sharing of a common and distinctive racial, national, religious, linguistic, or cultural heritage. Whites account for three fourths of the population in the United States. However, an increasing number of other racial and ethnic groups in the country contribute to the wide heterogeneity of the current population. In quantitative terms, these groups are known as the "minorities." In the United States, the largest minority groups are Hispanics or Latinos, African Americans, Native Americans, Alaska natives, and Asian and Pacific Islanders.

Significant information on the health status of these groups has become available (1). Whereas the reported prevalence and incidence rates of type 1 diabetes in these groups are lower than those in whites, those reported for type 2 diabetes and its complications are higher in these groups (1).

Type 2 diabetes is a heterogeneous disease that results from a combination of genetic and environmental factors. Many studies have shown that these minority groups have a strong genetic predisposition for the development of type 2 diabetes. The "thrifty gene" hypothesis has emerged as a possible explanation for this genetic tendency to the development of diabetes. This hypothesis, first proposed in 1962, suggests that populations of indigenous people who experienced alternating periods of feast and famine gradually developed adaptations that increased the efficiency of their storage of fat during periods of plenty to better survive famine. However, now that food supplies have become more constant and abundant, this genetic adaptation has become detrimental, leading to an increased prevalence of obesity and

type 2 diabetes in some populations (2,3). Much research has been devoted to identifying the precise nature of the "thrifty gene or genes." Unfortunately, no uniform genes across ethnic groups have been identified to fully support this hypothesis.

Environmental factors have undoubtedly contributed to the increase in risk for obesity and diabetes in these populations. The best data to support this concept come from the multiple studies that have found that the rates of type 2 diabetes and obesity are significantly higher in some minority groups in the United States than in the same racial and ethnic groups in their country of origin (4-13). Studies comparing their rates of diabetes in urban and rural areas also support this notion (14,15). The common elements of "Westernization" that increase the risk for obesity, diabetes, and related diseases include a diet higher in total calories and fat but lower in fiber and a decreased expenditure of energy because of labor-saving devices. In addition, particular aspects of preferred foods and lifestyle practices in each of these groups certainly play a role in the development of diabetes and its management. We now have a better understanding of how obesity, insulin resistance, diabetes, and cardiovascular disease are interrelated (16,17).

The high rates of diabetes in these populations represent a serious burden to the healthcare system in the United States. The burden comes not only from the high rates of diabetes and complications that they exhibit but also from the lack of widely available culturally and linguistically appropriate programs that demonstrate basic understanding of the needs and characteristics of each of the minority groups. Differences in cultural background do not impose a barrier for diabetes care per se. These differences do impose a barrier to the medical system and health professionals only when we lack the cultural competence to provide adequate care. A general call for action in developing research and clinical programs for minority populations has been posed by the U.S. government. New information being generated can increase our understanding of the challenges and opportunities in these groups. The goal of this chapter is to contribute to this effort by presenting information on various aspects of diabetes in the largest minority groups in the United States. For each group, general information is included on the population, diabetes epidemiology and pathophysiology, categories at risk for diabetes, microvascular and macrovascular complications, cultural and lifestyle factors related to diabetes, and prevention strategies.

DIABETES IN HISPANICS/LATINOS

The Hispanic/Latino Population

DEFINITION

Hispanic or *Latino* refers to a person of Cuban, Mexican, Puerto Rican, South or Central American, or other Spanish culture or origin regardless of race (18). Historically, Spaniards, blacks, and Native Americans have contributed, to one degree or another, to the contemporary Hispanic populations. An example of these contributions is presented in Figure 29.1.

DEMOGRAPHICS

According to the 2000 U.S. census, there are approximately 35 million Hispanics in the United States, representing 12.5% of the population. For the first time, Hispanics represent the country's largest minority group (18) (Table 29.1). It is certainly the fastest growing group, and it is estimated that, by the year 2050, Hispanics will number 97 million and will constitute 25% of the U.S. population (19). The largest Hispanic groups in the country are Mexican Americans (66%), Central/South Americans (15%), Puerto Ricans (9%), and Cuban Americans (4%). The majority of Hispanics live in the South Central and Southwestern United States, but their numbers are increasing rapidly in many states in the North and Northeast. The mean age of Hispanics is 36.7 years, whereas it is 43.8 years in whites. Approximately one third of the Hispanic population is younger than 18 years old; thus, Hispanics are considered to be the youngest population in the United States (18).

Diabetes Epidemiology

PREVALENCE AND INCIDENCE OF DIABETES

Type 1 Diabetes. Overall, the rates of type 1 diabetes are lower among Hispanics than among the white population, as shown in a study of Mexican-American and white children in Colorado (20). A study in Philadelphia found a similar incidence of type 1 diabetes in Puerto Rican children and their white counterparts (21). Because genetic, immunologic, and environmental factors are involved in the development of type 1 diabetes, differences

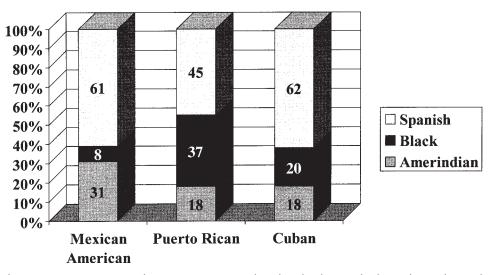

Figure 29.1. Genetic origins of major Hispanic groups based on distribution of polymorphic markers and trihybrid model of ancestry. (From Hanis CL, Hewett-Emmett D, Betrin TK, et al. Origins of U.S. Hispanics. Implications for diabetes. *Diabetes Care* 1991;14:618–627.)

Race/ethnicity	Number ^a	Total population (%) ^a				
Total population	281,421,906					
White/Caucasian	211,460,626	75.1				
Hispanic/Latino	35,305,818	12.5				
Black/African American	34,658,190	12.3				
Asian	10,242,998	3.6				
Native American and Alaska Native	2,475,956	0.9				
Native Hawaiian and other Pacific Islander	398,835	0.1				
Others	15,359,073	5.5				
^a Numbers and percentages do not add up to 100% because of the way data were collected. From US Bureau of Census. Table DP-1. Profile of Characteristics for the United States 2000.						

TABLE 29.1. Distribution of U.S. Population by Race/Ethnicity in the 2000 U.S. Census

in these factors may account for distinct prevalence rates among Hispanic subgroups.

Type 2 Diabetes. The most recent prevalence data in the United States are from the National Health and Nutrition Examination Survey III (NHANES III), conducted from 1988 to 1994 by the National Center for Health Statistics of the Centers for Disease Control and Prevention (22,23). This study included a representative sample of the U.S. civilian noninstitutionalized population to assess the prevalence of total, diagnosed, and undiagnosed diabetes, as well as categories at risk for type 2 diabetes, such as impaired fasting glucose (IFG) and impaired glucose tolerance (IGT) (24), in the general population as a whole and in non-Hispanic whites, non-Hispanic blacks, and Hispanics (25). The Hispanic population in this survey was represented by Mexican Americans, who constitute the largest Hispanic group in the United States. Overall, the prevalence of diabetes in Hispanic Americans was 1.9 times higher that in non-Hispanic whites. Figure 29.2 shows the prevalence rates, according to age and gender, of diagnosed and undiagnosed diabetes and IFG in adults older than 20 years of age in these various populations. The prevalence rates of diagnosed diabetes, undiagnosed diabetes, total diabetes, and IFG were significantly higher in Hispanic Americans than in non-Hispanic whites and similar or higher than in non-Hispanic blacks. When considering only those between the age of 40 and 74 years of age, the prevalence of diabetes (diagnosed and undiagnosed) was 11.2% for non-Hispanic whites and 20.3% for Mexican Americans. The prevalence of IGT, according to the 1980–1985 World Health Organization (WHO) (26,27) criteria, was 20.2% for Mexican Americans, and 15.3% for non-Hispanic whites. Similarly, other studies have reported higher prevalence and incidence rates of diabetes in Hispanics than in whites (28–32).

Subgroup Analysis. Age. In practically every age group, the prevalence of diabetes is higher in Mexican Americans than in non-Hispanic whites. The proportion of the Mexican-American population with diabetes increases from less than 1% among those younger than 39 years old to as high as approximately 25% among those 60 to 74 years old (25) (Fig. 29.3). These rates incorporate only diagnosed cases; thus, overall rates of diabetes are higher in all age groups. This is also applicable to young Hispanic adults, adolescents, and children, who have been found to have high prevalence of obesity and type 2 diabetes (33,34).

Gender. The NHANES III study showed a higher prevalence of diagnosed diabetes among Mexican-American women older than 20 years of age than among Mexican-American men (10.9% vs. 7.7%) (25). On the other hand, the prevalence of undiagnosed diabetes in the same population was 5.4% in men and 3.6% in women. Therefore, the overall rate of diabetes is similar in men and women (13.1% and 14.5%, respectively). In addition, although the prevalence of IFG was higher in men (11.6%) than in women (6.3%), that of IGT, which was evaluated only in those between 40 and 74 years of age, was higher in women (22.3%) than in men (18.2%) (25).

Hispanic subgroups. The Hispanic Health and Nutrition Examination Survey (HHANES) was conducted in 1982 to 1984

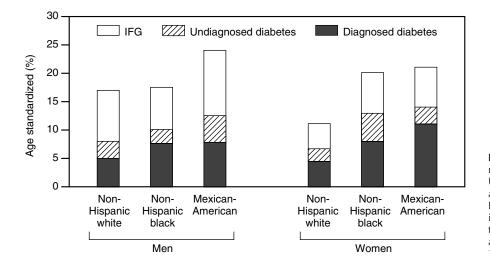

Figure 29.2. Prevalence of diagnosed and undiagnosed diabetes and impaired fasting glucose in the U.S. population greater than 20 years old, by sex and racial/ethnic group. (From Harris MI, Flegal KM, Cowie CC, et al. Prevalence of diabetes, impaired fasting glucose, and impaired glucose tolerance in U.S. adults: The Third National Health and Nutrition Examination Survey (NHANES), 1988–94. *Diabetes Care* 1998;21:518–524.)

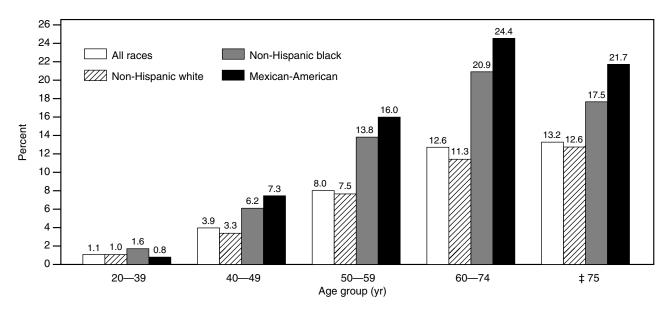

Figure 29.3. Percentage of U.S. population with diagnosed diabetes by age and race/ethnicity. Percentage is based on medical history interview in subject asked about previous diagnosis by a physician. (From Harris MI, Flegal KM, Cowie CC, et al. Prevalence of diabetes, impaired fasting glucose, and impaired glucose tolerance in U.S. adults: The Third National Health and Nutrition Examination Survey (NHANES), 1988–94. *Diabetes Care* 1998;21:518–524.)

to address the prevalence of diabetes in three Hispanic populations: Mexican Americans in the Southwestern United States; Cuban Americans in Miami, Florida; and Puerto Ricans in the New York city area (35). In this survey, the total rate for diabetes (diagnosed and undiagnosed) in adults between 20 and 74 years of age was 27.7% in Mexican Americans, 30.2% in Puerto Ricans, and 18.2% in Cuban Americans (the corresponding rates for non-Hispanic whites and non-Hispanic blacks in this survey were 13.6% and 22.6%) (Fig. 29.4). This lower rate of diabetes in Cuban Americans may be due to a lower proportion of Native American and African genes and a higher socioeconomic level. There are no available data for other Hispanic subgroups in the United States.

MORTALITY

Few studies address diabetes-specific mortality rates in the Hispanic population in the United States. The Starr County Diabetes Study found that Mexican Americans with diabetes, particularly those with chronic complications, such as proliferative retinopathy (36), experience premature and excessive mortality as compared with the general population. In addition, a study conducted in New Mexico showed that diabetes mortality rates

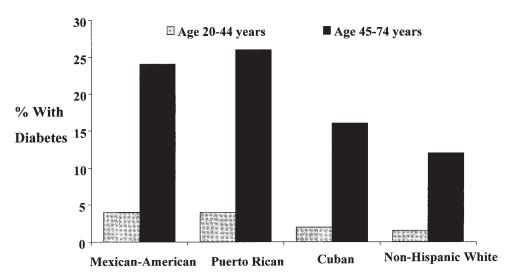

Figure 29.4. Prevalence of type 2 diabetes in some Hispanic subgroups and in whites: from HHANES data. (From Flegal KM, Ezzati TM, Harris MI, et al. Prevalence of diabetes in Mexican Americans, Cubans, and Puerto Ricans from the Hispanic Health and Examination Survey (HHANES), 1982–84. *Diabetes Care* 1991;14[Suppl 3]:628–638.)

among Hispanics in that area gradually increased between 1958 and 1994 and that these rates are higher than those in whites (37).

Pathophysiology of Type 2 Diabetes

GENETIC PREDISPOSITION

The three primary ancestors of Hispanics are Spaniards, native Indians, and Africans. Clearly, the rates of diabetes are higher in both the native Indian and African groups. The differences in rates of diabetes in the various Hispanic subgroups have been explained by the various degrees of genetic influence from these main groups (Fig. 29.1). Thus, a group such as the Puerto Ricans, who have a significant genetic contribution by Africans and native Indians, have shown a high rate of diabetes, whereas Cuban Americans, for whom the genetic contribution of these two groups is lower, have a lower rate of diabetes (35). Yet, even among Cuban Americans, whose reported rate of diabetes is the lowest among Hispanics, the rate of diabetes is higher than that among non-Hispanic whites (35) (Fig. 29.4). The prevalence rate for diabetes in Spain is higher than that in the non-Hispanic white population in the United States, suggesting that even Spanish admixture may be an important factor in explaining the higher rates of diabetes in Hispanics (38).

The nature of the precise genes that increase the risk for diabetes in this population is still unknown, although interesting information about potential genetic factors is now becoming available (39,40). Whatever the predisposing genes, it is evident that people with a family history of type 2 diabetes have an increased risk of the disease. The San Antonio Heart Study showed that the prevalence of diabetes among Mexican Americans who have first-degree relatives (e.g., parents) with diabetes is twice that of those with no family history of diabetes (41). In addition, the full metabolic profile of insulin resistance is fully established in the offspring of people with type 2 diabetes in this population (42). Strictly speaking, besides sharing a genetic background, first-degree relatives of persons with diabetes usually share environmental factors that may also participate in increasing the overall risk.

INSULIN RESISTANCE

Among people without diabetes in the NHANES III survey, insulin levels were higher in Mexican Americans than in non-Hispanic whites, a finding that suggests more insulin resistance in this population and, therefore, their greater predisposition for type 2 diabetes. Several other studies also have shown higher rates of hyperinsulinemia in Hispanics than in non-Hispanic whites, even after adjusting for obesity and body-fat distribution (43,44). In a more detailed evaluation of insulin resistance, the Insulin Resistance and Atherosclerosis Study found that nondiabetic Hispanics have significantly higher insulin resistance and a higher acute insulin response than do nondiabetic whites, although this difference disappears after adjustments are made for obesity and body-fat distribution (45). Therefore, although there is enough evidence to support a high prevalence of insulin resistance in Hispanics, the extent of its dependence on the degree and distribution of adiposity is not known.

INSULIN SECRETION

Acute insulin secretion has been reported to be higher in Hispanic Americans than in the non-Hispanic white population (45). This may represent a compensatory response of β -cell function to the degree of insulin resistance in this population. However, insufficient insulin secretion relative to the degree of insulin resistance is considered a crucial independent factor in the development of type 2 diabetes in this population (46).

OBESITY

Obesity is a major risk factor for type 2 diabetes in any population. Recent U.S. data show that the age-adjusted prevalence of combined overweight and obesity [body mass index (BMI) >25] in Mexican-American women older than age 20 years is 65.9%. The corresponding proportion in Mexican-American men is 63.9% (47). These rates are higher than in white women and white men, who have rates of 49.2% and 61%, respectively (47). Figure 29.5 shows the combined overweight and obesity (BMI >25) rates by gender in the Hispanic, non-Hispanic black, and non-Hispanic white population according to the NHANES III study (47). Other studies previously showed that Mexican-American adults and children, particularly women, have substantially higher rates of obesity than do non-Hispanic white Americans (48,49). The rate for diabetes has also been described to increase with each higher level of percent desirable weight in Mexican Americans, Puerto Ricans, and Cuban Americans (50). The localization of adipose tissue in the Mexican-American population has also been addressed, with upper body obesity being an important contributing factor for the development of type 2 diabetes (51,52). Low income level has also been reported to correlate with obesity. Among Mexican-American women age 20 to 74 years, the age-adjusted prevalence of overweight is 46% for women living below the poverty line as compared with 40% for those living above the poverty line (53). In an interesting finding, now applicable to many populations, low birthweight

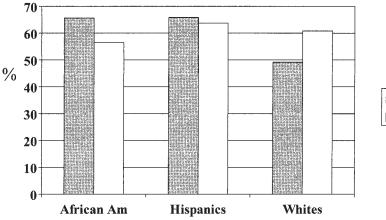

Figure 29.5. Age-adjusted prevalence of combined overweight and obesity rates (body mass index >25) in Hispanic, African-American, and white adults in the United States. (From Flegal KM, Carroll MD, Kuczmarski RJ, et al. Overweight and obesity in the United States: prevalence and trends, 1960–1994. *Int J Obes Relat Disord* 1998;22:39–47.) is associated with the development of type 2 diabetes in Hispanics (54).

Categories at Risk for Diabetes

IMPAIRED FASTING GLUCOSE AND IMPAIRED GLUCOSE TOLERANCE

Rates of IFG and IGT are higher in Hispanics than in non-Hispanic whites. The age- and sex-standardized rate of IFG in people older than 20 years of age in the NHANES III survey was 8.9% in Hispanics, 7% in blacks, and 6.8% in whites (25). Rates of IGT among adults age 40 to 74 years in the same study were also higher for Mexican Americans (20.2%) than for non-Hispanic white Americans (15.3%) and blacks (14%) (25).

GESTATIONAL DIABETES

The prevalence of gestational diabetes in Hispanics is two to three times higher than that in the general population (55). The risk of type 2 diabetes among Hispanic women who had gestational diabetes has been explored in a study of Mexican-American women in Southern California. This study showed that 12% of women with gestational diabetes progress to type 2 diabetes each year. This figure is about four times higher than that in the white population (56). Hispanic women with gestational diabetes represent an important group considered for diabetes prevention programs.

Microvascular Complications

RETINOPATHY

In the San Antonio Heart Study, the rate of diabetic retinopathy was 2.3 times higher among Mexican Americans than among non-Hispanic white Americans, even after controlling for duration of diabetes, severity of hyperglycemia, age, and systolic blood pressure (57). In concordance with these findings, the NHANES III study also found that the prevalence of diabetic retinopathy was twice as high in Mexican Americans as in whites and that this difference was not explained by duration of diabetes, glycemic control, or mode of diabetes treatment (58). In contrast, the San Luis Valley Diabetes Study found lower rates of retinopathy in Hispanics than in non-Hispanic whites (59,60). These opposite findings are not well understood but may reflect differences in some characteristics of the Hispanic groups included in these studies. The results of all three studies coincided in that severity and duration of diabetes was significantly associated with diabetic retinopathy.

The risk for microvascular complications is closely related to glycemic control. The NHANES III study found that 40.8% of Mexican Americans had glycosylated hemoglobin A_{1c} (Hb A_{1c}) values greater than 8% as compared with 35.7% of non-Hispanic whites (61). In a subgroup analysis by gender, 44.5% of Mexican-American men had Hb A_{1c} values greater than 8%. In this study, education, income, health insurance coverage, and number of physician visits per year were not associated with poor glycemic control and did not seem to explain the differences observed by ethnicity. Another study suggested that lack of outpatient health insurance is associated with a higher rate of microvascular complications in Mexican Americans (62).

NEPHROPATHY

All stages of diabetic nephropathy are more frequent in Hispanics than in non-Hispanic whites. The San Antonio Heart Study showed that the prevalence of clinical nephropathy, defined by the presence of proteinuria, was 2.8 times higher and that the prevalence of microalbuminuria was 3.5 times higher in

Mexican Americans than in non-Hispanic whites with diabetes. These differences remained statistically significant after adjusting for age and duration of diabetes (63). The NHANES III data also showed a higher prevalence of clinical proteinuria in Mexican Americans than in whites (11% vs. 5%) (50). However, the San Luis Valley Diabetes Study showed no difference in the incidence of diabetic nephropathy in Hispanics and non-Hispanic whites (59). Some clinical differences among these groups may explain these discrepant results.

The risk of end-stage renal disease (ESRD) due to diabetes, mostly type 2, has been reported to be six times higher in Mexican Americans than in whites (64,65). This increased risk does not seem to be completely explained by a higher prevalence of diabetes. Survival among Hispanics receiving hemodialysis appears to be better than among whites, perhaps because of a lower cardiovascular risk (66).

NEUROPATHY

The San Luis Valley Diabetes Study found no significant difference in the prevalence of diabetic neuropathy in Hispanics and non-Hispanic whites (59). In this study, symptoms and a physical examination, including vibration threshold, were taken into consideration to define diabetic neuropathy. In contrast, in the 1989 National Health Interview Survey, symptoms of sensory neuropathy were reported more frequently by Mexican Americans than by whites or African Americans (67).

Macrovascular Complications

CARDIOVASCULAR DISEASE

In the general population, no significant differences exist in the prevalence of nonfatal coronary heart disease (CHD), defined by electrocardiogram, among whites, blacks, and Hispanics (68). With regard to the diabetic population, studies in Texas and Colorado found lower rates of myocardial infarction in Mexican Americans than in non-Hispanic whites. Mexican Americans, men in particular, also exhibit a decreased prevalence of fatal myocardial infarction as compared with non-Hispanic whites (69,70). More studies are needed to determine whether this finding is consistent and applicable to other Hispanic subgroups.

Associated Cardiovascular Risk Factors. Findings from NHANES III indicate that the age-adjusted prevalence rate of metabolic syndrome was higher in Hispanics (Mexican Americans) than in the white population (31.9% vs. 23.7%). The ageadjusted individual metabolic abnormalities considered to define the metabolic syndrome were all higher in Hispanics than in whites: abdominal obesity, 45.7% vs 37.2%; hypertriglyceridemia, 37.7% vs 31.1%; low high-density lipoprotein (HDL) cholesterol, 39.6% vs. 37.9%; high blood pressure, 36.6% vs. 32.8%; and diabetes or IFG, 20% vs. 11.9% (71). With regard to hypertension, not all studies have shown a higher prevalence rate in Hispanics than in whites (72). In fact, the NHANES III study showed that, in the population with type 2 diabetes, the frequency of hypertension was significantly lower in Mexican Americans than in non-Hispanic whites (54% vs. 66%) (73). The prevalence rate of dyslipidemia was also lower in Hispanics than in non-Hispanic whites (51% vs. 65%) (73). Dyslipidemia in Hispanics is clearly associated with the degree of insulin resistance (74).

PERIPHERAL VASCULAR DISEASE AND AMPUTATIONS

Lavery et al. (75) found a higher incidence of diabetes-related lower-extremity amputations among Hispanics than among whites in Texas and California. In the San Antonio Heart Study, the rate of peripheral vascular disease also was higher in Mexican Americans with type 2 diabetes than among non-Hispanic whites, although in this case, this increased incidence was not statistically significant after adjusting for the prevalence of diabetes (76). Of interest are the lower in-hospital mortality rates due to amputations among Hispanics than among whites. It is not known whether this difference is related to a lower cardiovascular risk in Hispanics (77). Certainly, preventing amputations is an important task in people with diabetes in diverse populations (78).

CEREBROVASCULAR DISEASE

In a multicenter evaluation of nondiabetic subjects, the Insulin Resistance and Atherosclerosis Study found that common carotid artery intimal-medial thickness was significantly lower in Hispanics than in non-Hispanic whites, suggesting a lower degree of atherosclerosis (79). This difference remained even after adjusting for major cardiovascular risk factors and insulin sensitivity. This measure of atherosclerosis exhibited a clear relationship with the degree of insulin resistance in the study groups. No difference between Hispanics and whites was seen regarding the internal carotid artery measures (79). However, the degree of thickness of internal carotid artery plaque was lower in Hispanics than in blacks and whites in the Northern Manhattan Stroke Study (80).

Lifestyle and Cultural Factors

As previously mentioned, the prevalence of obesity is higher in the Hispanic population. An interesting cultural aspect about obesity is that the desire to lose weight may not be as strong among some Hispanics as among people of some other cultures. It is well known that in some societies women equate thinness with beauty; however, some Hispanic women, particularly older women, may equate physical robustness with physical health. As a result, being overweight may be considered normal and in some instances preferable to being slimmer (81,82). Food preferences are shared but are not necessarily the same for all Hispanic subgroups. There are differences in traditional foods among people from the many countries in Central and South America. The diet of Mexican Americans has been found to be slightly more atherogenic than the diet of whites (83). However, this concept cannot be generalized to all Hispanic subgroups. Even more, some traditional foods may have some beneficial effects in diabetes (84,85).

With regard to physical activity, the HHANES showed that the prevalence of diabetes was lower among Hispanic men with high levels of work-related physical activity than among those who had less physically demanding work (35). Unfortunately, The NHANES III survey found that 65% of Mexican-American men and 74% of Mexican-American women reported little or no leisure-time physical activity (86). Exercise was found to be inversely predictive of the incidence of type 2 diabetes among Mexican-American women (87).

The process of acculturation of Hispanics, and perhaps of other groups, to mainstream U.S. society has been described in terms of having two limbs: an ascending limb at which people adopt unhealthy food choices and become more sedentary, and a potential descending limb, at which people become progressively more affluent and try to adopt a healthier lifestyle (88). This latter stage, reflecting a higher level of acculturation, has been correlated with reduced prevalence of type 2 diabetes among Mexican Americans (89). For some other social aspects, lower socioeconomic status and education level is linked to a higher prevalence of diabetes (90,91).

Another important cultural aspect of diabetes care is language. A significant proportion of Hispanics do not speak English, and the healthcare system does not always provide services in Spanish. This issue has represented a limitation for healthcare access (92, 93). A study conducted in a group of Hispanic patients with diabetes showed that recall of the disease process and treatment information was higher in patients who were seen by bilingual physicians than in patients who were seen by physicians who spoke only English (94).

Like any ethnic group, the Hispanic culture is rich in beliefs, traditions, practices, and attitudes. Among Hispanics, family and religion play a crucial role in day-to-day life. All these aspects offer an opportunity to develop culturally and linguistically appropriate services and educational programs for Hispanics (95).

DIABETES IN AFRICAN AMERICANS

The African-American Population

DEFINITION

Black or *African American* refers to people who have origins in any of the black racial groups of Africa (18).

DEMOGRAPHICS

According to the 2000 U.S. census, there are 34.7 million African-American people in the country, representing 12.3% of the total U.S. population (18). The median age of this population is 30 years. Approximately 33% are younger than 18 years of age and 8% are older than 65 years of age. The majority of African Americans live in the South (54%), and 16% live in the Midwest, 18% in the Northeast, and 10% in the West. The ten states with the largest black populations are New York, California, Texas, Florida, Georgia, Illinois, North Carolina, Maryland, Michigan, and Louisiana. Between 1990 and 2000, the rate of increase in the black population was greater than that of the total population (15.6% vs. 13.2%) (18).

Diabetes Epidemiology

PREVALENCE AND INCIDENCE OF DIABETES

Type 1 Diabetes. Rates of type 1 diabetes appear to be lower in African-American children than in white American children (96). Incidence rates have been reported at around 5 to 8 per 100,000 per year in the African-American population, as compared with 14 to 17 per 100,000 per year in the white population. The distinct incidence rates reported in black populations may be due to the different proportions of racial admixture, particularly with the white population (97). It is known that genetic factors play a significant role in the development of type 1 diabetes. The major histocompatibility genes (HLA) most frequently associated with type 1 diabetes are infrequent in this population (98).

Type 2 Diabetes. The prevalence of type 2 diabetes in African Americans is higher than in the non-Hispanic white population and similar to that in Hispanic-Americans. Figure 29.2 shows the most recent national data according to the NHANES III survey conducted from 1988 to 1994. The prevalence rate of diagnosed diabetes in African Americans older than 20 years of age is 8.2%, as compared with 4.8% in whites. Among those age 40 to 74 years in this survey, the prevalence rate was 18.2% for blacks and 11.2% for whites. Therefore, the prevalence of type 2 diabetes in African Americans is approximately 1.6 times higher than in whites (25). Over the past 35 years, the number of people diagnosed with diabetes in this population has significantly increased. The total diabetes prevalence in African Americans

40 to 74 years old has increased from 8.9% in 1976 to 1980 to 18.2% in 1988 to 1994. Other studies have also reported a higher prevalence of diabetes in blacks than in whites (99). The incidence of type 2 diabetes has also been reported to be distinctly higher in the black population than in the white population (100,101).

The rates for undiagnosed diabetes and IFG are also higher in African Americans than in whites (Fig. 29.2). It is estimated that among blacks there is one case of undiagnosed type 2 diabetes for every two diagnosed cases. This is similar to the proportion for other racial/ethnic groups in the United States. Identifying patients with diabetes is a major task in this group, as it is in the general population.

Subgroup Analysis. Age. The proportion of the African-American population with diabetes increases with age, increasing from less than 2% for people younger than 39 years old to as high as 21% for those 60 to 74 years old (25) (Fig. 29.3). These rates are based only on diagnosed cases of diabetes; therefore, the rates for total diabetes, which include undiagnosed cases, would be higher. Type 2 diabetes frequently develops in children and adolescents from this population (33).

Gender. The NHANES III survey found that the prevalence of diabetes in the African-American population is higher in women than in men at all ages (25). Among those age 20 years or older, the prevalence rate of diagnosed diabetes was 9.1% for women and 7.3% for men. The prevalence of undiagnosed diabetes in this study was 4.5% in women and 2.7% in men. However, the prevalence of IFG was 6.4% in women and 7.7% in men, whereas the prevalence of IGT was 13% in women and 15% in men.

MORTALITY

Diabetes is the seventh leading cause of death in the general African-American population and the fifth leading cause of death in people 45 years of age or older (102). In all age groups, the diabetes-related mortality rate is higher in African Americans than in whites (103). The overall mortality rate is 20% higher for black men and 40% higher for black women as compared with the rates in whites. These increased mortality rates have also been found in high-income areas (104).

Pathophysiology of Type 2 Diabetes

GENETIC PREDISPOSITION

As postulated in the "thrifty gene hypothesis," some populations, such as Africans, developed a genetic adaptation to "feast and famine" cycles to use food energy more efficiently. It is believed that this protective change has now become an unfavorable situation that increases the risk of type 2 diabetes (2,3). Unfortunately, the precise genes that increase the risk for diabetes in the African-American population have not been clearly identified. However, these genes are very likely involved in increasing insulin resistance, decreasing insulin production, or both.

INSULIN RESISTANCE

African Americans have been found to have a higher degree of insulin resistance than their white counterparts. The NHANES III survey found that insulin levels were higher in African Americans without diabetes than in whites without diabetes (50). Hyperinsulinemia is a compensatory mechanism for overcoming peripheral insulin resistance and is thus an indirect measure of insulin resistance. This finding was particularly evident in African-American women and is consistent with the high rates of obesity and diabetes reported in black women. The Insulin Resistance and Atherosclerosis Study found significantly higher levels of insulin resistance and acute insulin response in nondiabetic African Americans than in nondiabetic whites, even after adjusting for obesity and body fat distribution (45).

In an alarming fashion, the full-blown syndrome of insulin resistance and type 2 diabetes are now frequently noted in African-American children and adolescents (33). African-American children have been found to have higher acute insulin responses and lower insulin sensitivity than white children, even after adjusting for body composition, social-class background, and dietary patterns (105).

INSULIN SECRETION

Deficient insulin secretion has been considered an important pathophysiologic element in the development of type 2 diabetes in African Americans. It has been identified not only in people with type 2 diabetes but even in those with impaired glucose tolerance (106).

Some interesting atypical forms of diabetes have been described in this population. A form of diabetes that presents with features of type 1 diabetes, with an evident insulin-secretion deficiency but without the usual HLA associations, has been reported (107). An interesting form of diabetes, called "Flatbush diabetes," has also been described (108). These individuals present with ketoacidosis and a subsequent clinical course of type 2 diabetes. They are negative for antibody to glutamic acid decarboxylase and have an increased frequency of HLA-DR3 and -DR4 antigens (108). In addition, a ketosis-resistant diabetic syndrome associated with malnutrition has been reported in Jamaica. This form is associated with impaired insulin function and phasic insulin dependence (109). Some transient remission due to recovery of β-cell function after intensive glycemic control has also been reported in some African Americans (110).

OBESITY

Consistent with the higher rates of diabetes and insulin resistance, the prevalence of obesity is higher in African-American adults than in whites. Recent U.S. data show that the ageadjusted prevalence of combined overweight and obesity (BMI >25) in black women older than 20 years of age is 65.8%. The rate in black men is 56.5% (47). The corresponding rates in white women and white men are 49.2% and 61%, respectively (47) (Fig. 29.5). The difference between blacks and whites is noted only among women. In addition, the rates of central obesity, which is related to an increase in visceral fat that is clearly associated with the risk of diabetes, hypertension, and dyslipidemia, are also higher in the black population than in the white population.

It is tempting to believe that the higher rate of diabetes among African Americans is merely related to higher rates of obesity. However, the prevalence of diabetes is still higher in this population than in whites after adjusting for the presence of obesity and its degree and type (50,69). The extent to which obesity per se contributes to the higher rate of diabetes in blacks is uncertain; however, as in all populations, obesity is clearly a factor that increases the risk of diabetes and its associated metabolic abnormalities.

Categories at Risk for Type 2 Diabetes

IMPAIRED FASTING GLUCOSE AND IMPAIRED GLUCOSE TOLERANCE

According to the NHANES III study (25), the prevalence rate of IFG, standardized for sex and age, among adults older than

20 years of age was 7% for non-Hispanic blacks, 6.8% for whites, and 8.9% for Hispanics (Fig. 29.2). Application of the WHO diagnostic criteria for fasting and postchallenge plasma glucose to the NHANES III data gives a prevalence of IGT in people between 40 and 74 years of age of 14% for non-Hispanic blacks, 15.3% for non-Hispanic whites, and 20.2% for Hispanics (25).

GESTATIONAL DIABETES

Gestational diabetes develops in approximately 2% to 5% of all pregnant women. The likelihood of developing gestational diabetes is higher among those who generally have risk factors for type 2 diabetes, usually due to a combination of genetic predisposition and acquired factors such as obesity, unhealthy dietary patterns, and physical inactivity. African-American women have a high risk of type 2 diabetes and gestational diabetes develops 50% to 80% more frequently than in white women (111).

Microvascular Complications

RETINOPATHY

According to the NHANES III data, the prevalence of diabetic retinopathy is 40% to 50% higher in African Americans than in white Americans (58). African-American women have been found to have worse glycemic control than white women (61). The NHANES III study found that 45.7% of non-Hispanic blacks had HbA_{1c} values greater than 8% as compared with 35.7% of non-Hispanic whites. In a subgroup analysis by gender, 50% of non-Hispanic black women had HbA1c values >8%. In this study, education, income, health insurance coverage, and number of physician visits per year were not associated with poor glycemic control (61). This factor may provide a partial explanation for the higher frequency of retinopathy. In addition, the high rates of hypertension in blacks also seem to play a role (112). However, in a 4-year follow-up study of middle-aged subjects with type 2 diabetes, the rate of development of retinopathy was higher (50% vs. 19%) in blacks than in whites. This result could not be explained by differences between the groups with respect to HbA1c or blood pressure levels, type of diabetes treatment, or gender distribution (113). These findings suggest that African Americans may have an underlying predisposition for the development of retinopathy and perhaps for other diabetes-induced microvascular complications. Further research is needed to clarify this aspect.

NEPHROPATHY

All stages of diabetic nephropathy are more prevalent among African Americans than among whites. Several studies have demonstrated that the rates of microalbuminuria and clinical nephropathy (macroalbuminuria) are very high in the African-American population (114-116). In addition, ESRD due to diabetes is about four times more common in African Americans than in whites. After adjustment for the underlying increased prevalence of diabetes, this number is reduced to 2.6 (115). The high frequency of ESRD in African Americans seems to be influenced by the high rates of hypertension in this population. However, a study that adjusted for systolic blood pressure found that blacks still had a 63% higher risk of developing ESRD (117). As reported for the Hispanic population, African Americans have better survival rates after they develop kidney failure than do white Americans (118,119). The reason for this is unclear. It may be that blacks receive transplants less frequently, and therefore more patients who are eligible for transplants are

placed on dialysis (119). In addition, the rates of voluntary withdrawal from dialysis are lower among African Americans than among whites. (120).

NEUROPATHY

Neuropathy is a very common complication in diabetes. Its prevalence depends on the diagnostic criteria. No particular difference in neuropathy rates has been reported in the African-American population as compared with whites or Hispanics (121).

Macrovascular Complications

CARDIOVASCULAR DISEASE

Although no significant differences in the prevalence of nonfatal myocardial infarction have been found among whites, blacks, and Hispanics in the general population (68), African Americans have the highest overall mortality rate due to CHD and the highest out-of-hospital coronary death rates, particularly at younger ages, of any ethnic group in the United States (122).

Associated Cardiovascular Risk Factors. A high incidence of hypertension has been reported in the African-American population. This increased rate seems to be related in part to the high prevalence of obesity and insulin resistance. However, there also seems to be a specific predisposition for the development of hypertension independent of the insulin resistance syndrome (123). Hypertension and left ventricular hypertrophy are more prevalent in African Americans, develop at younger ages, and are associated with mortality rates three to five times higher than the rates in whites (124).

Most population-based surveys indicate that total serum cholesterol levels are lower and the prevalence of hypercholesterolemia is similar or lower in African Americans than in whites (125). Levels of HDL cholesterol are approximately 20% higher in African-American men than in their white counterparts (126). Triglyceride levels in black men and women are generally lower than those in whites in both individuals with and without CHD (127). Levels of lipoprotein(a) are two to three times higher in African Americans than in whites, although they have not been independently associated with an increased cardiovascular risk (128-130). In the nondiabetic population, African Americans may exhibit the typical dyslipidemia associated with insulin resistance, consistent of high triglycerides, low HDL-cholesterol, and small LDL-cholesterol particles (73). Plasminogen activator inhibitor 1 activity has been found to be lower in African Americans than in whites, although this difference may be attributable to distinct dietary patterns (131).

PERIPHERAL VASCULAR DISEASE AND AMPUTATIONS

Among people with diabetes, the likelihood of an African American undergoing an amputation of a lower-extremity amputation is twofold higher than that in whites (75,76). An important contributing factor is the high prevalence of peripheral vascular disease in African Americans (132). In addition, rates of in-hospital amputation-related mortality are twice as high in African Americans as in whites (76).

CEREBROVASCULAR DISEASE

The Insulin Resistance and Atherosclerosis Study included the measurement of common carotid artery intimal-medial thickness in a white, black, and Hispanic nondiabetic population. African Americans had more atherosclerosis than did whites,

514 JOSLIN'S DIABETES MELLITUS

even after adjusting for traditional cardiovascular risk factors and insulin sensitivity. Within the African-American population, this measurement was not significantly related to the degree of insulin resistance, perhaps because of an absence of wide variation in the degree of insulin resistance in this group (79). A high rate of carotid atherosclerosis in blacks has also been reported in another multiethnic population (80). In the general population, rates of cerebral vascular disease have also been reported to be higher among blacks than among whites, but no information about people with diabetes is available (133).

Lifestyle and Cultural Factors

Obesity contributes to the development of diabetes and plays a major role in establishing the course of the disease. Therefore, there has been strong interest in assessing how particular lifestyle factors may promote obesity in this population. There is wide variability in lifestyle patterns among people within each ethnic group. However, many individuals share preferences and attitudes. It has been found that black people consume more fat and sodium and less fiber than do white people (134). This may be a factor that increases the risk to diabetes, although no study has shown a clear cause-and-effect relationship. Another important factor in the natural history of diabetes is physical activity. The NHANES III survey found that 50% of black men and 67% of black women reported little or no leisuretime physical activity (86). These numbers are slightly higher than in the white population. Lifestyle factors are believed to play a major role in the development of type 2 diabetes in this population (135).

Not only are dietary factors and limited physical activity probable contributors to the high rate of obesity in this population, but also some women may not be very willing to lose weight. A study suggests that some African-American women consider obesity and robustness as indicators of good health (136).

Socioeconomic factors certainly influence the development of diabetes and its course. In the African-American population, low-income status and low educational level have been linked to the development of type 2 diabetes (137).

Common beliefs, attitudes, and traditions are part of the African-American culture, as in other cultures. All these factors in combination with social and economic elements need to be taken into account when establishing programs for African Americans with diabetes and at risk for the disease (138,139).

DIABETES IN NATIVE AMERICANS AND ALASKA NATIVES

The Native American and Alaska Native Population

DEFINITION

Native American and *Alaska Natives* refer to people having origins in any of the original peoples of North, Central, and South America and who maintain tribal affiliation or community attachment (18).

DEMOGRAPHICS

There are 2.5 million Native Americans and Alaska Natives in the United States, representing 0.9% of the total population in the country (18). The median age of this group is 28 years, whereas it is 38 years for whites. Approximately 44% of members of these groups are younger than 18 years of age, and 6.3% are older than 65 years of age. More of the nation's Native Americans, Eskimos, and Aleuts live in Oklahoma than in any other state (13%). Arizona, California, New Mexico, and Alaska are the next most popular states of residence. The subgroups with more people are Cherokee, Navajo, Sioux 1, Chippewa, Choctaw, Pueblo 2, and Apache. Pima Indians, a well-known subgroup with high diabetes prevalence rates, represent 0.8% of the Native American group. Since 1990, the Native American population has grown by 12%, while the non-Hispanic white population has increased by 3%. The projected growth of this group is 40% over the next 20 years.

Diabetes Epidemiology

PREVALENCE AND INCIDENCE OF DIABETES

Type 1 Diabetes. Type 1 diabetes is relatively rare in Native Americans and Alaska Natives. Some of the reported cases may in fact correspond to people who have some additional European white genetic background (140).

Type 2 Diabetes. On average, Native Americans and Alaska Natives are 2.8 times more likely than non-Hispanic whites of a similar age to have diagnosed diabetes (140). The diabetes rates in these populations are increasing rapidly. The Centers for Disease Control and Prevention reported an increase in the prevalence of diabetes from 5.2% to 8.5% among Native Americans and Alaska Natives between 1990 and 1998, an increase of 65% in 8 years (141). The Indian Health Service reported an increase in the age-adjusted prevalence rate of diabetes in these groups from 6.2% to 8% between 1990 and 1997, an increase of 29% in 7 years (142). However, these rates do not seem to accurately reflect the actual diabetes epidemic in some of these populations. Among adults older than 20 years old in the Navajo community, the reported age-adjusted prevalence rate of diabetes is 22.9% (143). Another screening study that included three Native American populations found that 40% to 70% of adults 45 to 74 years old have diabetes (144). Among Pima Indians, the most widely studied Native American group, the prevalence of type 2 diabetes is approximately 50% among individuals 30 to 64 years old and is considered to be the highest in the world (145). There are many other studies showing high rates of diabetes in Native Americans and Alaska Natives (146-157). It is interesting that the prevalence of diabetes is slightly lower among Alaskan Eskimos and Inuits than among non-Hispanic whites (140).

Subgroup Analysis. Age. In both men and women in every age group, the prevalence of type 2 diabetes is higher in Native Americans and Alaska Natives than in non-Hispanic whites (142) (Fig. 29.6). Native American children and adolescents frequently manifest type 2 diabetes (33). Among Pima Indian children, the prevalence of type 2 diabetes in girls 10 to 14 years old increased from 0.72% in the period 1967 to 1976 to 2.88% in the period 1987 to 1996 (158).

Gender. Among Native Americans and Alaska Natives, more women than men have diabetes (142) (Fig. 29.6). However, between 1990 and 1997, the prevalence increased at a greater rate among men than among women (37% vs. 25%) (141).

Native American and Alaska Native subgroups. The prevalence rates of diabetes among the many Native American and Alaska Native groups appear to be different. The recent survey from the Indian Health Service has reported various diabetes prevalence rates by the main geographic regions where these groups are found. The prevalence rates vary from around 3% in the Alaska region to 17.4% in the Atlantic region (142) (Fig. 29.7).

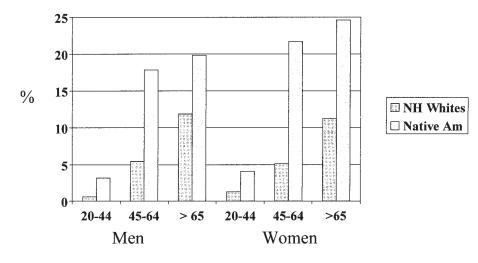

Figure 29.6. Prevalence of type 2 diabetes in Native Americans (*NA*) and Alaska Natives (*AN*) as compared with non-Hispanic (*NH*) whites by age group and gender. (From Rios Burrows N, Geiss LS, Engelgau MM, et al. Prevalence of diabetes among Native Americans and Alaska Natives, 1990–1997. *Diabetes Care* 2000;23: 1786–1790.)

MORTALITY

Diabetes was considered to be the sixth leading cause of death among Native Americans and Alaska Natives in the United States between 1984 and 1986. The adjusted mortality rate for diabetes in Native Americans was 4.3 times the rate in non-Hispanic whites between 1986 and 1988. Diabetes-related mortality rates are very similar in Aleuts, Eskimos, and Native Americans. In New Mexico, diabetes-related mortality increased by 564% and 1,110% for Native American men and women, respectively, from 1958 to 1994 (159,160). Several factors are thought to play an important role in increasing diabetes-related mortality among Native Americans and Alaska Natives, such as diabetes duration, the presence of cardiovascular risk factors, and proteinuria (140,161–167).

Pathophysiology of Type 2 Diabetes

GENETIC PREDISPOSITION

The nature of the primary genes responsible for increasing the risk of obesity and diabetes in Native Americans and Alaska Natives is still not well defined. In has been proposed that some genetic adaptation has occurred in many minority groups to survive the lack of constant food supplies in ancient times (2,3,168). One certain aspect is that individuals among the

Native American population with the least genetic admixture with other groups have a higher risk of developing diabetes, which suggests an evident genetic predisposition for the disease (140).

Although members from the same family tend to share environmental factors that could increase the risk for diabetes, the high occurrence of diabetes among descendants of individuals with type 2 diabetes also suggests an important genetic influence (161,169). The high rates of diabetes in some subgroups such as Pima Indians has been seen as an excellent opportunity to conduct diabetes-related genetic studies (170). Some interesting information is now available from these studies in Pima Indians and other groups about genes that could explain some of the metabolic abnormalities that lead to diabetes in these groups (171–175).

INSULIN RESISTANCE

The high prevalence of diabetes in Pima Indians has allowed investigators to establish important prospective studies to aid in understanding the natural history of type 2 diabetes. These studies have contributed to the concept of a dual defect that leads to the development of diabetes: insulin secretory dysfunction and insulin resistance (176,177). Recent elegant studies have shown that both phenomena deteriorate progressively as

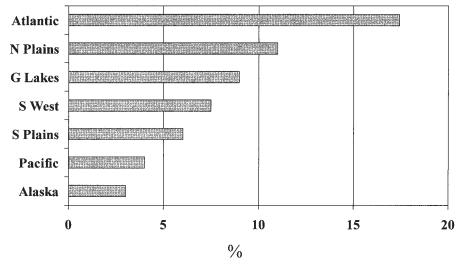

Figure 29.7. Age-adjusted prevalence of diagnosed diabetes by region among Native Americans and Alaska Natives from 1990 through 1997. (From Rios Burrows N, Geiss LS, Engelgau MM, et al. Prevalence of diabetes among Native Americans and Alaska Natives, 1990–1997. *Diabetes Care* 2000;23:1786–1790.)

516 JOSLIN'S DIABETES MELLITUS

individuals make the transition from normal glucose tolerance to impaired glucose tolerance to diabetes (178). In fact, both insulin resistance and insulin secretory dysfunction are independent risk predictors of worsening glucose tolerance during each stage of type 2 diabetes (179) (Fig. 29.8). Insulin resistance antedates the development of type 2 diabetes by many years and has been identified in young nondiabetic Pima Indians (180). The high rate of insulin resistance in this population is the result of lifestyle factors in addition to genetic predisposition. Some specific genetic abnormalities have been postulated to play a role in the development of insulin resistance (171–175).

INSULIN SECRETION

As already discussed, impaired insulin secretion is an important, independent factor in the progression to type 2 diabetes. Studies of Pima Indians have shown that insulin secretory dysfunction plays a significant independent role in the progression from normal glucose tolerance to IGT and to type 2 diabetes (178,179).

OBESITY

Obesity is an extremely common problem in Native American and Alaska Native communities (181). Approximately 95% of Pima Indians with type 2 diabetes are also overweight (182). Obesity increases the risk of developing type 2 diabetes in any population. Obesity is also an important factor among Pima Indians, and the duration of obesity has also been related to the development of type 2 diabetes (183,184). A more important role of central obesity over general adiposity as a predictor of type 2 diabetes has also been identified in Native American groups (185). Pima Indians have been identified as having a low metabolic rate that may contribute to the high rate of obesity in this group (140). In many populations, low birthweight has been associated with an increased risk for type 2 diabetes as adults. This association has also been found in Native Americans (186,187).

Categories at Risk for Type 2 Diabetes

IMPAIRED FASTING GLUCOSE AND IMPAIRED GLUCOSE TOLERANCE

In concordance with the high rate of obesity and type 2 diabetes among Native Americans and Alaska Natives, it is not surprising that a significant proportion of people in these groups have IFG and IGT (144,161). These are categories that indicate a considerable risk of developing type 2 diabetes.

GESTATIONAL DIABETES

The frequency of gestational diabetes has been reported for several Native American groups. In all of them, the rates are higher than in the general population (188–190). The rate for gestational diabetes varies among subgroups; for example, the rate of gestational diabetes is 14.5% among Zuni women, 5.8% among Yupik Eskimo women, and 3.4% among Navajo women. In all cases, the frequency of gestational diabetes is higher than in the white population, which is around 2%. Women with gestational diabetes have a high risk of type 2 diabetes. Type 2 diabetes develops during the first 10 years after pregnancy in approximately one third of Pima and Zuni Indian women who have had gestational diabetes (188).

Adult offspring of Pima Indian women who had gestational diabetes have a significantly higher risk of type 2 diabetes than do the offspring of women who did not have gestational diabetes (191–193). Therefore, exposure to diabetes in utero is a strong risk factor for diabetes in Pima Indians.

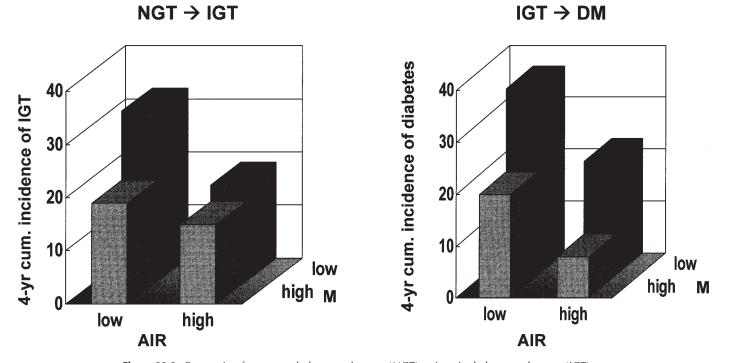

Figure 29.8. Progression from normal glucose tolerance (*NGT*) to impaired glucose tolerance (*IGT*) to diabetes mellitus (*DM*) in Pima Indians: independent effects of insulin action (*M*) and acute insulin secretory response (*AIR*). (From Weyer C, Tataranni PA, Bogardus C. Insulin resistance and insulin secretory dysfunction are independent predictors of worsening of glucose tolerance during each stage of type 2 diabetes development. *Diabetes Care* 2000;24:89–94.)

Microvascular Complications

RETINOPATHY

Diabetic retinopathy seems to be more prevalent among Native Americans and Alaska Natives than among the white population. The prevalence of diabetic retinopathy depends on the subgroup studied, duration of diabetes, presence of hypertension, and glycemic control, among others factors. Some studies of Pima and Oklahoma Indians show the high frequency of diabetic retinopathy (194–196).

NEPHROPATHY

As discussed for other minority groups, the rates of nephropathy at all stages are very high in Native Americans and Alaska Natives. High rates of microalbuminuria and clinical nephropathy have been reported (197–200). ESRD is the leading cause of death in Pima Indians (199). The rate of development of ESRD is six times higher in Native Americans with diabetes than among non-Hispanic whites with diabetes (201). An interesting finding among Alaska Natives is that ESRD is more likely to develop in women than men, and women are more likely to die of renal failure. Studies from other populations confirm this finding (202–204). The reason for these high rates of nephropathy among Native Americans and Alaska Natives is not well understood. However, there also seems to be a genetic predisposition for renal disease (205).

NEUROPATHY

Neuropathy can develop in Native Americans and Alaska Natives as a consequence of diabetes. No different rates of neuropathy have been reported in these groups in comparison to the rates in other populations (206,207).

Macrovascular Complications

CARDIOVASCULAR DISEASE

Cardiovascular disease is the leading cause of death among Native Americans with diabetes, particularly those with nephropathy (208,209). Cardiovascular mortality is higher in Native Americans than in non-Hispanic whites in the United States (210). However, the prevalence of coronary artery disease (CAD) in Pima Indians is not as high as expected for individuals with such a high rate of diabetes and hypertension (211).

The Strong Heart Study recently reported that prevalence of CAD was twofold to threefold lower among the communities in Arizona than among those in Oklahoma, South Dakota, and North Dakota. The lower prevalence of CAD among Native Americans in Arizona may be related to a low prevalence of smoking and a more favorable lipid profile, manifested by low concentrations of total and low-density lipoprotein cholesterol (212).

Associated Cardiovascular Risk Factors. Before 1950, the prevalence of hypertension in Native Americans was 8% to 10%, as compared with the national average of about 25% (213). However, in the past few years, hypertension has been reported to be higher in Native Americans than in the general population. This increasing rate may be due to changes in lifestyle (214). Similarly, cholesterol levels, which have traditionally been reported as lower in Native Americans than in the general population, have gradually increased over time (215).

PERIPHERAL VASCULAR DISEASE AND AMPUTATIONS

In general, rates of lower extremity amputation are high in some Native Americans but may vary by tribe. The rate of amputation is 3.7 times higher among Pima Indians than overall rates compiled previously for six states (216). Most studies suggest that amputations represent a major health problem in Native Americans (217,218). When data are analyzed by gender, several studies indicate a higher amputation rate among men than among women.

CEREBROVASCULAR DISEASE

Few data are available on stroke prevalence and incidence rates among Native Americans. The incidence of stroke in Alaska Natives was greatest among Eskimos, followed by Aleuts, and Indians. The overall incidence of stroke in Eskimo women was higher than in any other group studied (140).

Lifestyle and Cultural Factors

Native Americans and Alaska Natives have gone through an obvious process of lifestyle changes over many years. They have gradually incorporated a diet with more fat and less complex carbohydrates and have become more sedentary. These changes in the setting of the already discussed genetic predisposition for the development of obesity and diabetes have had a tremendously unfavorable impact on their rates of obesity and type 2 diabetes (219). An interesting study in Pima Indians showed that physical activity is associated with insulin sensitivity independent of its effect on body composition (220). There is a natural example of the severe impact that the adoption of an unhealthy diet and a more sedentary lifestyle can have on the development of type 2 diabetes. Pima Indians living in Mexico who consume a more traditional diet (less animal fat and more complex carbohydrates) and who are more physically active have a lower prevalence of type 2 diabetes than do Pima Indians living in Arizona (221).

It is well known that Native Americans have a genetic tendency for the development of obesity and, therefore, of type 2 diabetes (222). Culturally oriented programs to improve lifestyle in Native Americans with diabetes have been very successful in improving glycemic control and additional cardiovascular risk factors in this population (223–225). Native Americans and Alaska Natives have a rich culture with a vast array of traditions, beliefs, and behaviors. Understanding and respecting their culture has been a crucial element in establishing successful obesity and diabetes research and clinical care programs among these groups (226–228).

DIABETES IN ASIANS AND PACIFIC ISLANDERS

The Asian and Pacific Islander Population

DEFINITION

Asian refers to people having origins in any of the original peoples of the Far East, Southeast Asia, or the Indian subcontinent. *Pacific Islander* refers to people having origins in any of the original peoples of Hawaii, Guam, Samoa, or other Pacific Islands (18).

DEMOGRAPHICS

According to the recent 2000 U.S. census, there are 10.2 million Asians and Pacific Islanders in the country, representing 3.6% of the total population (18). Approximately 29% of them are younger than 18 years of age, and only 6.2% are older than 65 years of age, in contrast to the non-Hispanic white population, among whom the proportions are 24% and 14%, respectively. Since 1990, the Asian and Pacific Islander population has grown at a rate of about 4.5% per year. The Immigration Act of 1965 and the arrival of many Southeast Asian refugees under the

518 JOSLIN'S DIABETES MELLITUS

Refugee Resettlement Program after 1975 contributed to the increase in population observed in the past two decades. Six of every 10 Asians and Pacific Islanders reside in metropolitan areas in the western region, and approximately 73% are located within seven states: California, Hawaii, Illinois, New Jersey, New York, Texas, and Washington. The major subgroups are Chinese, Filipino, Asian Indian, Korean, Vietnamese, and Japanese. Some of the Asian subgroups, such as the Chinese and Japanese, have been in the United States for several generations. Others, such as the Hmong, Vietnamese, Laotians, and Cambodians, are comparatively recent immigrants. The major Pacific Islander subgroups are Hawaiian, Guamanian or Chamorro, and Samoan. Relatively few of the Pacific Islanders are foreign born.

Diabetes Epidemiology

PREVALENCE AND INCIDENCE OF DIABETES

Type 1 Diabetes. Type 1 diabetes among Asian children is relatively rare. The rate of type 1 of diabetes is significantly lower than among non-Hispanic whites. Both genetic and environmental factors are thought to be involved in the etiology of type 1 diabetes in any racial group. A good example of the influence of environmental factors is that the rates for type 1 diabetes in Japanese children in Hawaii have been reported to be higher than the rates for Japanese children in Tokyo (6).

Type 2 Diabetes. Few studies have addressed the prevalence of type 2 diabetes in Asian and Pacific Islander Americans in the United States. A study of Native Hawaiians showed that approximately 22% of persons older than age 30 years have type 2 diabetes. Among people between the ages of 60 and 64 years, about 40% of them have type 2 diabetes (229). This is considerably higher than the rate of type 2 diabetes in whites. In the Japanese population in the United States, approximately 37% of people between the ages of 45 and 74 years have diabetes (230-232). The prevalence of diabetes is lower in other subgroups, such as Polynesians (1.1% for men and 7.2% for women) (6). A distinct gender lifestyle pattern may explain this observed wide difference in diabetes prevalence. Similarly, in Western Samoa, a difference in diabetes prevalence in a rural and an urban community (3.4% vs 7.8%) has been found (6). Lifestyle factors, dietary habits, and level of physical activity play a major role in these differences.

Subgroup Analysis. Age and gender. The incidence of type 2 diabetes is increasing in young people, particularly members of minority groups (33). The rate of type 2 diabetes is also increasing gradually among Asians and Pacific Islanders, as it has been shown for Japanese children and adolescents (6). With regard to gender differences, there are no solid data to suggest that the prevalence of diabetes differs by gender per se. The study of Polynesians that shows a sevenfold higher rate of diabetes in women than in men seems to be explained by their clear differences in physical activity (6).

Asian and Pacific Islander subgroups. Filipinos have the highest prevalence of diabetes among the four largest ethnic Asian groups in Hawaii (Chinese, Filipino, Japanese, and Korean). However, the prevalence is higher in all groups than among whites (233).

MORTALITY

Diabetes is the fifth cause of death among Asians and Pacific Islanders, whereas it is the seventh leading cause of death in whites (6). However, a comparison of adjusted diabetes-related mortality rates in Asian and Pacific Islander Americans with those of other ethnic groups indicates that these rates are very close to the rate in whites (approximately 12 to 14 per 100,000) but two to three times lower than the rates reported for African Americans, Native Americans and Alaska Natives, and Hispanic Americans (6).

Pathophysiology of Type 2 Diabetes

GENETIC PREDISPOSITION

Among Asian and Pacific Islanders, like other minority groups in the United States, the rates of diabetes are higher than those in the white population. It is believed that genetic factors play a significant role in increasing the risk of developing type 2 diabetes in these groups. No data on specific genetic abnormalities that could explain this increased risk have emerged. However, as mentioned for other ethnic groups, whatever genetic factors are responsible for this predisposition may have been the result of an adaptation to conditions prevalent many years ago (2,3).

INSULIN RESISTANCE

Studies in Japanese-American and Japanese men with type 2 diabetes have provided interesting information. Insulin levels, an indirect measure of insulin resistance, have been evaluated in these two groups. Both groups exhibit hyperinsulinemia, consistent with the presence of insulin resistance. Insulin levels, measured during an oral glucose tolerance test, are higher in Japanese-American men than in Japanese men, suggesting a higher degree of insulin resistance. Japanese-American men are usually more obese than Japanese men. However, insulin levels in Japanese Americans continue to be higher than those in Japanese men even after adjusting for BMI. Therefore, factors other than obesity contribute to insulin resistance (234). As in all studied populations, insulin resistance is usually the result of a combination of genetic and environmental factors.

INSULIN SECRETION

A defect in insulin secretion is now considered an important element in the development of type 2 diabetes. It can be identified before the appearance of abnormalities in glucose tolerance. Studies of Japanese Americans have identified an early defect in insulin secretion before the development of type 2 diabetes (235). Once type 2 diabetes appears, this defect continues to have crucial importance in the progression of the disease.

OBESITY

Obesity, particular from visceral adiposity, was found to be a strong predictor of type 2 diabetes in a prospective study in Japanese-American men (236). Neither BMI, a measure of general adiposity (234), nor waist circumference (237) has been considered to be a good predictor of type 2 diabetes among Japanese Americans. Some specific measurements, such as increased leptin levels, are associated with an increased risk of type 2 diabetes in men, although not in women (238). Obesity in Asian-Americans and Pacific Islanders has become a significant problem, in part due to the adoption of a "Westernized" diet and a more sedentary lifestyle. This is reflected by data showing that Japanese people who have emigrated to Hawaii or the continental United States have twice the rates of obesity and diabetes of Japanese people in Japan (6).

Categories at Risk for Type 2 Diabetes

IMPAIRED FASTING GLUCOSE AND IMPAIRED GLUCOSE TOLERANCE

Studies of two different Asian and Pacific Islander subgroups have assessed categories at risk for type 2 diabetes. A study in Native Hawaiians showed a prevalence rate of IGT of 15.6% in the adult population. Studies in Japanese Americans have also shown a higher rate of IGT than in the general U.S. population (231,239). A recent report suggests that Japanese Americans with IGT based on the 2-hour plasma glucose level have significant metabolic abnormalities despite having a normal fasting plasma glucose level (240). Therefore, classification of Japanese Americans by fasting plasma glucose levels does not allow the identification of all people with unfavorable cardiovascular risk profiles.

GESTATIONAL DIABETES

Little information is available on the prevalence of gestational diabetes among Asian American and Pacific Islander women. Those that have been reported are similar to those of non-Hispanic white women in the United States (approximately 2% to 3% of pregnancies) (6).

Microvascular Complications

NEPHROPATHY

Asian Americans and Pacific Islanders have a higher rate of ESRD than do whites. However, the prevalence of ESRD is lower than in other minority groups, such as African Americans, Hispanics, and Native Americans (241). No data on the incidence of retinopathy or neuropathy are available for Asians and Pacific Islanders.

Macrovascular Complications

CARDIOVASCULAR DISEASE AND CARDIOVASCULAR RISK FACTORS

CHD is one of the leading causes of death for both diabetic and nondiabetic Asians and Pacific Islander men and women (6).

Japanese Americans with impaired glucose tolerance and diabetes have an increased risk of CHD (242). Visceral adiposity, blood pressure, and plasma glucose levels are independent risk factors for incident CHD in diabetic and nondiabetic Japanese Americans (243). Obesity in this population is also associated with CHD (242). The typical dyslipidemia of the insulinresistance syndrome, including high triglycerides, low HDL cholesterol, and small dense low-density lipoprotein particles, has been detected in this population. Dyslipidemia is associated with visceral adiposity and fasting insulin levels in nondiabetic Japanese Americans (244). There are no published reports on the rate of amputations, peripheral vascular disease, or cerebral vascular disease in this population.

Lifestyle and Cultural Factors

Asians and Pacific Islanders have also suffered from the "westernization" effect of some particular diets and the lack of physical activity. Japanese Americans consume more calories, protein, fat, and carbohydrates than do Japanese individuals living in Japan. For example, the mean daily intake of fat in Japanese-American men is approximately 32.4 g while that of Japanese men in Japan is about 16.7 g. The diet of the latter group is based more on fish and plants (6).

Data also suggest that Japanese Americans are more sedentary than Japanese living in Japan (6). Therefore, the combination of a more unhealthy diet and less physical activity on the presence of some genetic factors has contributed to the fourfold increased rate of obesity and type 2 diabetes in some Asian groups in the United States compared with the same groups in their country of origin (245). Figure 29.9 compares the rate of diabetes in Japanese Americans in Seattle with the rate in Japanese individuals in Tokyo (234). People who come to the United States who preserve their original lifestyle, including a more balanced diet and more physical activity, seem to have a lower rate of diabetes than do those who adopt a more unhealthy lifestyle (246).

Other important cultural and lifestyle factors that influence the development of type 2 diabetes are income and educational level. A low level of either of these has been associated with an increased risk for type 2 diabetes among Japanese Americans (247). Another important element that influences access to and success in the healthcare system is language. Speaking a language different from that of healthcare providers has been found to be a barrier to diabetes care in the Asian population (248). Culturally and linguistically oriented programs are crucial to improving diabetes care in this population.

PREVENTION OF DIABETES IN MINORITY GROUPS

As stated throughout this chapter, people from minority groups have a significant risk of type 2 diabetes and its complications. Once diabetes develops, it is extremely difficult to achieve good metabolic control in any population. In some minority groups, such as Hispanics and African Americans, glycemic control tends to be even worse than that in whites.

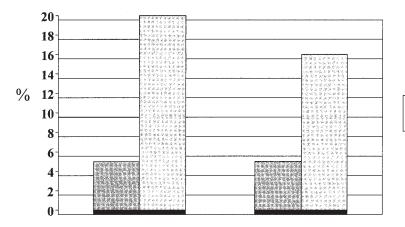

Figure 29.9. Prevalence of type 2 diabetes in Tokyo and Seattle among men and women greater than 40 years of age (1981 to 1988). (From Fujimoto W. The importance of insulin resistance in the pathogenesis of type 2 diabetes mellitus. *Am J Med* 2000;108[6A]:9S–14S.)

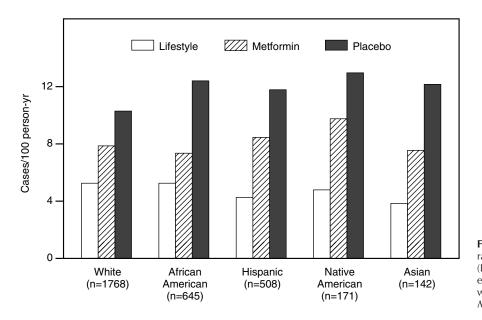

Figure 29.10. Percentage developing diabetes by race/ethnicity in the Diabetes Prevention Program. (From Knowler WC, Barrett-Connor E, Fowler SE, et al. Reduction in the incidence of type 2 diabetes with lifestyle intervention or metformin. *N Engl J Med* 2002;346:393–403.)

Because it is possible to identify individuals at risk for type 2 diabetes, the National Institutes of Health sponsored the recently completed Diabetes Prevention Program (249,250). This research project had the goal of preventing or delaying the progression to type 2 diabetes in individuals with IGT by having them participate in an intensive lifestyle modification program, taking metformin, or taking placebo. A total of 3,234 individuals were followed for an average of 2.8 years. Fortyfive percent of the people in the study were from minority groups: African Americans, Hispanics, Native Americans, and Asians and Pacific Islanders. People in the intensive lifestyle modification group achieved a mean weight loss of 5% of their initial body weight by following a healthier meal plan and increasing their exercise level. The incidence of diabetes was 11 cases per 100 person-years in the placebo group, whereas the corresponding numbers for the group taking metformin and the group in the intensive lifestyle modification were 7.8 and 4.8, respectively. Therefore, the lifestyle intervention reduced the progression to diabetes by 58% and metformin treatment reduced it by 31%. These beneficial effects were observed in all ethnic groups (251) (Fig. 29.10). The Diabetes Prevention Program will continue to observe this population for a few more years.

SUMMARY

Type 2 diabetes represents a serious health problem among minority groups in the United States. The prevalence and incidence rates for obesity, diabetes, and its vascular complications are usually higher in these groups than in the white population. In all these groups, genetic factors that have not yet been well identified increase the risk of development of type 2 diabetes. In addition, acquired factors such as a diet rich in saturated fat and carbohydrates combined with a sedentary lifestyle have increased the prevalence of obesity and type 2 diabetes to epidemic proportions in minority groups. All minority groups have a unique culture, with particular beliefs, attitudes, and traditions. Understanding and respecting these aspects of their lives are necessary elements in the development and implementation of culturally and linguistically appropriate diabetes care programs. Diabetes prevention programs represent an excellent opportunity to reduce the burden of diabetes and its complications in minority groups in the United States.

Type 2 Diabetes and the Epidemic of Cardiovascular Disease 527

Other Categories of Glucose Intolerance—Adding to the Epidemic 528

Conclusions 529

In recent years, the global community has been preoccupied with the threat of a resurgence of infectious diseases, old ones such as tuberculosis and newer ones such as human immunodeficiency virus–acquired immunodeficiency syndrome (HIV-AIDS) and the Ebola virus. However, diabetes is a growing public health problem throughout the world. Currently, approximately 171 to 194 million people in the world have diabetes, the majority of the cases being type 2 (1,2). This number is expected to increase to more than 330 million by the year 2025—a doubling within a single generation. This spectacular increase in the frequency of type 2 diabetes is being paralleled by a similarly alarming increase in obesity (3), which is one of the major risk factors for type 2 diabetes (4). Because of the close linkage between these two conditions, Ziv and Shafrir have suggested the term "diabesity" to describe this association (5).

This dual epidemic, which was largely ignored by the public health community until recently, has come as a great surprise. In addition, the public health community, both national and international, has been very slow to recognize the huge socioeconomic and public health threat from diabetes and its devastating complications such as retinopathy, nephropathy, neuropathy, and, most importantly, cardiovascular disease (CVD) (6,7). However, diabetes and its huge personal and socioeconomic costs are increasingly being recognized as a major global health and societal problem, particularly by the World Health Organization (8) and the World Bank (9). Diabetes is now among the five leading causes of death due to disease in most countries (10). The costs are enormous economically, as well as in terms of health. By the most recent estimates, for example, diabetes costs the United States approximately \$132 billion annually (11). years), although relatively low by international standards, was almost two and a half times higher than a figure from the Chinese province of Da Qing 8 years earlier. Two cross-sectional studies in an urban south Indian population showed that the prevalence in persons older than age 20 years had increased from 8.3% in 1989 to 11.6% in 1995 (15). In Denmark, a 38% increase in diabetes prevalence has been reported over 22 years (16). Our data on the national prevalence in Australia reveal a prevalence of diabetes of 7.4% (16), whereas 20 years ago, the best estimate was 3.4% (17). Overall, the highest rates are seen in Native Americans and Pacific Islanders, followed by Hispanics or Mexican Americans, people originating from the Indian subcontinent, Southeast Asians, and African Americans. The prevalence in Europeans is somewhat lower, and diabetes remains rare only among indigenous peoples living a traditional lifestyle.

We recently published global diabetes estimates for 2003 and projections for the year 2025 (2) in order to raise the profile of diabetes in a global perspective. Furthermore, we hoped to encourage governments to initiate or improve local diabetes monitoring and prevention strategies. We estimated that 194 million people were likely to have diabetes globally in 2003 i.e., about 5.1% of the world population. By the year 2025, the total number of people with diabetes is projected to reach 330 million worldwide (Fig. 30.1). The region most likely to experience the main brunt of the epidemic is Asia. Here, diabetes could become two to three times more common than it is at present. Over the next 25 years, India alone is expected to see an increase from 36 to 73 million people with diabetes, and China will see a rise from 24 to 46 million.

WORLDWIDE PREVALENCE OF DIABETES

Epidemiologic studies have provided overwhelming evidence that the prevalence of diabetes, particularly type 2 diabetes, is increasing rapidly in many nations (12). Between 1976 and 1988, the prevalence of diabetes (among people age 40 to 74 years) rose from 11.4% to 14.3% in the United States (13). In China (14), a prevalence of 3.1% in 1994 (in those older than 25

THE EPIDEMIOLOGIC TRANSITION

Paradoxically, for many countries, type 2 diabetes has evolved as a major health problem in part because of increasing longevity (4). During the past century, improved nutrition, better hygiene, and the control of many communicable diseases have dramatically improved longevity, but these benefits have unmasked many age-related noncommunicable diseases,

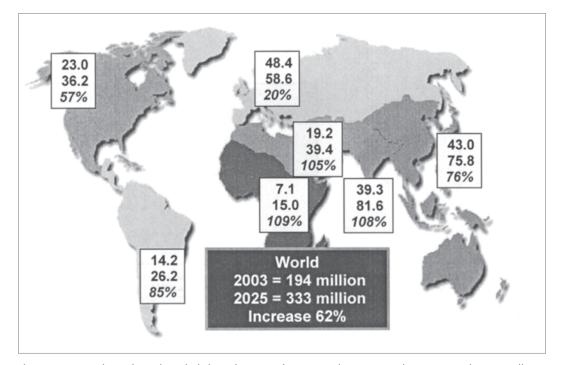

Figure 30.1. Numbers of people with diabetes by region for 2003 and 2025. Data shown are numbers (in millions) for 2003 (top number) and 2025 (middle number) and the percentage increase. (Data from Sicree R, Shaw JE, Zimmet PZ. The global burden of diabetes. In: Gan D, ed. *Diabetes atlas,* 2nd ed. Brussels: International Diabetes Federation, 2003:15–71.)

including type 2 diabetes and CVD (7,18). These formerly uncommon noncommunicable diseases have replaced many communicable diseases and are now major contributors to ill health and death.

This phenomenon of shifting disease patterns, termed *epi-demiologic transition* by Orman (19), has occurred in developed countries over the past 50 years but is now affecting many developing countries. The transition has catapulted type 2 diabetes from its position as a rare disease at the beginning of the 20th century to its current position as a major global contributor to disability and death and one of the major health challenges of the 21st century (7).

Although changes in lifestyle and disease patterns are seen around the world, it is in the developing nations, where traditional lifestyles have been lost, that these events are played out most dramatically. The use of the term *traditional lifestyle* has at least two dimensions that should be clearly delineated (20). *Traditional* in the context of the history of indigenous people can mean the time before contact with the European settlers (precontact), i.e., historical dimension. Alternatively, it can denote a lifestyle according to behavioral traditions, which have an impact on patterns of physical activity, composition of the diet, amount of food, and other factors of daily living, that is, the behavioral dimension. It is within this context that we use it here, particularly in relation to the diabetes epidemic in the Pacific and in the indigenous population of Australia.

In his book *The Call Girls* (21), the late Arthur Koestler suggested the term "Coca-colonization" as a means to describe the impact of Western societies on traditional sociocultural habits and way of life in developing countries. The devastating results of Western intrusion into the lives of traditional-living indigenous communities can be seen from the Eskimos in the Arctic Circle to the Maori (Polynesians) in New Zealand and into the remote and idyllic islands and atolls of the Pacific Ocean (7). During the 19th century, European explorers and voyagers brought many communicable diseases, such as measles, whooping cough, tuberculosis, influenza and venereal diseases, to the Pacific Island communities. In that century, nearly all of the islands suffered a drastic decline in population as a result of these imported diseases. In the mid-18th century, there were about 250,000 Maori in New Zealand. The intrusion of European ways, weapons, and diseases soon decimated their numbers to 90,000, so that by the early 20th century the Maori in that country seemed to be a dying race (7,22). The same scenario was repeated in Australia, with devastating effect on the Aboriginal population (6).

From a historical and teleological perspective, the main causes of morbidity and mortality in all countries of the world were epidemics of communicable diseases, including typhoid, cholera, smallpox, diphtheria, and influenza, until the latter part of the 19th century (18). While some of these diseases remain epidemic in many Third World countries, industrialization and progressive modernization of societies have seen major improvements in housing, sanitation, water supply, and nutrition. Accompanied by the development of antibiotics and immunization programs, this scenario has radically changed the profile of diseases—initially in developed countries and later in many developing countries.

THE EPIDEMIC IN PROGRESS—WHAT ARE THE MAJOR FACTORS?

At the same time that the threat of communicable diseases has decreased, rapid socioeconomic development and "Coca-colonization" have resulted in a change in the way of life from traditional to modern (21). In virtually all populations, higher-fat diets and decreased physical activity have accompanied the benefits of modernization. Exercise has been engineered out of our daily lives, both in the workplace and at leisure (23). These lifestyle changes have been well documented in Canadian (24) and Native-American communities, Pacific and Indian Ocean island populations (25), and Australian Aboriginal communities (26). When combined with increasing longevity, these changes form the basis of the dynamic type 2 diabetes epidemic we are witnessing today.

The explosion of type 2 diabetes in Native-American and Pacific Island populations (with rates of up to 40% in communities where diabetes was virtually unknown 50 years previously) points the finger squarely at environmental causes, albeit in populations with a high genetic susceptibility to type 2 diabetes (4). The increase has occurred far too quickly to be the result of altered gene frequencies. However, the magnitude of the differences between ethnic groups when exposed to similar environments also implicates a significant genetic contribution. Jared Diamond, the noted American biologist and author, has suggested that the lifestyle-related diabetes epidemic in Native Americans and Pacific Islanders probably results from the collision of our old hunter-gatherer genes with the new 20th century way of life (27). The Western lifestyle must have unmasked the effects of preexisting genes, because the consistent result has been diabetes within a few decades.

In these communities, the former dependency on hunting and gathering, and later on subsistence agriculture, was replaced with a modern pattern characterized by a sedentary way of life and a diet of energy-dense processed foods, high in saturated fat, and usually exported from neighboring and perhaps well-meaning developed nations (7). For example, Australia and New Zealand export large quantities of consumable products rich in animal fats (e.g., canned meats and fatty joints) to the Pacific Islanders, foods that their own populations would be loathe to eat. Neel's thrifty-genotype hypothesis proposes that the genes selected over previous millennia to allow survival in times of famine by efficiently storing all available energy during times of feast are the very genes that lead to obesity under conditions of a constant high-energy diet (28,29).

Furthermore, Drewnowski and Popkin have proposed the concept of nutrition transition-the impact of globalization on the human diet (30). Analysis of economic and food availability data for 1962 through 1994 reveals a major shift in composition of the global diet marked by an uncoupling of the classic relationship between income and fat intake. The increasing availability of cheap vegetable oils and fats has resulted in greatly increased fat consumption in low-income nations. This trend means that the nutrition transition occurs at a lower level of gross national product and is further accelerated by high rates of urbanization. They conclude that, while economic development has led to improvements in food security and better health in some instances, the nutrition transition has had adverse effects such as increased rates of childhood obesity. To this, one would add the burden of type 2 diabetes and cardiovascular diseases, each of which may be preceded or aggravated by obesity.

DEVELOPMENT OF TYPE 2 DIABETES AT A YOUNGER AGE — "NINTENDO-NIZATION"

As the prevalence of type 2 diabetes increases, the disease is encroaching on younger and younger adults. Traditionally, type 2 diabetes is thought of as a disease of the middle aged and elderly, with typical onset after 50 years. Although it remains true that this group maintains its high relative risk (in relation to the risk in younger adults), the signs from high-risk populations have been that onset in the group 20 to 30 years of age is increasing (12). Even children are now becoming caught up in the "diabesity" epidemic. Among children in Japan, type 2 diabetes is already far more common than type 1 diabetes, accounting for 80% of cases of diabetes in childhood. Type 2 diabetes has been reported in children in a number of other populations (31,32), primarily those already known to have a high prevalence of diabetes in the adult population. Until recent times, autoimmune type 1 diabetes was the major form of diabetes among children and adolescents. Less than 3% of diabetic children had type 2 diabetes or other rare forms of diabetes (33). The situation has changed dramatically in recent years, with reports indicating that up to 45% of children with newly diagnosed diabetes have what appears to be typical (i.e., not maturity onset diabetes of the young) type 2 diabetes (33).

The increase in the prevalence of type 2 diabetes in this age group is due primarily to the increase in participation in sedentary activities such as television and computer usage, either for games or school work, with consequent reduction in sports activities. Add to this the increasing availability of energydense foods high in saturated fats and we have a "witches brew" to promote obesity and type 2 diabetes. We can now add "Nintendo-nization" to the collection of terms such as "Cocacolonization" and "Westernization." The socioeconomic and public-health impact of this downward shift in disease onset on society will be considerable through effects on the work force and premature morbidity and mortality—not to ignore the negative impact on fertility and reproduction.

This decline in the age of onset of type 2 diabetes is an important factor influencing the future burden of the disease, since onset in childhood heralds many years of disease and an accumulation of the full gamut of complications. Type 2 diabetes in children and adolescents has now become a major new challenge in diabetes. The American Diabetes Association has recently issued a consensus statement on the problem (33), and a number of pharmaceutical companies have embarked on clinical trials of oral agents in this age group. Affected children face up to 40 to 50 years of therapy, raising the issues of compliance with diet and with oral and insulin therapies, as well as the risk of complications, both microvascular and macrovascular, at a relatively young age.

TYPE 2 DIABETES AND THE EPIDEMIC OF CARDIOVASCULAR DISEASE

Type 2 diabetes is a multifactorial disease and shows heterogeneity in numerous respects (34,35). Our understanding of type 2 diabetes and related disorders such as impaired glucose tolerance (IGT) and impaired fasting glucose (IFG) is undergoing a radical change, particularly as there are data suggesting that the risk of complications, at least from macrovascular disease, commences many years before the onset of clinical diabetes (10). Previously, type 2 diabetes was regarded as a relatively distinct disease entity, but in reality, it is a descriptive term and a manifestation of a much broader underlying disorder (36). The manifestations include the metabolic syndrome (Fig. 30.2) (12), a cluster of CVD risk factors, which apart from glucose intolerance include hyperinsulinemia, dyslipidemia, hypertension, visceral obesity, hypercoagulability, and microalbuminuria. This combination of risk factors is partly responsible for the increased risk of CVD in people with diabetes. Attention has recently been drawn to the CVD epidemic now being seen in many developing nations (10). It should be noted that while IGT is predictive of future diabetes, it also carries a substantial risk of both current and subsequent CVD. IGT not only is predictive of future diabetes but also carries a substantial risk of both current and subsequent CVD (37-39). A similar risk probably is associated with IFG, but this is presently not as well substantiated (40).

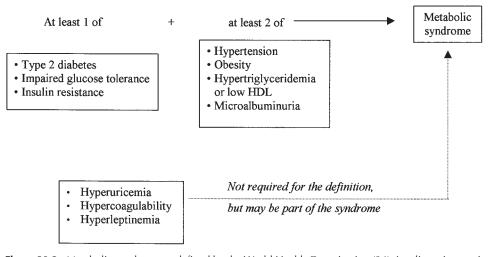

Figure 30.2. Metabolic syndrome as defined by the World Health Organization (34). Insulin resistance is defined as being within the highest quartile for the relevant population. Hypertension: BP \geq 140/90. Obesity: body mass index \geq 30 kg/m² or waist-to-hip ratio >0.90 for males and >0.85 for females. Hypertriglyceridema: triglycerides \geq 1.7 mmol/L. Low high-density lipoproteins: <0.9 mmol/L for men and <1.0 mmol/L for women. Microalbuminuria: urinary albumin excretion rate \geq 20 µg/min or albumin creatinine ratio \geq 30 mg/min.

OTHER CATEGORIES OF GLUCOSE INTOLERANCE—ADDING TO THE EPIDEMIC

We believe that at least 300 million people worldwide have IGT (2). The prevalence of IGT varies widely, being 3% to 10% in European populations (41). It is much higher in some newly industrialized nations and groups with high prevalence of type 2 diabetes, such as Asian Indians, Native Americans, Pacific Islanders, and indigenous Australians. Recent data now suggest increasing rates in Europeans, with the recent national Australian diabetes study noting a prevalence of IGT of 10.6% (17).

IGT represents a key stage in the natural history of type 2 diabetes, as these persons are at higher future risk for diabetes than are the general population (42). Approximately 5% of those with IGT progress to diabetes annually, but some revert to normal glucose tolerance and others continue to have IGT. Therefore, predicting which persons with IGT at baseline in whom type 2 diabetes will develop presents a challenge. Evidence suggests that those with IGT who have one or more components of the metabolic syndrome are more likely to progress to diabetes (43).

The recently defined category of IFG recognizes the fact that elevated but nondiabetic fasting levels of glucose also carry an elevated risk of future diabetes and probably of CVD as well (40, 42). It is now clear that significant differences between IFG and IGT exist, even though they represent, in a broad sense, disorders with similar implications. Although the risk of an individual's progressing to diabetes is similar for IGT and IFG, many more progressors can be identified by IGT (42). The majority of people with either IGT or IFG do not have the other condition; indeed, approximately 20% of people with a fasting glucose level in the IFG range already have diabetes according to the 2-hour glucose criterion (42). Finally, and perhaps of greatest importance, the 2hour postchallenge glucose level appears to be a better predictor of CVD and mortality than does the fasting glucose level (38).

In a study in Mauritius, we showed a definite gender difference in prevalence of IFG and IGT. IGT was more common in women and IFG was more common in men, and only a small but equal proportion of men and women had coexisting IFG and IGT (44). Other recent epidemiologic studies have reported similar sex differences in the prevalence of IFG and IGT (Table 30.1). The observation that IFG is more prevalent in males and IGT is usually more prevalent in females raises important questions about the underlying etiology of IFG and IGT and the ability of current glucose thresholds to identify high-risk categories equally among men and women.

Although the new category of IFG may broaden and improve our description of intermediate abnormal states in glucose metabolism, it should be seen as complementary to impaired glucose tolerance rather than as a replacement (42). Data from other populations have confirmed these findings; thus screening programs aimed at identifying people at risk of developing diabetes chance missing a considerable amount of information by relying solely on fasting plasma glucose levels.

Recent studies have highlighted the potential for lifestyle interventions focusing on dietary modification, physical activity, and weight loss in subjects with IGT to reduce progression to type 2 diabetes (45, 46). The American Diabetes Prevention Program and the Finnish Diabetes Prevention Study both

Glucose category	Country	Males (%)	Females (%)	Reference
IFG	Australia	8.1	3.4	17
	Mauritius	6.2	2.9	49

and Impaired	Glucose Tolerance in Males and Females
•	from Different Populations

showed that the incidence of diabetes could be reduced by 58% with intensive lifestyle interventions. The reduction in the incidence of diabetes was directly associated with changes in lifestyle. The U.S. study also found that among these overweight subjects with IGT, metformin led to a 31% reduction in diabetes incidence. Buchanan and coworkers (47) have demonstrated a substantial reduction in the risk of developing type 2 diabetes with the use of troglitazone, and the Heart Outcomes Prevention Evaluation (HOPE) study suggests the possibility that angiotensin-converting enzyme (ACE) inhibitors may have a similar effect (48).

CONCLUSIONS

The international diabetes and public health communities need to adopt a more pragmatic view of the epidemic of diabesity. The current scenario is symptomatic of globalization with respect to its social, cultural, economic, and political significance. Type 2 diabetes will not be prevented by traditional medical approaches. What is required are major and dramatic changes in the socioeconomic and cultural status of people in developing countries and the disadvantaged minority groups in developed nations.

CONCLUSION 544

Adipose tissue has three primary functions. Two are well recognized and defined: to serve as the site for storage of energy-rich fatty acids in the form of triglyceride and to effect the controlled release of the constituent fatty acids and glycerol in response to neural, endocrine, and local signals for metabolism at distant sites. A third and increasingly important role of adipose tissue is its function as an endocrine organ, releasing a variety of factors that regulate metabolism. Obesity is defined as a state of excessive adipose tissue mass and is best viewed as a syndrome or group of diseases rather than as a single disease entity. The importance of this state derives from its high prevalence in our society and its association with serious morbidity, not the least of which is a marked increase in the prevalence of type 2 diabetes. Specific syndromes of obesity, both in animal models and in humans, are associated with identified neural, endocrine, or genetic causes. However, the pathogenesis of obesity in the vast majority of humans is unknown and remains an unexplained chronic excess in caloric intake relative to energy needs. An understanding of obesity and its consequences requires the investigation of the many factors that control energy intake and energy expenditure, the two interrelated components of the energy-balance equation. As with our understanding of pathogenesis, our understanding of the molecular connection between obesity and its most important complications is limited, and our approach to therapy, as defined

by clinical success rate, is extremely poor. In this chapter, we will review the current understanding of the pathogenesis, complications, and treatment of obesity.

DEFINITION AND INDICES OF OBESITY

The distribution of body weight in the population is a continuous function without a clear separation between lean and obese. The most medically relevant criterion relates to the identification of a weight that confers morbidity. The selection of a specific threshold is somewhat arbitrary, and a number of different criteria have been used. Initially, the approach was through the use of life insurance data (Metropolitan Life) that assess mortality as a function of body weight per height, adjusted for frame size, with obesity defined on purely statistical grounds as a weight that is 20% or more above the average weight per height (1). Over the past decade, calculation of body mass index (BMI) has evolved as a more standard measurement used to correlate weight with morbidity and mortality. BMI is calculated by determining weight in kilograms and dividing by the height in meters squared. This measurement has been used to define four classes of body weight. A BMI of less than 18.5 is considered underweight and carries a modestly increased risk of morbidity

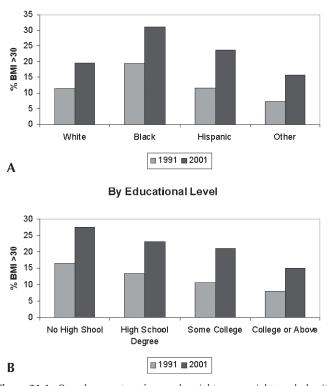

534 JOSLIN'S DIABETES MELLITUS

and mortality. A BMI between 18.5 and 24.9 is considered normal. A BMI of more than 25.0 but less than 29.9 is considered *over-weight* or *preobese* and, statistically, carries a slightly increased risk of comorbidities such as diabetes and cardiovascular disease compared with the risk in normal-weight individuals. A BMI of more than 30 is considered in the *obese* category, which is further subdivided into class I (BMI, 30 to 39.9), class II (BMI, 40 to 49.9), and class III (BMI, >50). These categories of obesity carry respective risks of comorbidities that are moderate, severe, and very severe, respectively (2). A second approach to defining the obese state involves quantitation of adipose tissue, either directly or indirectly. Values are obtained for a reference group viewed as normal, and obesity is defined as levels of adiposity exceeding that seen in the reference group.

The definition of obesity can be refined on the basis of the realization that the accumulation of adipose tissue in different depots has distinct consequences. Thus, many of the most important complications of obesity, including insulin resistance, diabetes, hypertension, and hyperlipidemia, are linked to the amount of intraabdominal fat, rather than to lower-body fat (i.e., buttocks and leg) or subcutaneous abdominal fat (3,4). Abdominal fat, typically evident on physical examination, can be estimated by determining the waist-to-hip circumference ratio (with a ratio >0.72 considered abnormal), or more accurately quantified by dual-energy x-ray absorptiometry (DEXA) scanning or computed tomography.

PREVALENCE OF OBESITY

It is obvious from casual inspection of the population that obesity is prevalent in the United States, although the precise prevalence

By Race, Ethnicity

Figure 31.1. Prevalence rates of normal weight, overweight, and obesity in the adult U.S. population in 1991 and 2001. **A:** Rate of obesity by race, ethnicity. **B:** Rate of obesity by educational level. (Adapted from data from the Centers for Disease Control and Prevention.)

figures vary to some degree, depending on the nature of the population surveyed. In the United States, the prevalence of overweight or preobesity, i.e., a BMI of 25 to 29.9, has remained fairly constant at 40% for men and 24% for women over roughly a 30-year period (1960 to 1994). However, in the same period, the prevalence of a BMI higher than 30 has risen significantly, especially over the past decade. In 2001 more than 20% of all adults had a BMI greater than 30, compared with 12% of all adults in 1991. Obesity among adults aged 18 to 29 doubled from 7% in 1991 to 14% in 2001. Among people aged 50 to 59, more than 25% have a BMI greater than 30. When analyzed by race and ethnicity (Fig. 31.1A), a BMI greater than 30 was most prevalent among black, non-Hispanic people. Interestingly, rates of obesity correlate inversely with educational level and are almost twice as high in adults who have not completed high school as in adults who have finished college or graduate school (Fig. 31.1B). This indicates that environmental and cultural factors can act as inhibitors to weight gain. At present 60% of the male population and 50% of the female population have a BMI greater than 25, which is associated with increased risk of morbidity and mortality.

As noted above, an important predictor of the morbidity and mortality associated with obesity is the quantity of visceral fat. A rough index of the relative amounts of visceral and abdominal fat is the waist-to-hip ratio. The alternative patterns of body-fat distribution have been described as pear shaped (low waist-tohip ratio) and apple shaped (higher waist-to-hip ratio). When the waist-to-hip ratio is less than 0.8, the relative risk of morbidities associated with obesity is lower than when the waist-tohip ratio is greater than 1.0. Hence, the metabolic syndrome, which is a clustering of obesity and other cardiovascular risk factors, is more likely to be associated with visceral obesity (5).

PATHOLOGIC CONSEQUENCES OF OBESITY

Obesity results in morbidity and mortality largely because of its association with other diseases, including diabetes, cardiovascular disease, hypertension, sleep apnea, endometrial cancer, colon cancer, and gallbladder disease. Overall, in the United States, the excess mortality of obesity accounts for 300,000 deaths per year. It was estimated that the total spent for both weight reduction and treatment of the consequences of obesity was \$100 billion in the United States in 2001. This represents 5.5% to 7.0% of all medical expenses (3).

Diabetes

The increased risk for type 2 diabetes in individuals with obesity is considerable. In persons aged 20 to 44, obesity is associated with a fourfold increase in the relative risk of diabetes (4). In a study of a cohort of more than 50,000 U.S. male health professionals, the risk of diabetes correlated strongly with BMI. In men with a BMI of 35 or higher, the multivariate relative risk of diabetes was 42.1 compared with the risk in men with a BMI of less than 23. BMI appears to be the dominant risk factor for type 2 diabetes. Even men with average relative weight had a significant increase in risk when compared with men in lower weight groups. A similar increased risk exists for women. Among 43,581 women enrolled in the Nurses' Health Study, the relative risk for type 2 diabetes at the 90th percentile of BMI was 11.2 (6). Weight was the single most important predictor of diabetes. After adjustment for BMI, lack of exercise and a poor diet (i.e., foods with a high glycemic index and high in trans fat) were also associated with increased risk of diabetes (7). Another study examined new diagnoses of diabetes in a population between 18 and 44 years of age (8) and found an inverse

correlation with age and BMI. Adults developing diabetes before age 44 had an average BMI of 39, whereas adults developing diabetes at 45 or older had an average BMI of 33. Among all adults, the odds ratio for developing diabetes is 6.38 for those with a BMI greater than 40 (9). The results of these and other studies lend support to the concept that the vast majority of cases of type 2 diabetes could be prevented by the adoption of therapies and lifestyle characteristics that decrease obesity.

Although the precise mechanism by which obesity contributes to insulin resistance and type 2 diabetes has not yet been defined, it is likely related to the production of various factors derived from the adipocyte that act on fat, liver, or muscle to impair insulin action. Obesity is itself associated with hyperinsulinemia, and insulin may induce insulin resistance through downregulation of the insulin receptor. Potential candidate substances produced by fat that may cause insulin resistance include tumor necrosis factor and other cytokines, such as interleukin-6, and resistin and adiponectin. Increased levels of free fatty acids are also capable of inhibiting insulin action. It is intriguing that a recent report found that treatment with highdose salicylate markedly improved insulin resistance, suggesting that obesity may induce an inflammatory state that contributes to insulin resistance (10).

Cardiovascular Disease

Obesity is an independent risk factor for cardiovascular disease (11), including coronary artery disease and congestive heart failure, in both men and women. Waist-to-hip ratio is the best predictor, and it is noteworthy that increased waist-to-hip ratio has an effect in women even at the relatively low BMI of 25. Visceral obesity is associated with increased occurrence of hypertension and an atherogenic lipid profile (12,13), both of which contribute to the development of cardiovascular disease. In addition, in the obese state, there is a need for perfusion of a greater mass of tissue, resulting in an increase in cardiac work. Blood volume, stroke volume, and cardiac output are all increased and result in increased ventricular mass, which is reversible with weight loss (14,15).

Pulmonary Disease

Abnormalities in pulmonary function may be seen in obese patients (16–18). These range from quantitative abnormalities in pulmonary function tests that have no established clinical significance to major dysfunction replete with symptoms and morbid consequences. The increased metabolic rate in obese subjects increases O₂ consumption and CO₂ production, and these changes result in increased minute ventilation. In subjects with marked obesity, the compliance of the chest wall is reduced, the work of breathing is increased, and the respiratory reserve volume and vital capacity are reduced; a resultant mismatch between ventilation and perfusion may result in hypoxemia. Severe obesity may cause hypoventilation, defined by the development of CO₂ retention. The full designation of the obesity-hypoventilation, or pickwickian, syndrome includes somnolence, lethargy, and respiratory acidosis and typically also includes sleep apnea. Such patients may have reduced ventilatory drive to hypoxia and hypercapnia, as well as obstructive or mechanical causes of hypoventilation, and sleep studies may be necessary to distinguish among these.

Gallstones

Obesity is associated with enhanced biliary secretion of cholesterol. This results in supersaturation of bile and a higher incidence of gallstones—particularly cholesterol gallstones (19). Fasting, as opposed to more limited caloric restriction, increases the saturation of bile by reducing the phospholipid component, and cholecystitis induced by fasting is a well-recognized problem in obese individuals.

Cancer

Excess weight has been associated with increased rates of cancer. A recent study examining data for more than a million patients enrolled in the Cancer Prevention Study demonstrates convincingly that obese individuals are at increased risk for a number of cancers (20). The most dramatic increase in risk is seen for liver cancer. The relative risk of liver cancer was almost 2-fold higher in men with a BMI of 30.0 to 34.9 than in normal-weight individuals, and it was 4.5-fold higher in men with a BMI greater than 35. In men with a BMI higher than 35, the risk of stomach cancer was increased 1.94-fold, that of kidney cancer was increased 1.7-fold, and that of esophageal cancer was increased 1.6-fold over the risk in normal-weight individuals. The effect of obesity on cancers of the gastrointestinal tract was not as great in women, but the increase in relative risk in women was the same as that in men for kidney cancer. In women with a BMI greater than 35, the relative risk of cancer of the uterus was 2.8, of cancer of the cervix was 3.8, and of breast cancer was 1.7.

ENDOCRINE CONSEQUENCES OF OBESITY

Many alterations in endocrine function are seen in patients with established obesity. These changes can be induced by overeating, and normal function resumes after weight loss. Therefore, these changes are viewed as being secondary to the obese state. A possible causal link has been sought between some of these abnormalities and the pathogenesis of obesity, and thus they have undergone considerable scrutiny.

Endocrine Pancreas

As discussed earlier, hyperinsulinemia is a pervasive concomitant of obesity. Hyperinsulinemia results from an increased rate of insulin secretion (21), although patients with intraabdominal obesity may have decreased hepatic clearance of insulin (22). Hyperinsulinemia follows weight gain and reverses with weight loss and is most likely a consequence of insulin resistance that accompanies the obese state. Given the fact that, in the animal model of ventromedial hypothalamic lesions, hyperinsulinism driven by the vagus nerve may precede obesity (23), the possibility that a defect in central control of insulin secretion exists in a subset of persons with obesity should be considered. Studies of glucagon, somatostatin, pancreatic polypeptide, and amylin secretion in obesity have not been particularly revealing. However, more recent studies suggest that neuropeptides such as neuropeptide Y and melanocyte-stimulating hormone may have direct effects on the islet (24,25).

Thyroid

Given the known effect of thyroid hormone on basal metabolic rate, it is reasonable to speculate that defects in this axis might be a factor in obesity. In general, studies of obese individuals have revealed normal levels of thyroxine (T_4) and thyroid-stimulating hormone (TSH) but increased levels of triiodothyronine (T_3) in a minority of subjects. The increased T_3 levels are probably secondary to increased carbohydrate intake, and they

536 JOSLIN'S DIABETES MELLITUS

decrease, as do values in nonobese subjects, in response to caloric restriction (26).

Gonadal Function

Marked obesity in men is associated with changes in both testosterone and estrogen metabolism, although these are usually without clinical consequences. Rates of estrogen production, primarily from androgen precursors, are increased, as are levels of estradiol (27). Decreased total testosterone levels are commonly observed and appear to be secondary to diminished levels of sex hormone–binding globulin (SHBG), with a preservation of normal levels of free testosterone. Levels of free testosterone may, however, be reduced in men with massive obesity (28). These changes may result in gynecomastia.

In women, marked obesity is associated with increased androgen production, increased peripheral conversion of androgen to estrogen, an increased rate of estrogen production, and decreased levels of SHBG. This constellation may be a major cause of the amenorrhea not infrequently seen in morbidly obese women. Upper-body obesity is associated with increased testosterone production, decreased SHBG, and increased levels of free testosterone in comparison to levels in obese women with lowerbody or gynoid obesity (29-31). The fact that upper-body obesity also is associated with hyperinsulinemia has led to the hypothesis that insulin may be a factor that contributes to hyperandrogenism through actions on the ovary, as seems to be the case in syndromes of extreme insulin resistance. The increased peripheral production of estrogen from androstenedione, which occurs to a greater degree in women with lower-body obesity, may contribute to the increased incidence of uterine cancer in obese postmenopausal women (32).

Adrenal Function

The relationship between obesity and altered adrenal function can be addressed from a number of perspectives. The first relates to the clinical issue of whether a given patient with obesity, particularly one with hypertension and glucose intolerance, has Cushing syndrome. In 90% of obese individuals, the overnight cortisol response to 1 mg of dexamethasone given at midnight is normal, a finding sufficient to rule out Cushing syndrome. The 10% of individuals who fail to suppress cortisol production adequately on this test will suppress cortisol production normally in the formal 2-day low-dose dexamethasone test (33).

Obesity, however, is commonly associated with abnormalities of the cortisol axis, with increases in the rates of cortisol production and levels of urinary 17-hydroxysteroids frequently observed. Despite these findings, serum cortisol levels including their diurnal variation—appear to be normal, and no clear defects in adrenocorticotropic hormone (ACTH) secretion have been observed (34). Thus, the precise basis for the increased cortisol production is unclear. One reason for interest in this area is the finding that cortisol is overproduced in a number of animal models of obesity, such as the *ob/ob* mouse and the *fa/fa* rat, and that removal of the adrenal gland markedly ameliorates many of the phenotypic and biochemical findings in these animals (35,36). The role, if any, of increased cortisol production in human obesity has not been established.

Pituitary Function

Obesity is clearly associated with defects in growth hormone secretion (37,38). Levels of growth hormone in response to many stimuli, including insulin-induced hypoglycemia, arginine, levodopa, exercise, sleep, and the physiologic regulator

growth hormone–releasing hormone, are reduced in obese individuals. Treatment with cholinergic antagonists may reverse this defect (39). Because administration of growth hormone will reduce the percentage of body fat (40), these observations raise the obvious question of whether functional growth hormone deficiency is present in obesity. On the basis of levels of insulinlike growth factor-1, this would appear not to be the case. Many investigations of pituitary adrenal function in obesity have been carried out, in part because of the persistent interest in whether subtle hypothalamic dysfunction might be present in this disorder. A variety of findings with no obvious clinical relevance have been made (37).

ETIOLOGY OF OBESITY

Maintenance of a normal body weight requires a match of food intake to energy expenditure. Chronic positive energy balance leads to storage of calories in fat, mostly as fat but also as increased lean body mass (41), whereas negative balance leads to utilization of stores, including energy stored as glycogen, fat, and lean body mass. Both nutrient intake and energy expenditure are regulated by a complex interaction between the periphery and the central nervous system. Although not all aspects of central-peripheral interactions involved in energy balance are understood, key factors have been identified. For example, leptin from the adipocyte, ghrelin from the stomach, peptide YY from the gut, and insulin from the pancreas are all involved in the central regulation of energy balance. In the brain, more than a dozen peptides have been implicated in appetite and satiety. Among these peptides, neuropeptide Y, melanocyte-stimulating hormone, and agouti-related peptide in the arcuate nucleus, as well as melanin-concentrating hormone in the lateral hypothalamus, have emerged as important regulators (Fig. 31.2).

It is clear that in mammals the energy-balance equation tips readily toward the overconsumption of calories. The relative threat of starvation to survival apparently has exerted greater evolutionary influence than the long-term consequences of obesity. Indeed, in the wild, the most common cause of death among mice is starvation, as these animals cannot sustain themselves for longer than 3 to 4 days without food. In humans, one excess pound of fat will provide 3,500 calories, which represents adequate fuel for 2 to 3 days in the absence of any food intake.

Role of the Adipocyte in the Regulation of Food Intake

The adipocyte plays an important role in energy homeostasis. To compensate for fluctuations in the availability of food, mammals consume more calories than immediately required for metabolic needs and store excess calories. Calories may be stored as glycogen in the liver, triglycerides in adipocytes (particularly white adipose tissue), and protein in muscle. Adipocyte physiology is regulated by a number of signals, including nutrient availability, hormones, and neuronal input. For example, during a fast, levels of glucose and insulin fall, whereas those of glucocorticoids and growth hormone rise; in consequence, adipocyte triglycerides are metabolized to fatty acids and released into the circulation.

Although this role of the adipocyte in metabolic homeostasis has long been known, its role as an endocrine cell has only recently been recognized. Data suggesting that the adipocyte functions as more than a passive, externally regulated site for the storage of energy date back 10 to 15 years to the description of secretory products such as adipsin and angiotensinogen. Adipsin, a serine protease, is secreted by adipocytes and was found to be markedly decreased in some obese models such as the *ob/ob* mouse (42). Nutritionally regulated angiotensinogen secretion also was reported (43). However, the role of the adipocyte as a secretory cell was not fully appreciated until the discovery of leptin, a 16-kDa protein of the cytokine gene family, through genetic analysis of the *ob/ob* mouse (44). Since the discovery of the *ob* gene, adipocytes have been recognized to synthesize other factors that may contribute to energy balance.

LEPTIN

A spontaneous mutation in the leptin gene is associated with morbid obesity, hyperphagia, insulin resistance, and infertility in mice. Intriguing studies involving parabiotic mouse pairs had suggested that the syndrome involved the absence of a circulating factor (45,46). Identification of leptin confirmed that absence of a hormone, made in adipocytes and secreted into the circulation, caused the obesity syndrome and that replacement of this factor led to correction of the phenotype (47). Subsequent studies demonstrated an important action of leptin in the hypothalamus (48). The critical importance of leptin in humans was confirmed in studies of morbidly obese children lacking functional leptin alleles. These children, unable to make leptin (49), demonstrate continuous hyperphagia and respond to exogenously administered leptin with a resolution of hyperphagia and significant reductions in body weight (50).

Although the complete absence of leptin is associated with morbid obesity in rare examples of rodent and human obesity, most obese mammals, including humans, have high levels of circulating leptin. Circulating leptin levels correlate well with available fat stores (51), and administration of leptin in most obese states does not lead to decreases in appetite. These findings suggest that the dominant physiologic role of leptin is that of a "starvation signal," which is important in switching between fed and fasted states rather than in serving as an antiobesity hormone (37,52). In rodents, decreased leptin during fasting is associated with a series of metabolic changes that result in the suppression of reproductive hormones, growth hormone, and thyroid hormones and in the activation of the hypothalamic-pituitary axis with a resultant rise in corticosterone level. These changes can be mitigated by the administration of leptin during the fast. Furthermore, in mice, fasting is associated with a disruption of the estrous cycle, an effect that lasts for

many days after the re-introduction of food. Administration of leptin during the fast attenuates this disruption. The physiologic dose response to leptin may be viewed as biphasic. Between absent and normal leptin levels, leptin is effective in signaling adequacy of fat stores, and leptin levels correlate with fat stores. However, when leptin concentrations rise above those associated with adequate adipose stores, leptin has little effect in limiting food intake and a state of "leptin resistance" develops.

ADIPONECTIN

Adiponectin (Acrp30) is a protein exclusively and abundantly expressed in adipose tissue. In mice, a single injection of adiponectin leads to a decrease in glucose levels, and in *ob/ob* mice, adiponectin abolishes hyperglycemia. In addition, treatment with adiponectin leads to an acute increase in fatty acid oxidation in muscle (53). In isolated hepatocytes, adiponectin leads to a reduction in the amount of insulin needed to suppress gluconeogenesis (54). In various forms of obesity, in both humans and mice, levels of adiponectin messenger RNA (mRNA) are decreased. At least one study has reported an increase in adiponectin after surgery for obesity (55). A recent study indicates that levels are genetically determined and may be associated with obesity (56). These data indicate that adiponectin is important in energy homeostasis and insulin sensitivity.

11-β HYDROXYSTEROID DEHYDROGENASE TYPE 1

The enzyme 11- β hydroxysteroid dehydrogenase type 1 (11- β HSD-1) plays an important role in determining intracellular glucocorticoid concentrations by regenerating active glucocorticoids from inactive cortisone. Activity of this enzyme is relatively increased in visceral fat as opposed to subcutaneous fat (57). Overexpression of the enzyme with a fat-specific transgene leads to a syndrome of visceral obesity that is associated with hyperphagia, insulin resistance, and hypertension (58). The activity of 11- β HSD-1 may be increased in humans with obesity.

Role of the Central Nervous System in the Regulation of Appetite

Although defects intrinsic to the adipocyte can lead to obesity, the establishment of excess adiposity requires the chronic

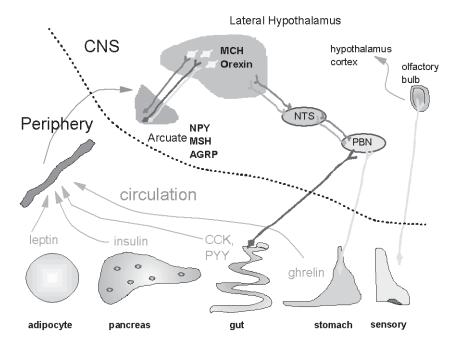

Figure 31.2. Factors in the periphery that impact energy homeostasis are from a variety of tissues and act in the central nervous system (CNS). Peptides known to be important for energy homeostasis include melanocyte-stimulating hormone (MSH), melanocyte-concentrating hormone (MCH), neuropeptide Y (NPY), agouti-related peptide (AGRP). and cocaine-amphetamine-related transcript (CART). Many other central peptides may also play a role in energy balance (orexin, corticotropin-releasing factor, urocortin, galanin, and neurotensin, among others); however, their roles are less well understood. Somatosensory inputs such as smell are also known to be important. CCK, cholecystokinin; PYY, peptide YY.

538 JOSLIN'S DIABETES MELLITUS

excessive ingestion of calories. The precise mechanisms by which appetite is regulated are still unknown; however, insights from animal models and from human beings with singlegene defects leading to obesity have made it clear that appetite and feeding are regulated processes. The initial observations that animals could be made lean or obese through hypothalamic lesions date back to studies performed in the 1930s and 1940s. Studies in rats and cats showed that electrical stimulation of the medial hypothalamus decreased eating, whereas surgically made ablative lesions led to hyperphagia and obesity. This led to the definition of the medial hypothalamus as a "satiety center." In contrast, electrical stimulation of the lateral hypothalamus led to increased feeding, whereas lesions of the lateral hypothalamus led to a syndrome of adipsia and aphagia. Hence, the lateral hypothalamus was identified as a feeding center. Despite these early findings, progress in understanding the role of the hypothalamus in obesity was slow. Indeed, for years obesity was viewed not as a medical process but as a moral fault. This view of obesity was partially modified when a series of studies in humans led to the observation that different individuals fed isocaloric diets normalized for weight might maintain, lose, or gain weight. However, the gradual change in the categorization of obesity from moral fault to a physiologic failure came with discoveries over the past decade that have defined a number of molecular mechanisms leading to leanness or obesity in both mice and humans. These discoveries also redefined the role of the adipocyte as a passive caloric storage depot to an endocrine cell.

The brain, particularly the hypothalamus, is key in the integration of signals that regulate appetite and feeding. The hypothalamus receives input from the periphery via neural afferents, hormones, and metabolites. Inputs from the vagus through the hindbrain provide information from the viscera, such as gut distention. Peripheral hormonal signals include leptin, insulin, cortisol, ghrelin, and cholecystokinin. Metabolites also may influence appetite, as it is known that hypoglycemia induces hyperphagia; however, the role of metabolites is less clear. A series of neuronal connections within the hypothalamus are involved in processing these signals.

Within the hypothalamus, the arcuate nucleus plays an important role in responding to signals from the periphery. A subset of neurons in this region of the hypothalamus express the long form of the leptin receptor and respond directly to the adipocyte hormone leptin. Leptin acts on one set of neurons that synthesize the two orexigenic peptides neuropeptide Y (NPY) and agouti-related peptide (AgRP) and a second population of neurons that synthesize the anorectic peptides melanocyte-stimulating hormone (α -MSH) and cocaine-amphetamine–related transcript (CART). Leptin acts to hyperpolarize the NPY/AgRP neurons, whereas it activates the α -MSH/CART neurons (59). A peptide in the lateral hypothalamus, melanin-concentrating hormone (MCH), also contributes to hunger, but it does not appear to be a direct target of leptin regulation.

The essential role of leptin in regulating these neurons is dramatically demonstrated in db/db mice, which lack the long form of the leptin receptor, and similarly in some human families that do not express the long form of the receptor. In both animals and humans (60), circulating levels of leptin are significantly elevated. However, because the hormone cannot signal the hypothalamus, affected individuals are hyperphagic and obese with a phenotype similar to that seen in animals lacking leptin.

THE MELANOCORTIN SYSTEM AND OBESITY

Thus far, the most extensively analyzed central system involved in the regulation of energy homeostasis is the melanocortin pathway. Disruption of this pathway along any of several steps leads to obesity in both mice and humans.

Insight into this pathway originally derived from examination of the obese, yellow mice known as agouti and expressing the mutated gene A^y (61). Normally, the peptide agouti is expressed only in skin, where it serves as a regulator of type I melanocortin 1 receptors (MC1-R) (62). Activation of these receptors by α-MSH leads to a conversion of yellow melanin to black melanin; agouti acts on the same receptor to prevent its activation by α -MSH. This system is responsible for coloration in mammals, as the relative signals from MSH and agouti lead to a mix of yellow and black melanin, which is perceived as brownish gray. The A^y gene has a mutation in the promoter that leads to constitutive expression of agouti in an unregulated fashion in all organs. In the skin, high levels of agouti block MSH signaling of MC1-R and yellow melanin is not converted to black melanin. Further analysis of the obese phenotype of these mice led to a recognition that ectopically expressed agouti blocked the action of MSH in the brain through the brain melanocortin receptors MC4-R and MC3-R (63).

Although the function of α -MSH as a neuropeptide that inhibits food intake had been described (64), the importance of this neuropeptide in energy homeostasis was not appreciated until analysis of the A^y mouse. This finding was confirmed by the generation of genetically engineered mice lacking either MC4-R or MC3-R. The phenotype of the MC4-R–ablated mouse closely mimics the obesity phenotype of the agouti mouse, although coat color is normal (65). Interestingly, the heterozygote animals also demonstrate weights intermediate between those of the homozygote and normal wild-type mice. The MC3-R knockout mouse also has abnormal energy expenditure.

Findings in the A^y mouse led to the search for an endogenous agouti-like factor that might regulate brain melanocortin receptors. An analogue of agouti, AgRP (66), with expression limited to arcuate neurons in the hypothalamus, was thus discovered. This neuropeptide plays an important role in energy homeostasis. Mice overexpressing AgRP mimic the phenotype of agouti mice, and AgRP is negatively regulated by leptin.

The melanocortin system has been shown to be important in humans. Screening of morbidly obese individuals with a history of early childhood obesity has revealed a prevalence of MC4-R mutations in up to 5% (67,68). Depending on the precise nature of the mutation, humans with a single mutated allele may be obese. A small number of individuals without functional genes for pre-opiomelanocortin (POMC), which is the gene encoding melanocortin, have a phenotype of earlyonset obesity, red hair, and adrenal insufficiency (69). This demonstrates the importance of the POMC gene in regulating both body weight and pigmentation and adrenal function in humans.

AN ADIPO-HYPOTHALAMIC AXIS AND ENERGY BALANCE

On the basis of currently available knowledge, at least one pathway regulating energy balance can be defined (Fig. 31.3). Leptin, made in the adipocyte, is released into the circulation. It crosses the blood–brain barrier and acts on leptin receptors on neurons that make either NPY/AgRP or POMC/CART in the arcuate nucleus. Leptin suppresses NPY neurons and activates the POMC neurons. Activation of the POMC neurons leads to the production of MSH, which acts on the MC4-R in the brain and leads to a reduction in feeding. Mutations in leptin, leptin receptor, POMC, and MC4-R lead to obesity in both mice and humans. Furthermore, mutations of prohormone-converting enzyme-1 (PC-1) in humans (70) and certain converting enzymes in rodents that prevent the processing of POMC also lead to obesity (71).

OTHER NEUROPEPTIDES

A second hypothalamic system involved in the regulation of appetite and, potentially, in energy homeostasis is MCH and its receptors (MCH1-R and MCH2-R). MCH is a nonadecapeptide with expression limited to the lateral hypothalamic area of all mammals thus far studied. The peptide sequence is identical in rodents, humans, and sheep. As a pharmacologic agent injected into the brain, MCH rapidly increases appetite (72). Mice genetically altered to lack MCH are lean and have both slight hypophagia and a slight increase in energy expenditure (73). Mice overexpressing MCH have mild obesity and insulin resistance. MCH neurons project throughout the brain, including the cortex and the hindbrain. Rodents express only one receptor, MCHR-1, whereas humans and dogs express MCHR-1 and a second receptor with limited homology to MCHR-1, designated MCHR-2. The potential importance of the MCH system in humans has not yet been evaluated.

NPY is another peptide expressed in the brain that induces rapid and significant increases in feeding when it is injected into rodents (16). Chronic infusions in rodents lead to sustained hyperphagia, obesity, and insulin resistance (74). However, the precise role of NPY in the regulation of appetite remains elusive, because mice deficient in NPY have normal energy homeostasis (75) except for impaired refeeding after starvation (76). Mice lacking two of the NPY receptors believed to mediate the appetite effects of NPY have mild obesity. It is interesting that, when mice lacking NPY are bred to mice without leptin, the offspring show an attenuation of the obesity seen in the leptindeficient mice and partial restoration of fertility (77). In addition, chronic infusion of NPY has recently been shown to lead to hypogonadism. These data suggest that excess NPY expression seen in hypoleptinemic states may be involved in mediating the infertility seen during starvation as well as in *ob/ob* mice and aleptinemic humans.

PERIPHERAL SIGNALS

A number of peptides originating from peripheral sources other than the adipocyte may be important in regulating body weight (78). These include but are not limited to ghrelin, cholecystokinin (CCK), glucagon-like peptide, and insulin. Such afferent signals may be responsible for short-term regulation of appetite and meal size.

CCK was the first afferent signal inhibiting appetite to be described (in 1975) (79,80). Injection of CCK stops feeding and has been shown to induce satiety in both rats and rhesus monkeys. More recent data indicate that CCK can act synergistically with leptin to induce greater reductions in feeding than those seen with leptin alone (81). Thus far, no deficits of CCK in human obesity have been defined, although CCK receptors remain a potential drug target.

Ghrelin, a peptide localized to the stomach and brain, is the endogenous ligand of the growth hormone secretagogue receptor. Ghrelin acts to stimulate appetite, and its secretion is decreased in both rodents and humans by the ingestion of nutrients (82,83) and increases before the initiation of a meal. In rats, chronic infusion of ghrelin, either systemically or into the cerebral ventricles, leads to hyperphagia and obesity, suggesting that it may play a role in long-term food intake (84). Recent findings indicate that ghrelin acts on NPY and AgRP neurons in the

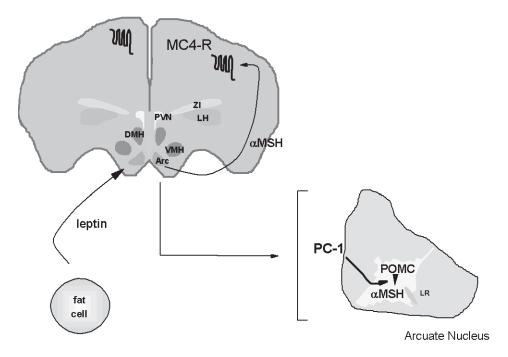

Figure 31.3. One pathway that is important in energy balance has been defined. Leptin, made in the adipocyte, is secreted into the blood. It crosses the blood–brain barrier and acts on cells in the arcuate nucleus (Arc), where it activates cells making the melanocyte-stimulating hormone (MSH) precursor proopiomelanocortin (POMC). POMC is converted to MSH (by prohormone-converting enzyme-1 [PC-1] in humans) and acts on one of the central melanocortin receptors, MC4-R. Disturbance of this pathway in rodents or humans leads to obesity, as documented by identification of mutations in leptin, leptin receptor, PC-1, POMC, and MC4-R. Other neuroanatomic areas involved in feeding that may participate in regulation of appetite and satiety include the lateral hypothalamus (LH) (melanin-concentrating hormone, cocaine-amphetamine–related peptide, orexin), the paraventricular nucleus (PVN) (corticotropin-releasing factor, urocortin), the zona incerta (ZI) (melanin-concentrating hormone), the ventromedial hypothalamus (DMH).

arcuate nucleus (17). Interestingly, levels of circulating ghrelin are lower in obese than in normal-weight humans. Furthermore, weight loss in the obese leads to an increase in ghrelin levels toward normal levels. Thus, the decrease in ghrelin in obese subjects may reflect a failed attempt to decrease food consumption in the context of increased adiposity. When the subjects diet and go into negative caloric balance, ghrelin levels increase as the body attempts to regain lost calories. A recent study examined ghrelin regulation after gastric bypass surgery, one of the few procedures known to result in long-term weight loss. In this group, ghrelin levels decreased markedly after bypass surgery, suggesting that exclusion of the fundus of the stomach leads to alterations in the regulation of ghrelin (18). However, much remains to be done to define the precise physiology of this peptide. At least one report indicates that human obesity is associated with decreased circulating levels of ghrelin (85).

Glucagon-like peptide-1 (GLP-1), which is synthesized in the gut, acts to inhibit appetite. Injection of GLP-1 inhibits food intake in the rat, and repeated injections lead to weight loss. In contrast, treatment of animals with the GLP-1 antagonist exendin leads to increased food intake and an increase in body weight (86). A long-acting GLP-1 derivative, NN2211, reduces food intake and leads to weight loss in both normal rats and rats with diet-induced obesity. After a 7-day treatment period, animals manifested decreased energy expenditure, typically associated with weight loss (87). However, ablation of GLP-1 in mice is not associated with altered energy balance.

Peptide YY (PYY) is another peptide synthesized in the gut that appears to inhibit food intake in both rodents and humans (88). This contrasts with its action when administered directly into the central nervous system, which is to increase feeding. Further study will be required to establish the role of PYY in human obesity.

Insulin enters the brain from the peripheral circulation and also may play a role in reducing food intake through central nervous system mechanisms. Insulin entry into the brain occurs via a saturable system (89), and chronic insulin infusion is associated with weight loss (90). A mouse model of selective ablation of the insulin receptor from the brain is characterized by mild obesity and increased sensitivity to diet-induced obesity (91). Analyzing the role of insulin is extremely complex, as obesity is associated with hyperinsulinemia, suggesting that in obesity either insulin transport into the brain or insulin signaling within the brain may be impaired.

Abnormal Regulation of Energy Expenditure

Energy expenditure is an important determinant of body weight. Energy expenditure can be divided into several components: the resting, or basal, metabolic rate (RMR); the cost of metabolizing and storing food (thermic effect of food [TEF]); exercise-induced thermogenesis; and adaptive thermogenesis. Adaptive thermogenesis includes regulated responses to diet and environmental temperature. These changes act both to provide protection from the environment and to regulate energy homeostasis in relation to energy intake (92,93).

The RMR normally accounts for between 65% and 75% of the total daily energy expenditure. RMR measures the energy expended for maintenance of normal body functions at rest and is obtained by taking measurements several hours remote from food intake or exercise. The rate is determined in large part by fat-free mass but also is influenced by sex, age, physical conditioning, and genetic factors. RMR in absolute terms is almost always increased in obese individuals; however, when

RMR is expressed in terms of fat-free mass, it is typically normal (36,94,95). These two expressions of RMR have different applications. RMR expressed in absolute terms is most relevant to the question of total energy expenditure in obese individuals (and by inference, if weight is stable, to food intake). RMR expressed per lean body mass is most relevant to the question of possible biochemical differences between lean and obese individuals that might predispose to efficient energy metabolism and weight gain. It is possible that some obese individuals in the so-called preobese state or after weight reduction have a reduction in RMR per unit of lean body mass. The molecular or physiologic basis for such a potential defect is not clear, but abnormalities of futile cycling (34) and energyexpensive processes such as ion pumping (35,44) have been proposed. It has been calculated that a low RMR by itself, i.e., in the absence of hyperphagia, would contribute only modestly to the tendency to gain weight, because the increased total RMR consequent to weight gain would counter any preceding reduction in RMR. In the absence of hyperphagia, an increased RMR would result in equilibration at a new, modestly increased weight. Thus, for major obesity to develop, dysregulation of food intake must coexist with any possible thermogenic defect.

TEF may account for as much 10% of energy ingested. It consists of the energy costs of absorbing and processing food and of thermogenesis in response to diet. Feeding acutely increases energy expenditure by as much as 25% to 40% in both rodents (38) and humans (39). The possibility that decreased TEF contributes to the development of obesity is controversial, and studies demonstrate both decreased and normal energy expenditure after meals (40,96).

Diet has significant effects on thermogenesis. During starvation, RMR can be reduced significantly, and a diet that diminishes body weight by 10% is associated with decreased energy expenditure (97). Nutrients in the diet also influence thermogenesis. For example, ingestion of low-protein diets increases overall total food consumption to meet protein demand. In this situation excess calories are not stored, but rather dissipated as heat (98). Interestingly, overfeeding is associated with increased energy expenditure, a process that may provide partial protection against the development of obesity and may be genetically determined (99). Environmental temperature also has significant effects on thermogenesis, as increased heat production is necessary to maintain body temperature with cold exposure. In rodents, exposure to a temperature of 4°C leads to significant increases in oxygen consumption. Acutely, part of this response is due to shivering. More chronically increased heat production comes from increased adaptive thermogenesis in brown adipose tissue. In humans, these effects are less marked, at least in part because of the ability of humans to vary the amount of clothing.

Adaptive thermogenesis in response to food intake and temperature change is regulated by the brain and is mediated by activation of the sympathetic nervous system, the hypothalamic-pituitary-thyroid axis, and various neuropeptides that have dual effects on appetite and energy expenditure (such as leptin, NPY, and MSH). These systems target uncoupling proteins, particularly in brown adipose tissue in rodents (100) and skeletal muscle in both rodents and humans (101). The significance of defects in adaptive thermogenesis in human obesity remains unclear.

The thermic effect of exercise is the most variable component of energy expenditure, and a possible causative role for this component in obesity has been studied. As with studies of food intake, progress has been limited by methodologic issues. Recent data derived from population studies indicate that

obese persons spend fewer hours per week physically active than do people whose BMIs are lower. There also is an inverse association between socioeconomic status and physical activity. However, the potential impact of physical activity on weight loss may be limited for any given individual. For example, expenditure of 220 calories requires approximately 25 minutes of rapid walking (i.e., 17 minutes per mile). A person engaged in a regular exercise program three times per week might expend an additional 700 calories, which represents about 20% of a pound of fat. Hence, although lifestyle changes are important for weight loss and contribute significantly to cardiovascular health, their overall impact on energy balance is small. Nonexercise activity also contributes to thermogenesis in humans. This activity is associated with fidgeting, maintenance of posture, and other physical activities of daily life. In some humans, overfeeding is associated with an induction of nonexercise activity, which serves to dissipate energy and reduce weight gain, whereas other individuals may fail to increase nonexercise activity and have increased fat storage (102). One study examined nonexercise activity, such as fidgeting, activities of daily living, and posture maintenance, and found a correlation of "spontaneous physical activities" with overall habitual physical activity (103). This suggests that activity levels may be either genetically or culturally determined in individuals and raises the possibility that a predisposition toward physical activity can decrease the predisposition to obesity.

In summary, although thermogenesis is important in maintaining energy balance, there are few data to suggest that most patients with established obesity have decreased rates of total energy expenditure. Indeed, as RMR increases with body weight, most obese patients have total increased thermogenesis, implying that their total energy intake is also increased in absolute terms. Some evidence supports the claim, frequently encountered in clinical practice, that individuals destined to become obese but who are not yet obese may have modest reductions in energy expenditure that would permit the development of obesity despite a low energy intake. However, even if such a defect is present, its basis is unknown, and it is unlikely, on the basis of current knowledge, that efficient energy metabolism on its own plays a major role in the generation or maintenance of the obese state. In contrast, after weight reduction, there is an overall decrease in thermogenesis (104), which makes maintenance of weight loss difficult.

Endocrine Factors

There is no established endocrine cause for most cases of obesity. However, endocrinologists frequently are consulted because of concern that a patient may have Cushing syndrome or hypothyroidism. Endocrine syndromes that may be associated with obesity are listed in Table 31.1. Although obese patients may have central obesity, hypertension, and glucose tolerance, they are free of most other stigmata of Cushing syndrome, and for the

 Table 31.1.
 Endocrine Syndromes Associated with Obesity

- 2. Hypothyroidism
- 3. Insulinoma
- Craniopharyngioma
 Turner syndrome
- 6. Male hypogonadism

most part this can be ruled out as a cause of obesity by the use of dexamethasone suppression testing (37,52). Some individuals with hypothyroidism become obese. This probably results from the decrease in metabolic rate and lower rate of lipolysis brought about by hypothyroidism. However, much of the weight gain in hypothyroidism is due to fluid accumulation with myxedema. Standard tests of thyroid function rule out the diagnosis in most obese patients. Other endocrine disorders that may be associated with obesity include insulinoma, male hypogonadism, growth hormone deficiency, and Turner syndrome.

TREATMENT OF OBESITY

Successful treatment of obesity, defined as treatment that results in sustained attainment of normal body weight and composition without producing unacceptable treatment-induced morbidity, is rarely achievable in clinical practice (96). Many therapeutic approaches can bring about short-term weight loss, but long-term success is infrequent regardless of the approach. Nevertheless, billions of dollars are spent annually in the United States in pursuit of this goal. Although many individuals diet solely in pursuit of cosmetic goals unrelated to any medically relevant definition of obesity, the need is great for effective and safe therapies for those individuals in whom obesity represents a major health risk.

Given the limitations, discomforts, and potential risks of available therapy, it is necessary to consider the risks of obesityrelated morbidity in any individual. It is clear that the morbidity of obesity increases with BMI and that, for any BMI, greater waist-to-hip ratios confer greater risk. Moderate risk begins at a BMI of 30 and doubles with a BMI between 30 and 40 (5). In addition to the risk conferred by an increased BMI, diabetes, hypertension, and an atherogenic lipid profile, when present, each increases the impact of obesity on health. Through evaluation of these factors and assessment of the likelihood that an individual patient will respond to a particular therapeutic regimen, an individualized long-term treatment plan must be developed.

Diet

Reduction of caloric intake is the cornerstone of any therapy for obesity and is discussed extensively in Chapter 32. The fundamental goal is the reduction of energy intake to a level substantially below that of energy expenditure. This simple prescription is difficult to accomplish despite a wide variety of specific dietary approaches. A number of factors complicate the ability to predict the results with any given diet (105–107). Because energy expenditure increases with increasing obesity at any level of caloric intake, individuals who are more obese will lose weight more rapidly than those who are less obese. The rate of weight loss at any level of energy intake also is influenced by factors that increase energy expenditure, such as exercise and thyroid function, and by gender and age, because women and persons of advanced age have lower metabolic rates for any body weight. As discussed below, there are claims that specific features of a diet, i.e., level of carbohydrates or proteins, may influence its efficacy. Importantly, many obese individuals believe that they are resistant to weight loss despite severe caloric restriction. The issues related to energy expenditure in obesity and the possibility that some individuals have a metabolic predisposition to efficient metabolism was discussed earlier. Whatever the answer to that question, it must be emphasized that there are no reliable demonstrations of failure of weight loss among obese individuals placed on diets of 1,200 kilocalories (kcal) or less while under strict observation. On the other hand, diets that produce weight loss for inpatients are frequently

^{1.} Cushing syndrome

unsuccessful when applied to outpatients, indicating problems with compliance with dietary regimens.

Apart from the initial weight loss consequent to natriuresis and fluid shifts, a deficit of 7,500 kcal is predicted to produce a weight loss of 1 kg (107). Therefore, a reduction in food intake by as little as 100 kcal per day should bring about a 5-kg weight loss over 1 year. It is clear from common experience, however, that attempts at dieting that rely on such small reductions in food intake are rarely successful. Thus, more severe reductions in energy intake are typically prescribed. Three general categories of calorie-restricted diets have been used (105).

Total starvation will produce the most rapid weight loss, although a greater fraction of the lost weight is from fluid losses than is found with other approaches. The extreme nature of the therapy, the need for close inpatient supervision, the excessive loss of lean body mass, and the occurrence of complications such as gout, renal stones, and hypotension have led to the virtual disappearance of this approach.

So-called very-low-calorie diets of 200 to 600 kcal were initially designed to supplement fasting, primarily with protein, with the goal being the prevention of loss of lean body mass (108). During the 1970s, formula supplements that contained low-quality protein derived largely from collagen and were deficient in essential amino acids led to excessive cardiovascular deaths (109). Contemporary versions of such diets use highquality protein derived from soy, casein, egg, or lean fish or fowl and adequate quantities of other nutrients, including unsaturated fatty acids, potassium, magnesium, vitamins, and minerals. Whether or not carbohydrate should be a component of such diets, with the goal of minimizing ketosis and reducing the decrease in triiodothyronine but with the possible side effect of reducing conservation of lean body mass, is a subject of debate and is discussed more fully in Chapter 32. Recent application of such diets under medical supervision has not been associated with unexpected deaths (110,111). Indeed, institution of such therapy virtually always has beneficial effects: a prompt reduction in blood pressure in hypertensive patients and in blood glucose levels in diabetic patients, typically allowing medication to be discontinued, at least for the duration of the diet. The average weight loss is 1.5 kg per week, although, for several reasons, including the decline in metabolic rate that follows loss of lean body mass, the rate diminishes as weight is lost (112,113). Because regaining weight after cessation of dieting is extremely common, such diets make sense only as part of an overall plan to modify food intake chronically.

Many different diets that provide 800 to 1,000 kcal per day are in common use, and with adequate compliance by the patient, these diets should result in weight loss. Balanced low-calorie diets, as well as those that feature low amounts of carbohydrate or protein, have been advocated by different authorities. There are also many programs that recommend specific food combinations or unusual sequences for eating, but none of these approaches has any proven merit. However, dietary composition may play a role in long-term success in weight loss and weight maintenance. For example, a study comparing a moderate-fat diet consisting of 35% energy from fat and a low-fat diet in which 20% of energy was derived from fat demonstrated enhanced weight loss assessed by total weight loss, BMI change, and decrease in waist circumference in the group on the moderate-fat diet. Retention in the diet study was greater among those enrolled in the moderate-fat group, as 54% of patients continued actively participating in the weight loss program in this group compared with 20% in the low-fat diet group (114).

Recently, increased interest has focused on the possibility that diet content may affect appetite. For example, diets with a low glycemic index may be useful in preventing the development of obesity; subjects given test meals with different glycemic indexes and then allowed free access to food ate less after eating meals with a low glycemic index. Some data suggest that diets with a high glycemic index predispose to increased postprandial hunger, whereas diets focused on glycemic index and information regarding portion control lead to higher rates of success in weight loss, at least among adolescent populations (115). Low-carbohydrate diets such as the Atkins diet appear to be associated with significant weight loss. However, this diet has not been systematically studied, nor has long-term maintenance of weight loss.

A key aspect yet missing from diet therapy is education regarding diet aimed at preventing initial weight gain. Among the population, general information on caloric content is quite poor. It is also a noteworthy paradox that over the past 30 years, the U.S. population has gained weight while focusing on reducing saturated fat in the diet. Indeed, total fat content in the diet is lower today than at any time in the past several decades, yet obesity has achieved epidemic proportions. One possibility is that the focus on "low fat" deflected attention from a focus on portion control. Between 1970 and 1994, total daily per capita calorie consumption increased by 500 calories (Fig. 31.4). Approximately 80% of this increase derived from higher daily carbohydrate consumption, which increased by 100 g. In comparison, protein consumption increased minimally and fat consumption remained constant. During the same interval, yearly per capita meat consumption increased by 13 pounds, whereas cereal consumption increased by 65 pounds (Fig. 31.5). Although consumption of all food groups increased, the disproportionate increase of carbohydrates and cereals suggests that the focus on low-fat foods, which are necessarily high in carbohydrates, may be contributing to the obesity epidemic. This could occur because individuals either are more likely to discount calories derived from carbohydrates and hence consume more of these calories or experience increased hunger as a consequence of carbohydrate intake and respond with an overall increase in calorie consumption.

Exercise

It is appropriate to consider the therapeutic use of exercise for any patient with obesity. Because exercise increases energy expenditure, the most obvious purpose of exercise in obesity is to shift the energy balance equation toward a net negative. Unfortunately, long-term compliance with exercise programs is limited. This and the relatively small impact of moderate exercise on net energy balance combine to support the view that exercise is at best a small aid to weight loss in clinical practice (116). For example, a 150-pound person engaging in moderate exercise such as walking uphill at a grade of 4% at a pace of 3 miles per hour for 30 minutes will expend only 150 calories. Nevertheless, given the potential benefit of exercise on blood pressure, lipids, cardiovascular fitness, insulin sensitivity, and sense of well-being, attempts should be made to incorporate an exercise program into the therapeutic approach. In addition, exercise has positive effects on weight maintenance and thus may help to avoid regain of weight.

Drugs

At present, few drugs are available for the treatment of obesity, and the available agents lead to successful weight loss in only a limited number of patients. Orlistat (Xenical) is a synthetic fat that impairs absorption of ingested fat by inhibiting intestinal lipase. Expected weight loss is on the order of 5 to 15 kg. However, in some patients this relatively small degree of loss may be sufficient to improve comorbidity. In patients

Food Trends 1970-1994

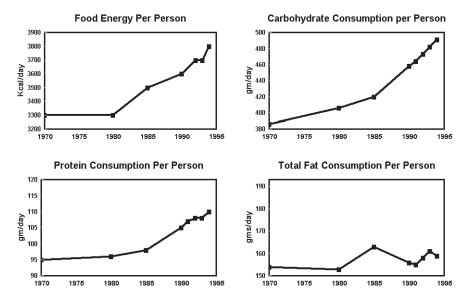

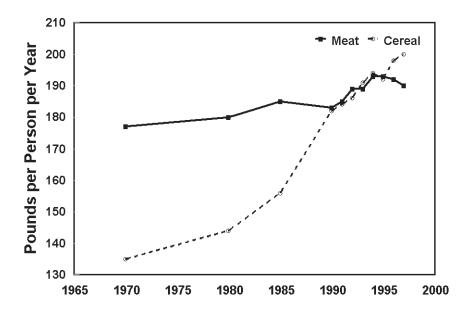

Figure 31.4. Daily per capita energy consumption. These panels show the source of calories. Overall daily energy consumption has increased by 500 calories over 15 years. Most of these increased calories derive from carbohydrate, as can be seen by comparing the increases in carbohydrate, protein, and fat consumption. (Adapted from data from the U.S. Department of Agriculture.)

with a recorded history of increasing weight gain over time, even the stabilization of body weight may be a desirable endpoint. Orlistat is not absorbed and has few systemic side effects, although supplementation with fat-soluble vitamins is recommended. Loose, fatty stools in some patients are a significant problem, leading to the termination of therapy. As with most other obesity treatments, it is unusual to sustain weight loss for more than 2 or 3 years after therapy.

A second available agent is sibutramine (Meridia), which inhibits reuptake of both serotonin and catecholamines at nerve intervals and acts both to decrease appetite and to increase thermogenesis (117). Expected weight loss is similar to that seen with orlistat. However, hypertension and tachycardia occur as relatively common side effects. This tends to limit the treatable population. Phentermine is still available and may be useful in some patients.

Food Trends 1970-1994

As seen with diet, long-term results after cessation of pharmacologic treatment are discouraging, with fewer than 10% of patients who achieved successful weight loss showing sustained long-term weight loss.

Surgery

Patients with massive obesity who are refractory to therapy are subject to major morbidity from their disease. A number of surgical procedures have been used to treat morbid obesity. Malabsorptive procedures such as jejunoileal bypass and biliopancreatic diversion lead to weight loss without changes in eating habits. These procedures have generally been abandoned because of their association with high rates of complications. Jejunoileal bypass may lead to hepatic failure, cirrhosis, protein malnutrition, vitamin deficiency, and metabolic bone disease.

Figure 31.5. Yearly per capita meat and cereal consumption. (Adapted from data from the U.S. Department of Agriculture.)

Biliopancreatic diversion is associated with protein malnutrition, metabolic bone disease, and vitamin deficiency.

These malabsorptive procedures have been supplanted by procedures in which the major element is restriction of stomach capacity, including gastroplasty, gastric banding, and gastric bypass surgery (118). Gastroplasty involves stapling the stomach to exclude the fundus. In gastric banding, a prosthetic band encircles the proximal stomach and may be placed laparoscopically. Gastric bypass partitions the stomach into a small proximal pouch and a distal bypassed fundus; a gastrojejunostomy is used to drain the pouch. This configuration can lead to a "dumping syndrome" when a carbohydrate-rich meal is ingested; the potential for experiencing symptoms of dumping, including lightheadedness, nausea, palpitations, and diaphoresis, may contribute a behavioral component to weight loss. The success of gastroplasty appears to be relatively low, as fewer than 40% of patients maintain 50% excess weight loss at 3 years (119). Gastric banding is associated with variable success.

At present the Roux-en-Y gastric bypass procedure is recommended in patients with a BMI higher than 40 or in those with a BMI higher than 35 and a comorbidity such as diabetes, hypertension, or arthritis. When this procedure is performed in appropriately prescreened patients, 80% lose significant amounts of weight, and weight loss can be sustained indefinitely. Patients need to be evaluated by a nutritionist and must fully understand the consequences of the surgical procedure. All programs also require a psychological assessment. Severe depression and a history of bulimia or anorexia would disqualify a patient. The surgical procedure appears to be well tolerated. Following surgery, approximately 95% of patients with diabetes will experience a significant improvement in their glucose tolerance, ranging from an ability to maintain euglycemia without any medication to a marked reduction in dose and number of antidiabetic drugs. Hypercholesterolemia and hypertension almost always improve.

CONCLUSION

Overweight and obesity are major health problems associated with increased risk of diabetes and numerous other illnesses. Although increasingly prevalent, the available pharmacologic treatments are poor. Surgery, particularly Roux-en-Y bypass, is an established and useful therapy; however, this is applicable only for patients with significant obesity.

Successful treatment of most overweight and obese individuals will depend upon the future development of new therapies. It also requires a paradigm shift in viewing obesity as a disease that requires treatment, rather than deferring treatment until the complications develop.

EXERCISE 553	CONCLUSION 559
FITNESS 556	

The recommendation for treating obesity is based on two premises. The first is that weight can be lost and that, once lost, the lower weight can be maintained. The second is that this improves health. The evidence suggests that both of these are true (1,2). A loss of 10% of baseline weight can be achieved and maintained (2). But losing weight and particularly maintaining weight loss is very difficult and often discouraging, and the failure rate is high. Given our still-limited knowledge of the etiology of obesity, the primary emphasis must be on self-control, and the primary agent for change is the patient, not the physician. Motivation and commitment from the patient are required, but the support, understanding, and knowledge of the physician are also extremely helpful.

Because physicians are accustomed to pharmacologic solutions for most of the diseases they treat, they are not well attuned to the tedious task of slow, difficult weight loss, with its plateaus, relapses, and disappointing statistics. As a result, other health professionals have become involved in treatment. Dietitians, exercise physiologists, psychologists, social workers, and nurses advise and treat patients who want to lose weight. While these other professionals can be very helpful and often are more effective, a physician should monitor the weight-loss program and treat any other associated risk factors and health problems that are present or may develop.

The assessment of obesity can be rapid and easy. A physician usually requires nothing more than a visual inspection to determine the need for weight loss. However, for a more quantitative assessment, there are simple techniques for categorizing and following a patient. The body mass index (BMI) is a useful guideline. It is calculated by dividing the weight in kilograms by the height in meters squared (kg/m²) (3). It can also be found from a table relating height and weight to BMI (Table 32.1). There is a fairly good correlation between BMI and body fat (4). However, this correlation is far from perfect, and very athletic persons can be misclassified due to their increased muscularity, although there are very few such disparities. Normal, over-

weight, and obese categories of BMI are shown in Table 32.2. The upper limit of the recommended BMI range is set at 25 because the mortality curve begins to increase at higher BMI values (5). There has been some argument that the BMI threshold should be set higher in some groups (women, older persons) and lower in others, such as Asians. However, the BMI of 25 is a reasonable and useful compromise (6), alerting individuals and populations to increased health risk.

Obesity aggravates or precipitates a number of other risk factors and diseases, including insulin resistance, impaired glucose tolerance, diabetes mellitus, hypertension, dyslipidemia, coronary heart disease, congestive heart failure, thromboembolic disease, restrictive lung disease, sleep apnea, gout, degenerative arthritis, gallbladder disease, and infertility (7,8) (Table 32.3). In cases in which one or more of these conditions are present, more stringent standards of weight seem appropriate (9). Although the loss of weight is likely to ameliorate any associated conditions, therapy targeted specifically for these disorders is also often necessary.

The physician also needs to assess body-fat distribution. An excessive amount of fat in the trunk (central fat, upper-body fat) carries more health risk than does fat on the lower body (peripheral fat, lower-body fat). Central fat is independently associated with risk factors such as insulin resistance, hypertension, and dyslipidemia (10,11) and is an independent predictor of coronary heart disease and diabetes (12–15). A simple assessment can be done by measuring waist circumference (Table 32.2). Measuring waist circumference is described in Figure 32.1.

Weight gain develops because energy intake exceeds energy expenditure. Once obesity supervenes, however, there may be a new weight stability, with caloric intake becoming equivalent once again to caloric expenditure. For a person to lose weight, energy intake must be decreased and/or energy expenditure increased to disequilibrate the energy balance equation and create a caloric deficit.

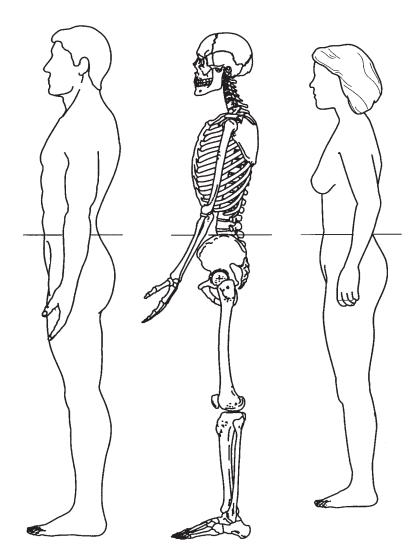

Figure 32.1. Measuring tape position for waist (abdominal) circumference. To define the level at which waist circumference is measured, a bony landmark is first located. The subject stands and the examiner, positioned at the right of the subject, palpates the upper hip bone to locate the right iliac crest. Just above the uppermost lateral border of the right iliac crest, a horizontal mark is drawn, then crossed with a vertical mark on the midaxillary line. The measuring tape is placed in a horizontal plane around the abdomen at the level of this marked point on the right side of the trunk. The plane of the tape is parallel to the floor and the tape is snug, but does not compress the skin. The measurement is made at a normal minimal respiration. (From National Heart, Lung, and Blood Institute. Clinical guidelines on the identification, evaluation, and treatment of overweight and obesity in adults—the evidence report. *Obes Res* 1998;6[Suppl]51S–210S, with permission.)

WEIGHT LOSS CAN IMPROVE HEALTH

Intentional weight loss in obese persons has been shown to improve health in both epidemiologic and clinical intervention studies. Williamson et al. (16) have shown that intentional weight loss decreases both cardiovascular and overall mortality. Weight loss also decreases morbidity (17).

Short-term studies have demonstrated that weight loss resulting from low-calorie diets, very-low-calorie diets, anorectic drugs, or bypass surgery is associated with increased insulin sensitivity, improved insulin secretion by islet cells, decreased hepatic glucose production, and improved glucose disposal (1,18-23). Wing et al. (24) conducted a long-term study in which diabetic patients lost an average of 5.6 ± 4.0 kg during the active intervention phase and maintained a weight loss of 4.5 ± 7.5 kg at 1 year. Those who were most successful in losing weight had significant improvements in fasting blood glucose and glycosylated hemoglobin values at 1 year even though they remained 20% above ideal body weight at the end of the study. Reductions in insulin dose or oral hypoglycemic medication were made for 100% of patients who lost 6.9 to 13.6 kg, 46% of those who lost 2.4% to 6.8 kg, and 40% of those who lost 0 to 2.3 kg. In the United Kingdom Prospective Diabetes Study (UKPDS) study (25), the response to diet was studied in 3,044 patients with newly diagnosed type 2 diabetes. Their mean fasting plasma glucose level was $12.1 \pm 3.7 \text{ mmol/L}$. The investigators determined that the weight loss needed to achieve normalization was 16% of ideal body weight in patients with initial fasting plasma glucose levels of 6 to 8 mmol/L, 21% in those with levels of 8 to 10 mmol/L, 28% in those with levels of 10 to 12 mmol/L, 35% in those with levels of 12 to 14 mmol/L, and 41% in those with levels greater than 14.0 mmol/L. At the 15-month assessment, 482 patients maintained normal fasting plasma glucose levels. On average, they had slightly lower fasting plasma glucose levels at study entry and had lost more weight than did other patients (25). After 3 months, 742 patients achieved normal fasting plasma glucose levels. However, it is important to remember that there will be nonresponders, and obese individuals who remain hyperglycemic after a weight loss of 2.3 to 9.1 kg are unlikely to improve with further weight loss and should be considered for treatment with hypoglycemic agents (26).

Weight loss through diet and exercise can reduce the risk of the conversion of impaired glucose tolerance to frank diabetes. This has been shown in studies in China (27), Finland (28), and the United States (29). In the Diabetes Prevention Program in the United States, which studied more than 4,000 patients over 5 years, the progression to diabetes was decreased by 58% (29).

Ross and Rissanen (30) have shown effects of diet and exercise on insulin sensitivity, preferential loss of visceral fat, and blood pressure. The effect of weight loss on hypertension has now been documented in a number of randomized clinical trials. Longterm studies have confirmed the effectiveness of weight reduction in lowering blood pressure and enabling some patients to become normotensive without the use of antihypertensive drugs and for others to reduce the dosage of required drugs or the number of drugs taken (31–42). The marked improvement found in many unmedicated hypertensive patients suggests that weight reduction should be the initial treatment for an obese person with hypertension. In patients for whom elimination of antihypertensive drugs is not a realistic goal, weight loss can potentiate the effects of drug therapy (40,41,43).

The dyslipidemia of obesity is characterized by high triglycerides, reduced high-density lipoprotein (HDL) cholesterol, and small dense low-density lipoprotein (LDL) particles (44,45). With weight loss, triglycerides fall, HDL cholesterol rises, and small dense LDL particles become larger and less atherogenic (45). Short-term studies have confirmed the value of behavioral, low-calorie diet, and very-low-calorie diet interventions in decreasing total and LDL cholesterol levels and the HDL/LDL ratio and lowering triglyceride levels (46–50). Additional long-term studies, of greater than 1 year, have also been done and have shown a sustained improvement in the lipid profile of overweight and obese patients (33,36,51–54). Although some of these lipid changes are relatively small, they should not serve as a disincentive to embarking on a weight-loss program, because even modest improvements in lipid levels are associated with a decreased risk of cardiovascular disease (1,17,55).

Few trials have explicitly addressed the relationship between weight loss and cardiovascular disease per se. A 10year study of 2,500 patients from the Framingham Study cohort conducted by Higgins et al. (36) found a positive association between weight loss and cardiovascular disease, although this finding almost certainly results from the fact that the study does not distinguish disease-related involuntary weight loss from voluntary weight reduction.

Respiratory function is often impaired in obese individuals because of reduced lung volume, altered respiratory patterns, and decreased respiratory system compliance (7). Obesityhyperventilation syndrome and sleep apnea are the most common respiratory disorders associated with severe obesity (8). Short-term studies of sleep apnea have indicated that weight loss resulting from low-calorie diets or gastric bypass surgery is associated with a marked reduction in apneic episodes and night awakenings and with a general improvement in sleep patterns (56–61).

Obesity is often associated with an increased risk of gout (62), as is increased central fat distribution (63). When persons lose weight, their uric acid levels may initially increase (1,64), but precipitation of gout by weight-loss therapy in asymptomatic patients is uncommon (65). Uric acid levels rarely become high enough to necessitate medical treatment (66). Occasionally, large amounts of uricosuria and a predisposition to renal uric acid stone formation occur. When the appropriate diagnosis is made, urine alkalinization is the treatment of choice.

Cross-sectional studies have repeatedly found an association between increasing weight and increased prevalence of osteoarthritis of the knee (67–69) and, to a much lesser extent, of the hip (70). There have been just a few studies that have related weight reduction to the reduction of the onset of arthritis (71) or to the improvement of arthritic symptoms (72).

Obese persons are at a greater risk for developing gallstones than are persons of normal weight, probably because their bile is more highly saturated with cholesterol, their gallbladders are larger and less contractile, and their triglyceride levels tend to be higher (7). An association between loss of large amounts of weight and gallstone formation has been reported, although this finding has not been observed consistently (73–76). However, once individuals lose weight, their risk of gallstone formation and of cholecystitis decreases because the risk factors previously cited improve.

Available data suggest that obese persons may have a greater tendency to depression than do lean persons, but there are no data to suggest that obese persons are more prone to psychosis (77,78). The depression generally improves with weight loss (79).

GOALS OF THERAPY

Obesity is associated with increased health risk, and this is especially so in patients with diabetes (80). The goals of therapy are to improve health risk. There are two ways to approach the risk—one is to modify weight and the other is to focus on and try to modify other health-related variables (81). Focusing on other health-related variables can be done with individuals for whom the initiation of a weight-loss program seems impossible or impracticable.

It is common for patients who are beginning a weight-loss program to have faulty and unrealistic beliefs about how much and how rapidly they can lose weight. It is important to counsel them in this regard to prevent disappointment and attrition.

Most obese persons wish to lose all of their excess weight and return to normal weight (82). While this may be realistic for someone whose BMI is close to normal (26 to 30), it is not realistic for individuals whose BMIs are higher. For these persons, a weight loss goal should be set for a reduction of 10% to 15% from their present baseline weight (2) for a number of reasons. First, it is very difficult for most persons to lose more than this, and it is consequently damaging for their self-image, sense of success, and satisfaction when they set goals that are unreasonable and generally unattainable. Second, if a patient is pushed to lose more, such as can occur with very-low-calorie (300 to 500 kcal) diets, experience has shown that, while persons can lose weight quickly, they will generally regain it almost as quickly (83).

BEHAVIORAL THERAPY

The traditional technique of handing a patient a printed description of a 1,200- or a 1,500-kcal diet, complete with specific menus and specific portion sizes, and telling him or her to increase exercise without further instruction, has generally been unsuccessful. With inadequate education and support, patients quickly abandon such programs and never increase their activity.

In an effort to prevent such failure, the use of behavioral therapy has increased. Approaches to changing behavior began with Ferster et al. (84) and were greatly popularized by Stuart (85). The goal of such therapy was to modify maladaptive eating by improving environmental control. The aim was to change eating behavior (86). This approach was found to be too narrow, and more recent adaptations have recognized obesity as much more complex than just maladaptive eating, with influences from genetic, physiologic, psychological, and social factors (87). The newer approaches have targeted not only eating but also physical activity. In the 1970s, cognitive-behavioral techniques were initiated (88–90). A number of psychologists have written about these treatment techniques (91–95).

Table 32.4 summarizes weight losses in randomized clinical trials that combined behavior modification with moderate

caloric restriction (96). It can be seen that there has been an improvement in weight loss over time, but generally because treatment programs are running longer, not because there is an increase in weight loss per week. On average, weight loss is close to 10% from baseline. It is depressing, however, that the baseline weight of the individuals being treated has increased dramatically, demonstrating how serious the problem of obesity is in the United States. The maintenance of the weight loss is difficult. While the majority are able to maintain their weight loss for at least a year, many regain most of their weight over the next 3 to 5 years (96,97). This seems to occur even when specific maintenance strategies are used in the program (98,99). It is interesting to note that some of the most successful results of behavioral programs have been reported in childhood obesity (100-102). Whether this is related to less fixed lifestyle habits at that age is not clear.

Behavioral change in a patient is attempted in small, possible, and reasonable steps with the help of a physician or other health professional. Behavioral change requires knowledge of nutrition, physical activity, and self. Nutritional knowledge means becoming familiar with the caloric content and energy density of foods, portion sizes, and less calorically dense cooking techniques. Knowledge about physical activity means learning about one's own capabilities and physical weaknesses and how to increase the time and the intensity of activity progressively and safely. Self-knowledge is crucial for dealing with individual maladaptive eating and activity behavior (103).

The first step in self-knowledge is to describe for oneself one's eating and activity behavior. Patients need to self-monitor so they will become aware of the amount, time, and circumstances of their eating and of their activity (or inactivity) patterns. This increased awareness is required so that corrective measures can be attempted. Once specific problems are identified, the next step is to begin to effect changes. Typical stimuli that lead to maladaptive eating behavior would be contact with persons or situations that increase stress, anxiety, or hostility. The particular stimuli should be identified, and patients need to make an effort to distance themselves from them. A further behavioral step is to develop techniques to control the act of eating and what is eaten. The most important of these is the technique of paying close attention to the act of eating. Others include becoming aware of the places where the person eats, the speed of eating, the portion sizes, and the frequency of eating. Some therapists have suggested that prompt reinforcement of behaviors that delay or control eating is very helpful. This would mean setting up some reward system (e.g., money, entertainment, and praise) as positive reinforcement for improved behavior (103).

 TABLE 32.4. Summary Analysis of Selected Studies from 1974 to 1990 Providing Treatment by Behavior Therapy and Conventional Reducing Diet

Adapted from Wadden TA, Bartlett S. Very low calorie diets: an overview and appraisal. In: Wadden TA, Van Itallie TB, ed. *Treatment of the severely obese patient*. New York: Guilford Press, 1992:44–79, with permission.

There has been an effort in recent years to incorporate relapse-prevention strategies into the treatment effort (92, 104–106). While it is not clear that this has been very successful, it points to the need to maintain an effort even though there may well be missteps along the way.

The program needs to be adapted to each patient's goals and skills rather than to a physician's idea of how a patient should behave. This individualization of treatment is crucial for enhancing the chances of success in a motivated person.

The advantage of a behavioral approach is that both the patient and the therapist (which may include the group) focus on specific variables that seem to govern a particular person's behavior. Central to a behavioral analysis is the search by a patient and therapist for solutions to soluble, concrete problems. They may be relatively modest. This simplifies and focuses therapy. It has been the experience in our weight-control program that conducting behavioral therapy in a group setting is highly efficacious. The group setting leads to focused inquiry, mutual support, and group encouragement that are conducive to success. Many physicians have embraced group therapy as a way of reaching more patients effectively at lower cost.

Another advantage of a behavioral approach is that it gives patients the major responsibility for the weight-loss strategy so that, with success, they can attribute increased power to themselves. The treatment is reinforced when patients believe that positive results are attributable to their own efforts, and they gain increased confidence and a desire to continue.

The most important advantage of a behavioral approach is that it allows patients to change habits under the natural social and environmental conditions that they live in day to day. Thus, the new habits learned during weight loss can be continued during the very difficult period of weight maintenance, which is lifelong. This may be more difficult in programs in which the patient is taken off natural foods for a time and placed on a liquid diet and then is suddenly confronted with a return to regular food and the need to modify behavior. The learning may come too little and too late and may lead to failure and weight regain. Appropriate safeguards must be called on to prevent this, such as early start of nutrition education and physical activity, with self-monitoring occurring as solid food is re-introduced. It must be remembered that a behavioral program produces the slowest initial weight loss because calorie reduction is not radical and patients are encouraged to eat a balanced and sensible diet. This helps the patient to develop a long-term view and strategy. For continuing success, a patient needs to remain in treatment not just until goal weight is achieved but also well into the weight-maintenance period.

WEIGHT GOALS

Years ago, the goal in weight loss was to return the patient to a normal weight, but this is no longer the case. The reason has been the inability of individuals to lower their weight to this level and then to maintain it. As a result, the aim has changed to that of attaining a "healthy weight," that is, a weight that lowers health risk. Thus, the National Heart, Lung and Blood Institute (NHLBI) Evidence Report (2) states that there is evidence that one can lose and maintain a loss of 10% from baseline weight. Blackburn (107) has championed this approach, suggesting aiming at a 10% weight loss. This is also the approach in the report by the Institute of Medicine (108).

Thus, the evidence suggests that it is better to aim for a slow, attainable, and sustainable weight loss. One kilogram of lost weight, which will be part fat and part lean body mass, is equivalent to about 7,000 kcal. A caloric deficit of 700 kcal per day

results in a 1-kg weight loss in 10 days; if the deficit is 1,000 kcal, it will take 7 days to lose 1 kg; if the daily deficit is 500 kcal, 14 days. Initial weight loss may be a bit faster because a water diuresis can occur. A nutritional and exercise regimen of diet and exercise that creates a deficit of 500 to 1,000 kcal per day is reasonable (2,29). Thus, a man weighing 100 kg whose calorie intake to maintain weight is 2,800 kcal needs to reduce intake to between 1,800 and 2,300 kcal. Such a diet should enable him to lose between 0.5 and 1 kg per week, assuming that there is no change in physical activity. If his ideal body weight is 70 kg, it would take him between 30 and 60 weeks to reach this weight. A clear realization of the need for the sustained effort over time required to reach the goal that is set is important for keeping a patient motivated and positively reinforced. Also, as mentioned, the goal should not be set at ideal weight but at a percentage from initial baseline weight that is known to improve comorbid conditions and that can realistically be maintained long term (1,17). For the previous case example, the goal should be set at 85 to 90 kg.

NUTRITION

Nutritional change is the most important component of a weight-loss program. To lose weight successfully, obese persons must lower caloric intake and maintain a reduced intake indefinitely. The nutritional change must be within the framework of a patient's current cultural food habits and preferences. While this is sometimes impossible when dietary habits are so poor that a radical restructuring is required, in most patients compliance is better when familiar foods are suggested. Factors such as available cooking facilities, ethnic background, family requirements, and economic background should not be ignored. Documentation of food intake (e.g., diet records) is an invaluable method of tracking dietary pitfalls, patterns, and progress, but physicians must be aware of perfect records unaccompanied by weight loss. These should serve as a signal that a patient may not be ready to work seriously on weight loss.

Energy expenditure should be estimated since resting metabolic rates (RMR) are not usually available to the average physician because obtaining them is too difficult and too expensive. A formula such as the Harris-Benedict equation for calculating basal metabolic rate can be helpful in estimating energy requirement (Table 32.5) (109). Multiplying the value thus obtained for RMR by 1.4 gives a reasonable approximation of 24-hour energy expenditure for a typical sedentary obese individual in our society. It is important to stress, however, that this will only give an approximation and will need to be adapted for each individual patient (110). An appropriate caloric deficit should be discussed with the patient. For example, a 120-kg male with a calculated 24-hour expenditure of 3,000 kcal may choose to lose 1 kg per week on 2,500 kcal per day rather than 1.5 kg per

TABLE 32.5. Harris-Benedict Equation (Energy Requirements)

Men: BEE = $[66 + (6.2 \times W) + (12.7 \times H) - (6.8 \times A)]$ **Women:** BEE = $[655 + (4.3 \times W) + (14.3 \times H) - (4.7 \times A)]$

BEE, basal energy expenditure; W, weight in kg; H, height in cm; A, age in years. For weight gain of approximately 1 kg/week, an additional 100 kcal/day should be provided. From Johnson MM, Chin R Jr, Haponik EF. Nutrition, respiratory function, and disease. In: Shils M, Olson J, Shike M, et al., eds. *Modern nutrition in health and disease,* 9th ed. Baltimore: Williams & Wilkins, 1999:1473–1490, with permission.

week on 2,000 kcal per day because for him the quantity of food eaten per day takes priority over the rate of weight loss. Such decisions should be made jointly by the patient and physician to help promote long-term compliance. A diet should be adequate nutritionally because it will be continued indefinitely, and this is possible without vitamin and mineral supplements only for diets of 1,100 to 1,200 kcal per day or more. To achieve this, patients must be instructed in the need for micronutrient-rich foods that they may not be used to eating regularly. With very hypocaloric diets, the nutrients most likely to be in deficit are iron, folacin, vitamin B₆, and zinc. If levels of calories fall below 1,200, vitamin and mineral supplements are necessary and should be prescribed: A multivitamin/multimineral tablet once a day is enough. Calcium should be supplemented at 1,000 mg per day and vitamin D at 400 IU per day to prevent bone mineral loss (111). Other extra macrominerals (sodium, potassium, magnesium) are usually not necessary unless patients go on very-low-calorie diets (300 to 500 kcal).

During weight loss, the goal should be reduction of adipose, rather than lean, tissue. While there is always some obligate loss of lean body mass (112), it should be kept to a minimum. Lean body mass can generally be spared during weight loss with a protein intake of 1.0 to 1.5 g per kg ideal body weight (calculated from Table 32.1 using a BMI of 25). The dietary sources of protein should be of high biologic value (e.g., egg whites, fish, poultry, lean beef, and low-fat dairy products). A vegetarian diet is acceptable, but the concept of protein complementation to assure adequate intake of essential amino acids must be explained to the patient and encouraged (113). The remainder of calories should come from carbohydrate (preferably highfiber foods) and fat. Although the macronutrient ratio of fat to carbohydrate can vary according to the patient's preferences, it is important to obtain the antiketogenic, micronutrient, highfiber benefits of carbohydrate, which occur with at least 100 g per day, and to get adequate amounts of fat-soluble vitamins and essential fatty acids from dietary fat.

In weight reduction, the emphasis therefore should be on micronutrient-dense food choices and away from "empty-calorie" selections. A brief discussion of basic nutrition will help alert the patient to appropriate food choices for maximizing the caloric restriction. A patient must learn that alcohol and sweets do not carry essential micronutrients. These should be avoided because they provide little more than excess calories. It should be made clear that although some fats are less atherogenic than others, all fats are high-energy, low-micronutrient foods and should be restricted to less than 30% of the total daily calories. Gram for gram, pure fat has more than double the caloric concentration of carbohydrate or protein (9 kcal/g vs. 4 kcal/g). Because carbohydrate often absorbs water during cooking, the actual caloric density of hydrated carbohydrate on the plate may be as low as 1 to 2 kcal/g. Decreasing fat foods in the diet will provide a substantial caloric decrease. In general, high-fat spreads, condiments, sauces, and gravies are far more detrimental in a weight-reduction program than are bread, potatoes, pasta, or rice, although a patient, if not properly instructed, can substitute carbohydrates totally for any fat restriction and end up eating as many calories as previously.

Many of the more popular media-touted diets have little scientific basis and simply play upon vulnerable persons' desperation to lose weight. These diets often ignore the concept of balanced nutrition by totally eliminating or providing insufficient amounts of a particular macronutrient (e.g., protein, carbohydrate, or fat). In time, this can result in a concurrent micronutrient imbalance. Such diets are unsound, and if they are followed for any significant time period, as any serious weight-control diet must be, untoward health consequences such as electrolyte imbalances, deficiency syndromes, or protein-malnutrition can ensue (114).

Very-low-calorie liquid diets (300 to 500 kcal/day) are generally counterproductive if carried out for a long period (83). Although weight loss can be large on such diets, the results are usually short-lived (114). A return to pre-diet weight after solid foods are resumed is the rule. Unless such diets are undertaken in the context of a complete medically supervised, stepwise program in which the very-low-calorie diet is replaced after a few weeks by a higher-calorie balanced diet and an intensive behavior-modification program, they accomplish little except for periodic loss of water and electrolytes. Such diets need to provide adequate high-quality protein to prevent protein malnutrition and possible cardiac morbidity (115). It is better to recommend diets that are no lower than 800 kcal. These have been found to be as efficacious and are safer (116).

An understanding of the U.S. Department of Agriculture food pyramid (Fig. 32.2) (117) may help the patient to adhere to a diet balanced in micronutrients and vitamins. By selecting judiciously from the grain, fruit, and vegetable groups (1–3), cutting down on the number of servings of the meat, milk, and fat groups (4–6), the patient can obtain adequate nutrients with a hypocaloric diet. Group 1 provides carbohydrate, protein, thiamine, niacin, vitamin E, iron, phosphorus, magnesium, zinc, and copper; group 2 and 3 provide carbohydrate, vitamins A and C, iron and magnesium; group 5 provides protein, fat, vitamins A and D, magnesium, calcium, phosphorus, and zinc; and group 6 provides essential fatty acids.

Patients are encouraged to select a wide variety of foods within these six food groups to alleviate boredom and monotony and thereby enhance compliance. The number of servings per day from each group will vary according to the individual's caloric restriction and macronutrient breakdown. Since portion sizes are crucial, they should be explained in terms of common household measures (e.g., spoonfuls, cups, ounces) and with the aid of food models. A patient should not lose more than 1% of body weight per week (114).

A common mistake made by patients is that they think that once they lose weight they can liberalize their diet. This is not true; as energy expenditure decreases with weight loss, an individual will need to continue to limit calorie intake if he or she does not want to regain the weight. Thus, the dietary plan that has been created should be continued. Patients generally plateau with regard to weight loss at about 6 months into their treatment program (118). At that point, the increased exercise and the decreased calorie intake come into a new equilibrium and no more weight is lost. To lose further at that time requires a stricter diet, greater exercise activity, or both.

EXERCISE

Because physical activity expends calories, increasing it is logical for any weight-loss program. Obese persons are generally very inactive. Many of them, particularly the heavier ones, have trouble walking even short distances and climbing steps and tend to avoid such situations. By staying so sedentary, they are close to their resting metabolic rate for most of the day. Increased physical activity has a strong impact on insulin sensitivity and improving glucose tolerance (119). Kelly and Goodpaster reviewed eight randomized studies (119) and found an improvement in insulin action. Exercise training can elicit improvement in insulin action in obesity within 1 week of intervention. In a study that compared the effect of aerobic to resistance exercise, they were found to be equally effective (120). Higher-intensity exercise is more effective (121). There is strong epidemiologic evidence that phys-

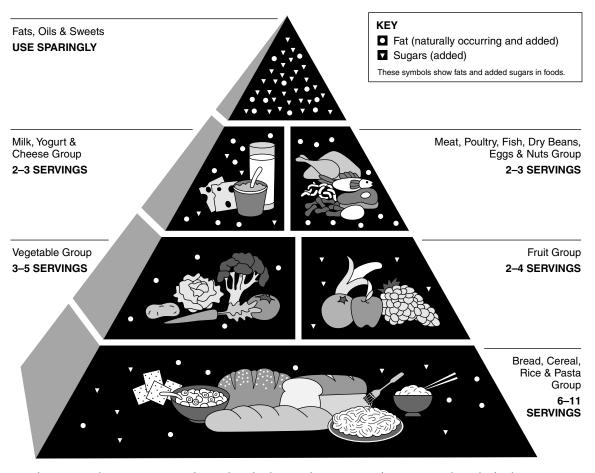

Figure 32.2. The US Department of Agriculture food pyramid. (From Center for Nutrition Policy. *The food guide pyramid.* Washington, DC: Department of Agriculture, 1996. Report number: Home and Garden Bulletin 252.)

ical activity can reduce the risk of type 2 diabetes (120,122–127). Aerobic exercise also reduces blood pressure independent of change in weight. The blood-pressure effect depends on the initial blood pressure but not on initial BMI or age (128).

The importance of exercise in weight control programs has been widely debated. The NHLBI Expert Panel (2) reported that, in 10 of 12 studies that met their review criteria, subjects in the exercise study arm had larger weight losses than did the no-exercise controls. In a meta-analysis of studies, Garrow and Summerbell (129) came to the same conclusion. Table 32.6 shows the results of ten randomized clinical trials showing that exercise produces greater weight loss than the no-treatment control (130). One can then ask if exercise in combination with diet produces greater weight loss than diet alone. The NHLBI panel (2) found that 12 of 15 randomized clinical trials showed a greater weight loss (1.9 kg) and greater reduction in BMI (0.3 to 0.5 unit) in the group with combined diet and exercise than in the group with diet only. Reviewing 13 of these studies, Wing (130) found, however, that only 2 of the 13 showed a statistically significant difference in the weight loss between the group with diet alone and the group with diet plus exercise (Table 32.6). In four of the studies that had a diet plus resistance exercise training condition, there was again no statistically significant difference.

Another question is whether exercise in combination with diet can produce better maintenance of weight loss than diet alone. The NHLBI panel (2) found a 1.5- to 3-kg greater weight loss in the combined diet and exercise condition. Miller et al. (140) did a meta-analysis in which they found a nonsignificant difference of 6.6 kg vs. 8.6 kg in the diet vs. diet/exercise groups. Wing (130), in her review of six studies, found that two showed a significantly greater weight loss at 1 year for the diet/exercise group but that four others did not.

It may be that many of the persons on diet alone studied above started to exercise and the persons on exercise stopped, because these studies have all been analyzed by intent-to-treat criteria. There are data suggesting that those persons who exercise tend to maintain their weight better (141–143). To date, few have studied the effect of weight-resistance studies as opposed to aerobic exercise on weight loss and maintenance. Also, time requirements and intensity of exercise need to be better studied. Schoeller et al. (144) reported a requirement of 47 kilojoules per kilogram of body weight per day for weight maintenance after weight loss. Klem et al. (145), using data from the Weight Control Registry, reported that successful weight losers expend at least 2,800 kcal per week in physical activity, a number very similar to that found by Schoeller et al.

Obese persons must first be taught to walk, then to walk faster, and then, if possible, to run or bicycle or do aerobic dance or swim. An exercise program, however, should start slowly. An obese person who is pushed too rapidly can experience discomfort and subsequent avoidance. Careful observation for treatment of skin intertrigo, dependent edema, and foot or joint injuries is mandatory, particularly in obese diabetic patients who may have neuropathy and peripheral vascular disease.

The patient must learn how many calories are spent in various exercise activities. Table 32.7 lists some of these activities

556 JOSLIN'S DIABETES MELLITUS

(146). However, most tables (including the one here) depicting caloric expenditure levels and type of activity have been compiled to reflect total caloric expenditure, not the amount above the resting metabolic rate. The actual caloric contribution of exercise is the difference between the calories expended per minute during exercise and the calories that a person would have expended just sitting or standing. It is instructive and often disappointing for patients to discover just how much exercise they must do to expend a significant number of calories. For instance, if an overweight woman's basal metabolic rate is 1,400 kcal per day, lying down awake she expends 1.1 kcal per minute; sitting, about 1.2 kcal per minute; walking slowly, about 1.9 kcal per minute; and walking on a treadmill at 4.0 miles per hour, 7.2 kcal per minute (147). Thus, the difference in caloric expenditure between sitting quietly and walking fast on a treadmill (at 4.0 miles per hour) is 6.0 kcal per minute. In an hour, the energy expended by walking 4 miles is only 360 calories higher than the subject would have expended just quietly sitting. A very significant and persistent commitment to exercise must be present for exercise to have any substantial effect on caloric balance and weight loss.

As a person loses weight, the energy expenditure required to carry his or her weight around decreases (147–149). As a result, for a given amount of time exercising, particularly if a person is carrying his or her weight, doing the same activity at the same intensity, less calories are lost. As a result, just to maintain energy expenditure at the same 24-hour level as before weight loss, more physical activity is required, either by increasing the amount of time or the intensity of the activity (148). This is a crucial point that must be explained to the patient; decreasing weight requires increasing activity because only maintaining activity similar to that before the weight loss results in a decreased energy expenditure.

FITNESS

It is known that unfit men have a higher cardiovascular mortality and all-cause mortality than do fit men, whether they are lean or obese (150–152). Decreased physical activity has been associated with an increased risk for diabetes, coronary heart disease, and stroke (122,153,154). At whatever level the BMI is in overweight individuals, it is important to advise increased physical activity. Exercise has been shown to improve lipid profiles (155), blood pressure (128), and insulin sensitivity (119).

PHARMACOTHERAPY

The combination of intense attempts at weight loss and of frustration at the difficulty of losing weight and maintaining it has led to a great interest in pharmacotherapy by patients and physicians. The renewed interest in pharmacotherapy is also an outgrowth of the recognition in recent years that obesity is a chronic disease with genetic underpinnings (156–158). Thus, the new thinking stresses the fact that a chronic disease cannot be cured but can be treated and that treatment is a life-long affair and may require medication for life rather than medication for a short period. The models for obesity then are diseases such as diabetes and hypertension, where chronic medication is an accepted modality of treatment for metabolic control and a cure is not the anticipated effect.

While drugs have a definite role in weight-loss programs, they are never primary but always adjunctive. Under no circumstances should they be used as the sole therapy, because the armamentarium is small and the efficacy quite low. Because obesity is a chronic and persistent condition, drug therapy should be started with the aim of continued use. As a result, safety aspects of the drugs are critically important.

Sibutramine and Orlistat

Only two drugs have been approved for long-term use in the United States: sibutramine (Meridia) and orlistat (Xenical). Their mechanisms of action differ. Sibutramine is both a norepinephrine and a serotonin re-uptake inhibitor working in the central nervous system at neural synapses. The re-uptake inhibition enhances the total time that these neurotransmitters remain in the neural synapse, increase their concentration in the synapse, and enhance neurotransmission. Weight reduction with sibutramine can be maintained for a year or longer at a significantly greater level than with placebo (159). The drug in randomized clinical trials produces at 6 months a 5% to 8% weight loss in comparison to a 1% to 4% weight loss for placebo (160-162). Because sibutramine enhances norepinephrine neurotransmission, it has an effect on blood pressure and heart rate. In randomized controlled trials, sibutramine did not lower blood pressure as much as did a similar amount of weight loss with placebo (161). There is also generally some elevation in heart rate (161). Careful monitoring is required when this drug is used, and it is not wise to use it in patients with more severe hypertension. Dosage begins with 10 mg a day and can go to 15 mg a day, in one morning dose. The drug has not been implicated in heart-valve abnormalities (163,164). Other adverse effects include dry mouth, headache, insomnia, and constipation (164). The drug improves lipid profile and uric acid levels, as well as glycemic control and insulin levels, as expected for the amount of weight loss (159,160,162,165,166).

Orlistat binds to gastrointestinal lipases. This inhibits the hydrolysis of ingested fat in the intestine and partially prevents its absorption. It effectively blocks absorption of about onethird of the fat ingested (167). Therefore, the more fat that is eaten the greater the steatorrhea. Randomized clinical trials have been carried out for up to 2 years (168,169). Weight loss at 1 year with orlistat was 10.2% in comparison to a loss of 6.1% with placebo (168). At 2 years, the orlistat group maintained a weight loss of 7.6% from baseline while placebo was 4.5% from baseline (168). To avoid excess steatorrhea, fat intake should not exceed 100 g or 35% of total calories. Levels of fat-soluble vitamins fall, even though they stay within the normal range (170). A multiple vitamin tablet should be taken daily to ensure maintenance of optimal levels of fat-soluble vitamins. Levels of cholesterol and triglycerides drop more than would be expected from the weight loss effect alone, no doubt related to its inhibition of fat absorption (171). Because the drug blocks the action of pancreatic lipase that is released when fat is ingested, it should be taken as the meal begins (120 mg three times a day). Side effects of the drug include flatulence with discharge, fecal urgency, fecal incontinence, steatorrhea, oily spotting, and increased frequency of defecation. The effects are generally not too severe, tend to get better with time, and certainly get better if fat intake is decreased.

Phentermine

Other anorectic drugs are available that have been approved for short-term use (3 months) in the United States. They act on the central nervous system, affecting either adrenergic or serotoninergic neurotransmission, or both. One such drug is phentermine, which is being widely used throughout the world for long-term therapy. There are two published long-term randomized clinical trials. The first was carried out for 24 weeks, with

phentermine given continuously or intermittently every other week (172). Weight loss was about 20.5% vs. 6% with placebo, as good as or better than the weight loss in the sibutramine and orlistat trials. The second was carried out for 6 months, with a weight loss of 12.6% as compared with 9.2% in the placebo group (173). While phentermine was part of the phen-fen (phentermine-fenfluramine) therapy that caused heart-valve abnormalities (174) and was therefore banned by the U.S. Food and Drug Administration (FDA), the onus was placed on fenfluramine and not phentermine (175). To date, long-term use of phentermine has not evoked any known toxicity, though no further formal randomized control trials have been done. Because the treatment of obesity needs to be long-term, the fact that no real efficacy or safety studies have been done long-term with this drug is a problem. No studies are available on the risk/benefit of long-term therapy. If this drug is used long-term, it would be wise for a physician to obtain a signed informed consent form from the patients.

Other Drugs

The U.S. pharmacopeia includes a number of noradrenergic drugs in addition to phentermine. These include diethylpropion, phendimetrazine, benzphetamine, and the amphetamines. These drugs are approved by the FDA only for short-term use (no more than 12 weeks) and have significant abuse potential. The amphetamines are Drug Enforcement Agency (DEA) schedule II and are no longer used. The others are DEA schedule III. There have been no long-term studies of efficacy or safety of these drugs, and so they should not be used for longer than 12 weeks.

A number of drugs that have been approved for other uses have subsequently been found to have a weight-loss effect. Bupropion, an atypical antidepressant, is a weak reuptake inhibitor of norepinephrine, serotonin, and dopamine. Small weight losses have been reported, and most recently an 8-week clinical trial showed a 4.9% weight loss from baseline for drug in comparison to a 1.3% weight loss of placebo (176).

Topiramate is an anti-epileptic agent that has also been found to cause weight loss. It is presently in clinical trials of safety and efficacy. Adverse effects of the drug include renal stones and dizziness, fatigue, cognitive dysfunction, and somnolence (177).

Metformin, a widely used drug for glucose control in patients with type 2 diabetes, has been used for many years in Europe and has a good safety record. In the UKPDS study, metformin limited weight gain in patients with type 2 diabetes as compared with the weight gain induced with other drugs, such as sulfonylureas or insulin (178). Because metformin can cause lactic acidosis, particularly in patients with renal insufficiency, congestive heart failure, pulmonary or liver disease, it should not be used in such patients.

Herbal Preparations and Dietary Supplements

There have been 6-month trials in Europe of the combination of ephedrine and caffeine for weight loss (165,179,180) as well as of the combination of ephedrine, caffeine, and aspirin (181). These have all been found to be more effective than placebo.

Although some herbal products have active ingredients that could have plausible mechanisms of action, few have been tested for efficacy and safety in long-term trials. Boozer et al. (182) has done a 6-month randomized clinical trial comparing herbal ephedra/caffeine with a placebo, with a significantly greater weight loss with the active substance. However, blood pressure did not drop as much in the drug group as in the placebo group for a given level of weight loss. At the moment, the data are insufficient to permit recommendation of any of these preparations (183).

Thyroid preparations, digitalis, and diuretics should not be used for weight loss. Inhibitors of carbohydrate absorption (α -amylase, α -glucosidase, and sucrase inhibitors) do not work as weight reduction agents. While interest in possible thermogenic agents is growing, no satisfactory one is available.

It is important to emphasize that drugs for weight loss should always be used as an adjunct to diet and exercise modification (2). Addition of lifestyle modification to drug therapy results in a significantly greater weight loss, as has been clearly shown in a randomized trial of 1 year's duration (184).

There have been few studies of the combination of the two FDA-approved drugs. Wadden et al. (185) added orlistat after 1 year of sibutramine treatment and found no enhanced effect.

WEIGHT MAINTENANCE

Maintaining reduced weight following the achievement of weight loss has been extremely difficult. The reasons for this phenomenon are not clear. Weight loss results not only in loss of fat but also in loss of lean body mass. The average loss of weight in obese persons comprises about 75% fat to 25% lean (186). For reasons that are not clear, the heavier the individual, the more protected they are against loss of lean body mass as weight loss progresses (112).

While the mechanisms for the powerful drive to regain weight are not totally clear, a number of forces are relevant to the cause of this regain of weight.

First, persons on hypocaloric diets decrease their basal metabolic rate and therefore require fewer calories (187). Thus, as the weight loss proceeds, the caloric deficit becomes less than it was originally. At the end of the weight-loss phase, a patient will have a lower metabolic rate than previously. This happens because, as the patient loses weight, he or she will also lose lean body mass and the metabolic rate is directly related to the lean body mass (188). Thus, the patient will require fewer calories at the end of a weight loss period than he or she required before starting to lose weight (189).

Second, as people lose weight, they become more efficient. That is, they require less energy to do the same physical task (190). Thus, when a person who after a weight-loss phase returns to the total physical activity done previously, she or he will be in positive caloric balance because fewer calories are required to accomplish the same physical task. It is incumbent on every patient who has lost weight to increase his or her physical activity, and to increase it markedly (to some an extra 500 to 700 kcal per day).

Third, levels of lipoprotein lipase (LPL), an enzyme that breaks down circulating lipoprotein triglycerides and thus facilitates the entry of free fatty acids into cells, are increased in persons who are obese (11). With weight reduction, the responsiveness of adipose tissue LPL to meals is increased (11,191), suggesting a better ability to dispose of the triglyceride. This physiologic avidity, then, of the adipose cells for the triglyceride makes the post–weight-loss period a particularly difficult one in terms of regain.

Finally, there seems to be a heightened sensitivity to palatable foods (192). While this has not been adequately studied, there seems to be an enhanced taste threshold and an increased natural intake after a period of deprivation (193).

A common psychological change is actually overconfidence: the feeling that the weight can be lost and that the individual can deal with maintenance without help. This is clearly not the case. Studies have repeatedly shown that the longer the relationship between patient and the therapeutic team is continued, the greater the likelihood of success (194). As a result, caloric intake should be liberalized very carefully and slowly after goal weight has been reached, with daily weight monitoring. A permanent reduction in caloric intake is required because a patient's total energy expenditure will drop after weight loss. All the lifestyle changes learned during the weight-loss period must be continued, including the increased physical activity. If weight-loss drugs have been successful and without adverse effects, their chronic utilization can be recommended, with careful tracking for potential adverse effects.

A National Weight Control Registry (NWCR) has recruited persons who have lost significant amounts of weight and have kept at least 30 lb off for 1 year or longer (195). Participants lost an average of 66 lb (30 kg), and 14% lost more than 100 lb (45.4 kg); 89% modified food intake and maintained relatively high levels of physical activity (2,800 kcal weekly on average) to achieve weight loss. The diet strategy of nearly 90% of participants restricted the intake of certain types and/or amounts of foods; 43% counted calories and lipid intake, and 25% restricted grams of lipid. More than 44% ate the same foods they normally ate, but in reduced amounts.

The importance of physical activity for the NWCR members is great. Nearly all exercised as part of weight-maintenance strategy. Many walked briskly for 1 hour a day; 92% exercised at home; and approximately one third exercised regularly with friends. Women tended primarily to walk and do aerobic dancing and men to engage in competitive sports and resistance training.

SURGERY

Surgery is being used increasingly in patients who are severely obese (BMI >40) and who have tried all other forms of therapy and have failed to lose weight (196). Because of the significant rates of morbidity and even mortality from surgery, however, it

is indicated only in patients in whom the obesity itself or an associated condition is severe. Patients with a BMI of \geq 40 without associated health problems or with a BMI \geq 35 and above with comorbid conditions can be considered for surgery (196). Obesity surgery should be performed only in centers with adequate support from anesthesia, pulmonary, cardiac, and metabolic divisions. The surgeon must be interested in the life-long follow-up of the patient. The surgery must be considered experimental, because no wholly adequate operation has yet been developed.

Various surgical procedures are being done for obesity. Vertical banded gastroplasty (VBG) is the most commonly done procedure. It consists of stapling the stomach vertically and creating a small opening 1 cm in diameter and a reservoir of 35 to 50 mL (Fig. 32.3B). Gastric banding is generally done laparoscopically and creates a configuration similar to VBG. Gastric bypass is a more complex operation in which a small 35- to 50mL reservoir is created at the upper end of the stomach and a loop of small intestine is brought up and anastomosed to the opening of this reservoir in a Roux-en-Y procedure (Fig. 32.3A). The gastric bypass is the most effective procedure being done today, producing the greatest weight loss. In the Swedish Obesity Surgery (SOS) trial, a loss of 23% ± 10% of excess weight occurred over a period of 2 years with vertical gastroplasty and of $33\% \pm 10\%$ with gastric bypass (197). Some surgeons are doing obesity surgery laparoscopically, using bands that are placed around the upper part of the stomach. Data available on gastric banding from the SOS show that the weight loss is even less than with the VBG (197). Side effects are less common and less serious than in the gastric bypass, and this operation is technically easier. The weight loss in all procedures can continue for up to 18 months and then levels off. Normal weight is not reached. The greater weight loss with the gastric bypass is traded off by greater surgical complications and mortality. Biliopancreatic diversion is not done in this country. The adverse effects are severe diarrhea and liver disease (198). Liposuction is a cosmetic plastic procedure for removing subcutaneous fat and cannot remove enough fat to affect health risk. Success rates of

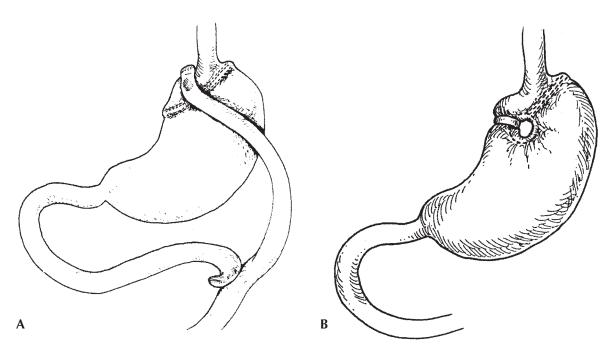

Figure 32.3. Surgical procedures for obesity. A: Roux-en-Y gastric bypass. B: Vertical banded gastroplasty.

A long-term study of the risk-benefit ratio of obesity surgery as compared with medical treatment is presently being carried out in Sweden (199). Most recently, the 8-year report (200) has shown that, while lipids and diabetes have continued to improve, blood pressure has returned to its preoperative levels (201). Diabetes prevalence has been essentially stable at 10.8% in the operated group, whereas it has increased from 7.8% to 24.9% at 8 years of follow-up in the medically treated group (201). Thus, the results so far are quite positive.

CONCLUSION

The approach to the treatment of the obese patient is a difficult one. It requires significant input of time from the physician and, it is hoped, from other health professionals, such as dietitians and exercise physiologists. Weight loss is extremely difficult to attain, and the maintenance of the weight loss is even more difficult. Lifestyle change is crucial and must be sustained. Obesity is only contained; it is never really cured. Persistent efforts by the patient and the physician are crucial. It is important to stress prevention early in the progression of overweight because weight loss at that point is easier and more sustainable.

CONCLUSION 578

An understanding of lipoprotein metabolism and how it influences diabetes is of particular importance because of the association of lipoproteins with cardiovascular disease, the leading cause of death among people with diabetes (1). Abnormalities in lipoproteins are very common in both type 1 and type 2 diabetes. Although alterations in lipoproteins appear to be an intrinsic part of these disorders, such alterations also are induced by diabetes-associated complications such as obesity and renal disease and are sometimes exacerbated by therapeutic regimens associated with the management of diabetic patients. The National Cholesterol Education Program (2) and the American Diabetes Association (ADA) (3) have focused attention on the necessity of managing lipid disorders. In diagnosing and treating lipid abnormalities in diabetes, particular consideration must be given to diabetes-specific targets, the relationship between glycemic control and lipoproteins, and the potential for a different response to lipid-lowering agents by individuals with diabetes. This chapter will review the basics of lipoprotein composition and metabolism, the alterations in

lipoprotein composition and metabolism in diabetes, and therapeutic approaches to the management of lipid disorders in patients with diabetes.

LIPOPROTEIN METABOLISM

Structure and Classification

Lipoproteins are microemulsions composed of lipids (cholesterol, cholesteryl ester, triglyceride, and phospholipid) and proteins (apoproteins). Their function is to transport non–watersoluble cholesterol and triglycerides in plasma. Lipoproteins are spherical particles containing a central core of nonpolar lipids (primarily triglycerides and cholesteryl ester) and a surface monolayer of phospholipids and apoproteins. Free cholesterol is present primarily in the surface monolayer. [For a detailed review of lipoprotein structure and metabolism, the reader is referred to references (4) through (16)].

TABLE 33.1. Human Plasma Lipoproteins

Lipoproteins have been classified on the basis of their densities during ultracentrifugation (Table 33.1). Chylomicrons, particles that are primarily triglyceride bearing, are produced by the intestine after exogenous fat undergoes digestion. Very-lowdensity lipoproteins (VLDLs), also triglyceride-bearing lipoproteins, are secreted by the liver and carry endogenously produced triglyceride. Intermediate-density lipoproteins (IDLs) represent remnants of the metabolism of triglyceride-rich lipoproteins and also can be intermediates in the conversion of VLDLs to low-density lipoproteins (LDLs) (8,13,14–16). LDLs are the major cholesterol-bearing lipoproteins and are those most strongly related to the occurrence of cardiovascular disease. Lp(a) is a subclass of the LDL fraction that consists of LDL complexed to a large glycoprotein resembling plasminogen; this complex has also been associated with atherosclerosis (17). High-density lipoproteins (HDLs) are the smallest and densest of the lipoproteins. Although HDLs also transport substantial amounts of cholesterol, they are negatively associated with cardiovascular disease. The metabolism and production of all lipoproteins are con-

trolled by the apoproteins contained within the complex, by enzymes and proteins that moderate lipoprotein metabolism, and by specific cellular receptors that direct their interaction with cells. All known apoproteins (Table 33.2) have been sequenced and their genes localized (18,19). Most are hydrophobic proteins and serve as ligands for specific receptors involved in the metabolism of the various lipoproteins and as cofactors for enzymatic activities involved in lipoprotein metabolism. Several other proteins and enzymes play key roles in plasma lipoprotein transport, including lipoprotein lipase (8,9,16,20,21) and hepatic lipase (12,22), which catalyze the delipidation of triglyceride-rich particles; lecithin-cholesterol acyltransferase (LCAT) (23), which is responsible for the synthesis of virtually all cholesteryl esters in plasma lipoproteins; and cholesteryl ester transfer protein (CETP) (24,25), which facilitates the transfer of cholesteryl ester and triglycerides between lipoproteins during their metabolism. A number of cell receptors (Table 33.3) govern lipoprotein binding and uptake and lipid flux; they are described in the following sections on metabolism.

Formation and Metabolism of Chylomicrons

Chylomicrons are responsible for the transport of dietary triglycerides and cholesterol. Dietary triglycerides are hydrolyzed in the gut, releasing monoglycerides and fatty acids that are then reesterified to form triglycerides in the intestinal mucosal cell (Fig. 33.1) (5,7,8,10,11,16). These triglycerides are assembled with newly absorbed cholesterol, apoprotein (apo) B₄₈, and the A apoproteins. Upon secretion from the enterocyte, these assembled particles enter the lymphatic circulation and then the bloodstream, where they acquire C apoproteins and apoE by transfer from HDL. As chylomicrons enter the plasma, the triglycerides are rapidly hydrolyzed by the enzyme lipoprotein lipase (LPL), which resides on the surface of capillary endothelial cells. LPL is synthesized primarily in adipose tissue and striated muscle (8,10,16,20,21). It is secreted and transported to the endothelial surface, where it acts on triglyceriderich particles. Its action requires the presence of $apoC_{II}$ on the

surface of the lipoprotein, whereas apoC_{III} inhibits LPL. LPL is induced in adipose tissue by insulin (26). The liberated free fatty acids are available for oxidative needs of peripheral cells, and excess free fatty acids are stored primarily in triglycerides in adipose tissue to serve as a future source of free fatty acids.

As triglyceride is depleted from the chylomicrons, phospholipids and A and C apoproteins are transferred to HDL. The residual chylomicron particle, which has lost 80% to 90% of its triglyceride and is now relatively cholesterol-enriched, is called a chylomicron remnant. These remnants are believed to be cleared by the liver via LDL receptor–like protein (LRP), a protein that resembles the apo B/E receptor but probably recognizes apoB₄₈ (27). The remnants thus enter lysosomes in the liver, from which cholesterol can enter metabolic pathways in the hepatocytes, including excretion into the bile. The remaining triglyceride enters the hepatic triglyceride stores.

Very-Low-Density Lipoproteins

VLDLs are synthesized in the endoplasmic reticulum of hepatocytes and are composed of endogenous triglyceride derived from plasma free fatty acids, from chylomicron remnants, and from de novo lipogenesis (Fig. 33.1) (5,7,8,11,14,15). Post-translational regulation of VLDL assembly by glucose, fatty acids, and insulin is the major determinant of secretion (28). The concentration of circulating free fatty acids governs the rate of triglyceride esterification in the liver, and glucose-especially when glycogen synthesis is impeded-may stimulate de novo production of free fatty acids and thus triglycerides. Triglyceride transfer protein in the hepatocyte regulates the transport and assembly of triglyceride with apoB (28,29). Insulin is required for VLDL production, both for apoprotein synthesis and for its role in regulating several enzymes involved in lipogenesis (30). On the other hand, increases in insulin have been shown to inhibit VLDL secretion in hepatocytes by phosphorylating apoB, which impedes the assembly of apoB with lipids (28,31), and increases in insulin have been shown to inhibit VLDL production in vivo in human studies (32).

Nascent VLDLs, as secreted into the circulation, contain apoB₁₀₀ and small amounts of apoC and apoE. After VLDLs enter the circulation, they are metabolized in the same manner as chylomicrons by the enzyme LPL, with the fatty acids that are liberated following the same fate as those liberated from chylomicrons. After secretion, VLDLs acquire more C and E apoproteins by transfer from HDL. In addition, free cholesterol is progressively exchanged to HDL, where it is esterified and the cholesteryl ester is returned to VLDL. As VLDLs become progressively depleted of triglyceride, a portion of the surface, including cholesterol, apolipoproteins C and E, and phospholipids, is removed and contributes to nascent HDL particles (33). The enzyme hepatic lipase also plays a role in the metabolism of smaller VLDL particles during the latter stages of the VLDL catabolic cascade (22). The smaller remnants of VLDL are triglyceride-depleted, cholesterol-rich particles, some of which are isolated in the IDL compartment, although some remain in the VLDL compartment. These remnant particles are cleared from the circulation primarily by receptors in the liver. These receptors include both the B/E receptor (see below) and possibly LRP (27), which acts on chylomicron remnants. A portion of VLDL remnants is further metabolized, possibly within the intracellular spaces of the liver, by a process involving hepatic lipase, to form LDL. During this process, the remainder of apoproteins other than apoE is lost.

The mechanisms that determine which and how many VLDL particles are converted to LDL are not clearly understood. VLDL particles are believed to be secreted in a spectrum of sizes with various degrees of triglyceride enrichment. The larger VLDL particles appear to be more rapidly cleared and less likely to be converted to LDL (34). On the other hand, smaller VLDL particles that are richer in cholesterol may be preferentially converted to LDL. When apoE is missing or defective (as in type III hyperlipidemia) (14), clearance of chylomicron remnants and VLDL remnants is much slower than normal. These remnants accumulate in plasma and are not readily converted to LDL.

Low-Density Lipoproteins

As indicated above, LDLs are products of the metabolism of VLDL (Fig. 33.1) (4,5,7,8). The only apolipoprotein in LDL is apoB, and only one molecule of apoB is present per particle of LDL. Clearance of LDL is mediated by a specific receptor (the B/E receptor) present on the surface of both liver and peripheral cells (4). Once it is bound to the receptor, the lipoprotein is inter-

THE LDL RECEPTOR PATHWAY

Figure 33.2. Binding and cellular metabolism of low-density lipoprotein (LDL). HMG, 3-hydroxy-3-methyl-glutaryl; ACAT, acyl CoA cholesterol acyltransferase. (From Brown MS, Goldstein JL. The LDL receptor and HMG-CoA reductase—two membrane molecules that regulate cholesterol homeostasis. *Curr Top Cell Regul* 1985;26:3–15, with permission.)

nalized by an endocytotic process (Fig. 33.2). The vesicle then fuses with a lysosome, where enzymes degrade the apoB and hydrolyze the cholesteryl ester to free cholesterol. Triglycerides and phospholipids may also be hydrolyzed. The influx of free cholesterol from LDL sets into motion a cascade of regulatory events aimed at controlling the cholesterol content of the cell. Esterification of cholesterol is stimulated by activation of acyl CoA cholesterol acyltransferase (ACAT). Simultaneously, *de novo* cholesterol production is inhibited by the inhibition of 3hydroxy-3-methyl-glutaryl (HMG)-CoA reductase, the rate-limiting enzyme in cholesterol biosynthesis. Finally, accumulation of intracellular cholesterol limits the further uptake of cholesterolrich lipoproteins by inhibiting synthesis of the B/E receptor.

LDL may also be removed by clearance mechanisms mediated not by the B/E receptor but by phagocytic cells; such mechanisms include uptake by both nonspecific endocytosis and via the scavenger receptors—classes A (SRA) and B type 1 (SRB₁, known as CLA₁ in humans), and conjugated diene lipid hydroperoxide 36 (CD-36) receptors, which recognize altered (oxidized or glycated) LDL (35–39). This process is thought to be responsible for cholesterol deposition in macrophages of the vessel wall.

LDLs represent a spectrum of particles varying in density from larger cholesterol-rich particles (phenotype A) to smaller cholesterol-poor particles (phenotype B) (40,41). The latter usually occur when levels of triglyceride-rich lipoproteins are elevated as a result of CETP-mediated exchange between triglyceride and the cholesteryl ester from LDL followed by lipolysis of LDL triglyceride (42). These smaller, denser LDL particles are more susceptible to modification by oxidation (and glycation, see below), after which they are recognized and taken up by macrophages.

High-Density Lipoproteins

HDLs also are represented by a spectrum of particles of various sizes and densities (5,7,13). HDLs are secreted by the hepatocyte as small, cholesterol-poor/protein-rich particles that contain the A apoproteins as well as apoE. Small (nascent) HDLs also are produced by the intestine (Fig. 33.1). Some HDL particles contain both apoA_I and apoA_{II}, whereas others contain only apoA₁. In the plasma, surface components of triglyceride-rich lipoproteins are transferred to HDL during lipolysis. In addi-

Plasma regulator	Major source	Function

Lecithin-cholesterol acyltransferase (LCAT)	Liver	Esterifies free cholesterol
Cholesteryl ester transfer protein (CETP)	Liver	Transfers cholesteryl ester and cholesterol between lipoproteins and cells

TABLE 33.4. Important Plasma Regulators of Lipoprotein Metabolism

tion, HDL particles are the sites of synthesis of cholesteryl ester from free cholesterol and lecithin through the enzyme LCAT, which circulates in association with HDL particles. HDLs participate in the catabolism of triglyceride-rich lipoproteins, serving as a source for cholesteryl esters and the C and E apoproteins and ultimately as the receptacle for surface components. During the lipolytic process, the size of the HDL particle increases. Larger particles are referred to as HDL₂ and the smaller HDL precursors are known as HDL₃.

HDLs, along with LCAT and CETP (Table 33.4), are important in the flux of cholesterol from cells to plasma lipoproteins and the liver (13,24,25,43,44). The ATP binding cassette 1 (ABC1) receptor, which is present on macrophages and other peripheral cells, facilitates the transfer of cellular cholesterol to apoA1, which is free in plasma or on nascent HDL particles. After conversion to cholesteryl ester by LCAT, the cholesteryl ester becomes trapped within the nonpolar center of HDL; this cholesteryl ester may circulate in HDL or be transferred to triglyceride-rich particles. The SRB1 receptor may also mediate the removal of cholesterol and cholesteryl ester from peripheral cells or macrophages to HDL through a process of selective lipid transfer. This receptor mediates the transfer of cholesterol and cholesteryl ester from cells to HDL and from larger HDLs to the liver. This process represents a pathway for "reverse cholesterol transport," by which cholesterol from peripheral cells can be removed and transported to the liver for excretion in bile.

The mechanisms that control clearance of HDL are not well understood. Hepatic lipase may hydrolyze HDL phospholipids, which in turn may promote net transfer of cholesterol from the surface of HDL to the liver. A specific HDL receptor (HDL_R) on the kidney catalyzes specific uptake and degradation of HDL particles (45). This receptor also provides cholesterol to adrenal cells for steroidogenesis.

LIPOPROTEIN ALTERATIONS IN TYPE 2 DIABETES

The following summarizes commonly observed lipoprotein changes and their possible metabolic determinants in individuals with type 2 diabetes (Table 33.5) (for additional details, see references 30,46–55).

Triglycerides and Very-Low-Density Lipoproteins

The most common alteration of lipoproteins in type 2 diabetes is hypertriglyceridemia caused by an elevation in VLDL concentrations. In clinical descriptions of diabetic hypertriglyceridemia, an emphasis is often placed on individuals with extremely high levels of plasma and VLDL triglycerides. It is clear, however, from population-based studies (53,56) that type 2 diabetes generally is associated with only a 50% to 100% elevation in the plasma levels of total and VLDL triglycerides. Thus, it is likely that subjects with type 2 diabetes who have concentrations of total triglycerides greater than 350 to 400 mg/dL also have genetic defects in lipoprotein metabolism, the expression of which may be exacerbated by hyperglycemia (57) (see below).

Metabolic Determinants

One of the determinants of diabetic hypertriglyceridemia is the overproduction of VLDL triglyceride (58–60), which is most likely due to the increased flow of substrates, particularly glucose and free fatty acids, to the liver. In addition, individuals with type 2 diabetes appear to have a defect in clearance of VLDL triglyceride that parallels the degree of hyperglycemia (58–61). Studies to date suggest that LPL activity is decreased in individuals with type 2 diabetes, especially those with moderate to severe hyperglycemia who exhibit both insulin deficiency and insulin resistance (62). However, *in vivo* clearance defects have not consistently been observed in patients with type 2 diabetes, especially in those with greatly elevated triglyceride levels.

The metabolism of VLDL apoB may also be altered in type 2 diabetes. Subjects with type 2 diabetes have a decreased fractional catabolic rate for VLDL apoB similar to that for VLDL triglyceride (60). Overproduction of VLDL apoB also occurs in

TABLE 33.5.	Lipoprotein Alterations in Type 2 Diabetes
Lipoprotein	Alterations
VLDL 1	Increased production of triglyceride and apoB Decreased clearance of triglyceride and apoB
LDL ↑→	Abnormal composition Increased production of LDL apoB Decreased receptor-mediated clearance Triglyceride enrichment
HDL↓	Smaller (more dense) particle distribution Glycation Oxidation Increased clearance of apoA
Chylomicron	Decreased proportion of large HDL Triglyceride enrichment Glycation Diminished reverse cholesterol transport Delayed clearance; remnant accumulation
chylonhelon	Delayed clearance, reminant accumulation

VLDL, very-low density lipoprotein; LDL, low-density lipoprotein; HDL, high-density lipoprotein; apo, apoprotein.

type 2 diabetes, and it has been suggested that this overproduction is further increased by obesity (60). Although obese diabetic subjects have a higher VLDL-B production than do lean individuals, VLDL-B production may already be maximally stimulated in obese nondiabetic individuals (60). Thus, the extent of overproduction of VLDL triglyceride may be greater than that of apoB in type 2 diabetes, a situation that results in the production of larger triglyceride-rich VLDL particles.

The alterations in VLDL metabolism in type 2 diabetes are related in part to insulin resistance. Several studies have shown correlations between VLDL concentrations and measures of insulin resistance (30,52). Hyperinsulinemia and the central obesity that typically accompanies insulin resistance also are thought to lead to overproduction and impaired catabolism of VLDL. Metabolic alterations in insulin resistance that lead to VLDL overproduction include (a) increased free fatty acid and glucose levels, which regulate VLDL output from the liver, and (b) elevated triglyceride levels in the liver, which inhibit apoB degradation and result in increased assembly and secretion of VLDL. In addition, LPL levels are reduced in insulin resistance, which interferes with the normal lipoprotein metabolic cascade and results in decreased clearance of VLDL.

Triglyceride elevations in type 2 diabetes may also be due to delayed clearance of postprandial particles (63). Mechanisms of delayed clearance of chylomicrons are similar to those discussed for VLDL clearance.

Very-Low-Density Lipoprotein Composition

In addition to increases in the amount of VLDL, changes in VLDL composition in type 2 diabetes may reflect or be the cause of alterations in VLDL metabolism. Several studies suggest that individuals with diabetes, especially those with severe hyperglycemia, may have larger triglyceride-rich VLDL (60,64). This increased ratio of triglyceride to apoB may be a reflection of a disproportionate influence of type 2 diabetes on VLDL triglyceride production (see above). Subfractions of VLDL have been found to be enriched in the proportion of cholesterol-rich particles (65). These compositional changes may have implications for the increased propensity for atherosclerosis among individuals with type 2 diabetes, because cholesterol-enriched VLDL may be atherogenic. Changes in the distribution of apoE would have important implications for VLDL metabolism in type 2 diabetes because apoE influences the affinity of binding to receptors. An increased proportion of apoE in the VLDL of type 2 diabetes has been reported (66). Although differences in distribution of apoE phenotypes in diabetes have not been demonstrated, apoE sialation has been reported to be higher in diabetic than nondiabetic individuals, a change that may impair binding to the B/E receptor (67).

Additional evidence for abnormal VLDL in type 2 diabetes is that VLDLs from persons with type 2 diabetes have altered metabolic properties *in vitro*. VLDL isolated from normotriglyceridemic patients with type 2 diabetes produced a greater cellular accumulation of lipids in mouse peritoneal macrophages than did VLDL isolated from either normotriglyceridemic or hypertriglyceridemic nondiabetic control subjects (68). Thus, altered VLDL composition may contribute to metabolic abnormalities as well as to the atherosclerotic propensity of the VLDL particles.

Remnant particles from delayed chylomicron clearance may also be present in the VLDL fraction; they are subject to the same compositional alterations discussed for VLDL.

Low-Density Lipoprotein Cholesterol

Studies examining plasma concentrations of total and LDL cholesterol in type 2 diabetes vary by population, with some showing higher and some showing lower levels in type 2 diabetes than in control subjects. Data from the National Health and Nutrition Examination Survey (NHANES II) indicate that levels of LDL cholesterol in whites with diabetes are higher than for blacks with diabetes, after adjustment for relevant covariates (56). Lower LDL concentrations are also seen in American Indians with diabetes (53). It should be pointed out that in most population studies, the density ranges chosen for quantitation of LDL (1.006 to 1.063) result in the inclusion of the IDL fraction. It is possible that the increase in LDL in type 2 diabetes is the result of an increase in this IDL fraction.

METABOLISM

In individuals with type 2 diabetes and relatively severe hyperglycemia, the clearance rate for LDL apoB is reduced (60,69). Mildly hyperglycemic individuals with type 2 diabetes may have increased LDL production as well (69). Because LDL binding is stimulated by insulin (70), defects in LDL clearance in type 2 diabetes may be due to insulin resistance or relative insulin deficiency. This possibility is supported by the observation that clearance of LDL in type 2 diabetes is positively related to plasma insulin levels and to the insulin response from oral glucose challenge (69). Direct removal of VLDL apoB is also increased in individuals with type 2 diabetes and large, triglyceride-rich VLDL (60). Thus, the concentrations of LDL in type 2 diabetes may be influenced by two opposing phenomena. On one hand, decreased clearance in type 2 diabetes may lead to increased LDL; on the other hand, increased direct removal tends to lower production. The resultant concentration may thus be dependent on the relative magnitude of these two processes. Nevertheless, these alterations in the flux of both VLDL remnants and LDL particles, coupled with the changes in LDL composition, indicate that LDL in individuals with type 2 diabetes has significant atherogenic potential.

COMPOSITION

The composition of LDL in type 2 diabetes is altered, and these changes also may contribute significantly to abnormal metabolism and atherosclerosis. An increase in the proportion of small, dense, triglyceride-enriched LDL has consistently been observed (64,71–73). LDL particles from individuals with diabetes have a decreased ability to bind to receptors, and this decrease in binding is inversely related to the size and ratio of triglyceride to protein in LDL (74). LDL in diabetic individuals has been shown to be more rapidly oxidized (75). This may be in part because of the increased oxidative susceptibility of small, dense LDL particles, which are prevalent in diabetic individuals. Oxidized LDL particles are believed to play a major role in stimulating the atherosclerotic process because of their recognition by macrophage receptors (Table 33.3).

Increased plasma triglyceride levels, low HDL levels, and small, dense LDLs usually occur together in a lipoprotein pattern often referred to as atherogenic dyslipidemia (76). This abnormal pattern occurs in insulin resistance, is exacerbated in diabetes (52,77), and is derived in part from alterations in apoB metabolism because triglyceride-rich VLDLs are the precursors of denser LDL particles (78). Small, dense LDLs are slowly catabolized because they do not bind well to the B/E receptor.

Nonenzymatic glycation (or glycosylation) of apoB also may influence LDL metabolism in diabetes. Small, dense LDLs are more rapidly glycated. The extent of glycation of LDL in individuals with type 2 diabetes who have moderate hyperglycemia is approximately 2% to 5% (79), and this degree of glycation of lysine residues has been shown to decrease LDL catabolism *in vivo* by 5% to 25% (80). Glycated LDLs also appear to exhibit altered interactions with endothelial cells, stimulate cytokine production, and enhance cholesteryl ester synthesis in human macrophages (81). Moreover, glycated LDLs are more readily oxidized. Thus, the glycation of LDL may represent an important mechanism by which atherogenesis is increased in type 2 diabetes. Together, glycation and oxidation render LDLs more immunogenic; the formation of antibody-antigen complexes stimulates macrophage accumulation and further foam cell formation (82).

Finally, a pattern of abnormal cholesterol transport and transfer in the plasma has been shown in patients with type 2 diabetes. The transfer of LCAT-synthesized cholesteryl esters to VLDL and LDL is inhibited, with a concomitant increase in their transfer to HDL; this abnormal metabolic pattern is reversed by insulin therapy (83). The block in cholesteryl ester transfer activity in patients with type 2 diabetes is correlated with an increase in free cholesterol content of both LDL and VLDL. Therefore, in type 2 diabetes, this abnormal cholesteryl ester transfer may be related to an increased risk for atherosclerosis.

High-Density Lipoprotein Cholesterol

Almost as common as the observation of increased VLDL concentrations in type 2 diabetes is the finding of decreased concentrations of HDL cholesterol in individuals with type 2 diabetes.

METABOLISM

Individuals with type 2 diabetes have an increased rate of HDL clearance, as measured by apoA_I and apoA_{II} kinetics (84-86). Significant correlations have been found between HDL clearance and plasma concentrations of HDL cholesterol and apoA₁, and the increase in HDL clearance was directly related to plasma glucose levels. The finding of increased HDL clearance is consistent with lower VLDL clearance and lower LPL activity. Because HDL concentrations, especially of larger HDLs, increase during the lipolytic process, the decreases in LPL activity and impaired VLDL catabolism have been shown to be correlated with decreases in HDL concentrations in patients with type 2 diabetes. Elevated hepatic lipase activity also may contribute to the decrease in HDL concentrations in type 2 diabetes, because this enzyme also plays a key role in the metabolism of HDL. The changes in lipoprotein and hepatic lipases may act in concert to decrease HDL levels in type 2 diabetes.

COMPOSITION

There are several indications that the composition of HDLs in type 2 diabetes may be altered (52). These differences may be in

part a reflection of alterations in the delipidation cascade. Decreased HDL concentrations in type 2 diabetes are reflected mostly in decreases in larger particles. As with LDL, in type 2 diabetes an increased proportion of triglyceride in HDL has been observed. These compositional changes appear to be related to the activity of adipose tissue LPL, because LPL deficiency may be a factor responsible for the altered distribution of HDL particles in untreated type 2 diabetes. Nonenzymatic glycation of HDL appears to interfere with HDL receptor binding (87). Thus, glycation of HDL may also play a role in the lower levels of HDL observed in diabetes. Finally, abnormalities in HDL composition have been noted even in individuals with optimal glycemic control (88). All of these alterations in HDL composition may impair the role of HDL in reverse cholesterol transport.

As stated above, the decreases in HDL concentration and changes in HDL composition are part of the dyslipidemia of insulin resistance. Changes in HDL metabolism in insulin resistance include (a) impaired VLDL lipolysis, which depletes HDL by impeding the transfer of apoproteins and cholesterol ester from triglyceride-rich lipoproteins to the HDL compartment; (b) increased activity of hepatic lipase, which facilitates HDL clearance; and (c) alterations in hepatic function, which inhibit production of $apoA_I$ (the main apoprotein of HDL) and/or hepatic secretion of nascent HDL (52).

Significant negative relationships between plasma concentrations of insulin and HDL have been observed in subjects with type 2 diabetes as well as a negative relationship between insulin resistance and HDL cholesterol that is independent of VLDL concentrations (53,63). These observations indicate that insulin or insulin resistance influences the concentration or composition of HDL in some way.

LIPOPROTEINS IN TYPE 1 DIABETES

The consideration of lipoprotein metabolism in type 1 diabetes is influenced by the requirement for insulin therapy. Thus, a spectrum of situations is possible, from the insulin-deficient ketoacidotic state with greatly elevated glucose, free fatty acids, ketones, and lipolytic hormones such as glucagon and epinephrine, to that seen when continuous insulin therapy is administered, in which an excess of insulin in peripheral plasma is found and glucose and fatty acid levels are close to normal (Fig. 33.3) (47–52). In the following sections, an attempt will be made to differentiate between these various degrees of control.

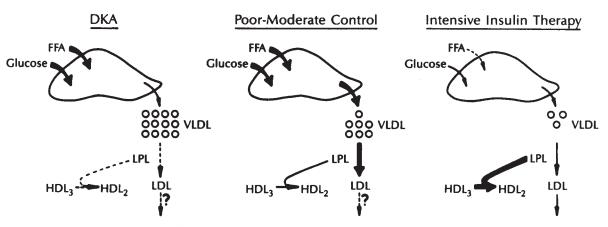

Figure 33.3. Spectrum of lipoprotein changes in type 1 diabetes with various degrees of control. DKA, diabetic ketoacidosis. See legend to Figure 33.1 for other abbreviations. (From Howard BV. Lipoprotein metabolism in diabetes mellitus. *J Lipid Res* 1987;28:613–628, with permission.)

Very-Low-Density Lipoproteins

Extreme elevations in VLDL levels have been recognized as being a common occurrence in diabetic ketoacidosis, the stage at which insulin concentrations are minimal (89). On the other hand, VLDL levels may not be elevated in individuals with type 1 diabetes who are receiving adequate therapy. It is now well established that elevations in VLDL triglycerides in type 1 diabetes are often correlated with the degree of diabetic control (90,91).

METABOLISM

In people with untreated type 1 diabetes, the fractional catabolic rate for endogenous triglyceride is decreased (92), as is the clearance rate for exogenous triglyceride (93). Thus, when insulin deficiency is extreme, clearance is impaired because the activity of LPL is dependent on insulin. In the early stages of insulin deficiency, production of VLDL is increased, probably because of the increase in mobilization of free fatty acids. This enhanced hepatic secretion of VLDL falls off in the later stages of ketoacidosis because of the decrease in hepatic protein synthesis secondary to the insulin deficiency. In poorly controlled but nonketotic patients with type 1 diabetes, both overproduction and decreased clearance are observed (94). Kinetic studies of VLDL triglyceride in subjects with type 1 diabetes with adequate conventional insulin therapy showed that production and fractional catabolic rates of VLDL triglycerides were normal when compared with rates in weight- and age-matched controls (95). Continuous subcutaneous insulin infusion produced a significant decline in VLDL triglyceride production to levels below those observed in nondiabetic subjects. There was no change in the mean fractional catabolic rate for VLDL triglyceride after insulin infusion. A similar decrease in plasma VLDL triglyceride production in type 1 diabetes was observed after treatment with the artificial β -cell (96). These latter studies indicate that rigorous insulin therapy can decrease rates of VLDL production and produce even subnormal levels of VLDL triglyceride.

During severe ketoacidosis when there is a marked insulin deficiency, hypertriglyceridemia is caused primarily by a deficiency in LPL activity, and overproduction of triglycerides may not occur despite elevated levels of free fatty acids. As insulin therapy is instituted, the situation changes. With moderate control (i.e., when insulin administration is suboptimal) there is both an overproduction of VLDL because of an increase in the level of free fatty acids and some deficiency in VLDL clearance because of the continued limitation in LPL. As stringent control is achieved with the administration of large amounts of peripheral insulin, VLDL clearance normalizes. VLDL production rates may fall to subnormal levels because excess insulin may suppress hepatic VLDL formation. Individuals with type 1 diabetes in this situation will have normal or even low-normal levels of circulating VLDL triglycerides.

Low-Density Lipoproteins

LDL concentration appears to vary directly with the extent of hyperglycemia. LDL levels are increased in poorly controlled type 1 diabetes. However, in many individuals with type 1 diabetes, LDL concentrations are not different from those of ageand weight-matched controls, and some type 1 diabetic subjects receiving insulin by means of a pump exhibit LDL concentrations considerably below those of controls.

METABOLISM

Fractional catabolic rates for LDL in subjects receiving conventional therapy or who have received 3 weeks of continuous subcutaneous insulin infusion are similar to those for nondiabetic controls. Improvement in glycemic control decreases LDL apoB production to levels below those of nondiabetic subjects. In uncontrolled type 1 diabetes, LDL fractional clearance is probably decreased because insulin appears to potentiate LDL binding to its receptor. With increased control, LDL metabolism may return to normal (97). Further, insulin deficiency may lead to overproduction of LDL in response to an increased influx of VLDL or its precursor or to impaired removal of VLDL remnants by the liver. Abnormalities in the VLDL particle also may influence conversion to LDL.

COMPOSITION

Individuals with type 1 diabetes may also have a preponderance of small, dense particles for the same reasons as those described for type 2 diabetes. LDLs isolated from patients with poorly controlled type 1 diabetes are taken up and degraded by fibroblasts at a lower rate than LDLs isolated from healthy subjects; when glucose concentrations are lowered by insulin therapy, the binding properties of LDLs return to normal (98). Glycated LDL and defects in cholesteryl ester transfer may be found in type 1, as well as in type 2, diabetes, although no studies on glycation in type 1 diabetes have yet been performed. Exposure of cells to lipoprotein-deficient serum obtained from patients with poorly controlled type 1 diabetes enhances the efficiency of LDL binding (99). It has been postulated that in type 1 diabetes, membrane changes may be induced that alter LDL binding.

High-Density Lipoproteins

It has been suggested that concentrations of HDL may be low in patients with untreated, insulin-deficient diabetes. Response of HDL to insulin therapy is slower than that of VLDL, but HDL increases with the degree of glycemic control. In several studies, HDL concentrations are similar or higher in patients with type 1 diabetes than in age-, sex-, and weight-matched controls. HDL levels may also be higher in those who are receiving insulinpump therapy (91–97).

METABOLISM

One factor responsible for the decrease in HDL in patients with poorly controlled type 1 diabetes is low LPL activity. The reduced activity impairs lipolysis of VLDL and subsequently slows formation of HDL particles (62). Levels of both HDL cholesterol and phospholipids in type 1 diabetes have been shown to correlate positively with LPL activity; thus, greatly increased catabolism of triglyceride-rich lipoproteins in the presence of excess insulin might augment the HDL compartment. An inverse correlation has been observed between HDL and hepatic lipase activity in the plasma of type 1 diabetic subjects. Hepatic lipase activity may be lower in well-controlled type 1 diabetes and associated with a high ratio of HDL₂ to HDL₃; thus, the role of this enzyme in regulating HDL levels and the possible influence of insulin on this process are similar to those postulated for type 2 diabetes (100).

COMPOSITION

HDL elevations in well-controlled type 1 diabetes are generally due to an increase in larger particles. These observations confirm the hypothesis that the action of insulin, whether it occurs through the activity of LPL or via some other process, hastens the transfer of material to the HDL₂ compartment. Data indicate that alterations in HDL composition may be found in type 1 diabetes much as they are in type 2 diabetes. Lower concentrations of HDL are associated with HDL particles that are smaller and richer in triglycerides. Abnormalities in both triglyceride and apoA₁ content have been observed in the HDL of individuals with type 1 diabetes (101), and $apoA_I$ and $apoA_{II}$ content may also be decreased. ApoA has also been reported to be glycated in patients with type 1 diabetes (102).

RATIONALE FOR THERAPY FOR LIPID ABNORMALITIES IN DIABETES

Atherosclerotic macrovascular disease is the leading cause of morbidity and mortality in patients with diabetes mellitus. Both men and women with diabetes have a significantly increased risk of myocardial infarction (MI) (103-105), stroke, and peripheral gangrene (104,105). The risk for developing coronary heart disease (CHD) begins prior to the development of type 2 diabetes. By the time the diagnosis of type 2 diabetes is made, more than half of all diabetic individuals already have clinical CHD (106). Haffner et al. (107) compared this phenomenon to a clock that begins ticking with the onset of insulin resistance and accelerates with the development of hyperglycemia. In a Finnish cohort of patients with type 2 diabetes, Haffner and colleagues (108) demonstrated that diabetic patients without previous MI have as high a risk for a first MI as do nondiabetic patients with a history of MI for having a second infarction. In addition, patients with diabetes have an increased rate of MIassociated prehospital mortality (105,109), as well as increased morbidity and mortality during and after hospitalization (110-112). This is particularly true for women with diabetes (53,113) These data provide a strong rationale for treating cardiovascular risk factors in diabetic patients as aggressively as in nondiabetic patients with clinical CHD. Thus, diabetes confers a risk that is equivalent to that of known CHD. The ADA and the American Heart Association consider type 2 diabetes a CHD equivalent (104,114).

The evidence is unequivocal that an abnormal lipid profile is a significant risk factor for atherosclerotic macrovascular disease in patients with diabetes (115,116). Modification of lipid and other risk factors has clearly been shown to lower mortality due to cardiovascular disease (CVD) in the general population (117–127). This has underscored the need for management of CVD risk factors (in addition to control of hyperglycemia) in individuals with diabetes (114,128–130). The United Kingdom Prospective Diabetes Study (UKPDS) demonstrates that controlling lipids and blood pressure may be significantly more effective in preventing CVD than is controlling hyperglycemia (122,131). Thus, in individuals with diabetes, the management of lipid disorders, as well as total risk-factor management, is of paramount importance.

DIABETIC DYSLIPIDEMIA

The dyslipidemia associated with type 2 diabetes and insulin resistance typically consists of elevated triglycerides and decreased HDL cholesterol level (132). In such individuals, LDL cholesterol levels are generally not significantly abnormal, although they may be somewhat elevated in whites (133) and lower in other racial/ethnic groups. The frequently mild abnormality in LDL cholesterol concentration associated with diabetes belies a qualitative abnormality in the LDL structure, i.e., decreased size and increased density of the LDL particle (134). The metabolic processes responsible for these abnormalities have been discussed previously.

Although triglyceride levels are usually mildly elevated, diabetic and insulin-resistant patients are subject to known, nonhyperglycemic factors that induce hyperlipidemia. For example, diabetes may occur in the presence of a familial syndrome of abnormal triglyceride or LDL metabolism and secondary causes of hyperlipidemia (135–141). Pharmacologic agents or alcohol abuse also may increase triglyceride and LDL cholesterol levels or further decrease HDL cholesterol concentrations (142–144). Coincident hypothyroidism and renal and liver disease also increase lipid levels (145).

Even when LDL cholesterol is normal or within a range that might be considered low in nondiabetic individuals, LDL appears to be a very potent contributor to the development of CHD (146). Recent data from the Strong Heart Study illustrated that, in American Indians, LDL cholesterol level was the most significant predictor of increased CHD, despite an average LDL cholesterol level of approximately 115 mg/dL (146). In this study, LDL was a strong predictor of CHD at levels as low as 70 mg/dL (146).

Multiple studies in the general population now conclusively demonstrate that LDL cholesterol lowering is very effective in both primary and secondary CVD prevention (147). Three large clinical trials-the Scandinavian Simvastatin Survival Study (4S) (129), the Cholesterol and Recurrent Events (CARE) trial (148), and the Long-term Intervention with Pravastatin in Ischaemic Disease (LIPID) Trial (125)—have all shown that the use of a statin drug to lower LDL cholesterol over a wide range of LDL levels in patients with preexisting CHD is very effective in preventing all-cause mortality, death due to atherosclerotic events, nonfatal atherosclerotic events, and the need for revascularization. Unexpectedly, these studies also showed a reduced incidence of stroke with statin therapy in patients with preexisting CHD. Several diabetes substudies (129, 153) have demonstrated significant improvement with regard to CVD mitigation and prevention (123-127, 149-152). Two additional trials in individuals without preexisting CHD, the Air Force/ Texas Coronary Atherosclerosis Prevention Study (AFCAPS/ TexCAPS) (126) and West of Scotland Coronary Prevention Study (WOSCOPS), have shown similar results.

The 4S trial, which initially studied 202 patients with type 2 diabetes, showed that cholesterol lowering effected a 55% reduction in risk of major CHD events, bringing the risk close to that for nondiabetic individuals (129). A later analysis of the 4S cohort using the new diagnostic criteria for diabetes of the Expert Committee on the Diagnosis and Classification of Diabetes Mellitus (154) (i.e., a fasting plasma glucose cutpoint of 7.0 instead of 7.8 mmol/L) increased the size of the diabetic cohort in 4S from 202 to 483 (155), with similar results with regard to the efficacy of lipid lowering in preventing CVD.

The CARE study included a large number of participants with type 2 diabetes as well as individuals with impaired glucose tolerance and insulin resistance (130). In this study, aggressive lipid lowering reduced CVD risk in diabetic individuals to that in their nondiabetic counterparts. A similar observation was made in the LIPID trial (125), although the percentage of diabetic participants was small. The AFCAPS/TexCAPS trial demonstrated that CHD could be prevented in diabetic patients who had no prior history of CHD (126). The therapeutic effect of statin therapy in these trials was a significant lowering of LDL cholesterol levels. At least one subsequent analysis indicates that reduction in CVD risk is proportional to the degree of reduction in LDL cholesterol (156,157). Further, statins have been shown to lower triglyceride and raise HDL cholesterol levels (158).

The Veterans Affairs High-Density Lipoprotein Cholesterol Intervention Trial (VA-HIT) examined the effects of gemfibrozil in patients with average to low LDL levels, moderately elevated triglyceride levels, and significantly decreased HDL cholesterol (159). In this study, gemfibrozil therapy increased HDL cholesterol concentrations by 6% and lowered triglyceride levels by 31%. These changes in lipid levels resulted in a 24% decrease in relative risk of CVD. Results in the subcohort of 627 patients with diabetes were identical (159). Finally, the Post Coronary Artery Bypass Trial showed similar angiographic improvement between diabetic and nondiabetic subjects with aggressive therapy with lovastatin and low-dose warfarin (160).

Although none of the previously described trials was designed primarily for patients with diabetes, they strongly indicate that controlling lipid abnormalities in patients with diabetes is effective in preventing or ameliorating CVD. The first trial designed to study a diabetic population, the Diabetes Atherosclerosis Intervention Study (DAIS), examined the effects of fenofibrate therapy in patients with type 2 diabetes (161,162). This trial was also a secondary prevention trial, with its primary outcome an improved coronary angiogram with fenofibrate therapy. At the end of the 3-year study, in a cohort of 418 patients, repeated angiograms showed a significant 40% reduction in focal atherosclerotic lesions with a similar (although not statistically significant) reduction in diffuse atherosclerotic disease (163,164). Although the trial was not powered to observe clinical outcomes, fenofibrate also reduced the combined endpoints of MI, revascularization, and death by approximately 23%. The most impressive study of lipid reduction in patients with diabetes is the Heart Protection Study (164a). In this trial 20,536 adults were randomized to either simvastatin, 40 mg, or antioxidant vitamins. Of the participants in this trial, 5,963 were known prospectively to have diabetes mellitus. Of this group, 1,981 had existing CHD and 3,982 were without prior CHD. Simvastatin therapy resulted in a significant 20.2% reduction of CHD events. Antioxidant vitamins were ineffective in preventing CHD. Additional trials in patients with diabetes are in progress and will be reported in the near future. It is hoped that these trials will provide final conclusive evidence concerning the management of lipid disorders in patients with type 2 diabetes.

At present, there are no interventional studies of lipid lowering in patients with type 1 diabetes, whose lipid abnormalities differ significantly from those of patients with type 2 diabetes. Patients with type 1 diabetes are reported to have accelerated CVD, and their lipid abnormalities are very responsive to glucose control. (90,91,95–97,115) Severe hypertriglyceridemia secondary to hyperchylomicronemia and an increased concentration of VLDL may occur in patients with type 1 diabetes when acute glucose metabolism is significantly abnormal. Patients with moderately controlled type 1 diabetes have less severe abnormalities of all lipid subfractions. There have been reports of elevated Lp(a) in uncontrolled type 1 diabetes, but the studies are not consistent (165).

In view of the observed increase in CVD in type 1 diabetes (166–168) and the increased prevalence of lipid abnormalities in those patients (116), a trial of lipid lowering is needed. Because the lipid abnormalities of type 1 diabetes often respond to glu-

cose control, the results of the Diabetes Control and Complications Trial (DCCT) are germane (169). Although therapy with hypolipidemic drugs was not used in the DCCT, microvascular and neurologic complications of type 1 diabetes were mitigated in patients who received intensive insulin therapy, with a nonsignificant reduction in macrovascular disease (170). This trend toward reduced macrovascular disease is of double importance because of the concern that intensive insulin therapy per se might be atherogenic.

GOALS OF THERAPY

The Adult Treatment Panel III (ATPIII) of the National Cholesterol Education Program (NCEP) has established the goal of an LDL cholesterol level less than100 mg/dL for patients with preexisting CHD or CHD risk equivalents (171). In this subset of patients, the NCEP has also determined that an HDL cholesterol level less than 40 mg/dL and a triglyceride level higher than 150 mg/dL are major CHD risk factors (172). In a recent addendum to the ATPIII report, an optional goal of achieving an LDL-C of less than 70 mg/dL was proposed for very-high-risk individuals such as patients with diabetes and known CHD (172a).

Because of the significant increase in cardiovascular risk conferred by diabetes and insulin resistance, the ADA has convened a series of consensus panels to discuss the goals for therapy in patients with diabetes (172). Because CVD risk in individuals with diabetes is equal to that of nondiabetic individuals who have pre-existing coronary disease, the ADA recommends that a similar LDL cholesterol goal of 100 mg/dL be set for all patients with type 2 diabetes. The categories of risk for type 2 diabetes as determined by lipid levels are summarized in Table 33.6.

In patients with diabetes, lipid abnormalities other than elevated LDL cholesterol are also potentially atherogenic. Hypertriglyceridemia has been implicated as an important contributor to atherosclerotic CVD (ASCVD) in patients with diabetes (173). Both the World Health Organization Multi-National Trial (174) and the Paris Prospective Study (175) have shown that hypertriglyceridemia is a significant predictor of subsequent cardiovascular mortality in persons with diabetes. In the Stockholm Ischaemic Heart Disease Secondary Prevention Study (176), lowering triglyceride levels was the most important factor in decreasing total and cardiovascular mortality. As discussed previously, abnormalities in VLDL composition and delayed clearance of chylomicron remnants may contribute to the accelerated ASCVD in patients with diabetes. In addition, individuals with diabetes are known to accumulate IDL and remnants of VLDL, which are definitely known to be atherogenic (177). The presence of small, dense LDL is also correlated with hypertriglyceridemia (173,178); this more atherogenic form of LDL begins to accumulate when triglyceride levels exceed 100 to 150 mg/dL (178).

TABLE 33.6. Degree of Risk of Coronary Heart Disease by Lipoprotein Level (mg/dL) in Type 2 Diabetes

	HDL		HDL	
Risk	LDL	Men	Women	Triglyceride
High Borderline Low	≥130 100–129 <100	<35 35–45 >45	<45 45–55 >55	≥400 200–399 <200

HDL, high-density lipoprotein; LDL, low-density lipoprotein.

Data from American Diabetes Association. Management of dyslipidemia in adults with diabetes. *Diabetes Care* 2000;23[Suppl 1]:S57–S60.

Epidemiologic studies have shown an inverse relationship between HDL concentration and CHD (179). As stated previously, the VA-HIT (159) and Stockholm (176) studies demonstrated a significant effect of a therapeutically induced increase in HDL in the prevention of CHD. Further, the Cholesterol Lowering Atherosclerosis Study (CLAS) (180) and Familial Atherosclerosis Treatment Study (FATS) (181) suggest that increases in HDL play a role in slowing the progression of CHD. Raising HDL levels in patients with type 2 diabetes can be extremely difficult, although the VA-HIT study suggests that pharmacologic therapy can be effective and desirable (182).

Recent studies suggest that non-HDL cholesterol is a better predictor of CHD risk than is LDL cholesterol alone (183,184). Non-HDL is determined by subtracting HDL cholesterol from total cholesterol and reflects the remaining amount of LDL and VLDL. Because the latter lipid classes also are differentiated by the presence of apoB₁₀₀, non-HDL cholesterol is highly correlated with total apoB. In AFCAPS/TexCAPS, total apoB was the best predictor of cardiovascular risk; non-HDL cholesterol provided an acceptable and readily available surrogate for total apoB (126). This is particularly applicable to the dyslipidemia that accompanies insulin resistance and type 2 diabetes, when HDL cholesterol is often low and triglyceride levels are high because of accumulation of atherogenic remnant triglyceride-rich lipoproteins: remnant VLDL and chylomicrons. The therapeutic goals for patients with type 2 diabetes are shown in Table 33.7.

The lack of interventional data in patients with type 1 diabetes makes it difficult to set specific goals for lipid therapy. The recommendation of the most recent ADA consensus panel, however, represents the best available advice of a panel of experts (3). One significant difference between type 1 and type 2 diabetes is that the intensive insulin therapy in type 1 usually normalizes and often increases HDL levels and improves other lipid abnormalities (115).

TREATMENT OF HYPERGLYCEMIA IN PATIENTS WITH DIABETES

Nonpharmacologic Therapy

A great deal of epidemiologic evidence indicates that patients with even mild hyperglycemia are at increased risk for macrovascular disease (185). Although there is little evidence from interventional studies that control of hyperglycemia in patients with type 2 diabetes will prevent macrovascular disease, the UKPDS (186) and other clinical trials (187,188) demonstrated a reduction in microvascular disease in individuals with either type 1 (189) or type 2 (186,190) diabetes. Therefore,

TABLE 33.7. Proposed Therapeutic Goals for Men and
Women with Type 2 Diabetes

Lipid fractions	Ideal goal (mg/dL)
Total cholesterol	≤170
LDL cholesterol	<100 ^a
HDL cholesterol	≥45 for men
	≥55 for women
Triglycerides	≥200
Non-HDL cholesterol	<130

LDL, low-density lipoprotein; HDL, high-density lipoprotein.

^a Optional goal for very-high-risk individual: <70.

Adapted from American Diabetes Association. Management of dyslipidemia in adults with type 2 diabetes. *Diabetes Care* 2000;23[Suppl 1]:S57–S60.

glycemic control should be a high priority in both patients with type 1 diabetes and those with type 2 diabetes. Recent evidence indicates that there is therapeutic value in immediate control of blood glucose in individuals with type 2 diabetes who are experiencing an acute MI. The Diabetes Mellitus, Insulin Glucose Infusion in Acute Myocardial Infarction (DIGAMI) study demonstrated an 11% reduction in mortality during the first year among diabetic patients who received an insulin/glucose infusion within 24 hours after acute MI (191). The benefits of such aggressive therapy persisted for 3.5 years.

Hyperglycemia in both forms of diabetes accentuates the typical lipid abnormalities seen in each diabetic syndrome. Controlling glucose has been shown to decrease triglyceride levels and to increase HDL cholesterol levels in both type 1 and type 2 diabetes, as stated previously. The nonpharmacologic and pharmacologic therapies for hyperglycemia have been discussed previously and will not be repeated here. However, it is worth noting that several of the hypoglycemic agents used to treat patients with diabetes have primary effects on lipid levels in addition to their effects on hyperglycemia. Metformin has been shown to lower triglyceride levels in individuals with type 2 diabetes (192), and several of the thiazolidinediones also may lower triglycerides and raise HDL (193). Thiazolidinediones must be used with caution, however, because their use is often associated with increased levels of LDL cholesterol (194,195). Data from several small studies suggest that this increase in LDL concentration may be the result of conversion of small, dense LDL to a more buoyant form (196). This claim requires further investigation, especially because of the lack of conclusive evidence from prospective interventional trials that such a change in LDL size will be beneficial.

Nonpharmacologic treatments for hyperglycemia should be vigorously applied to patients with diabetes, because these therapies can retard the progression of and improve the lipid abnormalities associated with the disease (197). In addition to its effects on hyperglycemia (197) and lipids (198), exercise has positive benefits on cardiac physiology (199). Because of recent controversy concerning the appropriate diet for patients with diabetes and lipids abnormalities, nutritional therapy will be discussed in more detail in the following section.

EXERCISE

Although exercise programs have not been shown to consistently improve glycemic control in patients with type 1 diabetes, exercise has long been advocated for these patients for its other beneficial effects (200). A position statement from the Council on Exercise of the ADA advocates exercise for patients with type 1 diabetes because of its potential to improve cardiovascular fitness (199). Several studies have shown that exercise in patients with type 1 diabetes decreases triglyceride levels and increases HDL cholesterol levels (199,200). The ADA Council on Exercise also has pointed out possible risks of exercise for individuals with type 1 diabetes: hyperglycemia, hypoglycemia, ketosis, cardiovascular ischemia and arrhythmias, exacerbation of proliferative retinopathy, and injury to the lower extremities (199).

In patients with type 2 diabetes, exercise may be even more important than in those with type 1 diabetes for the management of both hyperglycemia and dyslipidemia (199,200). Several prospective epidemiologic studies have shown that individuals who are less physically active have higher risk of developing type 2 diabetes (201–205), and a randomized trial showed that increased physical activity decreased the incidence of diabetes in individuals with impaired glucose tolerance (197). In considering the appropriate role of exercise in patients with type 2 diabetes, the ADA Council on Exercise emphasized the reduction of

ASCVD risk factors in its position statement (199) and recommended that moderate levels of physical activity be incorporated into daily living (206,207). Improvements in blood glucose, insulin resistance, and lipoprotein profile are thought to be realized by the cumulative effect of frequent, smaller bouts of activity (207). Again, however, the Council on Exercise points out risks of exercise in patients with type 2 diabetes, which are the same as those outlined for patients with type 1 diabetes (199). The Council strongly recommended that before individuals with type 2 diabetes begin an exercise program, they should undergo an evaluation specifically designed to diagnose previously unknown hypertension, nephropathy, retinopathy, neuropathy, and silent ischemic heart disease, which would include an exercise stress cardiogram for all patients older than 35 years.

In addition to direct effects on lipoproteins, exercise has several indirect benefits for lipoproteins in patients with type 2 diabetes (200,206). First, there is some evidence that weight-loss programs that incorporate exercise will be more successful than those focused on diet alone in maintaining weight reduction, with a resulting beneficial effect on lipid levels, as described below. In addition, there are direct effects of exercise training on reducing insulin resistance, a factor that may contribute to dyslipidemia, as discussed above. Exercise has also been shown to increase HDL cholesterol levels and lower triglycerides in individuals with type 2 diabetes.

DIET

Weight Loss

Weight loss is the conservative form of therapy for type 2 diabetes and has been discussed in Chapter 32. As stated previously, weight reduction in patients with type 2 diabetes has multiple benefits. A decrease in insulin resistance and hyperinsulinemia would be expected to have beneficial effects on hyperglycemia and dyslipidemia. Weight reduction in type 2 diabetes has been shown to lower triglyceride concentrations, increase HDL levels, and, in some studies, to lower LDL cholesterol levels (208,209). Even when hypoglycemic drug therapy is necessary, an appropriate diet will minimize the dose of drug required to control glucose levels.

Diet Composition

The dietary management of diabetes is discussed further in Chapter 36. The diet for patients with diabetes that is recommended by both the ADA (3,210) and the NCEP Expert Panel (2) (Table 33.8) stresses reducing the amount of saturated fat to less than 10% of total calories. This is the most important dietary strategy to lower LDL cholesterol. Cholesterol intake should be reduced to less than 300 mg per day. A maximum of 30% of total fat is recommended for most individuals, although there is flexibility depending on triglyceride levels (3,210). The rest of the diet should consist of 15% to 20% of calories from protein, five to eight servings of fruits and vegetables, and at least six servings of whole-grain products per day. Complex carbohydrates may account for 50% to 60% of total calories consumed. It is emphasized that this increase in the amount of complex carbohydrates in the diet should be accompanied by a concomitant increase in fiber intake (2,210–212). This is important because soluble fiber has an independent effect on cholesterol lowering (213). The NCEP has a second level of dietary recommendations for those with more severe hyperlipidemia (2), which include reducing saturated fat to less than 7% of calories and cholesterol to less than 200 mg per day.

There has been controversy concerning the desirable carbohydrate content of the diet in diabetes (211,214–217). For many years, it was believed that dietary carbohydrate should be restricted to prevent the complications of diabetes. In addition, studies in nondiabetics (218) and some studies in diabetics (216,217) have suggested that diets high in carbohydrate, especially those containing a large amount of simple sugars and low fiber, lead to increases in triglyceride levels and decreases in HDL levels, both of which will exaggerate the pattern of dyslipidemia already present in diabetes. There was also concern that metabolic control might deteriorate with increased consumption of carbohydrates, although this has not been borne out in clinical studies comparing high-carbohydrate and lowcarbohydrate diets (219–221).

Most studies in diabetes (both types) have shown that replacing foods high in saturated fat with foods containing predominantly complex carbohydrate lowers both total and LDL cholesterol levels (212,215,222–224); this response has been noted in both lean and obese diabetic subjects. Decreases in HDL cholesterol concentrations have been observed in some (216,217) but not other studies in which complex carbohydrate replaced saturated fat (222). Decreases in HDL concentrations appear to be less pronounced in subjects with diabetes who have lower initial HDL concentrations. Significant increases in fasting triglyceride concentrations have been seen in some studies of subjects with type 2 diabetes on various solid-food, highcarbohydrate diets, usually when there is no additional increase

 TABLE 33.8. Dietary Guidelines of the American Diabetes Association and the National Cholesterol Education Program

Nutrient	Step 1 diet	Step 2 diet
Total fat Saturated fat Polyunsaturated fat Monounsaturated fat Carbohydrates Protein Cholesterol Total calories	<30% of total calories <10% of total calories ≤10% of total calories 10%-15% of total calories 50%-60% of total calories 10%-20% of total calories <300 mg/d To achieve and maintain desirable body weight	<30% of total calories <7% of total calories ≤10% of total calories 10%–15% of total calories 50%–60% of total calories 10%–20% of total calories <200 mg/d

in the amount of fiber (222,223). An additional advantage of diets that are higher in carbohydrate and diets lower in fat is that they are lower in calories for comparable portion sizes and thus may promote weight reduction.

An alternative dietary approach that appears promising for the treatment of dyslipidemia in patients with type 2 diabetes who cannot or will not follow a high-carbohydrate diet is a diet high in monounsaturated fatty acids (184,216). Such diets reduce triglyceride and LDL concentrations and sometimes produce less lowering of HDL concentrations than do high-carbohydrate diets.

An additional dietary consideration for diabetic patients concerns intake of omega (ω)-3 polyunsaturated fatty acids. These fatty acids, which are found predominantly in fish oils, have a hypotriglyceridemic action in nondiabetic persons (225). Epidemiologic studies and clinical trials (226,227) provide evidence that diets high in fatty fish may help prevent CVD, and this effect has been attributed to the presence of ω -3 polyunsaturated fatty acids (228). Fish-oil supplements have been shown to reduce serum triglyceride levels in studies of patients with type 2 diabetes (229,230). However, increases in LDL cholesterol and apoB concentrations may occur in hypertriglyceridemic subjects given fish oil, a situation often observed in subjects with diabetes (231,232). Clinical trials have established that fishoil supplementation does not have an adverse effect on glycemic control (232,233). Thus, diabetic patients should be encouraged to eat fish, and ω-3 supplements should be considered in those with cardiovascular disease.

Because of the role that oxidative processes play in acceleration of atherosclerosis, it has been widely suggested that antioxidant supplements (vitamins E and C) be prescribed to individuals with diabetes. Although there have been no randomized trials in patients with diabetes, two recent trials have shown that vitamin E supplementation does not lower risk for cardiovascular disease (234,235), raising the possibility that other micronutrients present in vitamin E– and C–containing foods may be protective. Thus, dietary guidelines stress increased intake of vegetables, fruits, and grains so that micronutrients may be derived from whole foods rather than from vitamin supplements.

In summary, on the basis of the NCEP and ADA recommendations, several changes in typical American diets should be made to lower LDL and prevent diabetic dyslipidemia, including decreasing saturated fat and cholesterol and increasing fruits, vegetables, grains, and dietary fiber. When followed consistently, these recommendations can often reduce or even eliminate the need for hypolipidemic medications.

Pharmacologic Therapy for Type 1 Diabetes and Its Relation to Dyslipidemia

Secondary causes of dyslipidemia should always be investigated before initiating pharmacologic therapy. As stated previously, the usual secondary pathologic and pharmacologic causes of lipid abnormalities are more frequently detected in patients with diabetes (135,136,141), and their effects on lipid metabolism are often more pronounced in conjunction with the diabetic syndrome. The presence of known CHD mandates aggressive therapy for lipid abnormalities in all patients with diabetes. The ADA consensus panel recommends aggressive lipid-lowering therapy regardless of whether CHD is present or absent (3,145).

In diabetic patients with known CHD and LDL cholesterol higher than 100 mg/dL, immediate pharmacologic therapy to correct diabetic dyslipidemia should be instituted. Combined diet, exercise, and hypolipidemic drug therapy should be instituted for all diabetic patients with CHD immediately upon confirmation of myocardial ischemia or infarction. A strong case can be made for initiating hypolipidemic drugs in the hospital when a patient is admitted for an acute coronary event or ischemia. Discharging patients on lipid-lowering therapy gives them and their referring physicians an important, strong message concerning the necessity for control of lipid risk factors. Early initiation of lipid-lowering therapy was shown to improve patient compliance (236) and maintain target lipid levels at 6-month follow-up (237). In addition to the importance of lowering LDL cholesterol levels, results of the VA-HIT and DAIS studies suggest that therapy to correct triglycerides (238) and HDL cholesterol (239) abnormalities may be of extreme importance in patients at high risk for coronary events (164). When triglycerides and/or HDL cholesterol are the targets for therapy, lowering of non-HDL cholesterol levels should be considered as a potential therapeutic goal (183).

Diet and exercise should always be an adjunct to pharmacologic therapy because these modalities will often be synergistic in the control of lipid abnormalities. Because LDL cholesterol is often spuriously lowered following an acute ischemic event, lipid levels should continue to be monitored after hospital discharge and the dose of hypolipidemic drugs titrated to maintain lipids at target levels. Patients who adopt intensive lifestyle changes (i.e., begin dieting and exercising) may be able to discontinue pharmacologic therapy (240).

The same lipid-lowering drugs are used in patients with and without diabetes. Table 33.9 shows the principal classes of lipid-

lowering drugs and their effect on each lipid fraction, and Table 33.10 illustrates the various drugs available in each of these hypolipidemic classes, the usual effective dose, and the maximal daily dose for each medication.

HMG CoA REDUCTASE INHIBITORS (STATINS)

As shown in at least five large clinical trials (123–127), the statin drugs are the most effective pharmacologic agents for the prevention of CHD in both diabetic and nondiabetic patients and should be considered as the first line of therapy in patients with diabetic dyslipidemia. Although the primary effect of statins is to reduce LDL cholesterol levels, they are also effective in lowering triglyceride levels and have variable effects on HDL cholesterol. Statins competitively inhibit the rate-controlling enzyme of endogenous cholesterol biosynthesis, 3-hydroxy-3-methylglutaryl coenzyme A (HMG CoA) reductase, thus reducing cellular cholesterol production (241). The resultant decrease in levels of intracellular free cholesterol increases the activity of LDL receptor–mediated catabolism of LDL cholesterol (127,132,238).

The effect of the statin drugs on triglyceride levels is proportional to both baseline triglyceride levels and the degree of LDL lowering. Statins have little effect at triglyceride levels less than 150 mg/dL, a moderate effect at triglyceride levels in the 150- to 250-mg/dL range, and significant, dose-dependent reductions (22% to 45%) at triglyceride levels higher than 250 mg/dL (242). There also is evidence that statins may have clinically significant effects on HDL metabolism (158,243). Several of the previously mentioned large clinical trials demonstrated the ability of the naturally occurring statins-simvastatin, pravastatin, and lovastatin-to raise HDL levels. Questions recently have been raised about the effects of the more potent synthetic statins on HDL levels, and it has been suggested that higher doses of these statins may actually lower HDL cholesterol concentrations (158,243,244). In patients with diabetes, statins should be initiated at recommended doses and titrated at approximately 6week intervals to achieve desired goal levels for LDL cholesterol. As in the general population, liver function tests should be administered at approximately 3-month intervals for the first year.

Six statins are now available (Table 33.10); they differ primarily in their effectiveness in lowering LDL at their maximum dose. The appropriate drug should be chosen to achieve the degree of LDL reduction that is desirable to reach the goal level. One potential significant difference between the drugs is their metabolism by hepatic cytochrome P450 enzymes (245,246). Pravastatin has a pattern of metabolism different from that of the other four agents: simvastatin, lovastatin, atorvastatin, and fluvastatin. Pravastatin is not metabolized by any of the P450 enzymes. Therefore, if prolonged use of a concomitant medication that inhibits P450 enzymes is required, the use of pravastatin should be considered. Typical examples of drugs that inhibit the P450 enzyme system are erythromycin and other macrolide antibiotics, oral antifungal agents, and protease inhibitors. Myositis has sometimes been observed when these medications have been used with one of the statins that requires metabolism by these hepatic enzymes (247). Even grapefruit juice is known to have effects on statin metabolism (248,249), and patients taking statins should be counseled to avoid grapefruit juice or to consume it in moderation (250). Although myositis and rhabdomyolysis have been reported side effects of statin-fibrate combinations in the past, 21 clinical trials conducted in the past decade have shown this combination to be effective and safe, with low incidences of complications (251).

Statin drugs are more effective if they are taken at night, particularly at bedtime, with the exception of atorvastatin, which is longer acting than the other statin drugs. In the event that a patient develops side effects such as liver function abnormalities or myositis with one of the statins, that agent should be discontinued. After the abnormality has resolved, one of the other statins can be tried cautiously with careful monitoring of liver function and creatine phosphokinase (CPK) levels. In the previously-cited five large clinical trials, which included more than 30,000 patients over an approximately 5-year period, the statin drugs effectively lowered LDL cholesterol levels and were also extremely well tolerated, with no significant differences in other causes of morbidity or mortality between the placebo and intervention groups (123–127). In addition to decreased total mortality, no increases in cancer, violent deaths, or suicidal deaths occurred in these trials; these had been observed in previous lipid-lowering studies prior to the use of statins (252).

The mechanism by which these agents prevent atherosclerotic events is very interesting. Although early trials that used coronary arteriography showed decreased angiographic progression in most patients and small degrees of regression in a minority of patients, the more significant effects on clinical endpoints suggested new mechanisms of action. It now appears that stabilization of small, lipid-rich plaques (253) and restoration of normal endothelial function (254) may well be the predominant modes of action of statin drugs in preventing atherosclerotic events. Because these beneficial effects occur relatively quickly (prevention of ischemic events can be observed as soon as 1 month after commencement of therapy) (255), lipid-lowering therapy with a statin drug should be instituted promptly, particularly in patients with pre-existing CHD.

A variety of pleiotropic effects have been associated with statin therapy, including reduction in thrombogenicity, inhibition of cellular proliferation, anti-inflammation, and changes in oxidative potential. The weight of the evidence, however, indicates that the reduction in coronary events is a class effect of the statins that is most closely related to the reduction in levels of LDL cholesterol (141,157,247,256).

FIBRIC ACID DERIVATIVES

The two recommended fibrates now available in the United States, gemfibrozil and fenofibrate, are described in Table 33.10. Although clofibrate can still be prescribed, it is not recommended because of the significant side effects observed in previous clinical trials (257,258). The predominant effects of fibrates are to significantly lower triglyceride levels and raise HDL cholesterol levels; however, fibrates differ in their effect on LDL cholesterol. Gemfibrozil has been prescribed widely for a number of years and was the drug used in the Helsinki Heart Study. In this trial, patients with the dyslipidemia typical of diabetes (i.e., hypertriglyceridemia and low HDL levels with or without elevation in LDL) were most responsive to the protective effects of gemfibrozil (259). One of the concerns with gemfibrozil, however, has been the association of an increase in LDL with a lowering of triglycerides (159,260). Fenofibrate, which has recently become available in the United States, has the advantage of lowering LDL levels, along with having effects similar to gemfibrozil on triglyceride and HDL concentrations (261).

As discussed previously, in addition to the Helsinki Heart Study, the more recent VA-HIT study has shown that gemfibrozil raises HDL levels, thus reducing the risk of macrovascular disease, including stroke (182). The DAIS trial has shown a similar effect for fenofibrate on angiographic outcomes and effects similar to gemfibrozil on clinical endpoints (164).

In patients with particularly high triglyceride levels and lower levels of LDL cholesterol, fibrates should be considered as initial therapy. Doses of fibrate should be instituted as indicated in Table 33.10, and serum triglycerides should be monitored. Effects of fibrate drugs on triglycerides may be observed within several weeks because of the rapid turnover of VLDL, as discussed previously.

Although it has been debated whether triglycerides are a risk factor for CHD, as discussed previously, recent data from a number of clinical trials indicate that even a moderate degree of hypertriglyceridemia in patients with diabetes increases the risk for a coronary event (262). A recent meta-analysis has shown a significant effect of triglyceride as a cardiovascular risk factor (263) and follow-up in the Prospective Cardiovascular Muenster (PROCAM) study has had similar results (264). It is interesting that extreme hypertriglyceridemia is not associated

with the same degree of CHD risk (265), probably because the triglyceride-rich lipoproteins seen in patients with insulin resistance and type 2 diabetes are generally of the remnant variety and those seen in patients with higher levels of triglycerides exist in a larger, more buoyant, less atherogenic form. Extreme hypertriglyceridemia, particularly in type 1 diabetes, confers a significantly increased risk of pancreatitis (265) and should be lowered to the range that will reduce the risk of CHD without harming the pancreas (171).

BILE ACID SEQUESTRANTS

Cholestyramine and colestipol were among the earliest hypolipidemic drugs studied. Cholestyramine alone was shown to reduce CHD risk in the Lipid Research Clinics Coronary Primary Prevention Trial (LRC-CPPT) (119), the National Heart, Lung, and Blood Institute (NHLBI) Type II Intervention Trial (266), and in a secondary prevention trial conducted by the NHBLI that examined angiographic endpoints (267). Cholestyramine combined with a statin also was effective in reducing CHD risk (268-271). Low doses of a bile acid resin can further lower LDL cholesterol levels when combined with statins, fibric acid derivatives, or nicotinic acid. When used in the presence of preexisting hypertriglyceridemia, bile acid sequestrants may significantly raise triglyceride levels (141) and increase the risk of pancreatitis (136,141,272). In addition, patients with diabetes often have gastroparesis and other gastrointestinal syndromes that may be worsened by the use of bile acid sequestrants. Therefore, small doses of bile acid sequestrants can be used, after triglyceride levels are controlled, as adjunctive therapy to achieve additional LDL lowering and avoid the potential gastrointestinal side effects associated with higher doses of these agents. The new bile acid sequestrant, colesevelam hydrochloride, will eliminate or diminish such side effects (273).

INTESTINAL ABSORPTION INHIBITOR

Ezetemibe represents the first agent in a new class of lipid-lowering drugs, the intestinal cholesterol absorption inhibitors. This drug inhibits a sterol transferase located in the brush border of the small intestine, thereby reducing the absorption of intestinal intraluminal cholesterol. Dietary cholesterol contributes only 25% of the intraluminal cholesterol available to this transferase, with the remaining 75% coming from the liver. By inhibiting cholesterol absorption, chylomicron cholesterol, and chylomicron remnant cholesterol concentrations are reduced, with a significant decrease in the absorbed cholesterol delivered to the liver. A resulting upregulation of hepatic LOL receptors leads to a 18% to 20% reduction in LDL cholesterol concentration. In addition, triglycerides are reduced and HDL-C is slightly increased.

NICOTINIC ACIDS

Nicotinic acid, or niacin, is a cofactor in intermediary metabolism at physiologic doses less than 20 mg/dL (137). However, doses of 1,000 mg or more per day have significant positive effects on all lipid abnormalities. Niacin was the first agent to be shown to prevent CHD in the Coronary Drug Project (274) and was shown to lower all-cause mortality at 15-year follow-up (275). Niacin is the most effective drug in raising HDL levels, even at doses as low as 1,000 mg per day (136,141). Higher doses are usually required to alter triglyceride or LDL metabolism (276). The principal problem in using niacin is that it increases insulin resistance (137,140,141). Therefore, in individuals with type 2 diabetes, niacin should be used very sparingly and only in patients with severe hypertriglyceridemia that does not adequately respond to

other forms of therapy such as a fibric acid derivative or fish-oil capsules (277). As mentioned above, small doses (1,000 mg per day) may be used to raise HDL cholesterol levels, but glucose metabolism should be followed very carefully. Because the undesirable effects are predominately on insulin resistance, there is no significant contraindication to the use of niacin in individuals with type 1 diabetes. However, this is seldom necessary because the triglyceride abnormalities in patients with type 1 diabetes usually respond to glucose control (115).

Niacin also has a number of other significant side effects, of which the most common are flushing and various dermatologic manifestations such as pruritus and rash (278). Niacin may be very hepatotoxic (279), particularly in some of the over-thecounter, long-acting forms. In addition, niacin is known to exacerbate inflammatory bowel disease, ulcers, and asthma.

COMBINATION THERAPY

Patients with severe diabetes-associated dyslipidemia often may require more than one drug to maximize control of all lipid fractions. Ezetemibe or bile acid sequestrants can be added to a statin to further decrease LDL-C levels without significant drug-drug interactions. In the case of the bile acid sequestrants, triglyceride levels should be reduced before this class of drugs is used in combination with a statin. When patients treated with gemfibrozil to control hypertriglyceridemia are noted to have an increase in LDL cholesterol level or when the LDL reduction induced by fenofibrate or gemfibrozil does not reach goal levels, a bile acid sequestrant can be added to the treatment regimen after triglyceride levels are under control (141). The combination of gemfibrozil or fenofibrate with a bile acid sequestrant and the combination of nicotinic acid with a bile acid sequestrant have both been shown to be effective in treating combined hyperlipidemia (141,280-282). Although the risk of using either niacin or a fibric acid derivative with a statin drug increases the risk of myositis, as discussed previously, the combination may be indicated in carefully selected patients with high-risk lipid profiles (251). Because both niacin and fibric acids may be hepatotoxic, the presence of abnormal liver function at baseline is a contradiction to combination therapy, and liver function should be carefully monitored during therapy. Niacin-induced hepatoxicity increases the risk of myositis from the resultant abnormality of drug metabolism associated with hepatic dysfunction (141). A fibrate/statin combination can be very effective in patients with the mixed dyslipidemia characteristic of type 2 diabetes and therefore may be necessary if control cannot be achieved by a single agent. Recent pharmacokinetic studies have indicated that gemfibrozil significantly increases the serum concentration of all statins secondary to the inhibition of the glucuronidation step in statin metabolism. For this reason, only fenofibrate should be used as combination therapy with any statin. In cases of mixed dyslipidemia, the statin dose should be maintained at the starting dose and the patient should be warned about the potential side effects of the fibrate/statin combination. CPK levels do not need to be monitored unless the patient develops signs or symptoms of myositis, in which case the statin should be immediately discontinued and CPK levels measured. A CPK level more than ten-times normal mandates immediate discontinuation of the combination therapy to prevent the more severe complication of rhabdomyolysis. There are no apparent differences among the statins and fibrate drugs in terms of the development of myositis. Any combination may be used, and all patients receiving them should be monitored closely. The previously discussed medications that are known to inhibit the metabolism of statin drugs (e.g., macrolide antibiotics, oral antifungal agents, and

protease inhibitors) should not be used concomitantly because they will increase the risks associated with the statin/fibrate combination. Triple-drug therapy with nicotinic acid, a bile acid sequestrant, and a statin has been used in patients with severe hyperlipidemia (283). This triple-drug regimen is capable of lowering LDL cholesterol levels by 70% to 80% and can thereby normalize LDL levels even in patients with heterozygous familial forms of hypercholesterolemia or mixed hyperlipidemia.

OTHER CONSIDERATIONS

The Elderly Patient with Diabetes

Because the incidence of type 2 diabetes and of hypercholesterolemia increases with age, diabetic dyslipidemia is a frequent finding in older individuals. Although most of the major clinical trials have not studied elderly patients, the available data from a few studies and from epidemiologic studies such as the Framingham Study indicate that lipid disorders continue to be of concern in the geriatric age group (284-286). Because type 2 diabetes frequently has its onset when individuals are older than 60 years of age and because glucose intolerance increases the atherogenic potential of dyslipidemia and augments the natural tendency of cholesterol levels to increase with age, elderly people with diabetes are of special concern to the clinician (287). Studies from Framingham have suggested that CHD risk is significantly increased in elderly individuals with diabetes; therefore, it seems appropriate to reduce cholesterol levels in this group (286). Nonpharmacologic therapy should be effectively used before therapy with hypolipidemic drugs is considered. When drug therapy is necessary, both fibric acid derivatives and the statin drugs are effective hypolipidemic agents and seem to have no age-related side effects. However, as with all drug therapy for the elderly, special consideration should be given to the changes in metabolism that occur with aging, and doses should be carefully titrated for older individuals. The major clinical trials of statin therapy described previously (4S, LIPID, CARE, WOSCOPS, AFCAPS/TexCAPS, and HPS) (123-127) have all included patients over 60 years of age. Substudies of this older cohort have shown effectiveness of statin treatment equal to that in younger patients, with no evidence of increased toxicity.

Diabetic Nephropathy

Diabetic nephropathy is a frequent complication of both type 1 and type 2 diabetes. Diabetic renal disease usually presents with microalbuminuria and hypertension and then progresses to nephrotic syndrome and/or chronic renal insufficiency (288,299). A number of lipid abnormalities have been observed in patients with diabetic nephropathy, with hypertriglyceridemia and low levels of HDL cholesterol being the most common. However, combined hyperlipidemia and isolated elevations in LDL cholesterol levels also are seen in patients with diabetic renal disease (290). Bile acid resins have been administered to patients with nephrotic syndrome secondary to diabetes, and because these agents are not absorbed through the gastrointestinal tract, they do not appear to increase side effects in patients with renal disease. However, because of their limited capacity to lower LDL cholesterol levels and their propensity to elevate triglyceride levels, these agents are often not effective in controlling the lipid disorders of diabetic renal disease (290).

Statins used in patients with nephrotic syndrome appear to be effective in lowering LDL cholesterol levels and are well tolerated in patients with no deterioration of renal function (291). Because they are metabolized primarily by the liver, statins

should also be safe for patients with mild renal insufficiency. However, because statins have not been studied in patients with more severe forms of diabetic nephropathy, they cannot be recommended for patients with significant deterioration of renal function. Atorvastatin has been used in patients with moderate renal insufficiency without side effects and with significant efficacy in reducing LDL cholesterol levels (292).

For patients whose primary lipid problem secondary to diabetic nephropathy is hypertriglyceridemia, fibric acid derivatives are of potential therapeutic benefit (293). Early studies with clofibrate in patients with renal insufficiency or nephrotic syndrome identified a significant problem with myositis, which in some cases was severe enough to produce rhabdomyolysis and worsening of renal failure (247,288,289,294). Although some studies have indicated that gemfibrozil and fenofibrate are beneficial in patients with nephrotic syndrome, fibric acid derivatives should be used with caution in patients with diabetic nephropathy because the predominant route of metabolism of these agents is renal excretion (290).

CONCLUSION

Macrovascular disease is the number one cause of morbidity and mortality in type 2 diabetes and is becoming increasingly important in type 1 diabetes. Although there has been an impressive decrease in CVD-related mortality in the general US population over the past 30 years, patients with diabetes have not experienced the same degree of decrease (295). Not only is diabetes an independent risk factor for arteriosclerosis, it also is frequently associated with insulin resistance and the accompanying risk factors of obesity, hypertension, and dyslipidemia. Hence, total risk factor management is mandatory in patients with diabetes, an approach strongly supported by the UKPDS and DAIS studies (131,164). Subgroup analyses of the participants in the major prospective statin trials also support aggressive management of LDL cholesterol levels (123-130). In addition, the therapeutic approach to any single risk factor must be designed so that it does not introduce or worsen other cardiovascular risk factors.

There is growing evidence not only that dyslipidemia is one of the most important contributors to arteriosclerosis but also that other risk factors for CHD may be lipid-dependent (296). Hence, an understanding of the pathophysiology and treatment of diabetic dyslipidemia is essential for the successful management of patients with diabetes.

It seems particularly appropriate to end this discussion with an often-quoted statement made by Dr. Elliot Joslin (297) in 1927.

I believe the chief cause of premature development of arteriosclerosis in diabetes, save for advancing age, is an excess of fat, an excess of fat in the body (obesity), an excess of fat in the diet, and an excess of fat in the blood. With an excess of fat diabetes begins and from an excess of fat diabetics die, formerly of coma, recently of arteriosclerosis.

Treatment of Diabetes Mellitus

General Approach to the Treatment of Diabetes Mellitus

Ramachandiran Cooppan

DIABETES AS A WORLDWIDE HEALTHCARE PROBLEM 587

CHANGING DIAGNOSTIC CRITERIA FOR DIABETES 587

AN INITIAL APPROACH 589

The Patient History 589 Physical Examination 589 Laboratory Studies 590

Since the last edition of this textbook, major scientific advances have increased our understanding of the pathophysiology underlying both type 1 and type 2 diabetes and have fueled new approaches to therapy. New insights into the mechanism of insulin action and insulin resistance, greater understanding of the mechanisms of controlling insulin secretion, and advances in genetics and in immunology have contributed to this explosion of knowledge. Furthermore, a number of randomized prospective studies demonstrating the benefits of tight glycemic control and the availability of new oral therapies and insulin formulations provide a compelling rationale for improving the overall level of diabetes care.

The results of the Diabetes Control and Complications Trial (1), the Kumamoto Trial (2), and the United Kingdom Prospective Diabetes Study (3) have provided conclusive evidence that tight glycemic control will prevent the onset, as well as delay the progression, of the long-term microvascular complications of type 1 and type 2 diabetes. A more recent follow-up of the Kumamoto study (4) noted that the optimal degree of glycemic control to prevent or delay complications is a glycosylated hemoglobin (HbA_{1c}) level of less than 6.5%, a fasting glucose level of less than 110 mg/dL, and a 2-hour postprandial blood glucose level of less than 180 mg/dL.

DIABETES AS A WORLDWIDE HEALTHCARE PROBLEM

Diabetes mellitus has become an international healthcare crisis that requires new approaches to prevention and treatment. During the last 20 years, the prevalence of diabetes has increased dramatically in many parts of the world. Although genetic factors play a role in the etiology, especially of type 2 diabetes, the EDUCATION 590 CLINICAL GOALS 591 INITIATION OF THERAPY 593 FOLLOW-UP 595

growing problem of obesity that parallels improved economic status in some developing countries is a major environmental factor in this epidemic of diabetes. On the other hand, in many parts of the developing world, low birth weight and maternal malnutrition during pregnancy may be a major factor underlying the insulin resistance syndrome and thus in an increased risk of diabetes in later life.

At least 120 million people throughout the world suffer from type 2 diabetes, and it is projected that the number will increase to 220 million by the year 2010. This disease is now a worldwide public health issue that not only costs many nations millions of dollars for healthcare but also robs many developing economies of their most precious resource, their workers. Data almost a decade old gave an estimated prevalence of type 2 diabetes in the United States of 14 million persons that caused an estimated 300,000 deaths and resulted in healthcare expenditures of \$100 billion (5).

Some of the world's most highly indebted and poorest nations do not have sufficient resources to pay back their debt and to also provide care for patients with diabetes, adding to the problem. In these areas, a lack of adequate insulin supplies is a major problem for young children with type 1 diabetes, and many do not survive more than 1 year after onset of disease. Solutions to this problem must be forthcoming, because treatment for patients with type 1 diabetes exists and should be widely distributed (6).

CHANGING DIAGNOSTIC CRITERIA FOR DIABETES

In 1997, the American Diabetes Association (ADA) changed the diagnostic criteria for diabetes mellitus and recommended that

the use of Roman numerals for the two major forms of diabetes mellitus be discontinued and that Arabic numerals 1 and 2 be used instead. The earlier change in the classification from insulin-dependent diabetes mellitus (IDDM) and non-insulindependent diabetes mellitus (NIDDM) to type 1 or type 2 was an attempt to move away from a treatment-based classification to one based on underlying pathophysiology. This new system removed the confusion that emerged when patients classified as having NIDDM under the old nomenclature were treated with insulin because of disease progression. Would these patients now be classified as having IDDM or were they merely patients with NIDDM who now required insulin therapy? The pathophysiologic approach allows for the spectrum of changes in the underlying disease process that develop with time and provides a rationale for treatment changes based on this progression.

In making these changes, the ADA also revised the diagnostic criteria for diabetes and introduced a new category, impaired fasting glucose (IFG). The old criteria required a fasting plasma glucose level of 140 mg/dL or higher or a glucose level of 200 mg/dL or higher 2 hours after a 75-g glucose challenge to establish a diagnosis of diabetes. These older criteria also were in line with the recommendations of the World Health Organization. The new criteria were developed to allow earlier diagnosis of diabetes that would, in turn, lead to early treatment and, it is hoped, to a reduction in diabetes-related complications (7). Studies in Egypt and the United States demonstrated a correlation between the development of retinopathy and a fasting glucose level of more than 108 to 116 mg/dL (8,9). Not all groups are enthusiastic about these changes in the diagnostic criteria. Some are concerned that undo emphasis on the fasting glucose concentrations will reduce the use of the oral glucose tolerance test that may be necessary to identify individuals with impaired glucose tolerance (IGT), which is associated with greater rate of progression to clinical diabetes and is a risk factor for cardiovascular disease (10,11). Furthermore, there is concern that the new criteria may increase the prevalence of diabetes in many parts of the world and strain already limited healthcare resources (12,13), although, of course, the new criteria do not increase the actual prevalence of diabetes but only that of diagnosed diabetes.

Advances in molecular biology and genetics have helped to elucidate the mechanism of insulin action and to identify specific gene mutations [e.g., glucokinase gene in maturity-onset diabetes of the young-2 (MODY 2)] that can lead to diabetes. In addition, outcome data clearly support the benefits of strict glycemic control in retarding both the development and progression of the long-term microvascular complications in both type 1 and type 2 diabetes mellitus. These studies on glucose control have been complemented by studies on macrovascular disease that demonstrate the major benefits derived from aggressive treatment of hypercholesterolemia and elevated blood pressure in patients with diabetes.

The increase in the number of oral medications for treating type 2 diabetes has now made it possible for providers not only to choose therapies based on the underlying pathophysiology of diabetes but also to use drugs that work synergistically by addressing different pathophysiologic abnormalities. The benefits of this approach, which often allows the use of submaximal doses of different agents, are improved glycemic control and a reduction of the adverse effects of the medications used. The challenge in type 2 diabetes is to start treatment early and to use combination therapies that address both the insulin resistance and insulin secretory defects of the disease. The introduction of rapid-acting human insulin, as well as the new long-acting insulin analogues, has made it possible to approximate normal insulin secretion through the use of basal and premeal (bolus) insulin regimens. The "cure" for diabetes still eludes us. However, the progress made in the development of new approaches to growing and transplanting β -cells and in immunosuppressive therapy lends hope to the possibility that transplanted β -cells, even those not rendered immunoneutral, will survive for the long term and render patients with type 1 diabetes insulin-independent (14).

The approach to a chronic disease such as diabetes requires treatment goals that include both the maintenance of the wellbeing of the affected individual and the prevention of the longterm complications associated with the disease. The relationship of glucose control to the microvascular complications has been validated; the challenge is to make practical use of this information by improving the delivery of appropriate care. This requires close collaboration among all members of the healthcare team involved in the care of patients with diabetes. Despite the dramatic results of the Diabetes Control and Complications Trial (DCCT), for most patients, there has been no major shift in the care of type 1 diabetes that will provide the benefits noted in the intensive therapy trials.. It is gratifying that those patients who were in the intensive treatment arm of DCCT and are now part of the Epidemiology of Diabetes Interventions and Complications (EDIC) trial have continued to benefit from participation in the intensive treatment arm for as long as 4 years after the trial's end. Unfortunately, this group has experienced some deterioration in overall glycemic control outside the environment of a rigorously controlled clinical trial (15). The cost-effectiveness of intensive treatment also has been examined and found to be worthwhile compared with the cost of treating the complications when they occur. To achieve aggressive goals of glycemic control, self-monitoring of blood glucose (SMBG) must be a standard for all patients. Moreover, patients should have access to the appropriate monitoring equipment, independent of the type of diabetes, and with the frequency of testing determined by the medical professionals and the patient.

Many variations of practice guidelines for diabetes are now available; however, adherence to these guidelines has not been optimal in many instances (16). There are many reasons for this, and these must be assessed carefully if progress is to be made in this area. Current treatment guidelines are based on outcomes data derived from controlled clinical trials and extensive physician experience. A mechanism is now needed to translate these guidelines into a format that will be both practical and realistic in clinical practice. The care of patients with a chronic disease such as diabetes, while benefiting from the modern revolution in information technology, still has as its basis the caring, compassionate, and understanding relationships between the patient and members of the healthcare team. Unfortunately, current reimbursement systems do not support the establishment or maintenance of these relationships and thus work against efforts to provide optimal care to patients with diabetes.

The major clinical issue in patients with type 2 diabetes, in addition to that of achieving symptomatic control of hyperglycemia, is the enormous risk of cardiovascular disease and the problems arising from microvascular complications. An appreciation of the interrelationships of the various risk factors that lead to coronary heart disease and the benefits of treating these vigorously is growing rapidly. Multiple studies on cholesterol lowering [Scandinavian Simvastatin Survival Study (4S) and Cholesterol and Recurrent Events trial (CARE)] (17,18); blood pressure control [United Kingdom Prospective Diabetes Study (UKPDS) and Hypertension Optimal Treatment (HOT) study] (19,20); and the use of aspirin (21), inhibitors of angiotensin-converting enzyme [Heart Outcomes Prevention Evaluation trial (HOPE)] (22), and β -blockers reveal significant benefits in patients with diabetes. While these randomized controlled clinical trials have been conducted primarily in subjects

without diabetes, the subgroups with diabetes also had significant reductions in major cardiovascular events and death. The recent data from the Atherosclerosis Risk in Communities (ARIC) Study showed that the risk for diabetes in patients with hypertension is increased by two and a half. The study also noted that the risk of development of diabetes was not increased by thiazide diuretics but was increased by β -blockers. However, the benefits of the use of β -blockers following myocardial infarction have been validated in the literature, so the risk of developing diabetes should be considered of secondary importance in this group of patients (23).

The treatment plan for patients with diabetes also will be affected by the prevalence of the disease in the population. The prevalence of type 2 diabetes is higher in certain ethnic groups, such as Native Americans (especially the Pima Indians) (24), Hispanic Americans, African Americans, and Asian Americans (25–27). For many of these groups, access to good medical care is affected by factors such as socioeconomic status, insurance coverage, cultural background, language barriers, individual and group health beliefs, educational level, and peer behavior. These factors present special problems that will have to be addressed if these patients are to achieve optimal outcomes.

Diabetes in the older population also is a special issue because of the increase in the prevalence of diabetes with aging, the multiple other conditions being treated in the elderly population, and the risks associated with polypharmacy. There is an urgent need to approach the treatment of diabetes in these patients with enthusiasm and to set appropriate goals for therapy. Treatment must be individualized, and the relationship of risks to benefits must always be carefully evaluated, but age, per se, is not a reason to alter the target goals for glycemic control. Although most elderly patients with diabetes have type 2 disease, many of them have type 1 (insulin-dependent diabetes) disease-not only because type 1 diabetes can present for the first time in the elderly but also because many patients with type 1 diabetes are living long enough to be included in the elderly group. The elderly do not always present with the classical symptoms and signs of hyperglycemia, so the physician must consider this diagnosis, especially in those with neuropathy, nonhealing ulcers, and recurrent infections (28).

Although this chapter will focus on the general approach to the treatment of the patient with diabetes in the outpatient setting, the principles also apply to inpatients. The material presented here is intended as a general overview of the treatment of diabetes; other chapters in this text are devoted to specific issues.

AN INITIAL APPROACH

Once the diagnosis of diabetes has been established, the question of initiating therapy must be addressed. Those patients who present with diabetic ketoacidosis or who are markedly hyperglycemic and symptomatic should be admitted to the hospital for urgent treatment. The need for hospitalization at diagnosis applies primarily to patients with type 1 diabetes, especially children.

At this initial stage, the physician or healthcare professional who is seeing the patient should obtain a detailed history and perform a complete examination with appropriate laboratory testing. The future progression of the patient's care will be affected by a number of factors, including the physician's treatment philosophy, the patient's healthcare beliefs and competence at self-care, and the availability of a team consisting of a dietitian, diabetes educator, exercise physiologist, and, when needed, social workers and psychologists. Unfortunately, not all components of this team may be available in the general office practice; however, most communities do have these resources, and patients should be referred to them, as appropriate, to achieve optimal glucose control.

The approach must consider the "whole person" with diabetes, not just the levels of glycemic control to be achieved or the therapy to be used to accomplish this (i.e., insulin or oral antidiabetic therapies). To this end, a strong, integrated team approach is the one most likely to succeed. Although, as noted above, the complete team may not exist in most cases, the physician and the patient can make considerable progress together, with other components of the team, especially the diabetes educator and dietitian, coming from the community.

The Patient History

A detailed history is the foundation of good diabetes care. Knowledge about the age of the patient and the clinical presentation often help the physician determine whether the patient has type 1 or type 2 diabetes. This is not a laboratory-validated diagnosis but a clinical assessment to assist in choosing the initial treatment. The clinician bases the classification on aspects of the patient's history such as age, body weight, family history, duration of symptoms, and the results of the blood glucose and the HbA_{1c} determinations. Considerable heterogeneity exists, especially in type 2 diabetes, in the clinical presentation as well as in the underlying pathophysiology. Some patients actually may have a slowly progressive form of autoimmune diabetes. These tend to be younger adults and generally require insulin therapy relatively soon. These patients can be diagnosed by measuring certain autoimmune markers in the blood, such as antibodies to insulin and glutamic acid decarboxylase (GAD). The increasing prevalence of type 2 diabetes in adolescents makes it necessary to differentiate type 1 from type 2 diabetes in this group of patients. Another problem is the difficulty in assigning a definite date for the onset of diabetes, particularly for type 2 diabetes, which can be asymptomatic for many years, a determination that has implications concerning the risk for diabetes complications. At the Joslin Clinic, both patients with new-onset diabetes and those seeking consultation for existing disease are mailed a detailed metabolic questionnaire about symptoms, current therapy, family history, exercise patterns, and other medical problems and therapies. Particular attention must be paid to histories of coronary artery disease, peripheral vascular disease, hypertension, and renal disease in the patient and the family. Patients also are asked to keep a record on a dietary assessment sheet or in a food diary for 2 or 3 days, including the times of their meals and the types and quantities of foods eaten. This information helps the dietitian design an appropriate meal plan based on the patient's food preferences and lifestyle. With new information-technology systems, patients can access these questionnaires electronically and enter the information from home. This will avoid mail delays, help get the information in a timely manner, and enhance the patient's visit with the physician.

Physical Examination

The physical examination is a fundamental part of the initial evaluation. Special attention should be paid to the height and weight, body mass index (BMI), blood pressure (lying down and standing up), and vascular status. A careful examination of peripheral pulses and auscultation of carotid and femoral vessels for bruits is extremely important in obtaining a baseline for the future. The neurologic examination must include a careful search for evidence of neuropathy. Not only are muscle strength and reflexes tested, vibration, position sense, and appreciation of application of a 10-g monofilament to the feet must also be assessed. While these clinical methods lack the precision of a detailed laboratory neurologic evaluation, they still permit the clinician to obtain a baseline picture and to obtain further investigations in appropriate patients.

In a study of 189 patients with diabetes and 88 control subjects, Thivolet et al. (29) used a graduated tuning fork to measure the sensitivity of the feet to vibratory sensations and noted that 51% of patients with clinical symptoms of neuropathy in the extremities, 70% of those with absent tendon reflexes, and 75% of those with abnormal nerve-conduction velocities had limited vibration sensation. On the other hand, the study by Dyck et al. (30) revealed the problems present in assessing the epidemiologic data on diabetic neuropathy. Part of the problem is the variety of clinical types of neuropathy and the characterization of neurologic dysfunction. With multiple clinical entities and variable presentation, the best the clinician can do is to look for and document the presence of neuropathy. In a recent study, Perkins et al. (31) reported on the usefulness of four simple tests: 10-g Semmes-Weinstein monofilament examination, superficial pain sensation, vibration testing by the on-off method, and vibration testing by the timed method. They found excellent sensitivity and specificity for each of the tests from the reported operating characteristics. The timed-vibration method took longer to perform than the others, but each of the other tests took less than 10 seconds and should therefore be part of the annual examination for neuropathy. If the history and physical examination are atypical for diabetes, an additional workup should be undertaken and a referral to a neurologist considered.

The physician also should pay special attention to the patient's feet, carefully palpating the dorsalis pedis and posterior tibial, popliteal, and femoral pulses. Skeletal deformities such as hallux valgus, bunions, callouses, and hammertoes must be carefully documented. The combination of vascular disease and neuropathy is the major cause of foot infection and nontraumatic amputation in patients with diabetes.

Finally, a careful funduscopic examination is done, although this should not substitute for an evaluation by an ophthalmologist with experience in diabetic eye disease. Some new methodologies using nonmydriatic digital retinal imaging serve as an excellent screening technique to prioritize the need for formal ophthalmologic evaluation.

Laboratory Studies

The choice of laboratory tests performed is in part determined by the clinical presentation of the patient. If the patient is in a state of diabetic ketoacidosis or is symptomatic from marked hyperglycemia, the degree of hyperglycemia, the acid-base status, electrolytes, and the presence of acetone are urgently assessed. For the nonacute situation, at the patient's first visit, the minimum tests required are a complete urinalysis and determinations of blood glucose and HbA1c. It is now usual to add to these a chemistry panel that includes measurements of lipids, liver and kidney function, and electrolytes and a complete blood count. If possible, the lipid measurements should be done on the patient in the fasting state to obtain an accurate determination of the triglyceride level. It may be necessary for the patient to make a separate visit to the office or laboratory for these tests. In most cases, lipids also are evaluated on the first visit. Total cholesterol, triglycerides, high-density cholesterol, and low-density cholesterol are determined. Lipid studies are an important aspect of diabetes assessment because of the high risk of macrovascular disease, especially in the patient with type 2 diabetes (32).

A test for microalbuminuria also is recommended, since the presence of microproteinuria heralds the future development of

renal disease (33,34) and is an independent risk factor for cardiovascular disease. Many different methods are available for determining the presence and degree of albumin excretion, including an albumin-to-creatinine ratio in a spot urine, timed urine collection, and 24-hour urine collection. The latter test also allows the determination of creatinine clearance. The test for albumin-to-creatinine ratio is now widely available and can easily be performed in the office, with the caveat that moderate to intense physical activity may result in a false increase in albumin excretion. It is usually not necessary in clinical practice to measure islet cell antibodies, insulin autoantibodies, or anti-GAD antibodies in patients at the clinical onset of the disease. The presence of anti-GAD antibodies may identify a subgroup of patients with adult-onset diabetes who actually have a slowly evolving form of autoimmune type diabetes [latent autoimmune diabetes of adults (LADA)]. These tests, together with the intravenous glucose tolerance test, are used in research settings to determine which patients are at high risk for developing diabetes (35,36). The routine measurement of insulin levels or C-peptide is not recommended as a routine test in clinical practice. In selected instances, these measurements may indicate the more appropriate selection of therapy. In the older patient or in patients with high blood pressure or a family history of cardiac disease, a baseline electrocardiogram should be performed. If additional cardiovascular risk factors are present or if the patient is planning to begin an exercise program, consideration should be given to performing a cardiac stress test. The physician can order a chest x-ray film and other studies as needed. Patients with type 1 diabetes should also have a thyrotropin level measured on the first visit because of the frequent coexistence of immune-mediated thyroid disease.

EDUCATION

For the patient with a chronic disease, education is a lifelong process and an opportunity to improve self-care techniques and to recognize the onset of complications. Access to printed educational materials and to the services of skilled diabetes nurse educators will help facilitate this process. Access to diabetes educational materials on the Internet is increasing, and providing advice about the most reliable sites for information can be an important part of the educational process. Care must be taken not to overwhelm the patient with a surfeit of information. The onset of diabetes, either type 1 or type 2, is a difficult time emotionally for the patient, and the physician must be a source of encouragement as well as a provider of treatment. The family should participate in the educational process as much as possible. In adults with diabetes, involving the spouse in the educational process can be very rewarding; however, the patient must be encouraged to accept responsibility unless there are mitigating conditions. The initial goals of education are to help the family understand the basic pathophysiology of diabetes and the differences between the insulin-dependent and non-insulin-dependent forms.

Patients with type 1 diabetes and their families learn basic skills necessary for the patient's survival. Such necessary skills include (a) insulin administration; (b) SMBG and testing for urine glucose and ketones; (c) adjusting insulin dosage and food intake for exercise; and (d) sick-day care and prevention of ketoacidosis and treatment of hypoglycemia.

Patients with type 2 diabetes are taught similar skills, although the emphasis is very much on the nutritional program and weight control. It is important for patients to realize that the loss of even small amounts of weight (10 to 20 lb) can be very beneficial for overall glucose control. The ability to self-monitor blood glucose also is important in these patients. Exercise helps obese patients lose weight, and if they request more than a simple exercise prescription, it is appropriate for the physician to refer them to an exercise physiologist. Care should be taken in prescribing vigorous exercise programs to older patients, especially those with diabetic complications such as neuropathy or retinopathy. There is also the issue of coronary disease and silent ischemia. If a question arises about the presence of coronary artery disease and whether exercise can be undertaken with safety, the patient should be referred to a cardiologist for appropriate testing. A study in 1999 by Janand-Delenne et al. (37) of 203 patients with type 1 or type 2 diabetes noted that 20.9% of male patients with type 2 diabetes had silent myocardial ischemia with significant lesions on cardiac catheterization. The authors thus recommended routine screening for men with type 2 diabetes of more than 10 years' duration or even less for those with more than one cardiovascular risk factor. Once the patient is cleared for an exercise program, he or she should exercise three to four times a week for at least 30 minutes for the program to be of any benefit.

Those patients who will be receiving oral hypoglycemic therapy must become knowledgeable about the action of these medications and their adverse effects. They also must understand that many patients will fail to respond to these agents with time and will need insulin therapy. When medication is prescribed, it is essential not only to instruct patients on how to take the pills but also to counsel them on when to stop taking them to avoid potentially serious adverse side effects. This is very important, because the number of new medications for diabetes has increased rapidly and, for many of them, we do not know the long-term effects.

At the initial visit it also is appropriate to discuss briefly the rationale for glucose control and the potential for complications. At this time, the physician's interpretation and understanding of the current literature on the relationship between the control of diabetes and complications and familiarity with the standards of care set by the ADA will be extremely important. If the physician is vague and noncommittal in presenting this issue, the patient may assume that tight control is not necessary. By individualizing therapy and building on a solid foundation of basic skills acquired by the patient, the physician is in a unique position to guide the patient toward improved control.

CLINICAL GOALS

It is evident from the earlier discussion that the type of diabetes influences the form of therapy chosen. In the patient with newonset diabetes who has acutely decompensated type 1 diabetes or in the patient with previous diagnosed diabetes who is in poor control, the goals will include (a) elimination of ketosis; (b) elimination of symptoms of hyperglycemia such as polydipsia, polyuria, vaginitis, fatigue, and visual blurring; (c) restoration of normal blood chemistry values; (d) regaining of lost weight; and (e) restoration of sense of well-being. At this time, the emphasis for patients with previously diagnosed diabetes is on restoring those behaviors that will improve diabetes control and that will allow them to once again fully participate in their care. Glucose control at this time is directed toward getting patients to monitor their blood glucose, to improve adherence to prescribed medications, to become more confident at administering insulin, and to gather data on the patterns of glucose testing. This information becomes very important when one is working with the patient to plan the changes in insulin dosage and timing that will ensure that the glycemic goals set will be achieved.

Once the initial goals have been met, one can proceed to work on the plan necessary for long-term success. The general aim is the maintenance of health and well-being through control of the disease. It is important not to foster a lifestyle that is completely dominated by diabetes. Patients should control their diabetes and follow their desired lifestyle as much as possible. This is not always easy to accomplish, especially in patients with very unstable or "brittle" type 1 disease. A minority of patients are severely incapacitated, and care must be taken to set realistic goals and promote behavior that is not self-deprecating. For many patients and parents of young children, working with a counselor, psychologist, or psychiatrist can help alleviate feelings of guilt and depression.

As discussed in Chapter 42, for young children the goals are the maintenance of normal growth and development. Again, the lifestyle should be as close to normal as possible, without diabetes becoming the focal point of the family's existence. Ideally, children should be comfortable at school, participate in sports, and socialize with their peers without being made to feel different.

Marrying and having a family is important for young adults with diabetes. Helping women who wish to have children achieve a successful pregnancy is a very important aspect of diabetes care. Unless the physician has considerable experience in this area, it is preferable for the patient to be referred to a multidisciplinary team skilled in managing these high-risk pregnancies. However, all physicians should educate young women with diabetes on appropriate birth control methods and the importance of good glycemic control before conception.

Underlying all these goals is the desire to control the diabetes optimally so that long-term microvascular and macrovascular complications can be minimized. Since there currently is no way to predict who will develop long-term complications, it seems prudent to set a goal of optimal glycemic control, within the limits of safety, for all patients.

Before proceeding with therapy, it is useful for the physician to discuss with patients the different levels of success that may be achieved in the treatment of diabetes. In general, the goals of therapy can be referred to as minimal, average, and intensive. The goals as defined by the ADA (38) follow.

Minimal goals

- 1. HbA_{1c}, 11% to 13%; or total glycosylated hemoglobin (HbA₁), 13.0% to 15.0%
- 2. Many SMBG values of higher than 300 mg/dL
- 3. Tests for urinary glucose almost always positive
- 4. Intermittent, spontaneous ketonuria

Average goals

- 1. HbA_{1c}, 8% to 9.0%; or HbA₁, 10% to 11.0%
- 2. Premeal SMBG of 160 to 200 mg/dL
- 3. Tests for urinary glucose intermittently positive
- 4. Rare ketonuria

Intensive goals

- 1. HBA_{1c}, 6.0% to 7.0%; or HbA₁, 7% to 9%
- 2. Premeal SMBG of 70 to 120 mg/dL and postmeal SMBG of less than 180 mg/dL
- 3. Tests for urinary glucose essentially never positive
- 4. No ketonuria

In the most recent standards of glycemic control (38a), the ADA recommends an HbA_{1c} of less than 7%, a preprandial plasma glucose level of 90 to 130 mg/dL, and a postprandial plasma glucose level of less than 180 mg/dL.

Assessment of the level of diabetes control is best accomplished by measuring biochemical parameters. Clinical indexes such as body weight, frequency of polyuria, polydipsia, number of hypoglycemic reactions, fatigue, and sense of well-being are important clinical parameters but can be misleading about the overall level of control. It is true that patients with very poor control often can be identified easily by their symptoms; however, patients whose fasting glucose levels are 140 to 180 mg/dL and postprandial glucose levels are 180 to 240 mg/dL can feel quite well and present a false clinical picture of satisfactory diabetes control. In the past, daily urinary glucose measurements and random office glucose tests were relied on. However, the accuracy of urine testing can suffer in the presence of a high renal threshold, renal disease, or bladder neuropathy, and these limitations are not eliminated by the use of a double-voided urine specimen. Testing for the presence of ketones is still best accomplished with a urine sample.

During the last two decades, general availability of two innovations has revolutionized our approach to therapy. The first of these was SMBG (39), and the second was the development of reliable assays for glycosylated hemoglobin.

Self-Monitoring of Blood Glucose

Since its development, SMBG has developed into a sophisticated monitoring system. A variety of glucose-monitoring devices are now available that give a digital readout of the blood glucose concentration. The devices continue to be improved, and the time required for the test to be completed is now as short as 5 seconds. In addition, the size of the blood samples required has decreased, and many meters use a direct activation system. Some of the newest meters allow blood sampling both from the finger and from the forearm, thereby reducing the overuse and callousing of the fingers. These devices appear accurate enough for routine use by patients. For convenience, mechanical lancet devices are available for obtaining blood. Some of the newer glucose monitors include computerized memory to record the blood glucose levels, and some can be used in conjunction with more elaborate personal computers. Special machines are available for visually impaired patients. One concern about SMBG is the accuracy of the recordings as compared with those obtained in the laboratories of large clinics or research settings that use more sophisticated instruments. The patient may encounter many problems with SMBG in everyday use, even after receiving careful instruction on the technique by a diabetes nurse educator. One such difficulty involves the patient's ability to obtain a drop of blood, place it accurately on the reagent strip, and time the monitor carefully. Newer monitors that do not require wiping or timing and that allow the use of very small amounts of blood can help minimize these errors. A study performed by Jovanovic-Peterson et al. (40), in which four meter systems were compared, demonstrated the least variance from the control system (a glucose autoanalyzer) with a "no-wipe" system. Use of this system, which eliminated the need for blood removal and timing, greatly decreased the variability in test results.

For SMBG to be effective, its use must be accompanied by an educational program that helps the patient understand the factors affecting any particular blood glucose level and that provides appropriate options for corrections or adjustments. This knowledge is particularly necessary for patients involved in intensive insulin treatment programs.

There has been some discussion about the value of routine SMBG in patients with type 2 diabetes who are using diet or oral agents for control (41). Although these patients rarely will make treatment changes on the basis of information from SMBG, it can reinforce dietary principles and reveal the benefits of exercise and medication. Patients with type 2 diabetes who are receiving insulin should definitely use SMBG. Hypo-glycemia occurs both in patients being treated with sulforyl-

urea drugs and those receiving insulin; in this setting SMBG can confirm a low glucose level and may help the healthcare provider adjust therapy on a more timely basis. The frequency of monitoring can easily be adjusted to the individual patient's needs and circumstances. SMBG is therefore an extremely valuable tool for daily diabetes management. The recent introduction of a subcutaneous continuous glucose-sensing monitor that can obtain a 3-day profile of blood glucose levels (240 readings) can be a very useful tool in selected patients. Such data can be very important in assessing the dose of preprandial insulin, in identifying unrecognized hypoglycemia, and in revealing the dawn effect. Rapid advances in new glucose monitoring systems are expected over the next few years.

Glycosylated Hemoglobin Assays

In the last decade a number of studies on glucose control and diabetic complications have been completed, and all use HbA_{1c} as a surrogate marker for risk. The standards of care of the ADA were revised based on the fasting blood glucose level as well as on the HbA_{1c} from these studies. Currently, laboratories can measure either the total glycosylated hemoglobin or the A_{1c} fraction. The latter is the test used in the large outcome studies. However, the assays have not been standardized, and because commercial laboratories use different methods, the reference ranges vary, making it difficult for the clinician to use the results if they vary constantly. Clinicians should use the same laboratory to measure A_{1c} in the same patient over time.

In normoglycemic subjects, a carbohydrate moiety is attached to a small proportion of hemoglobin A, thus creating what is called *glycosylated* or *glycated* hemoglobin (42). The glycosylated hemoglobin can be separated into three distinct fractions, which are designated A_{1a} , A_{1b} , and A_{1c} . Because of electrophoretic behavior of these minor hemoglobins, they are referred to as *fast hemoglobin*. The A_{1c} fraction is the most reactive site of the *N*-valine terminal of the B-chain, which accounts for 60% of the bound glucose.

In conditions of sustained hyperglycemia, such as in diabetes mellitus, the proportion of hemoglobin that is glycosylated increases substantially (43). This glycosylation is the result of posttranslational modification of hemoglobin A molecules; the binding of glucose is a nonenzymatic process that occurs continuously during the life of the red blood cell. Thus, the amount of glycosylated hemoglobin reflects the glycemic control of a patient during the 6- to 8-week period before the blood sample was obtained, given the average life span of a red blood cell of 120 days (44). The amount of glycosylated hemoglobin correlates well with fasting and postprandial blood glucose levels. Currently, the glycosylated hemoglobin can be measured by ion-exchange high-performance liquid chromatography (HPLC), affinity chromatography, and immunologic methods. In the DCCT study, an ion-exchange HPLC method was used, and data from this study have been adopted as the reference standard for assessing glucose control.

A recent study by Schnedl et al. (45) noted that there are more than 700 known variants of hemoglobin that may affect the currently used assays for glycosylated hemoglobin. They evaluated the effect of the following hemoglobin variants: Hb Graz, Hb Sherwood Forest, Hb O Padova, Hb D, and Hb S. They noted that the HPLC boronate affinity assay lacked the resolution necessary to separate out the variants and that the immunoassays resulted in falsely low levels of Hb Graz. It is therefore recommended that laboratories establish and validate assays for the local population to make allowances for any hemoglobin variants. The glycosylated hemoglobin assay is presently one of the most widely applied tests in the management of diabetes. It is useful for the assessment of glycemic control in patients with type 1 diabetes and in patients with type 2 diabetes.

Glycosylated hemoglobin values must be assessed with caution in patients with unstable diabetes. Levels of blood sugar in these patients fluctuate from very low to very high on an almost daily basis, a situation that can lead to unwanted symptoms of hyperglycemia and dangerous episodes of hypoglycemia (38). A study by Brewer et al. (46) suggested that using a pie-shaped graph of SMBG data with defined target-range parameters can aid patients and their families attain the desired HbA_{1c} goals. The authors set the target range for SMBG values for different times of the day and then determined the number of values that needed to be within or above that range to achieve the desired HbA_{1c}. For young adults 17 to 35 years of age using a target range of 70 to 150 mg/dl, at least 38% of the values needed to be in the target range and no more than 48% above the range to achieve an HbA_{1c} of less than 8%. The assay of glycosylated hemoglobin should be done every 3 to 4 months, with the goal of adjusting therapy to obtain the lowest value that does not place patients at undue risk for hypoglycemic reactions. In patients who have reached a goal and are very stable, the test can be done every 6 months. However, it is important that the information obtained from the test be communicated to the patient to use to improve adherence to the prescribed treatment plan. At present the HbA_{1c} is the best surrogate marker we have for setting goals of treatment. Efforts are under way to standardize the procedure for measuring glycosylated hemoglobin. Ultimately, this would result in a certification process for manufacturers and thus ensure standardization of the results used by the healthcare professional in setting glucose control goals for their patients.

INITIATION OF THERAPY

For most adult patients, initiation of treatment is safely accomplished in the outpatient setting. Very young children and patients with diabetic ketoacidosis or severe, uncontrolled diabetes usually require hospitalization. Although the decision to use insulin usually is made by the physician, it is extremely important to explain the rationale to patients and to include them in the decision process. Many have an understandable fear of injections and often regard this therapy as an indication of the presence of a more severe form of the disease. Insulin therapy needs to be presented as any other treatment option, and patients should be made to understand that one, two, or three injections per day may be needed, depending on their response. The physician also should review the issue of control and complications and develop initial goals with the patient.

At the Joslin Clinic, the decision to start insulin therapy is followed by a referral to a diabetes nurse educator, who will instruct the patient or a family member on the techniques that will be required. Patients will administer their first injection at this time under supervision. This also provides an opportunity to teach patients about the types of insulin available and their characteristic peaks and durations of activity and to review strategies for dealing with hypoglycemia and hyperglycemia. The present availability of very-fast-acting human insulin analogues, as well as a nonpeaking basal human insulin analogue, has increased the need to emphasize to patients the importance of coordinating the timing of meals and insulin injection according to the type of insulin used. The techniques for mixing regular with intermediate-acting insulins may be reviewed if the physician believes that these are appropriate insulin formulations for a specific patient. Premixed insulin [70% neutral protamine Hagedorn (NPH) and 30% crystalline zinc insulin or 75% neutral protamine lispro (NPL) and 25% lispro] can be used initially in patients who may not be able to master the mixing of insulins. This simplifies the treatment program, especially when patients have problems understanding and performing the mixing maneuvers. Furthermore, these premixed insulins are now available in prefilled syringes with a simple dose-dialing mechanism. In many cases, limitations in mixing insulins are due to problems such as cataracts, degenerative joint disease, previous cerebrovascular accidents, or severe neuropathy.

Most new patients who require insulin will receive human insulin of recombinant DNA origin. Allergy and lipoatrophy are uncommon with human insulins. Beef insulin and mixed beef–pork insulin should be avoided unless there are specific indications for their use or if human insulin is not available. These latter insulins are now being phased out in the United States. Patients also are instructed on SMBG at this time and are asked to maintain close contact with the nurse educator, who in turn reviews adjustments in insulin therapy and the patient's progress with the physician. In most patients, the blood glucose levels can be expected to be brought under control over a 4- to 6-week period. The patient often is seen several times within this interval so that the physician can monitor progress, modify therapy, and review any interim problems or concerns.

Most patients are not started on an intensive management program at this time, as it is necessary to allow the patient to adjust to the emotional and lifestyle changes that follow a diagnosis of diabetes. Intensive therapy with multiple daily injections or continuous subcutaneous insulin infusion is used for women who plan a pregnancy, patients who cannot control their glucose levels by conventional therapies, or patients whose lifestyles or complications, especially hypoglycemic unawareness, demand the greater flexibility and control that intensive programs offer (47).

Patients with known diabetes in poor control or with complications of diabetes will undergo a similar evaluation and physical examination. Attention is focused here on the patient's general approach to the disease, with a particular focus on the patient's acceptance of the disease and its treatment requirements. The Joslin Clinic offers an outpatient program called "DO IT," in which patients are seen by a team over a period of three and a half days. This program allows a comprehensive review of the patient's problems and for these problems to be addressed on an individual basis. This program has become necessary because, with the changing healthcare-insurance environment, the old inpatient education programs are no longer available in many institutions. Many patients have an overwhelming fear of hypoglycemia. Some will deliberately avoid using rapid-acting insulin or will omit their evening injections, which predictably results in hyperglycemia. Others will overcompensate and treat any symptoms as a sign of potential hypoglycemia and some will start to monitor glucose levels with excessive frequency in an effort to discover lower values in the hope of avoiding severe hypoglycemic reactions. It is important to review the nutritional programs, exercise habits, alcohol intake, and psychosocial status of these patients. Even some patients with diabetes of long duration do not appropriately time their insulin injection to their ingestion of calories. Also, some patients make the mistake of regularly injecting insulin at hypertrophied sites, with resultant unpredictability of insulin absorption. In general, no acute changes in the insulin program are made at an initial visit, but the patient frequently is asked to monitor blood glucose three to four times a day for the next month, with the focus being on the nutritional program. Changes of insulin therapy are made by telephone or at future visits. Patients with major psychological problems are referred to a psychologist or psychiatrist. Unless these issues are addressed, diabetes control will continue to be a problem.

Some patients will require hospitalization. At the hospital, the focus of the treatment will be education and close monitoring to identify potential problems such as nocturnal hypoglycemia with rebound hyperglycemia, hypoglycemic unawareness, or inherently unstable diabetes. Even though the present economic climate is making it more difficult to hospitalize these patients, there is no way of satisfactorily addressing some of these problems in the outpatient setting. If the patient is hospitalized, it is important to attempt to reproduce the patient's normal lifestyle as closely as possible, including the timing and content of meals and exercise. Complicated diabetes requires individualized therapy that is both complex and time-consuming. For appropriate individualized care to be provided for patients, specific issues that may interfere with optimal control must be identified and addressed carefully and sympathetically. Solutions that offer the patient the greatest opportunity for a successful outcome should be sought in consultation with the patient and the patient's family. Very often individuals with unstable glucose control will need to have their glycemic goals changed to avoid dangerous hypoglycemia, despite earlier encouragement to maintain "tight control."

Patients with type 2 diabetes may require insulin when they are first seen, particularly if they are very symptomatic and have lost weight. In some instances, insulin can be discontinued when control is achieved and adherence to diet has taken effect (48). However, many patients will require insulin indefinitely; this becomes obvious when they become ketonuric and hyperglycemic with a reduction in insulin dose.

The basis of therapy in type 2 diabetes is to promote lifestyle changes with a nutritional program designed to reduce calories and encourage weight loss. An exercise program is an essential part of any effort to lose weight. Glycemic control can often be improved by caloric restriction alone, even before significant weight loss occurs. At the same time, it is also important to pay close attention to the risk factors for macrovascular disease. This means controlling lipids and hypertension and counseling on smoking cessation and the value of glucose control. Patients with type 2 diabetes also are taught SMBG, and the frequency of testing is individualized. SMBG is always the preferred method of glucose monitoring, with urine testing being used only in special situations.

The decision to use oral antidiabetic therapies is generally made after a trial of nutritional therapy unless the initial random glucose level is higher than 350 mg/dL. In general, a 4- to 12-week trial period of diet and lifestyle modification is reasonable, and if the fasting glucose concentration remains higher than 140 mg/dL or postprandial values are higher than 200 mg/dL, treatment with oral pharmacologic agents is initiated. Much has changed in this area since the last edition of this textbook. The last 5 years have seen the introduction not only of new sulfonylureas but also of new nonsulfonylurea insulin secretagogues. The latter drugs are often more rapid acting than the sulfonylureas and may be very well suited in treating postprandial hyperglycemia. The biguanide metformin, which has been available in many parts of the world for decades, was introduced into the United States relatively recently. The α -glucosidase inhibitors offer another option for controlling blood glucose levels, especially after meals. A totally new class of oral medication, the thiozolidinediones, also is available. Drugs in this class are novel insulin-sensitizing agents that work through specific nuclear receptors.

The physician now is presented with a number of choices and tries clinically to match the presumed underlying abnormality in the individual patient to a particular pharmacologic approach. Because type 2 diabetes involves a dual defect, the early use of combination therapy may be very advantageous. Customarily, the patient will start with a sulfonylurea or an insulin sensitizer. It is very important for the healthcare provider to be aware of the contraindications to the use of each drug as well the monitoring requirements to avoid serious adverse reactions. Failure of control with a single drug will result in the use of a combination regimen that can take advantage of the different mechanisms of action. Substitution of drugs from one class to another is rarely successful; however, the addition of a drug from another class often improves glucose control.

The recently completed UKPDS demonstrated that many of the oral monotherapies will fail to control the blood glucose levels for longer than 5 years (3). Much of the failure is due to the progression of the β -cell defect, with continued reduction in insulin production. Some patients who fail to obtain control with the maximal dose of oral medication may benefit from the combined use of insulin and oral medication. Usually a bedtime dose of intermediate-acting insulin or a basal insulin analogue (48a) is given, with the oral drug being continued (49). If the patient has high blood glucose levels following supper, a mixture of a short-acting and an intermediate-acting insulin can be given before supper. It is often useful to use a premixed insulin (70/30 human insulin mixture or 75/25 lispro mixture) in patients who have difficulty with mixing or adjusting insulin dose. Several studies of combination therapy have been completed. Generally, patients who have residual endogenous insulin secretion respond best, although patients' responses vary greatly and treatments must be individualized (48).

For every patient, diabetes management must include a careful nutritional assessment and the implementation of a *realistic* dietary program. The goal of nutritional therapy in type 2 diabetes is the control of blood glucose levels, normalization of lipid levels, and maintenance of ideal body weight. For young children with diabetes, the goal should be the maintenance of normal growth and development, as well as of a reasonable body weight.

In general, the dietitian will prescribe a meal plan based on the individual patient's type of diabetes and mode of treatment. Patients receiving exogenous insulin must pay particular attention to the timing of meals and snacks to prevent undue fluctuation of the blood glucose levels. The meal plan is individualized with respect to weight goals, personal food preferences, and exercise habits. Many obese patients with diabetes may require special weight-loss programs and behavior modification therapy to maintain weight loss. Unfortunately, most patients do not succeed in their efforts to lose weight and to maintain weight loss for prolonged periods.

Diet therapy often is referred to as the cornerstone of treatment, particularly in type 2 diabetes. For the patient to benefit maximally from this aspect of patient management, a team approach, which includes the services of a skilled registered dietitian, is recommended. Although these skills are not always available in physician's offices, they are offered in local community hospitals and by some dietitians in private practice. A detailed discussion on this component of treatment is presented in Chapter 36 on nutritional therapy.

Exercise plays an important role in diabetes management. For patients with type 1 diabetes, exercise should not be thought of as the major way of improving glucose control but rather as part of the overall approach to maintaining a healthy lifestyle. Physical activity can benefit the patient by lowering the blood glucose level if overall control is good. However, care must be taken to instruct the patient on the possibility of physical exercise provoking hypoglycemic reactions or worsening control when undertaken in the presence of higher blood glucose levels and ketonuria. Furthermore, patients with the com-

plications of retinopathy and neuropathy can place themselves in jeopardy with excessive exercise.

In general, patients who are free of complications can engage in any type of exercise. Certain activities, such as scuba diving, have to be assessed in light of the certification requirements issued by appropriate organizations. Patients often may benefit from a consultation with an exercise physiologist. In patients with type 2 diabetes, an individualized exercise program should be part of the overall treatment plan. Exercise helps promote weight loss, optimize glycemic control, and reduce cardiovascular risk. These patients need to be screened for early neuropathy or peripheral vascular disease before they start an exercise program. Silent ischemia is more common in patients with diabetes than in the general population, and appropriate patients should have a stress test before starting the exercise program. Routine screening of men with type 2 diabetes of longer than 10 years' duration or less if they have more than one cardiovascular risk factor is recommended because of the high prevalence of myocardial ischemia with significant lesions among men with type 2 diabetes (37). The program should be done three to four times a week to be effective, with appropriate warm-ups, setting target exercise levels with monitoring of pulse rate and cooling-down time. A further discussion of this important area appears in the editorial by Nesto (50) in the issue of *Diabetes Care* that published the above study [reference (37)].

FOLLOW-UP

A critical part of diabetes management is regular follow-up of patients. This is based on the goals established with the patient in the initial management plan. At each visit thereafter, the patient's progress is reviewed and ongoing problems are addressed. The frequency of visits depends on the individual patient, type of diabetes, goals of control, and other medical conditions. Patients starting insulin therapy need to be seen frequently initially, but once their condition has stabilized, they can be seen three to four times a year. In addition, patients are encouraged to maintain telephone contact with the other team members. Some patients with type 2 diabetes need to be seen only every 6 months.

As part of this follow-up process, an interim history is obtained, results of glucose monitoring are reviewed, and new problems or illnesses that affect diabetes control are addressed.

A comprehensive physical examination is done annually. At interim visits, previously abnormal findings are reevaluated and height, weight, and blood pressure are determined. For younger patients, an assessment of sexual maturation should be done. A complete, dilated eye examination by an ophthalmologist should be performed annually in all patients older than 30 years and in patients 12 to 30 years old who have had diabetes for more than 5 years.

A test for glycosylated hemoglobin should be done at least quarterly in patients with type 1 diabetes and semiannually in those with type 2 diabetes. The patient with adult-onset diabetes also may benefit from having either a fasting or postprandial glucose level checked as a means of judging overall glycemic control. A determination of fasting levels of triglycerides, cholesterol, and high-density lipoprotein (HDL) cholesterol should be performed annually and more often in patients with dyslipidemia. Urinalysis done at least yearly is useful. After 5 years of diabetes, patients should be tested for microalbuminuria yearly. If proteinuria is present, the patient's creatinine and blood urea nitrogen levels should be closely monitored; in addition, aggressive antihypertensive therapy and protein restriction should be considered.

At each visit the overall management plan, including the nutritional program and the exercise plan, is reviewed and modified as required. In addition, the overall emotional status of the patient is reviewed. This type of comprehensive care is extremely important for patients with a chronic, life-long disease such as diabetes. This chapter has reviewed the general principles of management of diabetes. Many of the details will be found in other chapters in this textbook. Since the last edition there have been many important advances in the understanding of the pathophysiology and treatment of diabetes. New diagnostic criteria have been developed, and new goals of treatment have been defined. Many studies demonstrating the value not only of glucose control but also of risk factor reduction and cardiovascular disease have been published and incorporated into the routine approach to diabetes management. In addition, therapeutic choices have increased greatly, and therapy can now be based on the underlying pathophysiologic mechanisms of disease. The primary goal in treating patients with diabetes is to help them avoid short-term problems and long-term complications. A recent study of adults with type 1 or type 2 diabetes investigated cognitive representations of illness, self-regulation of diabetes, quality-of-life, and behavioral factors. The authors found that individuals' understanding of diabetes and their perceptions of control over the disease were the most important predictors of outcome (51). This reinforces the need to continue to provide ongoing selfeducation for patients and to provide them with the evidence, now available, that control of diabetes is possible and that complications can be avoided.

To the practicing physician, diabetes offers the challenge of providing optimal patient care at every visit. It allows the physician the opportunity and privilege to practice not only the science but also the art of medicine.

CONCLUSION 607

This building given by thousands of patients and their friends provides an opportunity for many to control their diabetes by methods of teaching hitherto available to the privileged few.

Chiseled in stone on the front of the Joslin Clinic Building, erected in 1955, the above inscription reflected Elliott P. Joslin's conviction that education was not just a part of diabetes treatment, it was the treatment. Dr. Joslin's concern about educating both patients with diabetes and their families began more than 100 years ago, when such instruction was considered by many to be a luxury. Over the last two decades, the importance of education has become more widely recognized. As the World Health Organization commented in 1980, "Education is a cornerstone of diabetic therapy and vital to the integration of the diabetic into society" (1).

This growing recognition of the vital role of education in the treatment of diabetes led to the development and periodic updating of the National Standards for Diabetes Education by the National Diabetes Advisory Board in 1983 (2–4). This was followed by the development of a recognition program for diabetes education by the American Diabetes Association (ADA) (5) and of a certification program for diabetes educators by the American Association of Diabetes Educators (6) now administered by a separate organization, the National Certification Board for Diabetes Educators.

Progress in making educational programs available to everyone with diabetes has been slowed by the reluctance of thirdparty payers to reimburse for educational services in the United States (7). This is now changing. In 2001, the Center for Medicare and Medicaid Services (CMS) began paying for Medicare patients to attend group diabetes education programs and for medical nutrition therapy visits. Many private insurers followed suit. However, diabetes education programs are still at risk, with many closing their doors because of poor reimbursement. One nationwide study found that more than 60% of people with diabetes have received little or no diabetes education (8,9). Unfortunately, little evidence suggests that this is changing. Despite the obstacles, however, healthcare professionals who treat people with diabetes continue their commitment to patient education through the development of new programs and research into more effective methods of teaching the principles and practice of diabetes self-care.

WHY IS SELF-MANAGEMENT EDUCATION IMPORTANT IN THE TREATMENT OF DIABETES?

The importance of improved glycemic control in delaying the onset and progression of serious microvascular complications is now clear (10,11). Treatment of diabetes leading to improved control is a 24-hour-a-day activity and often includes important changes in lifestyle, most of which persons with diabetes must provide for themselves on a daily basis. These efforts require careful balancing of various lifestyle functions and activities that are integral parts of the daily routine. Thus, the goal of diabetes self-management education is not simply to increase knowledge about diabetes, but rather to support individuals with diabetes and their families in their efforts to incorporate diabetes treatment into their lifestyles. Of course, the more that people with diabetes understand how to make these required changes and what the rationale is behind them, the more successful they will be in their diabetes self-management.

Diabetes self-management education provides many benefits. Education allows people with diabetes to take control of their condition, integrating the daily routines of self-monitoring and discipline into their lifestyle rather than permitting this condition to overwhelm them and control their lives. Education in diabetes self-management trains people to take the necessary actions to improve their metabolic control, which helps maintain health and well-being and reduces the risk of diabetic complications. The well-educated person with diabetes may also decrease the costs related to the condition—both the direct cost of medical care and the indirect costs related to lost income or productivity (12).

Diabetes education is both an art and a fledging science. Only within these past 20 years has research begun to examine the role and effectiveness of education in diabetes self-management, and future research is needed to further evaluate and clarify optimal methods for this educational process (4). In addition, in this litigious age, as the value of education gains credence, the provision of proper education to people with diabetes by a healthcare provider may help reduce the risk of malpractice suits.

The evolution of the scientific component of diabetes education has traveled a long and somewhat bumpy road. Initial studies examining diabetes education were difficult to design, perform, and evaluate, and when they were completed, their validity was often the subject of controversy among healthcare professionals. One reason for this disagreement was the assumption by researchers studying diabetes education that it was an integral component of care. Thus, the usual study design contrasted intensive education with less-intensive education rather than with no education or a "placebo" form of education.

Some small studies comparing these two forms of education showed no differences in glycemic control between groups. For example, a trial comparing minimal versus intensive education showed similar improvement in the two groups (13). Good control was related to the duration of school education, absence of anxiety, and quality of control and degree of self-confidence upon entry into the study. A similar study, with admitted socioeconomic bias affecting some of these factors, showed that education led to improvements in knowledge and behavior but not in improvements in metabolic control (14). However, during the last two decades, many randomized clinical trials and smaller studies have examined the efficacy of diabetes education (4), and several well-done meta-analyses (15-19) that evaluated the quality of education summarized the results of research in diabetes education. These meta-analyses, along with more recent trials (20–24), provide convincing evidence that diabetes education is effective in supporting patients' efforts to improve and/or maintain physiologic and quality-of-life outcomes.

Currently, research in diabetes education has moved beyond the question of whether it is important and is beginning to focus on the science of education, addressing questions that clarify educational outcomes, determine which groups of patients respond best to which form of education, and evaluate which are the most efficient and cost-effective methods of providing education (25–28). Diabetes education already encompasses the family and social support; researchers are now beginning to consider public-health aspects of diabetes education at the community and possibly the national level (29).

Education Improves Well-Being and Quality of Life

People with diabetes must make what some perceive as being overwhelming lifestyle changes, yet their failure to accept these changes may result in inadequate diabetes control. Emotions related to the psychological burden of diabetes, such as anxiety, depression, and poor self-confidence, have been shown to be associated with poor control (13, 30–33). Thus, a properly designed education program not only should present facts but also should address the emotional responses to diabetes. Education improves self-care practices (16,17,22,34) but a mere increase in knowledge and skills does not guarantee an improvement in metabolic parameters (14). Several psychological factors, having been implicated as barriers to improved glycemic control, play an important role in translation of knowledge and skills into the desired metabolic results. These factors include emotion-based coping styles (35,36), diabetes-related emotional distress (33), and lack of readiness to change (37). For individuals to be willing and able to make all the necessary lifestyle changes, they must have knowledge and skills *plus* a positive emotional outlook about their diabetes, believing that the changes they make will lead to better health.

An educational program that demonstrably improves parameters of emotional well-being in addition to addressing self-care practices has been shown to lead to improved metabolic control that was sustained over 6 months (38,39). The authors of these studies suggested that emotional well-being itself may contribute to improved self-care (38). Others contend that, for many patients, education about diabetes and self-care alone enhances emotional well-being (40-42), which further boosts self-care ability. In the first randomized controlled trial to demonstrate an additive effect of psychological intervention on glycemic control, Grey and her colleagues (43,44) demonstrated that adolescents who received training in coping skills along with methods of intensive diabetes treatment improved glycemic control and self-care behaviors more than did adolescents who received only intensive treatment instruction. However, whether emotional well-being leads to improvement in self-care or vice versa has not been clearly determined. More research is needed to clarify the associations among education, improved self-care, and improved emotional outlook.

Education Improves Self-Care Management

Even after one accepts that emotional well-being is a crucial component of the educational intervention, the complexity of the diabetes treatment regimen itself often leads to confusion and misunderstanding that interferes with the ability to manage one's diabetes. Diabetes education can play an important role in clarifying the treatment regimen, reinforcing the skills necessary to successfully manage diabetes, and supporting efforts to integrate self-management behaviors into one's life. Several meta-analyses and clinical trials examining the effects of diabetes education found that education leads to improved self-care behaviors as well as to improved knowledge, and metabolic and psychological outcomes (15-17,19,22,34,38,45). Rubin and his colleagues (45) noted a differential effect among self-care behaviors: behaviors requiring changes in lifestyle such as in diet and exercise were more difficult to maintain over time than were less-demanding behaviors such as self-monitoring of blood glucose (SMBG).

Education Improves Metabolic Control

The Diabetes Control and Complications Trial (DCCT) and the United Kingdom Prospective Diabetes Study (UKPDS) established the principle that improvement in glycemic control is beneficial and that maintaining glucose levels as near to normal as possible results in reduction in the risk of development and progression of serious microvascular complications. The importance of education to the training of patients with diabetes about their treatment and to supporting their self-management efforts to improve their glycemic control became apparent early during the 9-year course of the DCCT (46,47). Moreover, the importance of a multidisciplinary team consisting of at least one healthcare practitioner/educator such as a registered nurse or nutritionist was definitively documented (46–48). The roles of other team members, such as the podiatrist, psychologist, ophthalmologist, pharmacist, exercise physiologist, among others, are now being recognized as well (12,20–22,38,39,49–51).

Although initial studies attempting to demonstrate that education improves diabetes control produced variable results, again it was through meta-analyses that examined the cumulative evidence that the conclusion can be drawn that diabetes education can result in a moderate to large effect on improving glycemic control (15–19). For glycemic control, the magnitude of this effect was particularly evident in studies that were completed after measurements of glycosylated hemoglobin (HbA_{1c}) came into widespread use (15). Traditional diabetes education also resulted in improved knowledge and self-care behaviors with a small effect on psychological outcomes (17). Padgett and coworkers (16) found that diet instruction had the largest effect size while relaxation training had the weakest.

Other studies also have underscored the importance of selecting the right outcome criteria for measurement. If the wrong outcomes are measured, education may not appear to be responsible for the desired improvements, both when looked at in relation to various outcomes other than metabolic control (52) and when examined over extended periods (34,53). For example, the Diabetes Education Study reported minimal differences between the education and control groups in measurements of their knowledge but found numerous, significant differences in their skills and self-care behaviors. Such studies suggest that adult learning theory holds true: Individuals tend to learn what is important to them and what they can relate to their own life experience (54). Not surprisingly, discrepancies may exist between what healthcare providers teach and what individuals with diabetes perceive as important. These studies also point out the difficulties of measuring the effects of education after a single educational intervention that focuses primarily on facts about diabetes rather than on behaviors and that does not include ongoing follow-up (55) or that measures outcomes in terms of selected metabolic parameters only. Such limited studies often fail to detect all the potential long-term benefits of an ongoing educational experience (56). Others have made the important point that improved glycemic control may not be apparent unless other treatment factors, such as the treatment regimen and individual metabolism, are taken into account (57).

Although the studies cited suggest that education does improve metabolic control, most studies do not examine education in isolation. In an extensive review of the diabetes education literature, Clement (58) emphasized that negative studies did not examine diabetes education that was integrated into medical treatment. Therefore, one must conclude that education alone does not improve metabolic control. This point was nicely demonstrated in a randomized controlled study of nurse case management that included a 12-hour education program. After 1 year, the combined medical/education case management approach led to a greater improvement in glycemic control as measured by HbA_{1c} of 1.1% as compared with the control group receiving the usual care (21). These data and the emphasis that the DCCT placed on education to help patients reach glycemic targets (46,48,59-61) support the suggestion that the maximal benefit of diabetes education is realized when education is integrated into diabetes care.

Education Enhances the Prevention and Early Detection of Complications

Evidence is now emerging that diabetes education plays an important role in the prevention and early detection of diabetes complications. In fact, the Revised National Standards for Diabetes Self-Management Education have included prevention, detection, and treatment of both acute and chronic complications among the ten content areas for diabetes education (4).

A case–control study of 886 subjects with long-term diabetic complications and 1,888 control subjects without complications found that, in addition to being male, older, and having type 1 or insulin-treated type 2 diabetes, patients who did not receive any kind of educational intervention were at increased risk of developing complications. Furthermore, self-management of insulin, a skill that is usually dependent on receiving diabetes education, had a protective effect on the risk of complications (62).

In a randomized control trial of 352 patients and four healthcare provider practice teams, Litzelman and her colleagues (23) found that patients with type 2 diabetes who were assigned to an educational intervention with patient, healthcare provider, and educational systems were less likely to have serious foot lesions and more likely to report appropriate self-care behaviors than were patients assigned to usual care. In addition, healthcare providers who received practice guidelines, informational flow sheets on foot-related risk factors, and who had reminder notices placed on their patients charts were more likely to examine patients' feet and to refer patients for podiatry appointments.

Education Decreases Costs of Care

While it is generally agreed that education can be a major factor in decreasing costs of hospitalization, not until this fact can be proven conclusively regarding diabetic patients will ample money be made available for the needed education.

This statement by Joslin's Dr. Leo Krall (63) opened the section in earlier editions of this text that discussed how education could decrease the cost of diabetes care. Finally, in this edition, the evidence is beginning to accrue that, indeed, Dr. Krall's wish for data may be coming true. However, the path to this conclusion has followed a difficult and convoluted route, and the conclusion has been slow to gain acceptance among many, particularly those responsible for paying the bills. In addition, as Krall pointed out at the Joslin symposium held at the 2000 International Diabetes Federation meetings, from a worldwide perspective, economic environments vary—not all of them resembling that of the United States.

Yet, spurred by the managed-care movement, cost-effectiveness and the impact on quality of life are now being measured, and slowly the recognition that diabetes education is a reasonable expense is beginning to gain acceptance. This trend is seeing a confluence of endpoints. Medical professionals are looking to improve parameters such as HbA_{1c} values or complication rates, assuming that the good stemming from improvements in these numbers is justification in and of itself. However, the people who pay the bills—the managed-care executives initially and, ultimately, the consumers of healthcare services—view parameters such as dollars and cents and, in particular, impact on quality of life for dollar spent to ensure that the benefits reaped by an intervention such as education warrant the expense.

Demonstrating that education is a cost worth bearing has been promulgated over the last few decades. However, during the 1990s, enough momentum seemed to have gathered for people to finally begin to accept this principle. Prior to that, a traditional endpoint was a reduction in hospitalizations, which may not necessarily reflect the entire picture in this new millennium in which outpatient medicine and pharmaceutical costs are a focus of the cost-conscious healthcare insurance executives. Nevertheless, hospitalizations are still costly and serve as a reasonable yardstick. To get a sense of the battle that has been waged, we should look back to 1981, at the dawn of the era of "intensive insulin therapy" heralded by the availability of SMBG and HbA_{1c} measurements. This quiet revolution in diabetes management gave us the tools to target normoglycemia more realistically and to monitor glucose patterns in a normal setting without the need for hospitalization, yet increasing the importance of self-care skills if these new tools were to be used to their optimal efficacy.

At that time, educational deficits were clearly a cause for increased costs of medical interventions. In 1981, Geller and Butler (64) judged that 27% of the hospital admissions for diabetes complications over a 1-year period were the result of educational deficits and that an additional 20% were due to a combination of educational, psychological, and socioeconomic deficits. In a 1985 edition of this textbook, Krall (63) recounted the classic, but not scientifically controlled, report of 100 patients surveyed who were admitted to the Joslin Diabetes Center with foot infections. Only 38% of these patients had received any diabetes education. The same year, Scott et al. (65) from New Zealand suggested that education lowers admission rates among patients with diabetes. Of a group of 902 insulinusing patients, 79 required hospitalization, of whom 11% had received education previously and 89% had not.

In a 1983 report from Maine (66), based on its experiences as one of the few states that at that time provided some reimbursement for diabetes education, 38.5% fewer people were hospitalized and 28.3% fewer hospitalizations were necessary among patients who had participated in an educational program. The experience in Rhode Island reported in 1985 by Fishbein (67) also demonstrated a reduction in the number of admissions after attendance in an outpatient education program.

However, these and other studies that have appeared over the years had seemingly not provided convincing proof that education does save money. Criticisms of various studies, exemplified by a review by Kaplan and Davis (68), typified the dilemma. Reviewing studies used by the ADA to support thirdparty payment for outpatient education and nutritional counseling (69), these authors identified various defects in study design such as deficiencies in the use of control groups, in patient randomization, in cost accounting, and in clearly demonstrating actual savings. They also pointed out that duration of hospital stay and rate of hospital admission can be affected by multiple factors influencing hospitalization practices that are unrelated to diabetes education or even to actual medical conditions.

The crux of the argument at that time was expressed succinctly by Anderson (70) in a reply to the Kaplan and Davis report (68), pointing out that patients appear to need education to follow their daily routine of diabetes self-care. As with the impact on medical parameters cited earlier, asking that an educational program *alone* results in reduction in cost without considering the other variables that affect such outcome measures is ascribing more power to educational intervention than is warranted.

However, during the 1990s we passed a significant milestone, as those who view healthcare in the aggregate, rather than one patient at a time, began to recognize that patient education was an important component of the multifactorial effort to achieve improvements in diabetes control and reductions in complications and thus achieve better outcomes. Studies such as the DCCT and UKPDS provided enough momentum to establish the economic value, albeit indirect, of patient education. Although the DCCT had already proven that intensive therapy reduces microvascular and neuropathic complications (7,71), the cost-effectiveness of intensive therapy itself was subsequently

demonstrated (72). Implicitly, patient education is central to establishing a successful intensive therapy program, and thus patient education contributes to a cost-effective outcome.

Concurrently, other studies examined the costs of care for patients with diabetes in the managed-care environment. In a health maintenance organization (HMO) in which 3.6% of the patients had diabetes, these patients accounted for more than three times their allotment of costs, or 11.9% of total healthcare delivery costs, attributable in significant part to long-term and short-term complications (73). This study suggests that reducing the occurrence of complications would generate savings, accomplished through disease management, which includes to a considerable degree, of course, patient education. Other studies further underscore these economic benefits of improving diabetes control and preventing complications (74–76), as well as the benefit of adding quality time to a person's life (77).

The ADA has participated in this argument for many years, strongly advocating proper support for patient education. Even before the DCCT results became available, the ADA stated that every patient has a right to accessible and affordable patienteducation services (78) and has issued a policy statement that "supports and encourages reimbursement for outpatient education and nutrition counseling that meet acceptable standards for persons with diabetes" (69). Again, in 1990, the ADA issued a policy statement (79) that noted "the omission of outpatient education as a benefit in many insurance and healthcare financing plans constitutes a major barrier to the availability and accessibility of these services" and supported "adequate reimbursement and payment for outpatient diabetes education services that meet accepted standards." Such lack of coverage may be the result of either the failure of insurance companies to include coverage in their policies or a choice made by employers not to include such coverage in the insurance benefits they offer their employees when arranging insurance benefits.

More recently, the ADA stated (80) that "self-management education is a critical part of the medical plan for people with diabetes, such that medical treatment of diabetes without systematic self-management education can be regarded as substandard and unethical care." The ADA suggests that such education will ultimately reduce costs.

Throughout this period, economic factors as well as technologic advances have exerted an increasing influence on the setting for and scope of diabetes patient education. The ability to perform SMBG has eliminated the need to hospitalize a person just to monitor multiple glucose levels throughout the day. Inpatient education programs are now restricted to people with medical conditions that cannot be adequately addressed in an outpatient setting and thus justify hospitalization; the shorter hospital stays now mandated limit the extent of material that can be taught (81). Thus, diabetes education must increasingly be delivered through outpatient programs (82).

Ironically, however, the evolution from inpatient to outpatient education has been negatively influenced by economic factors as well. Inpatient education frequently was provided as part of the "overhead" service covered by the cost of hospitalization. However, because education is often inadequately covered by insurance in many states, the cost of outpatient education is often borne directly by the patient. Thus, because inpatient education is restricted and outpatient education is unaffordable, all education may be unavailable for most patients.

Outpatient education does, however, have advantages over inpatient education. There is flexibility of timing of the sessions, extension of the educational experience over weeks or months, ability to educate in a normal life setting rather than in an artificial inpatient environment, and the opportunity for follow-up sessions. The trends of recognition of both the quality and the importance of outpatient education hopefully will continue, but until all people with diabetes can have some access to insurancesupported outpatient education, the full potential cannot be met.

In summary, we are finally reaching the point at which most people accept that patient education can improve diabetes control and decrease the risk of acute and chronic complications and thus is a significant component of an overall management plan. These results, in turn, can lead to reduced costs and improved quality of life. Patient education *alone* does not accomplish this, but patient education as part of a comprehensive management program does. Thus, the cost of educational services and the supplies that must accompany them, such as test strips and meters, are slowly being included in many coverage plans—not universally, but it is happening.

The following was written in the last edition of this text: "We hope that in the next edition of this textbook the report on the financing of diabetes education will be quite different!"

Well, it is! Maybe it should not be termed "quite" different, but it is different enough and definitely evolving enough in the right direction to be most encouraging!

Malpractice Protection

Sensitivity to the potential for malpractice lawsuits for alleged negligence has become part of the practice of medicine. This concern also extends to the act of conveying information about diabetes. Legal precedents in United States law exist that require healthcare providers to be sure their patients receive adequate education and that outline the potential liability for either not educating or poorly educating their patients (83).

In light of the progress during the last decades in demonstrating that improved control and avoidance of complications can be accomplished through education, the risk of potential lawsuits stemming from inadequate or improper education is theoretically significant. Although economic motivation pushes healthcare organizations to recognize the need to support patient education, the humanistic approach of the healthcare providers that leads to the recommendation for such education (with, we hope, some crossover motivation in the best of all worlds!), both groups may be further encouraged by the potential for liability of not doing so.

Therefore, it is prudent for healthcare professionals to ensure that their patients receive education of proper quality. Unless a program is known to meet established standards, programs recognized by the ADA or educators certified by the National Certification Board for Diabetes Educators are the most reliable sources of proper education. Healthcare professionals should encourage patients to attend such programs and document in the patient's record that they did so.

THE DIABETES EDUCATION PROGRAM

Diabetes self-management education is the process of providing people with diabetes with experiences that favorably influence their understandings, attitudes, and practices related to living well with diabetes (84). At its best, an educational program empowers those with diabetes to achieve optimal selfmanagement of their condition (85). A successful educational program does not occur by accident; it is carefully planned by the healthcare team and then executed by that team with the individual with diabetes as an integral part of the team. The most successful diabetes self-management education is individualized (37,61,86,87), is integrated into medical treatment, and addresses psychosocial and behavioral components of care (88,89). The goal of any educational program is to help patients with diabetes gain the knowledge and skills that enable them to care for themselves and to develop the attitudes that will enable them to make behavioral changes. A national task force representing organizations interested in diabetes (ADA, Veterans Administration, Centers for Disease Control, Indian Health Service, American Dietetic Association, American Association of Diabetes Educators, Diabetes Research and Training Centers) has recently revised the National Standards for Diabetes Education (4) (Table 35.1). These standards provide guidelines for the format of diabetes education and a clear outline of the content areas that should be addressed (4). The ADA provides an education recognition program that evaluates diabetes education according to the National Standards and certifies those programs that meet or exceed the standards.

The Educators

In the years after the discovery of insulin, Dr. Joslin was among the first to recognize that the responsibility of patient care lay mainly with the patients themselves. "The patient is his own nurse, doctor's assistant and chemist," he wrote in the first comprehensive guide to self-care, *A Diabetic Manual for the Mutual Use of Doctor and Patient*, in 1924 (90), shortly after the discovery of insulin. Recognizing the need for patient education, Joslin showed his nurses how to give insulin, calculate the diet, and balance insulin requirements with that diet. These nurses then visited patients in their homes throughout New England, sometimes staying with families for weeks, to teach patients and families to plan menus, prepare food, and administer several injections daily.

The role of the "teaching nurse" has since evolved and expanded and now includes other healthcare providers with special diabetes-related skills. Diabetes educators, as they are now called, include nurses, nutritionists, social workers, exercise physiologists, psychologists, pharmacists, and physicians. Their expertise in diabetes care and education may qualify them to take an examination to become Certified Diabetes Educators (CDEs) or Board-Certified Advanced Diabetes Managers (BC-ADM).

These diabetes educators form the basis of the team approach to diabetes education (91). Working together in both inpatient and outpatient settings, each member of the team provides the patient with specialized expert services. For example, nurses help patients master the skills necessary to inject insulin and monitor blood glucose levels and adapt these skills to their lifestyle, nutritionists work with patients to develop realistic meal plans, and psychologists and social workers focus on coping mechanisms. The person with diabetes and key family members are now recognized as important players in the team who must be involved in the educational program (92–94). This multifaceted team effort, which includes the patient and the physician, provides the most complete approach to diabetes education and care (12,20,22,39,50).

The Setting for Education

Education for diabetes care may be provided in a variety of settings, such as clinics, hospitals, education centers, a physician's office, or the patient's home (95). The program can be formalized and presented in a classroom setting or provided in a oneto-one fashion. It may be presented in a carefully planned educational session or may arise spontaneously from responses to questions asked during a routine office visit (96).

In educational sessions, the size of the groups may vary and the forms of interaction used may include, but not be limited to, discussion, lecture, and interactive learning activities (97–99). Innovative educational techniques, such as programs incorpo-

TABLE 35.1. National Standards for Diabetes Self-Management Education (DSME)

Standard 1. The DSME entity will have documentation of its organizational structure, mission statement, and goals and will recognize and support quality DSME as an integral component of diabetes care.

Standard 2. The DSME will determine its target population, assess educational needs, and identify the resources necessary to meet the self-management needs of the target population(s).

Standard 3. An established system (committee, governing board, advisory body) involving professional staff and other stake holders will participate annually in a planning and review process that includes data analysis and outcome measurements and addresses community concerns.

Standard 4. The DSME entity will designate a coordinator with academic and/or experiential preparation in program management and the care of individuals with chronic diseases. The coordinator will oversee the planning, implementation, and evaluation of the DSME entity.

Standard 5. DSME will involve the interaction of the individuals with diabetes with a multifaceted educational instructional team, which may include a behaviorist, exercise physiologist, ophthalmologist, optometrist, pharmacist, physician, podiatrist, registered dietitian, registered nurse, other health care professionals, and paraprofessionals. DSME instructors are collectively qualified to teach the content areas. The instructional team must consist of at least a registered dietitian and a registered nurse. Instructional staff must be certified diabetes educators or have recent didactic and experiential preparation in education and diabetes management.

Standard 6. The DSME instructors will obtain regular continuing education in the areas of diabetes management, behavioral interventions, teaching and learning skills, and consulting skills.

Standard 7. A written curriculum, with criteria for successful learning outcomes, shall be available. Assessed needs of the individual will determine which content areas listed below are delivered.

• Describing the diabetes disease process and treatment options

- Incorporating appropriate nutritional management
- Incorporating physical activity into lifestyle
- Using medications (if applicable) for therapeutic effectiveness
- Monitoring blood glucose and urine ketones (when appropriate), and using the results to improve control
- Preventing, detecting, and treating complications
- Preventing (through risk-reduction behavior), detecting, and treating chronic complications
- Goal setting to promote health and problem solving for daily living
- Integrating psychosocial adjustment to daily life

• Promoting preconception care, management during pregnancy, and gestational diabetes management (if applicable)

Standard 8. An individualized assessment, development of an educational plan, and periodic reassessment between participant and instructor(s) will direct the selection of appropriate educational materials and interventions.

Standard 9. There shall be documenting of the individual's assessment, educational plan, intervention, education, and follow-up in the permanent confidential education record. Documentation also will provide evidence of collaboration among instructional staff, providers, and referral sources.

Standard 10. The DSME entity will use a continuous quality improvement process to evaluate the effectiveness of the education experience provided and determine opportunities for improvement.

rating computers, the Internet, and other audiovisual media, can enhance the educational program (99–102).

Availability of staff, the needs of patients, the subject matter, and economic factors often dictate the choice of setting. For example, general information about the various kinds of insulin and their respective activity patterns might be presented in a group setting. However, the teaching of specific skills such as drawing insulin into the syringe is best carried out on an individual basis or in small groups that are no larger than six people. This small size provides the healthcare professional with the opportunity to help each patient individually learn the techniques necessary for carrying out these essential activities. Similarly, general information about monitoring glucose levels might be presented in a group setting, but the actual learning of the skill should take place in a setting in which every patient can benefit from the individual attention of the healthcare professional. However, we must also keep in mind that reimbursement guidelines often dictate the details of such education sessions and their structure.

In addition, as with many other "school" settings, the educational experience is not limited to formalized instructional sessions; much of diabetes education occurs through the interactions among patients that take place in diabetes treatment units and camp-type settings (103,104). Information and understanding gained through the sharing of personal experiences can help patients improve both self-management and coping skills in ways not possible with more formalized instruction.

An example of such a program is the Diabetes Outpatient Intensive Treatment (DO IT) program at Joslin Diabetes Center (Table 35.2). This behavior modification program has evolved from the historic Diabetes Treatment Unit, an inpatient program originally intended for diabetes education and treatment. Because of current reimbursement for this education, the DO IT program permits the same medical management, with accompanying education and group cohesiveness but on an outpatient basis. During this 3.5-day program, patients are evaluated by a physician, nurse, dietitian, exercise physiologist, and mental health professional. After the initial assessment, the remaining 3 days consist of medical care and education. Free time is also available for social interaction among patients. Follow-up shortly after completion of the program is recommended, both via telephone and office visits, to ensure that patients are able to apply what they have learned during the program to their everyday lives.

Since 1992, the Joslin's DO IT program has been a recognized education program as per ADA standards. One criterion necessary to achieve this recognition is to prove the effectiveness of the program as it relates both to clinical aspects of diabetes care and to the quality of life of these persons with diabetes. These outcomes data have shown an average decrease in HbA1c of levels of 1.5% over a 3- to 6-month period following the participation in the DO IT program. Attendees whose HbA1c levels were greater than 10% were shown to reduce the level by an average of 2.5% during the same time period. In a clinical survey conducted after the program, participants of the program reported a 38% improvement in their perception of their diabetes-related problems. In addition, program evaluation has shown a decrease in emergency department visits, hospitalizations, and lost time from work or school for patients after their participation in the DO IT program.

Who Should Be Educated

The National Standards for Diabetes Education recognizes that diabetes education is an integral component of diabetes care (4), and the ADA recommends education for all people with diabetes at the time of diagnosis and at regular intervals throughout their lifetime (5). These standards recognize the right of each person to understand the nature of his or her condition, to be given the tools to manage and control the condition, and to have this information updated routinely. Unfortunately, we are far short of that goal. However, in a survey of 2,318 persons with diabetes, 59% of those with type 1 diabetes, 49% of those with insulin-treated type 2 diabetes, and 24% of those with type 2 diabetes not treated with insulin had attended a class or program about diabetes at some time during the course of their illness (8). The challenge for the team is to gain access to the patient at regular intervals and to meet the needs of each patient through assessment, implementation, and evaluation.

Patient Assessment

Assessment of the patient's and family's readiness to learn is the first step in the educational process (37,105). Concurrent illnesses, new diagnosis of diabetes, or psychosocial problems may affect a patient's willingness or ability to learn. A patient who has just received a diagnosis of pancreatic carcinoma may not be ready to discuss insulin administration. Similarly, a patient recovering from surgery may be more interested in starting on solid food than learning self-monitoring techniques. The key to assessment is communication with the patient. If education starts when the patient is emotionally and experientially ready, there is a better chance of engaging him or her in the entire educational process (106).

The emotional response to diabetes can have an impact on the patient's ability to hear and absorb information. Denial may be the patient's first reaction to the diagnosis of diabetes and can impair his or her ability to learn (107). The healthcare provider can assist the patient by recognizing this response as denial, acknowledging that it may be a stage in the long process of adapting to a chronic illness, and supporting the patient's effort to cope with the disease. Involvement in support groups and individual therapy may help the patient move from denial to successful adaptation.

Assessment of knowledge, skills, and attitudes about diabetes is an ongoing process that starts with the initial chart review and interview. Many patients do not recall medical advice and some report never having received specific self-care recommendations (108-110). Assessment of the person's knowledge of his or her actual treatment prescription is as important for those with diabetes of long duration as for those with newly diagnosed diabetes. Use of a conversational style, rather than a question-and-answer session, helps to establish rapport and to give the healthcare professional some idea of the patient's lifestyle (111). The healthcare professional should learn to listen to the patient, to be sympathetic and understanding, and to accept that the patient's priorities may not be the same as those of the healthcare team. It is important to remember that diabetes is an intrusion into daily life, that most people will still have significant gaps in their knowledge about diabetes even after having the condition for 20 years, and that it is ultimately the patient who makes the final decisions about how he or she will approach the disease (94,112). Recognizing and accepting these realities will allow the healthcare professional to set reasonable, achievable, and mutually acceptable goals. The initial assessment should be clearly documented in the chart and updated on a regular basis (4,113–115).

Because the backgrounds of the team members may be very different, many different assessments take place. A registered dietitian, for example, may assess the current eating habits of someone newly diagnosed with diabetes and provide that person with a meal plan as close to this as possible. An exercise physiologist may teach a person with diabetes how to correctly adjust his or her insulin dose to prevent hypoglycemia during exercise. A nurse educator may assess a patient's skills and general diabetes knowledge and provide him or her with the necessary information. In some institutions, CDEs are seen as just that: diabetes educators.

604 JOSLIN'S DIABETES MELLITUS

Using this rationale, any CDE can meet the diabetes education needs of a patient to a certain extent. For example, if a patient needs to learn how to self-administer insulin and no nurse educator is available to do this, as a CDE, a registered dietitian or exercise physiologist could teach this skill. Then, at a later date, the patient may follow up with a nurse educator to review technique as well as acquire other necessary information related to insulin. Patients starting exercise programs can review general insulin or food adjustment with a nurse educator and then schedule to see an exercise physiologist for more detailed adjustments.

At the Joslin Clinic in Boston, educators use a team approach to patient assessment and education. A "new patient" to the clinic will see an educator solely for an educational assessment (i.e., to determine the patient's current level of diabetes knowledge and skills and to schedule appointments with "appropriate" educators based on this assessment). This serves two purposes: It enables the patient to recognize diabetes educators as a part of his or her healthcare team and allows an effective and efficient way to recognize and address the needs of the patient. The primary goal is to identify and focus on the educational needs of the patient.

The assessment process provides an opportunity for the patient and family to express their healthcare beliefs and their agenda for that visit and to express particular needs or goals (116). The information gained not only provides the healthcare team with data about educational needs but also guides the team in management issues. The team has the opportunity to answer questions, provide positive feedback, and encourage proper self-care behaviors.

In addition to assessing the patient's readiness to learn (37) and stage of adaptation to diabetes (117), the healthcare professional must obtain information on the patient's ethnic or cultural background, occupation, socioeconomic status, support systems, personality type, and health beliefs before looking at the patient's knowledge of diabetes (118). Other factors that may have an impact on learning include age, gender, literacy level, and level of education (119). This information is invaluable in getting a sense of the patient and the approach to education and treatment that would be most helpful and reasonable for that patient.

An evaluation of functional ability helps the healthcare provider plan how to teach skills such as SMBG and insulin administration (120). The patient's dexterity may be affected by arthritis or neuropathy. Vision changes due to retinopathy may be evident at a relatively young age. Some patients have a difficult time admitting to their vision deficit, so it is important to assess the patient's skill in these areas at the initial visit and again at regular intervals. Relatives or close friends should definitely be included in this part of the assessment process to determine whether they are willing and able to assume some responsibility for care of the patient.

Reported educational level appears to be a poor predictor of reading ability, because a person's actual reading level may be significantly lower. Nevertheless, it may be helpful to ask about educational experience (121). In this context, a question concerning how the person learns best will provide some guidelines for deciding whether to use audio, video, or written materials or a one-on-one or classroom setting. Recent research suggests that health literacy, the ability to understand instruction and health information, may impact how well individuals manage their diabetes (122).

What Is Taught

The educational plan is developed by the team—addressing educational needs and treatment goals identified by both the patient and the team. Education begins with "survival" knowledge (i.e., the information absolutely necessary for a person with diabetes to have to function independently and safely at home). For some, this may be as simple as identifying when to call the healthcare provider. For others, SMBG and use of insulin and glucagon may be survival skills. Everyone with diabetes must also have some general knowledge about diabetes to understand when it is necessary to call the healthcare provider for help.

The educational assessments done by various diabetes educators provide the basis for the individualization of teaching. Having determined the patient's knowledge about diabetes, psychosocial history, attitudes about diabetes, and eating and exercise habits, the educator can then formulate an educational plan that reflects the patient's specific needs.

As outlined by the National Standards for Diabetes Self-Management Education (Table 35.1) (4), the actual content of the diabetes education program is based on assessed needs of the individual or individuals. Diabetes education programs do not need to be structured in the model of a medical or nursing course on diabetes (89) but instead should be structured in a way that provides maximal benefits for patients in terms of health outcomes. Many education programs begin with areas identified by the patient as priorities. Addressing the patient's pressing issues then allows the patient to be more attentive to the issues the provider has identified as important (89).

The National Standards recommend that the curriculum include an explanation of diabetes disease process and treatment options to help individuals make informed treatment choices and facilitate self-directed behavior. An explanation of treatment modalities, including the use of insulin, insulin delivery systems, oral antidiabetes medications, the meal plan, and exercise, are important aspects of the curriculum. Other key components of a well-rounded educational program are methods for incorporating nutritional management and physical activity into one's lifestyle. The goals of monitoring; the types, descriptions, and limitations of monitoring devices; and instruction in the use and interpretation of SMBG results are also necessary parts of initial and ongoing education.

Patients also need information about the recognition, treatment, and prevention of acute complications such as hyperglycemia, hypoglycemia, and ketoacidosis and the prevention of chronic complications through risk-reduction behaviors (foot inspection and care). The effects of illness on diabetes and sickday rules are a critical part of any diabetes education. Guidelines for monitoring blood glucose and urine ketones, for modifying food intake, and when to call the healthcare team are essential skills for the patient. Equally important components of care include helping patients set realistic, achievable goals for their diabetes care and discussion of the psychosocial adjustment to diabetes. Finally, patients may need specialty education during specific times such as preconception or pregnancy, the onset of complications, or the initiation of new treatments.

The section on prevention, treatment, and rehabilitation of chronic complications should include strategies for coping with the physical changes and losses that complications may bring. It is extremely important to stress the benefits that blood glucose control can have for both the short- and long-term. Focusing on the prevention of complications through risk reduction is a vital part of this section. A discussion of personal adaptation to life with a chronic disease and the impact of diabetes on the family will also help patients understand some of their feelings.

Care of the skin, teeth, and feet is part of the hygiene segment of a diabetes education program. Self-care measures that help prevent complications, address the need for regular checkups, and outline the effects of smoking, alcohol, and drug use are addressed in this section. The class on the benefits and responsibilities of care explores the patient–professional partnership in planning care and helps the patient develop shortand long-term goals. Exploration of the use of healthcare systems and community resources can help the patient find support and services in the community.

Educational Methods

Diabetes education has benefited from principles of adult learning (54) and instructional design (123). The use of basic educational principles as guides can increase the success of a diabetes education program, regardless of its setting. However, continued evaluation of the applicability and usefulness of principles borrowed from educational theory is important for the continued improvement of educational programs in diabetes (119). For example, the active involvement of the patient in all aspects of the educational endeavor, including decisions about the treatment program, is one such principle that is not universally recognized as being important for successful diabetes education.

Unfortunately, many diabetes education programs frequently foster too passive a role for the patient (124). Many educators have suggested that when patients participate in decisions about their care (86), improvements are seen in measures of both clinical condition and attitudes about health-related quality of life. In a controlled study, Greenfield and associates (125) met with patients before a scheduled office visit with their physicians to review past medical concerns and to focus and improve patients' information-seeking skills. Patients rehearsed negotiation skills, addressing obstacles, such as feelings of embarrassment or intimidation, that stood in the way of their gaining information from the physician. Patients so coached were twice as effective as those in the control group at eliciting information from the physician. Improvements in levels of HbA₁ were significantly greater in these individuals, as were reductions in factors such as days lost from work as a result of illness.

Others also have emphasized the relationship between treatment adherence and the ways in which the physician and the patient reach treatment decisions (126–129). Commenting on some of these studies, Sims and Sims (130) concluded that patients will adhere to their treatment plans more consistently if they feel a sense of ownership of the plans. Today, emphasis is placed on the influence of patient priorities on that person's ability to manage the self-care tasks required for their diabetes treatment. Each individual's priorities and life issues must be considered when the diabetes team, including the patient, sets goals and targets (112,131). The self-care goals that are set should be concrete, realistic, and measurable (132,133).

A study of adolescents (134) in a summer-school program for young people with diabetes demonstrated another important principle: Education and learning are more effective when people have an opportunity to actively address the questions and problems that actually affect them. One group of participants was randomly assigned to a social learning intervention approach to identify situations in which social pressures made it difficult for them to maintain their treatment regimen, and they rehearsed appropriate responses to these situations. The second group of adolescents underwent a more didactic, factoriented diabetes education program. Subsequent HbA₁ values were significantly lower among the adolescents in the social skills intervention group. Variables significantly correlated with good metabolic control included self-reported adherence with a diabetes regimen and attitudes toward self-care.

Of course, providing complete didactic information that is personally connected is also important and is associated with higher patient satisfaction. Ley et al. (135) provided patients with additional physician visits that were designed to assess previous patient education and understanding and to clarify areas of misunderstanding. These patients showed significantly more satisfaction with their care than did the control group. In a review of this subject, Tabak (136) concurred that patients' satisfaction is clearly related to the amount of information available that contributes to their understanding of their condition and that they can use in caring for themselves. It is also important that the provision and acquisition of information span a reasonable time period if patients are to remember and use it. For example, a study of a diet education program given over either 3 days or 11 weeks showed that the longer program was associated with significantly greater improvements in dietary behaviors (137). The need to pace both the provision and use of information has been demonstrated by others as well (109).

Reinforcement and repetition are also important components of an educational program (108). Often, this is accomplished through the preparation of written materials for patients. Unfortunately, there is frequently a mismatch between a patient's reading skills and the level of comprehension required to understand the materials (138,139).

In one study (140), only 28% of the patients had reading skills at or above the ninth-grade level: 59% read at the fifth- to eighth-grade level and 13% had reading skills below the fifth-grade level. By contrast, an evaluation of the educational materials used with these patients showed that 87% were written at the ninth-grade level or above, 13% at the fifth- to eighth-grade level, and none below the fifth-grade level. This means that 87% of the materials were comprehensible to only 28% of the patients, 13% were understood by 87%, and none were readable by 13%!

Formulas have been developed to determine the reading level of educational materials (141-145). Typically, recommendations for readability suggest that educational materials be geared toward the sixth-grade reading level. However, materials should be selected based on assessments of the reading levels of the targeted populations. Helpful strategies are available for developing health education materials for low-literacy groups (146). Most word-processing programs have readability statistics functions such as the Flesch-Kincaid grade level that will determine reading level. Education materials should also be available in the primary language of the targeted population. The National Institute of Diabetes and Digestive and Kidney Diseases of the National Institutes of Health maintains an up-to-date Web site (www.niddkk.nih.gov/health/diabetes/ diabetes.htm) that provides diabetes health information, as well as reviews of diabetes information publications, in easy-to-read formats. These reviews are available in both English and Spanish. Joslin's Web site (www.joslin.org) is another source of useful diabetes information.

Finally, a successful education program provides patients with an opportunity to explore their attitudes toward the material being taught and to understand its implications for dayto-day living. Factors such as the patient's familial, social, and cultural environments; socioeconomic status; other health problems; and overall psychological and emotional well-being provide frames of reference from which patients approach diabetes care and their participation in it (149). The goals for diabetes education developed by the ADA acknowledge the importance of these factors (92). Anderson et al. (147) suggest a means of adapting an educational program to the patient's frame of reference through activities that stimulate an exploration of the meaning of diabetes to the patient and of the psychological adaptations required for the patient to cope with his or her concept of the disease.

Clearly, the implementation of the educational principles discussed above is most effective when the healthcare professional has received training in teaching skills (124,148–152).

Unfortunately, many health professionals involved in diabetes education are not adequately trained in these skills. Such training is strongly encouraged.

When Education Should Take Place

Education for diabetes care is an ongoing, life-long undertaking. However, there are identifiable stages in the progression of diabetes when educational interactions are particularly recommended. The ADA identified diabetes education goals for individuals and their families at diagnosis and throughout their life (92,96).

DIAGNOSIS STAGE

Upon receiving a diagnosis of diabetes, many people are overwhelmed both by the condition itself and by the idea of all the information they think they must absorb. Therefore, people with newly diagnosed diabetes should start by learning the minimum basic skills required for survival. They should learn to maintain reasonably satisfactory management of their diabetes while carrying out essential daily activities. They should become familiar with the medical nutritional principles that they will be following and be able to choose foods in the correct amounts to follow their meal plan. Patients should be taught SMBG, and some need to learn how to inject insulin. This initial education provided at or around the time of diagnosis can occur over several days, particularly if the person is hospitalized, or in small increments over several days or weeks for those who are outpatients.

ONGOING STAGE

Once patients have mastered the essential "survival skills" of diabetes management, they should progress to a more in-depth program of ongoing diabetes education to help them become even more sufficient at self-care and therefore at preventing complications. The challenge for patients in this stage is to learn and follow a complex and demanding regimen when the benefit of preventing complications is distant (117). Key issues concern adapting diabetes self-management to work, school, social, and family settings while coping with more typical life issues and crises. Self-management education programs are available in many education centers, clinics, hospitals, and community public-health programs. These programs, such as the DO IT program at the Joslin Clinic described earlier, not only provide information, knowledge, and skills but also support patient efforts to incorporate self-care tasks into everyday life (Table 35.2).

Periodic educational updates are extremely important after patients complete the initial in-depth training to enable them to meet changing needs at different times of their lives. People can learn new ways of managing diabetes, develop skills that enable them to adapt their management program to changing needs, and familiarize themselves with new resources and advances available for diabetes care.

ONSET OF COMPLICATIONS AND OTHER MAJOR POINTS OF CHANGE

Times of major life and health changes can signal the need for revisions in diabetes management and often make supplementary educational exposure necessary. Throughout the course of a pregnancy, for example, nutritional needs will change and insulin treatment programs may become more intensified, and pregnant women must learn to make these changes properly.

Another milestone at which supplementary education is necessary is at the appearance of early symptoms or signs of a major complication. This is typically a time when patients undergo enormous anxiety and fear and often seek diabetes education to help improve their glycemic control (117). Because improved control can slow the progression of major complications (7), diabetes education programs focus on helping individuals make lifestyle changes to integrate more successful selfmanagement practices. For example, patients can learn to make changes in their routine that, if instituted early enough, may slow down the progression of kidney dysfunction. However, even for motivated patients, lifestyle changes can be difficult and frustrating.

MAXIMIZING THE EFFICACY OF EDUCATION

As pointed out previously, knowledge does not equal adherence to the self-care recommendations of the treatment plan. Nonadherence is not unique to diabetes nor is it a new problem. In fact, there are low rates of adherence with recommended treatment in a variety of chronic conditions. Older studies show that only 50% of patients are compliant with long-term medication and that only 25% are compliant when the condition is asymptomatic (153). In studies specific for diabetes, 80% of those studied administered insulin in an unacceptable manner, 58% gave the wrong dose, and 75% did not follow dietary recommendations (83). Other recent studies reflect similar results (154–156).

Difficulty with following the therapeutic recommendations presents a substantial obstacle to the achievement of medical treatment goals, diminishes the potential benefits of the treatment regimen, and makes evaluation of treatment efficacy inaccurate (157). There is no common profile of a nonadherent patient. Age, sex, education, income, or personality type cannot predict a patient's ability to successfully self-manage diabetes. Also, patients may be nonadherent in one area and not in others (158).

The patient's ability to manage diabetes is affected by a number of factors. The first is the individual's knowledge of the selfmanagement recommendations. With a thorough assessment of the patient's knowledge of diabetes and of self-management recommendations, diabetes education can address this barrier by correcting misconceptions, determining patient priorities, and encouraging changes in behavior by helping patients set achievable and measurable goals. Acknowledgment of the imperfections and frustrations of the treatment plan helps to prepare the patient for the inevitable setbacks (159).

The second factor that impacts self-management behaviors is the patient's beliefs about healthcare. The health-belief model looks at whether the patient believes that he or she has diabetes, that it is serious, that the treatment is beneficial, and that the barriers to care are outweighed by its benefits (160–164). Health beliefs can be complicated and interrelated; thus, modification of some health beliefs alone may not result in improved physiologic outcomes of diabetes care (163,165,166). For example, health beliefs about the seriousness of diabetes of 79 participants were not related to clinic attendance, dietary intake, weight loss, or fasting glucose levels but did predict reductions in body mass index after 1 year (166). In addition, the realities of a person's life and the priorities the individual holds may differ from those of the healthcare provider. For example, a mother may put more emphasis on child-care duties or family requirements than on her own healthcare requirements. This type of barrier is difficult to overcome. In some cases, therapeutic goals and recommendations may require restructuring so that they better fit the patient's priorities and achieve at least some improvement in glycemia. Other approaches may involve the help of social services and of mental health professionals.

The characteristic coping styles of a patient may also be factors that determine adherence. Those patients who typically use a problem-focused coping style may be better able to self-manage their diabetes than those who employ a more emotionfocused approach (35,36). Denial of diabetes will not allow the patient to enter into an aggressive treatment regimen. On the other hand, those patients who tend to be obsessive/compulsive may need to be given permission to do less rather than encouraged to do more.

Another important factor is the treatment regimen itself. The greater the complexity and duration of the regimen, the more negative is its impact on treatment adherence (158). The more we ask patients to do and the longer we ask them to do it, the less likely they will be able to sustain compliance. In a study of patients with type 2 diabetes treated with oral medication, Paes et al. (156) found that patients taking one pill per day were adherent to the medication prescription on 79% of days, however, those taking two or three pills per day took medications as prescribed on only 66% and 38% of days, respectively.

The healthcare team can help modify this adherence barrier. A simplified and tailored regimen designed to meet individual lifestyle needs is more likely to be implemented successfully than is one that focuses on metabolic control alone. Clear, specific, simple, and concrete information and instructions in a diabetes education program will go far toward reducing the perceived complexity of treatment and improving the rate of adherence (108,167).

A final critical factor in the patient's ability to self-manage their diabetes is the healthcare provider. He or she can listen to the patient and modify the treatment regimen and/or alter his or her relationship with the patient as needed. In fact, the healthcare provider may be one of the most important factors influencing adherence.

The relationship between the healthcare provider and patient itself can have a positive or negative effect on compliance. Impersonality, inability to listen, and lack of warmth in the relationship between the healthcare provider and the patient can adversely affect patients' adherence to treatment (168). On the other hand, the healthcare provider's use of selfdisclosure and positive nonverbal communication, such as smile, touch, and eye contact, can have a positive impact on compliance. Although time for providers is a precious commodity in today's stringent healthcare environment, taking a few minutes to check whether patients understand their selfmanagement tasks, to address anticipated difficulties with the treatment regimen, or to answer additional questions can be quite beneficial to both the patient's self-management behaviors and to the healthcare provider/patient relationship.

In addition to working on a positive relationship with the patient, the healthcare provider can simplify the form of treatment and support the patient's efforts to manage his or her care.

ASSESSING OUTCOMES

"Outcome" refers to the hoped-for effect of an educational effort on diabetes management and overall quality of life for people with diabetes. Assessments of educational outcome have traditionally focused on physiologic improvements, which are the changes most easily measured. Today, these assessments attempt to determine how changes in knowledge and skills contribute to better self-care behavior and improvements in blood glucose levels, decreased complications, reduced use of healthcare services, and improved quality of life (20,24,55,147,169,170). However, as suggested earlier, healthcare professionals are recognizing that assessing outcomes by examining only the knowledge acquired and the skills learned as the sole factors involved in effecting beneficial self-care practices and metabolic control is too narrow a focus (57,70). There are many steps between an educational encounter and a medically or economically valuable outcome, with multiple factors influencing the process along the way. Knowledge and skills are only two factors that influence self-care behavior, and self-care behavior, although crucial for success, is only one component of a favorable outcome.

For example, improvements in self-care practices are unlikely to occur unless the patient is also helped to actively integrate his or her therapeutic regimen into the many facets of daily life. If the patient is expected to assume only a passive role in determining the regimen or in performing tasks and if his or her personal values and needs are ignored, no true progress is likely (78).

The ultimate purpose of assessing outcomes of educational efforts is to justify the cost and to ensure that the desired goal of improved health is reached. However, measuring the efficacy of education has been limited by the difficulty or impracticality of demonstrating a direct link between educational interaction and desired outcome while controlling for the other variables. Therefore, before beneficial outcomes can be measured, educational programs must be designed to address the multiple factors that encourage active patient participation in self-care that ultimately bring about an associated improvement in metabolic control, overall health, and quality of life (89). For example, one program made an effort to help patients develop a more accepting and positive personal response to having diabetes and to its treatment (147). Another program successfully affected self-care patterns, levels of HbA1, and emotional well-being by specifically addressing these issues (38). Joslin's DO IT program also demonstrated improvements both in the glucose control parameters and in quality-of-life measurements. Currently, therefore, assessments of outcome look beyond knowledge and skills and focus on behaviors. Identification of about three specific, desired behavioral changes during the educational encounter permits subsequent evaluation based on whether these changes have occurred.

The challenge remains to design outcome assessments that trace the further progression from educational intervention, through behavioral changes, to desired outcome in terms of measurable medical parameters, improvements in quality of life, or economic parameters. To determine the exact effect of education, however, one must control for the other variables that affect the outcome, a challenge that remains formidable. Finally, assessment of all aspects of the process of education is as important as assessing outcomes (4,171).

CONCLUSION

Diabetes education programs that are evolving as part of multifaceted diabetes management efforts provided by skilled healthcare teams can help patients reach higher levels of adherence, metabolic control, and satisfaction by leading to their even more active participation in self-care. With such models of excellence and the growing recognition of the cost-effectiveness of educational intervention, these educational programs should be recognized as the bargain they are rather than as an additional financial burden on society. Diabetes patient education services must become accessible to all people with diabetes as an important component of the effort to extend quality medical care to all. To continue Dr. Krall's pattern of looking forward, we trust that by the *next* edition of this textbook, the hoped-for universal availability of patient education will be closer to a reality.

SUMMARY 629

A BRIEF HISTORY OF NUTRITION AND DIABETES

More than 50 years ago, Elliott Joslin stated:

The diet in health is made up chiefly of carbohydrate; the diet in diabetes before the discovery of insulin was made up chiefly of fat. Insulin has changed all this. The task of the modern diabetic is not so much to learn how to live comfortably upon less carbohydrate and more fat, but rather to balance the carbohydrate in his diet with insulin so that he can utilize it and thus keep his urine sugar-free. (1)

Little did Dr. Joslin realize that his guidelines would still hold true at the beginning of the 21st century.

Patients have identified "diet" as one of the most challenging aspects of their diabetes regimen. However, countless events have resulted in positive changes in nutrition science as it relates to diabetes. From the rigidly controlled, semistarvation diets in ancient times to the present "all-foods-can-fit," we have arrived at nutrition science as we know it today—medical nutrition therapy.

One of the earliest references to a so-called diabetic diet was noted in a medical writing as far back as 1550 B.C., although for the first 3,500 years of diabetes history, no clear distinction was made between type 1 and type 2 diabetes. The writings recommended a diet high in carbohydrates, which included fruit, wheat grain, and sweet beer to stop the passing of too much urine. Aretaeus, a follower of Hippocrates, first used the name *diabetes* in the first century A.D. to describe the "melting down of flesh and limbs into the urine" (2). He concluded that diabetes was a disease of the stomach and should be treated with milk, gruel, cereals, fruits, and sweet wines. Milk, water, wine, and beer were used as the main fluids to relieve excessive thirst until the second century A.D., when diabetes was thought to be a disease of the kidneys. At this time, restriction of fluids was recommended. By the sixth century, diabetes was thought to be directly caused by overeating and thought to be a disease of "sweet urine" (3).

Little information about diabetes and food is mentioned again until the late 1600s, when the suggested diabetic diet returned to foods higher in carbohydrates, such as milk, bread, and barley water. Also, at this time, opium was introduced as a staple of the diet to decrease appetite, as physicians recognized that those people with diabetes who ate the least food lived the longest.

In the late 1700s, a French physician began prescribing undernutrition or semistarvation diets, interspersed with frequent periods of fasting, for those with diabetes. Finally, a physician from England related carbohydrates to high glucose levels and excessive urination. Again, the diet reverted back to low carbohydrates and included more fat and protein in the form of milk, butter, suet, and rancid meats. Low-carbohydrate vegetables were added only when the urine became completely sugar free. Although fat in the diabetic diet was further liberalized to add enough calories for survival, most people with diabetes could not adhere to the extremely limited quantity of food. Those people with diabetes who were "thin" did not survive, whereas those people with diabetes who were "fat" improved.

In the early 1900s, Dr. Frederick M. Allen, in the United States, developed his starvation diet and was one of the first to tailor foods in diets to his patients' preferences while still providing only 1,000 calories a day. Although many of his patients were malnourished, he is credited with helping many survive before the introduction of insulin therapy in 1921 (3).

The starvation diet disappeared with the discovery of insulin. The prescribed diabetic diet was still 4% carbohydrate, 21% protein, and 75% fat—all measured and weighed to exact amounts. Although no consistent food lists were available at the time, the carbohydrate foods were categorized according to the amount of carbohydrate each food contained, e.g., 5%, 10%, and 20% vegetables. Vegetables were cooked three times, the water changed each time to remove as much carbohydrate as possible. Even after insulin was initiated, Dr. Elliott P. Joslin continued to use a high-fat, carbohydrate-restricted diet for his "severe diabetics" and noted in his first preinsulin *Diabetic Manual* that "olive oil forms an excellent lunch for a diabetics" to 23% carbohydrate, 15% protein, and 62% fat.

In the 1940s, it became evident that there was a great need to develop consistent and standardized food values and to design a simple method for planning the diabetic diet. The American Dietetic Association, the American Diabetes Association, and the diabetes branch of the U.S. Public Health Service developed a method that became what we know today as the exchange system. Six "convenient" sample meal plans were developed that detailed the grams of carbohydrate, protein, and fat for various calorie amounts. These plans were developed to be used by the health professional, who would modify the plan to suit the particular needs of the patient. Although the meal plans were not meant to be distributed to patients, they soon became widely available. In the early 1970s, the sample meal plans were being used extensively. These preplanned diets did not focus on nutrition education or on follow-up by a registered dietitian. Patients quickly lost their motivation to adhere to these diets, and their interest in nutrition quickly diminished. A 1973 publication by Kelly West, *Diet Therapy of Diabetes: An Analysis of Failure*, examined deterrents to successful diet therapy, which included lack of physician support in promoting adequate nutrition care and of third-party reimbursement for dietary instruction for outpatients (4).

In the 1970s, the high-carbohydrate diet was rediscovered (5,6), and the officially recommended diet was higher in complex carbohydrate and lower in fat and protein than most of the earlier diets. The attitude toward sucrose and other sugars became more liberal. The American Diabetes Association began emphasizing the need for nutrition education about the exchange system. This eventually led to the publication in 1971 of the Association's *Principles of Nutrition and Dietary Recommendations* (7). The exchange lists for meal planning were revised in 1976, 1986, and again in 1995; each revision placed an increasing emphasis on carbohydrates. These changes reflect a move from the main focus on the lethal effects of short-term complications (ketoacidosis and hypoglycemia) to a new focus: concern about long-term complications.

The exchange system continued to be taught and used and was perceived as the diabetic diet until the 1980s. However, surveys from dietitians who provided nutrition education for patients with diabetes identified a need for a variety of mealplanning methods to be used in addition to the exchange system. In 1987, the Diabetes Care and Education Practice Group of the American Dietetic Association promoted the concept of the individualization of the meal planning approach to diabetes nutritional care with new nutrition resources for diabetes meal planning (8). More and more people with diabetes were seeking a dietitian's care and counseling for updating their methods of meal planning.

Current medical nutrition therapy recommendations for overall health of persons with diabetes are the same as those for all healthy Americans, as seen in the *U.S. Dietary Guidelines* 2000 (9). These guidelines include the following:

- Aim for a healthy weight
- Choose a variety of grains daily, especially whole grains
- Choose a variety of fruits and vegetables daily
- Choose a diet that is low in saturated fat and cholesterol and moderate in total fat
- Choose beverages and foods to moderate your intake of sugars
- Choose and prepare food with less salt
- If you drink alcoholic beverages, do so in moderation.

The volume of research on issues of nutrition and diabetes and the number of changes in nutrition recommendations over recent years are now greater than ever. The evolution of new knowledge is rapidly affecting the management of diet for the patient with diabetes. Therefore, the 2000 Dietary Guidelines, which are published every 5 years by the Department of Health and Human Services (HHS) and the Department of Agriculture (USDA), are currently in the process of review in light of recent scientific evidence to determine if revision is needed in the 2005 sixth edition. The USDA's Food Guide Pyramid, which was introduced in 1992, is also under review. Prominent experts in nutrition and health are now proposing a revised food guide pyramid that clearly emphasizes the benefits of healthy fats, daily exercise, and avoidance of excessive intake of calories. Recommendations promote high fiber, healthy and unprocessed carbohydrates, as well as adequate consumption of fresh fruits

The availability of a greater variety in the types of oral antidiabetes agents and insulins, together with the availability of technology from self-monitoring of blood glucose to continuous blood glucose sensors and insulin pump therapy, has allowed increased flexibility in meal planning. A continued research focus on the glycemic response of the nutrients—carbohydrate, protein, and fat—is gradually changing how we think about diet in diabetes.

The dietary management of type 2 diabetes is now recognized to be quite different from that of type 1 diabetes. Our knowledge about the treatment of obesity in diabetes also has increased. In addition, attention is being given to the special considerations required among different subgroups of people with diabetes, specifically the needs of ethnic minority groups, pregnant women, growing children and adolescents, and the elderly. Emphasis is placed on providing individualized, flexible meal plans that people are willing and able to follow. Dramatic changes in our methods of diabetes education have also been instituted in recent years. New strategies, knowledge, and techniques for teaching and improving the overall management of diabetes, as well as dietary management, were clearly demonstrated in the 1993 published results of the Diabetes Control and Complications Trial (DCCT) for those with type 1 diabetes (10) and the smaller Stockholm Diabetes Intervention Study (11) of similar design. These studies recognized the importance of a coordinated team approach to the achievement of nutrition goals. The diabetes team used in the DCCT consisted of the patient and family as the primary participants, a diabetes nurse educator, a registered dietitian, a behaviorist, and the diabetologist. Today, exercise physiologists also have been included as important members of the diabetes team. The DCCT also provided specific information about important nutrition intervention strategies, based firmly on scientific evidence. In 1994, shortly after publication of the DCCT clinical findings, the American Diabetes Association published a revised set of nutrition guidelines, refocusing on an "individualized approach to nutrition self-management that is appropriate for the personal life-style and diabetes management goals of the individual with diabetes" (12).

The results of another 20-year landmark study, the United Kingdom Prospective Diabetes Study (UKPDS) (13), for those with type 2 diabetes, were published in 1998 and further

confirmed that the intensive use of pharmacologic therapy, together with diet and exercise, would have clinical benefits. In 1996, recruitment began for a more recent randomized clinical trial, The Diabetes Prevention Program (DPP) (14). The DPP was designed to test strategies to prevent or delay glucose concentrations and impaired glucose tolerance (IGT). This major clinical trial compared intensive lifestyle intervention (diet and exercise) with metformin treatment in 3,234 people with impaired glucose tolerance. Lifestyle intervention worked as well in men and women and in all ethnic groups, reducing the risk of getting type 2 diabetes by 58%. It also worked well in people age 60 and older, reducing their development of diabetes by 71%. Metformin was also effective in men and women and in all ethnic groups, reducing their risk of getting type 2 diabetes by 31%, but not as effective in the older volunteers and in those who were less overweight. The trial ended a year early because the data had clearly answered the main research questions. This is the first major trial to show that diet and exercise can prevent or delay diabetes in a diverse American population of overweight people with IGT and a major step toward reversing the epidemic of type 2 diabetes in the United States. A recently launched trial, the Look AHEAD (Action for Health in Diabetes) study, will examine how diet and exercise affect heart attack, stroke, and cardiovascular-disease-related death in people with type 2 diabetes.

Diet still remains the cornerstone of diabetes self-management, but additional research is needed to improve the contribution that diet can make for effective diabetes self-management.

GOALS OF MEDICAL NUTRITION THERAPY

Today, there is no one "diabetic diet." The current nutrition recommendations can be defined simply as "a nutrition prescription based on assessment and treatment goals and outcomes" (15). The 1994 American Diabetes Association nutrition recommendations redistributed the calories provided from the various macronutrients (12), and these recommendations still hold true today. Table 36.1 gives a historical perspective of nutrition recommendations. The American Diabetes Association recommends that the distribution of calories from carbohydrate and fat be based on nutritional assessment and on blood glucose, weight, and lipid goals, with continued emphasis on a diet with fewer than 10% of calories from saturated fats and with 10% to 20% of calories from protein (lean).

	Distribution of calories (%)					
Year	Carbohydrate	Protein	Fat			
Before 1921	_	Starvation diets	_			
1921	20	10	70			
1950	40	20	70			
1971	45	20	35			
1986	<60	12-20	<30			
1994	Based on nutritional assessment and treatment goals	10–20	Based on nutritional assessment and treatment goals; <10% of calories from saturated fats

TABLE 36.2. Goals of Medical Nutrition Therapy

- 1. Attain and maintain optimal metabolic outcomes, including
 - Blood glucose levels as near normal as possible to safely prevent or reduce the risk for complications of diabetes
 - Optimal serum lipid profile to reduce the risk for macrovascular disease
 - Blood pressure levels that decrease the risk for macrovascular disease
- 2. Prevent and treat chronic complications of diabetes by
 - Modification of nutrient intake and lifestyle for prevention and treatment of obesity, dyslipidemia, cardiovascular disease, hypertension, and nephropathy
- 3. Improve health through healthy food choices and physical activity
- 4. Address individual needs, such as
 - Personal and cultural preferences and lifestyle while respecting the individual's wishes and willingness to change

The goals of medical nutrition therapy are summarized in Table 36.2, which outlines the most recent recommendations of the American Diabetes Association (15) and are discussed in more detail below.

Goals in Type 1 Diabetes

The primary goals of therapy for persons with type 1 diabetes are as follows:

- Provision of an individualized meal plan based on usual food intake and lifestyle. This plan is used as the basis for integrating insulin therapy into the usual eating and exercise patterns.
- Consistency of carbohydrate intake to allow the synchronization of mealtimes with times of insulin action for persons receiving *fixed insulin regimens*.
- Determination of premeal insulin dose and postprandial blood glucose response by monitoring of blood glucose levels and adjusting insulin doses for the amount of total carbohydrate consumed for persons receiving *intensive insulin therapy*.
- Prevention of weight gain is desirable, with attention therefore paid to total caloric intake from carbohydrate, protein, and fat, for persons with improved glycemic control.
- Adjustment of rapid- or short-acting insulin for deviations from usual eating and exercise habits is the preferred choice for prevention of hypoglycemia. Additional carbohydrate may be needed for unplanned exercise.

Goals in Type 2 Diabetes

The primary goals of therapy for persons with type 2 diabetes depend on body weight and level of glucose control.

- Emphasis on lifestyle changes that result in reduced caloric intake and increased energy expenditure through physical activity for those who are overweight and insulin resistant
- Achievement and maintenance of glucose, lipid, and blood pressure goals by reduction in dietary intake of carbohydrate, saturated fat, cholesterol, and sodium when necessary
- Maintenance of moderate caloric restriction and a nutritionally adequate meal plan with a reduction of carbohydrate and total fat—especially saturated fat—together with an increase in exercise for those with excessive weight
- Increase of activity and exercise to improve glycemia, decrease insulin resistance, and reduce cardiovascular risk factors

CALORIES

The diet of the diabetic patient should contain the minimum number of calories which the normal individual would require under similar conditions. If the patient is allowed more than the minimum amount of food there is far more likelihood that a portion will be lost, unassimilated, and appear as sugar in the urine. (1)

Prescribing enough calories (kilocalories, or kcals) to achieve and maintain a desirable weight should be carefully considered. Caloric requirements for persons with diabetes are not different from those for persons without diabetes, assuming the person with diabetes is not losing calories through glycosuria. Caloric needs vary with a patient's weight, age, gender, activity level, and genetic background. The recommended calorie level is based on the weight that the patient and his or her healthcare provider acknowledge as one that can be achieved and maintained, for both the short term and the long term. This may not be the same as ideal body weight.

Persons with type 1 diabetes are often thin when the diagnosis is first made, and the diet should include enough calories to ensure normal growth and development and to sustain the usual level of physical activity. For infants, children, and adolescents, caloric intake should maintain consistent growth curves based on energy needs during periods of growth and

TABLE 36.3. Estimating Caloric Intake and Desirable Body Weight for Adults

Estimating caloric intake

Basal calories: 10 kcal/lb desirable body weight
Add calories for activity
If sedentary, add 10% of estimated base calories
If moderately active, add 20% of estimated base calories
If strenuously active, add 40% of estimated base calories
Adjustments^a

Estimating desirable body weights from frame size

Women
100 lb for first 5 ft plus 5 lb for each additional inch
Men
106 lb for first 5 ft plus 6 lb for each additional inch
Small frame
Subtract 10%
Large frame
Add 10%

^aAdjustments are approximate; weight changes should be monitored and compared with caloric intake.

sexual maturation. The prescribed calories must be adjusted on a regular basis. If diabetes is not properly controlled, growth may be retarded and the height potential may not be reached. Any abnormal or unexplained deviation in growth and weight demands an assessment of diabetes control, eating patterns, and caloric intake, as well as insulin dosage.

Persons with type 2 diabetes are often overweight when the diagnosis is first made. A moderate weight loss (5 to 9 kg), irrespective of the patient's starting weight, is perhaps the most important aspect of medical nutrition therapy and is associated with an improvement in lipids, blood glucose, and blood pressure (15–19). Weight loss leads to a reduction in insulin resistance and has long-term effects on the maintenance of reduced blood glucose levels. Overweight and obese patients with type 2 diabetes should be encouraged to attain a reasonable weight rather than attempting to achieve the traditionally defined desirable or ideal body weight. Setting intermediate weight goals may be use

ful when a patient becomes overwhelmed by the magnitude of his or her necessary weight loss. Weight management also should include behavioral modification to encourage healthy eating behaviors, together with increased physical activity. A moderate reduction in calories of approximately 250 to 500 kcal per day less than the average daily intake (calculated from a food history) can result in losses of 2 to 4 kg per month, a rate that is considered excellent.

Several different means of estimating desirable body weight and caloric needs are included in Table 36.3. The recommended calorie level need not be absolutely precise but should be considered a starting point for fine-tuning during follow-up until a level has been established that will help the patient achieve his or her goals for weight and blood glucose levels.

There is evidence to support the use of body mass index (BMI) (Table 36.4) in risk assessment for the diagnosis of diabetes or response to weight loss. The BMI provides a more accurate

measure of total body fat than does assessment of body weight alone. Measurement of waist circumference (20) is particularly helpful when patients are categorized as normal or overweight. Men whose waist circumference is greater than 40 inches and women whose waist circumference is greater than 35 inches are at high risk of diabetes, dyslipidemia, hypertension, and cardiovascular disease because of excess abdominal fat. The relationship between BMI and waist circumference for defining risk is shown in Table 36.5.

CARBOHYDRATE

The diet of the normal and diabetic individuals differs very little these days, chiefly because of the discovery of insulin. At one time my hospital patients did not have over 30 grams of carbohydrates per day, or the equivalent of about one ounce or two tablespoons of sugar. Today no patient has less than 150 grams of carbohydrate or the equivalent of 10 tablespoonfuls of sugar or 10 slices of bread. (1)

Calories from carbohydrate are variable and should be individualized on the basis of nutritional assessment, diabetes treatment goals, other medical issues, and the patient's eating habits and response of blood glucose to carbohydrate intake.

If protein contributes 10% to 20% of calories, carbohydrate and fat can be distributed between the remaining 80% and 90% of calories, after the blood glucose and lipid levels are taken into account (21). Although carbohydrate foods vary in the ability to promote good health, the total amount of carbohydrate consumed is more important than the source or the type of carbohydrate. Even sucrose-containing foods may be substituted for other carbohydrate grams and are acceptable as long as these foods are within the context of a healthy meal plan and metabolic control and desirable body weight are maintained.

A nutrition prescription (based on nutritional assessment and treatment goals) may result in a reduction in carbohydrate and dietary fat—particularly saturated fat—which in turn reduces cardiovascular risk. Although there are supportive studies indicating that high-carbohydrate meal plans improve glucose tolerance and insulin sensitivity (21–24), there is still some disagreement about what constitutes the optimal percentage of carbohydrate for persons with diabetes (25,26). Although some researchers are concerned about high-carbohydrate diets and their potential for influencing glucose and lipid metabolism and blood pressure (27–32), others have demonstrated that the limited elevation in lipids can be prevented if carbohydrate and fiber in the diet are increased in parallel (33–35). Joslin Diabetes Center has recently updated nutrition recommendations for people with type 2 diabetes who are overweight and obese. Although additional research will be required to define the maximum nutrients that promote both blood glucose control and weight loss success, we currently assess each patient individually to determine an appropriate meal plan composition based on reducing calories to achieve a negative caloric balance and using the guidelines below:

Carbohydrates. No more than 40% of total daily calorie intake should come from carbohydrates, which should be mainly low-glycemic-index foods such as vegetables, fruits, and whole and minimally processed grains. Refined carbohydrates or processed grains and starchy food such as pasta, bread, cereal, and white potatoes should be avoided or consumed in limited quantities.

Protein. To maintain muscle mass and energy expenditure, 30% of total daily calorie intake should come from protein. Preferable protein sources include fish, particularly cold water fish such as salmon, tuna, or sardines, and chicken, turkey, and other poultry and soy, rather than red or processed meat. Furthermore, data suggest that protein aids in the sensation of fullness and that low-protein meal plans are associated with increased hunger. Thus, protein may serve to reduce appetite and assist one in achieving and maintaining the desired lower calorie level.

Fat. Of total daily calorie intake 30% should come from fat, which should be mainly derived from monounsaturated and polyunsaturated fat (e.g., nuts, olive oil, canola oil) and fish, particularly those high in omega-3 fatty acids. Meats high in saturated fat, including beef, pork, lamb, and high-fat dairy products, should be consumed only in small amounts. Similarly, foods high in trans-fatty acids should be avoided.

The above distribution of nutrients for overweight and obese people with type 2 diabetes will

- Promote long-term weight loss in those with type 2 diabetes. The combination of restricting calories while increasing the intake of protein and low-glycemic-index foods may diminish the sensation of hunger.
- Improve blood glucose control because of the relatively lower carbohydrate content and the lower glycemic index of those carbohydrates that are consumed.

- Improve the body's response to insulin (insulin sensitivity), whether or not weight loss is achieved.
- Improve blood lipid profile, particularly triglycerides and high-density lipoprotein (HDL) cholesterol, whether or not weight loss is achieved.
- Reduce the stress on the insulin-producing cells in the pancreas by reducing the need for as much insulin.

It is also important to recognize that a meal plan prescription alone is not sufficient to maximize significant and sustained weight loss. Physical activity, behavior modification, and good support systems are extremely important adjuncts to the dietary prescription described above.

Glycemic Index

All complex carbohydrates and all simple carbohydrates (or sugars) traditionally were thought to generate different blood glucose responses based on molecular structure. However, an inconsistent relationship of glucose response demonstrated from so-called simple and complex carbohydrates suggests this terminology may be misleading and restrictive in meal planning. The position of the American Diabetes Association is that priority should be given to the total amount rather than the source of carbohydrate. Controversy is ongoing about whether the ingestion of similar amounts of carbohydrate foods produces different blood glucose and insulin responses and whether this information will have useful clinical applications.

In 1981, Jenkins et al. (36) suggested that the blood glucose and insulin response to a food could be expressed as a glycemic index, which quantifies the postprandial glucose response to a particular food in comparison to the response to a standard amount of glucose, or an attempt to classify foods by the extent to which they raise the blood glucose level. Glucose alone produces the largest increase in blood glucose level and is assigned a glycemic index of 100. Fiber-rich foods, acidic foods, and high-fat foods often have low glycemic indexes. The glycemic index of sucrose, a disaccharide made up of glucose and fructose, is lower than that of some starches, such as potatoes, because sucrose contains less pure glucose.

Those in favor of replacing foods having a high glycemic index with foods having a low glycemic index refer to studies demonstrating the value of the glycemic index in the dietary management of diabetes (37-46). However, others find that the study results are not consistent or predictable and not clinically useful (47-50). Another controversy exists over the impact of meals with a high glycemic index versus meals with a low glycemic index on weight loss and satiety. Ludwig (41) suggests that the ingestion of low-glycemic-index foods typically induces higher satiety than does the ingestion of high-glycemicindex foods and is followed by the intake of fewer calories at subsequent meals. It is theorized that slower rates of digestion and absorption of low-glycemic-index foods stimulate nutrient receptors in the gastrointestinal tract for a longer period, resulting in a longer period of feedback to the satiety center in the brain. Brand-Miller et al. (42) suggest that high-glycemic-index meals dictate differences in satiety and caloric intake because of the faster digestion and absorption and high insulin responses, and that they expand fat stores. Pi-Sunyer (49) takes the position that the data are not yet sufficient and that most of the data relating high-glycemic-index meals to increased food intake were collected in single-meal experimental designs. Although the weight-loss benefit of a low-glycemic-index diet compared with a high-glycemic-index diet is still only a hypothesis, it may be helpful to use the glycemic index as an additional weightloss tool. A low-glycemic-index diet consisting of vegetables, fruits, and legumes, a moderate amount of protein and unsaturated fats, and fewer refined carbohydrate foods-along with overall decreased calorie intake and increased physical activity—will assist patients in their weight-loss efforts (40). As more long-term research trials on glycemic response to single foods and complete meals are conducted, the usefulness of this concept as a teaching tool is increasing (Table 36.6). However, the glycemic response to food depends not only on the amount and type of carbohydrate but also on other variables (Table 36.7), which could impact the glycemic effect of the carbohydrate food eaten. To further determine the impact of carbohydrate foods on blood glucose levels, researchers have come up with a way to describe the extent to which the blood glucose rises (GI) and remains high. This is called the glycemic load (GL). The GL provides a measure of the level of glucose in the blood, but also

TABLE 36.6.	Glycemic Index of	Common Carboh	ydrate Foods, Usi	ng Glucose as Standard
-------------	-------------------	---------------	-------------------	------------------------

Greater than 70%	55%-70%	Less than 55%
Greater than 70% French baguette, 1 oz Black bread, 1.7 oz Corn flakes, 1 cup Rice Chex, 1 Rice cakes, 3 plain Vanilla wafers, 7 Dates, 5 Watermelon, 1 cup Tofu frozen dessert, $\frac{1}{2}$ cup Angel food cake, 1 oz Jelly beans, 10 large Life Savers, 6 Baked potato without fat Rice, instant, 1 cup	55%–70% Pita bread, 2 oz White bread, 1 oz Cheerios, 1 cup Shredded wheat, $\frac{2}{3}$ cup Stoned Wheat Thins, 3 Shortbread cookies, 4 Pineapple, 2 slices Raisins, $\frac{1}{4}$ cup Ice cream, $\frac{1}{2}$ cup Blueberry muffin, 2 oz Coca-Cola, 1 can Honey, 1 tbsp White boiled potato Basmati white rice, 1 cup	Less than 55% Pumpernickel, whole grain, 1 oz Sourdough bread, 1.5 oz (acid) All-bran with extra fiber, $\frac{1}{2}$ cup Frosted flakes, $\frac{3}{4}$ cup Social Tea biscuits, 4 Twix chocolate cookie, 2 oz Cherries, 10 large Banana, 1 medium Ice milk, $\frac{1}{2}$ cup Pound cake, 3 oz Chocolate bar, 1.5 oz M & M chocolate peanuts, 1.7 oz Sweet potato Brown rice, 1 cup

TABLE 36.7. Factors Affecting Glycemic Response

the insulin demand produced by a normal serving of the food. The GL considers a food's GI as well as the amount of carbohydrate per serving and gives a more detailed picture.

- The GI determines how rapidly a particular carbohydrate food may raise blood glucose.
- The GL determines how much impact a carbohydrate food may have on blood glucose levels, depending on the number of grams of carbohydrate in a serving.

GI *divided* by 100 (glucose is set to equal 100) *multiplied* by the carbohydrate grams/serving = GL (51)

For example, it may be recommended that carrots be eliminated entirely owing to their very high GI value of 92. Common sense, however, tells us that carrots are a vegetable and provide fiber and healthy nutrients. For example:

 1/2 cup carrots
 GI 92/100 × 4 g carb = GL of 3.7 = Low GL

 2 cups carrots
 GI 92/100 × 16 g carb = GL of 15 = Medium GL

In general, the GI is highest if high GI foods are eaten in large quantities. Low GI foods usually have a low GL, but medium to high GI foods can range from low to high GL. Therefore, you can reduce the GL by limiting foods that have both a high GI and a high carbohydrate content.

Most agree that the ability of a person to adhere to a dietary regimen is inversely related to the complexity of the regimen. Calculating the glycemic index at each meal may be burdensome for some individuals. Because the exact effect of food on a person's blood glucose level is an individual response to specific foods and meals, patients are encouraged to identify their own glycemic index for certain foods by using self-management of blood glucose. Therefore, we may propose the use of the glycemic index as an adjunct to the dietary management tools already in use by our patients.

Information about glycemic index may be reviewed with patients who (a) track their carbohydrate intake and keep blood glucose and food records; (b) monitor their blood glucose levels at least two or three times per day and are willing to evaluate blood glucose levels following meals; (c) follow up with a registered dietitian to evaluate out-of-range blood glucose values that may be due to consumption of particular types of carbohydrate foods; (d) express an interest in making additional modifications in their eating plan to fine-tune glycemic control; and (e) express an interest in using information about glycemic index for helping to guide food choices for weight control.

The primary goal is for patients to achieve both glycemic and weight control while eating a variety of nutritionally balanced foods. It is not necessary to completely avoid foods with a high glycemic index, because many are healthy, nutritious foods that can be eaten in moderation. However, patients should be encouraged to include more unprocessed, high-fiber foods, for which a lower glycemic response has been generated. Examples of high-fiber foods include lentils, beans, legumes, raw and unpeeled fruits and vegetables, or foods that have been minimally cooked (52).

Because knowledge of food composition and physiology is not sufficient to permit a consistent prediction of glycemic responses, the principle that food choices can be refined to obtain maximal control of blood glucose remains a possibility for motivated individuals who closely monitor their blood glucose levels. Awareness of differences in glycemic response to food has played an important role in expanding our thinking about how to improve dietary management and our understanding of what occurs in the daily management of individuals with diabetes.

Sucrose

The inclusion of sucrose in the total carbohydrate content of the diet has not been found to impair blood glucose control in individuals with either type 1 or type 2 diabetes (15). Consumption of modest amounts of sucrose by persons with diabetes is acceptable as long as both metabolic control and weight are maintained. For instance, several investigators found no significant difference between the blood glucose responses of persons with diabetes when they consumed sucrose and when they consumed only starch (53–56).

In a recent study (57), nine children with type 1 diabetes were studied in a controlled setting to compare glycemic responses of isocaloric mixed meals that contained 2% sucrose (sucrose-free diet) and 17% sucrose (sucrose-containing diet). Insulin infusion was started the night before the beginning of the study period so that all of the children had fasting euglycemia. Diets were carefully matched for nutrient and energy content, with only small differences noted for fiber. The glycemic response was lower with the 17% sucrose diet than with the 2% sucrose diet over the 4-hour study period. The peak blood glucose response was earlier and lower with the 17% sucrose diet. The results suggest that moderate amounts of sucrose isocalorically exchanged for starch lowered the glycemic response between breakfast and lunch in children who were euglycemic before breakfast.

Other investigators have studied the blood glucose response in adults with type 1 and type 2 diabetes and found no significant difference between the blood glucose responses to their consumption of sucrose and the responses to their consumption of only starch (55,58). The crossover study of Bantle et al. (55) with 12 patients with type 2 diabetes involved two study diets—a high-sucrose diet (19% kilocalories from sucrose) and a high-starch diet (<3% kilocalories from sucrose) for 28 days. The sucrose and starch diets provided about 55% kilocalories from carbohydrate, 15% kilocalories from protein, and 30% kilocalories from fat. The two diets contained almost identical amounts of dietary fiber, cholesterol, polyunsaturated fat, monounsaturated fat, and saturated fat. No significant differences were noted between the study diet with 19% of kilocalories from sucrose relative to a diet deriving its energy from starch on the mean plasma and urinary glucose, fasting serum cholesterol, HDL cholesterol, low-density lipoprotein (LDL) cholesterol, and triglycerides levels.

Available studies have allowed children and adults with diabetes to feel less constrained by allowing them a diet more consistent with the sucrose-containing diet of their peers. Realistic guidelines for including sucrose-containing foods in the diet also improves patient adherence to overall dietary management. However, sucrose does encourage the development of dental caries, and sucrose-containing foods may contain a significant number of calories, especially when combined with fat in dessert foods such as baked goods, ice cream, and chocolate bars. This may contribute to elevated serum lipid levels and weight gain in some people if they are not carefully monitored. These findings are indications of how glycemic indexing is making us reconsider strongly held doctrines and permitting us to develop improved dietary recommendations.

Fiber

The population with diabetes in the United States consumes, on average, only 16 g of fiber per day (59), which is below the recommended intake of 20 to 35 g/day for those with or without diabetes. Previous studies on fiber in diabetes have had somewhat inconsistent results, probably as a consequence of previously unrecognized differences in the amounts, types, and properties of fiber. The benefits of fiber in improving serum cholesterol levels and colonic function are well established (60), and the American Diabetes Association currently recommends the consumption of 20 to 35 g of fiber daily on the basis of these benefits. However, the effects of fiber on glycemia have been considered to be minimal (15).

Several studies have demonstrated that diets particularly high in fiber (especially soluble fiber) are associated with lower blood glucose and serum lipid levels. Water-soluble fibers, such as the pectins, gums, storage polysaccharides, and a few hemicelluloses found in fruits, legumes, lentils, roots, tubers, oats, and oat bran, have little influence on fecal bulk but may reduce serum levels of glucose and insulin (61-65). Wolever (66) reported that the amount of soluble fiber in whole foods is not closely related to glucose response but discerned a weak, but significant, correlation between the total dietary fiber and the glycemic response to a food. He postulated that the cell walls of foods that elicited a low glycemic response were sturdy and high in cellulose and hemicellulose. However, the differences in fiber components of foods did not explain all the variation in glycemic response. Water-insoluble fibers, such as cellulose, lignin, and most hemicelluloses found in whole-grain breads, cereals, and wheat bran, affect gastrointestinal transit time and fecal bulk but have little impact on plasma glucose, insulin, or cholesterol levels.

New evidence that high dietary fiber intake is beneficial in type 2 diabetes confirms previously published research (67–69). In a recent crossover study, Chandalia et al. (70) demonstrated that intake of dietary fiber, particularly soluble fiber, above the amounts recommended by the American

Diabetes Association improves glycemic control and decreases hyperinsulinemia in patients with type 2 diabetes, in addition to the expected decrease in plasma lipid concentrations. Thirteen patients with type 2 diabetes followed two diets, each for 6 weeks. Both diets consisted of unfortified fiber foods, 15%protein, 55% carbohydrate, and 30% fat. The high-fiber study diet provided 50 g of total fiber daily, with soluble and insoluble fiber providing 25 g each. The American Diabetes Association study diet contained 24 g of total fiber per day, with soluble fiber contributing 8 g and insoluble fiber contributing 16 g. Daily plasma glucose levels were 10% lower with the highfiber diet than with the American Diabetes Association diet. Rendell (71) stated that this study clearly pointed out the importance of dietary intervention in patients with diabetes and that the "decrease in the degree of hyperglycemia achieved in the study by Chandalia et al. by increasing patients' fiber intake is similar to that typically obtained by the addition of another oral hypoglycemic drug to the therapeutic regimen." As expected, the high-fiber diet resulted in lower fasting plasma total cholesterol, triglyceride, and very-low-density lipopolysaccharide (VLDL) concentrations than did the American Diabetes Association diet.

Although it is unclear if improved glycemic control associated with high fiber intake is due to an increase in soluble fiber, insoluble fiber, or both, the total amount of fiber from unfortified whole foods has now been better defined. A practical way of proceeding is to determine the current level of fiber in a patient's diet and to increase the amount of fiber *gradually* to a maximum of 50 g/day. The gradual introduction of the fiber minimizes gastrointestinal problems such as osmotic diarrhea and flatulence. Increased fiber intake should be accompanied by an increase of fluid intake and careful attention to self-monitoring of blood glucose levels. Intake of large quantities of fiber can delay or reduce peak glucose responses to carbohydrate and perhaps predispose an individual receiving antidiabetes medication to hypoglycemia if the dosage of the medication is not adjusted to compensate for this effect.

PROTEIN

The quantity of protein required by diabetic patients varies with age, weight and activity of the case as well as with the condition of the kidneys. It is a safe rule at the beginning of treatment to increase the protein gradually up to the same quantity as that required by a normal individual. This is approximately 1 to 1.5 grams per kilogram body weight for adults but for children it may reach 3 grams. (1)

In a typical Western diet, the estimated protein intake is 1.1 to 1.4 g/kg of body weight for a 70-kg person ingesting 2,000 kcal/ day, an amount considerably greater than the minimum recommended by the National Academy of Sciences (72). The 1989 Recommended Dietary Allowance (RDA) for protein continues to stand at 0.8 g/kg of body weight for adults. This translates to about 10% to 20% of total daily calories from protein from both animal and vegetable sources. There is no evidence to support a higher- or lower-than-average protein intake for those with diabetes.

Individuals whose diabetes is under good control appear to have the same protein requirements as individuals without diabetes. Thus, when insulin levels are normal, protein is conserved in the body and the use of amino acids for glucose synthesis is limited (73). However, severe insulin deficiency increases the loss of body protein, and those with poorly controlled diabetes may have increased needs for protein because their liver may use protein to synthesize glucose. A study by Nair et al. (74) demonstrated that withdrawal of insulin resulted in a 97% increase in protein loss in subjects with type 1 diabetes.

Although there is no evidence that restricting protein will prevent or delay the onset of nephropathy (75), several small studies have suggested that patients with overt nephropathy would benefit from a prescribed protein restriction of 0.6 g/kg per day. Limiting protein consumption to 0.6 g/kg per day (although study participants achieved a restriction of only 0.7 g/kg per day) suggested a modest lowering of the rate of decline in the glomerular filtration rate. However, the Modified Diet in Renal Disease Study (only 3% of participants had type 2 diabetes and none had type 1 diabetes) did not indicate any clear benefit of protein restriction (76). The general consensus is to prescribe a protein intake of 0.8 g/kg per day in those patients with overt nephropathy, with a possible lowering to 0.6 g/kg per day once the glomerular filtration rate begins to decline and careful monitoring for possible protein deficiency and muscle weakness (15).

Because past dietary recommendations for persons with diabetes sometimes emphasized protein and because the average American eats more protein than is necessary to maintain health (15% to 20% of calories), current recommendations suggest that people with diabetes consume amounts similar to those consumed by people without diabetes. Evidence suggests that this amount of protein is not harmful.

Protein and Glucose Concentration

As early as 1915, Janney reported that 3.5 g of glucose could be produced as the result of a beef-protein meal for every gram of nitrogen excreted in the urine. If beef protein is 16% nitrogen, 56% of beef protein can be converted to glucose (77). However, several studies completed after Janney's calculation that focused on the effect of protein on glucose response suggested that protein ingestion by patients with and without diabetes did not elevate blood glucose levels. These important findings were "lost," and Janney's theoretical calculation prevailed. In recent years, several studies conducted by Nuttall et al. (78-80) continue to support that glucose concentration did not increase after protein ingestion in people with or without diabetes. In 1999, Gannon et al. (81) reported that the ingestion of 50 g of lean beef protein by participants with type 2 diabetes resulted in the appearance of only about 2.0 g as glucose in the circulation more than 8 hours later. This result was compared with that for patients who consumed only water. Although the ingestion of beef increased glucose concentration by 0.1 mmol/L at 1 hour, the concentration then decreased similarly to that of participants who consumed only water. Further questions arose when the plasma insulin level remained steady in the water group but the insulin level increased threefold and the plasma glucagon increased 50% in the protein group. If gluconeogenesis from protein is found, researchers can only theorize why glucose does not appear in the general circulation. Several theories, noted in a review of available research by Franz (77), suggest the following:

- The glucose converted from protein is much less than the theorized 50% to 60%, and the smaller amount of glucose from protein that actually enters the general circulation is offset by a corresponding increase in glucose use, as long as enough insulin is available.
- The conversion of glucose from protein is in fact 50% to 60%, but this glucose does not actually enter the general circulation. Gluconeogenesis from protein may occur slowly over 24 hours, and the glucose is disposed of over this long period.
