• Increased insulin secretion caused by dietary protein results in rapid storage of the glucose as glycogen in the liver and skeletal muscles. This glycogen can be broken down to glucose when needed; however, the body does not identify the glucose entering the general circulation as a product from protein or carbohydrate.

Current studies of protein and its effects on blood glucose concentration have possible clinical implications for both type 1 and type 2 diabetes. For those with type 1 diabetes, possible increases in the protein content of the diet, which seems to have a minimal impact on glucose concentrations, while decreasing the carbohydrate content, may improve and stabilize blood glucose excursions. For those with type 2 diabetes, the ingestion of more protein along with less carbohydrate may increase the concentration of circulating insulin. These possibilities demonstrate the importance of examining the beneficial or potentially harmful effects of ingesting higher amounts of protein for those with diabetes.

FAT

The discovery of insulin has lowered the fat in the diabetic's diet, because he can take more carbohydrate. Indirectly, . . . this may retard the development of hardening of the arteries. How much fat should a diabetic patient eat? The safest answer would be: as little as possibly above the normal quantity in order to maintain normal body weight. (1)

People with type 1 diabetes who maintain good control of blood glucose with insulin have plasma lipid levels similar to those of the general population of the same age and gender. However, the prevalence of hyperlipidemia and coronary heart disease (CHD) among patients with type 2 diabetes is twofold to fourfold higher than in the general population. Frequent lipid abnormalities are hypertriglyceridemia and decreased high-density lipoprotein cholesterol (HDL-C), although concentrations of low-density lipoprotein cholesterol (LDL-C) are often not significantly different from those in control populations. However, patients with type 2 diabetes are twice as likely as control populations to accumulate smaller, denser LDL particles, which may increase the risk of CHD even if LDL-C levels are not significantly increased (82,83).

According to recent research, different types and sources of fat have beneficial or detrimental effects on lipid levels.

- Monounsaturated fats are liquid at room temperature and derived primarily from oleic acid. Major dietary sources are olive, canola, and peanut oils; avocados; nuts; and olives. These nonessential fatty acids (NEFAs) help lower LDL-C levels and possibly raise HDL-C levels. Generally, about 10% to 15% of total calories may come from monounsaturated fats.
- *Polyunsaturated fats* are liquid at room temperature and derived from linoleic, linolenic, and arachidonic acids. Major dietary sources are corn, safflower, sesame, and soybean oils. These essential fatty acids (EFAs) are known to lower both LDL-C and plasma cholesterol levels. Omega-3 fatty acids, a type of polyunsaturated fat, lower plasma triglyceride and very-low-density lipopolysaccaride cholesterol (VLDL-C) levels. Major dietary sources are fatty fish, flaxseed and other vegetable oils, shortenings, and liquid or partially hydrogenated margarines.
- Saturated fats are mostly solid at room temperature and synthesized in the body from acetate. Major dietary sources are animal products such as butter, meat, lard, poultry skin, whole milk, cheese, sour cream, cream cheese, and tropical oils such

as coconut, cocoa butter, palm oil, and palm kernel oil. These NEFAs increase total serum cholesterol and LDL-C levels.

• *Trans-fats* are semisolid at room temperature. The chemical process of hydrogenation causes unsaturated fatty acids to become more saturated and alters the position of hydrogen atoms around the double bond (on opposite sides, or *trans*). This process increases the shelf life of foods. Major dietary sources are polyunsaturated vegetable oils in solid margarines, salad dressings, shortening, and many baked goods. Trans-fats increase LDL-C and decrease HDL-C and are associated with an increased risk of CHD.

Guidelines of the National Cholesterol Education Program: Adult Treatment Panel III

Research advances in the prevention and management of high cholesterol in adults led the National Cholesterol Education Program (NCEP) Expert Panel on Detection, Evaluation, and Treatment of High Blood Cholesterol in Adults (Adult Treatment Panel III, ATP III) to issue major new clinical practice guidelines in 2001 (84). In 1985, this program began to promote greater awareness by physicians and patients of CHD risk status by blood cholesterol level and to provide recommendations for dietary treatment and educational programs. Earlier guidelines were issued in 1988 and 1993.

The 2001 ATP III guidelines recommend a new set of therapeutic lifestyle changes (TLCs) that intensify the use of nutrition, physical activity, and weight control in the treatment of elevated blood cholesterol (Table 36.8). These guidelines reflect changes in the eating habits of Americans, including a decrease in the consumption of saturated fats and cholesterol. The present recommendations allow up to 35% of daily calories from total fat, provided mostly from unsaturated fat, which does not raise cholesterol levels. Abnormalities in lipid and carbohydrate metabolism in those with diabetes must be carefully assessed because of the potential risk of promoting higher triglyceride levels with a high-carbohydrate diet while attempting to decrease total and saturated fats to lower LDL-C (85). Some patients with high triglyceride or low HDL levels or both may need to eat more unsaturated fats to keep their triglyceride or HDL levels from worsening.

ATP III also encourages use of foods that contain plant stanols and sterols or are rich in soluble fiber to boost the LDLlowering power of the diet. Plant stanols and sterols are included in certain margarines and salad dressings. Foods high in soluble fiber include cereal grains, beans, peas, legumes, and many fruits and vegetables. Additional guidelines stress the importance of weight control, which enhances the lowering of LDL levels and increases HDL levels; and physical activity, which improves HDL values and, for some, LDL values (86).

The recommendations for dietary fat intake for those with diabetes depends on treatment goals for existing hyperlipidemia and risk of CHD, as well as goals for blood glucose and weight. If the recommendations for dietary protein are for about 15% of total calories per day, the remaining 85% to 90% of calories may be distributed through fats and carbohydrates. The first line of defense is to get fewer than 7% of the allotted calories from saturated fat, with dietary cholesterol limited to less than 200 mg/day. Up to 10% of total calories should be from polyunsaturated fats, and up to 20% of total calories should be from monounsaturated fats. However, consumption of omega-3 polyunsaturated fats found in seafood does not need to be decreased in people with diabetes. The remaining calories can then be derived from complex carbohydrates, including whole grains, fruits, and vegetables.

Fat Replacers

The medical need to decrease fat in the diets of those with type 2 diabetes has increased the demand for palatable, lower-fat foods and has led to the creation of fat replacers. Fat replacers are used in many fat-free, nonfat, reduced-calorie, and low-fat foods in an attempt to lower fat and calorie intake. At present, most fat replacers are carbohydrate-based, but some are protein- or fat-based. One fat-based replacer, olestra, was approved by the Food and Drug Administration (FDA) in 1996 for use in snack foods and crackers. Studies of this synthetic oil indicated that it has the potential to lower total cholesterol and LDL-C in persons consuming either a high- or a low-cholesterol diet (87).

Although fat replacers have the potential to reduce total and saturated fat in the diet, patients must be educated to use them wisely within the context of an overall food plan. Unfortunately,

TABLE 36.8.Therapeutic Lifestyle Changes: Nutrient Composition of Therapeutic Lifestyle Changes Diet					
Nutrient	Recommended intake				
Saturated fat ^a	Less than 7% of total calories				
Polyunsaturated fat	Up to 10% of total calories				
Monounsaturated fat	Up to 20% of total calories				
Total fat	25%–35% of total calories				
Carbohydrate ^b	50-60% of total calories				
Fiber	20–39 g/day				
Protein	Approximately 15% of total calories				
Cholesterol	Less than 200 mg/day				
Total calories (energy) ^c	Balance energy intake and expenditure to maintain desirable weight and prevent weight gain				
^b Carbohydrate should be derived grains, especially whole grains; from the second state of the second sta	-raising fat that should be limited in the diet. predominantly from foods rich in complex carbohydrates, including uits; and vegetables. many patients with type 2 diabetes are not aware of the potential high-calorie content of fat-free foods made with fat replacers. These foods are created by using mixtures of carbohydrates or proteins to simulate the properties of fat and cannot be eaten liberally without affecting caloric intake, glycemia, and weight.

Plant Stanol Esters

A new dietary approach to helping manage serum cholesterol levels is now being used in the United States. Plant stanol esters (PSEs) occur naturally in plant products, especially oils, and are the saturated derivative of sitosterol known as sitostanol. PSEs are structurally similar to cholesterol and are virtually unabsorbed by the body. PSEs are found in soy and olive oils, corn, rye, rice, wheat, and wood. More than 20 published studies support the cholesterol-lowering effects of stanol esters. A landmark 15-month study by Miettinen et al. (88) in Finland focused attention on the cholesterol-lowering benefits of PSE in the form of margarine with and without sitostanol. After 1 year, total cholesterol was reduced by up to 10% and LDL-C by up to 14%; HDL-C and triglycerides were unaffected. A U.S. multicenter study (89) conducted in 1999 demonstrated the efficacy and safety of PSE spreads. At 2 weeks, significant reductions in total cholesterol and LDL-C were reported in all groups. At 12 weeks, an average reduction in LDL-C of 12% versus baseline was achieved. Researchers have concluded that PSE may be useful in the dietary approach to cholesterol lowering and suggest a benefit by adding PSE to NCEP III nutrition recommendations. The trade names of current plant PSE spreads on the market include Benecol® and Take Control®.

Soluble Fiber and Cholesterol

Chandalia et al. (70) also reaffirmed the results of previous reports of the cholesterol-reducing effects of soluble but not insoluble fiber. Thirteen patients with type 2 diabetes followed two diets, each for 6 weeks. The effects of the American Diabetes Association diet (total fiber, 24 g: 8 g of soluble fiber and 16 g of insoluble fiber) were compared with a high-fiber diet (total fiber, 50 g: 25 g of soluble fiber and 25 g of insoluble fiber). The high-fiber diet reduced total plasma cholesterol concentrations by 6.7%, reduced triglyceride concentrations by 10.2%, and reduced VLDL-C by 12.5%. The LDL-C was 6.3% lower with the high-fiber diet. There were no significant differences in HDL-C. This study demonstrated the positive effects of a high-fiber diet, particularly soluble fiber, on lowering plasma lipid concentrations.

Educating Patients about Fat Intake

A primary strategy for patients with hypercholesterolemia, before they use cholesterol-lowering medications, is nutrition education. Key education points for patients with diabetes should include the following:

- Understanding the difference between dietary and blood lipids and how to change and decrease the dietary fats to lower blood lipid levels.
- Reducing total fat intake to 25% to 35% of calories based on nutrition assessment, with fewer than 7% of calories from saturated fat while meeting needs for essential fatty acids (seafood).
- Shifting the emphasis from animal to vegetable sources of fat.
- Encouraging the use of liquid, unsaturated oils, plant stanols, and tub or liquid margarines and reducing the use of foods with partially hydrogenated oils.

- Emphasizing an increase in fiber by the inclusion of more whole grains, vegetables, and fruits.
- Recognizing that fat provides a concentrated source of calories in the diet and in body stores for those who want to lose weight loss or are obese.
- Reducing or eliminating alcohol intake for those with dyslipidemia, especially those with elevated triglyceride levels.

ALTERNATIVE SWEETENERS

Nutritive Sweeteners

In the past, the use of sucrose and glucose alone or in foods high in these sugars (corn syrup, fruit juice, honey, molasses, dextrose, and maltose) was restricted for those with diabetes. This dietary approach was a means of limiting excursions of blood glucose and limiting calories in the overweight person with diabetes. This approach gave rise to the development of alternative sweeteners-both caloric and noncaloric. For years, these alternative sweeteners have played a dominant role in providing persons with diabetes with sweetness in their diet, much as they do for those without diabetes. Some patients with diabetes may feel that sweeteners help them adhere to their "diet," contribute to better diabetes control, and are beneficial for weight reduction. Unfortunately, little scientific evidence supports these beliefs. The American Diabetes Association notes that "there is no evidence that foods sweetened with these sweeteners have any significant advantage or disadvantage over foods sweetened with sucrose in decreasing total calories or carbohydrate content of the diet or in improving overall diabetes control" (15).

Although fructose has previously been promoted as producing a smaller increase in blood glucose than equal amounts of sucrose and most starches, evidence suggests potential negative effects of large amounts of fructose (twice the amount usually consumed, or 20% of daily calories) on serum cholesterol and LDL-C (90). However, no recommendations have been made to avoid foods with naturally occurring fructose, such as fruits and vegetables, or even modest amounts of fructose-sweetened foods.

Sugar alcohols (polyols) such as sorbitol, mannitol, xylitol, isomalt, lactitol, maltitol, and hydrogenated starch hydrolysate are less sweet than sugar but do add bulk to foods. They are manufactured from monosaccharides, disaccharides, or polysaccharides for use in foods. Of note, sorbitol does not contribute to the sorbitol pathway that has been implicated in neuropathy and retinal changes. Once sorbitol has been metabolized in the liver, it is no longer available to the body (91). Polyols may elicit less of a glycemic response because they are absorbed more slowly and provide only 2.4 to 3.5 kcal/g as compared with 4 calories/g from other carbohydrates. The incomplete absorption of sugar alcohols, producing osmotic diarrhea when ingested in large amounts (50 g/day for sorbitol, 20 g/day for mannitol), constitutes the main drawback to their use (21). Sorbitol and mannitol must have warning labels affixed that state, "Excess consumption may have a laxative effect."

There is no concrete evidence that sugar alcohols reduce total calories or the total daily carbohydrate intake of those with diabetes. However, it is important that those with diabetes have a good understanding of the potential of nutritive sweeteners to affect blood glucose levels and to account for these effects.

Nonnutritive Sweeteners

Acesulfame K, aspartame, saccharin, and sucralose are the common noncaloric intense sweeteners used at present in the United States. All have been approved by the FDA. An acceptable daily intake (ADI) is determined for these intense sweeteners, as for all food additives. ADI is defined as the amount of a food additive that can be safely consumed on a daily basis over a person's lifetime without having any adverse effects. The ADI also includes a 100-fold safety factor.

ACESULFAME K

Acesulfame K (acesulfame potassium) is a white, odorless, crystalline sweetener. It has no caloric value and is 200 times sweeter than sucrose. It is described as having a clean, fresh taste that does not linger, but some perceive that it has a bitter taste when used in large amounts (92). Acesulfame K is a derivative of acetoacetic acid with a structure somewhat similar to that of saccharin. Approved for use by the FDA in 1988, it is marketed in the United States under the brand name Sunette® when used as an ingredient in foods and as Sweet One[®] when sold as a table-top sweetener. Its advantages are its remarkable stability both in liquids and during baking or cooking. Acesulfame K is not metabolized by the body and is eliminated unchanged in the urine. It is heat stable and blends well with other sweeteners. The amount of potassium in this sweetener is minimal (only 10 mg of potassium per packet). No safety concerns have been raised about acesulfame K, and it is reported to be safe for all individuals. The ADI for both adults and children is 15 mg/kg per day (one packet contains about 0.4 g) (93).

ASPARTAME

Aspartame is a protein sweetener. It is the methyl ester of Lphenylalanine and L-aspartic acid. Intestinal esterases hydrolyze aspartame to aspartic acid, methanol, and phenylalanine. Medical nutrition therapy controls the use of aspartame products in persons with phenylketonuria, a homozygous, recessive inborn error of metabolism that makes them unable to metabolize the amino acid phenylalanine.

Aspartame is 160 to 220 times sweeter than sucrose. Aspartame contains 4 kcal/g but because of its intense sweetening ability provides negligible calories. It was first approved for use in 1981 and is marketed as NutraSweet[®] both in food products and as a table-top sweetener. Aspartame does not alter glycemic control in individuals with diabetes (94). It is metabolized in the gastrointestinal tract and at recommended intakes does not accumulate. Aspartame may decompose with long exposure to high temperatures and is not heat stable. The ADI for adults and children is 50 mg/kg body weight (37 mg in one packet, 200 mg in a 12-oz diet soda).

The FDA has addressed many concerns related to ingestion of aspartame for individuals with and without diabetes. A variety of safety concerns have been raised, i.e., that mild, nonspecific symptoms such as headaches, dizziness, and menstrual irregularities are associated with its ingestion and that the byproducts of metabolism (methanol or its by-product formate) are toxic. This prompted the Centers for Disease Control and Prevention (CDC) to further evaluate aspartame. The CDC reported that data "do not provide for the existence of serious widespread, adverse health consequences" (95). Aspartame has repeatedly been determined to be safe for both the general public and people with diabetes.

SACCHARIN

Saccharin is a heat-stable, synthetic sweetener that is 200 to 700 times sweeter than sucrose. Saccharin is without caloric value because it is not metabolized and is excreted unchanged. Concern about the carcinogenic potential of saccharin has lingered for years, although a review of the literature has not yielded evidence that can justify governmental restriction (96–98). Although saccharin is synthetic and not a food additive, the Joint Expert Committee of Food Additions of the World Health Organization has set an ADI of 5 mg/kg body weight per day. The FDA has stated that saccharin poses no health hazard.

SUCRALOSE

Sucralose is the most recent noncaloric sweetener to be approved by the FDA (in 1998), and its use has been confirmed by many regulatory agencies throughout the world. It is 600 times sweeter than sugar and marketed under the name of Splenda[®]. Sucralose is made from sucrose through a chemical process that alters the sucrose molecule by replacing three hydrogen/oxygen groups with three chlorine atoms. Sucralose is not recognized by the body as either a sugar or a carbohydrate. It does not affect carbohydrate metabolism and is eliminated unchanged by the body (93,99).

Sucralose is heat stable and may be used in cooking and baking. The FDA states that no adverse or carcinogenic effects are associated with consumption of sucralose. The ADI for adults and children is 15 mg/kg body weight per day (93).

SODIUM

Salt is of great service to the diabetic patient. The percentage of salt (sodium chloride) in the ocean and in the human blood is alike and the body tends to keep it constant. The first essential for a low sodium diet is to omit all salt either in the preparation of food or at the table. (1)

The recommended sodium intake for people with diabetes is the same as that for people without diabetes, with the main goal being not to exceed 3,000 mg/day. Some health professionals do, however, recommend no more than 2,400 mg/day, which is equivalent to 1 teaspoon of salt. Because the recommendations are the same as those for the general population, guidelines should be directed toward the entire family. Severe sodium restriction, however, may be harmful for persons whose diabetes is poorly controlled or who have postural hypotension or fluid imbalance.

Persons with diabetes have not been found to be more sensitive to sodium than persons without diabetes or to be at greater risk of developing hypertension associated with high sodium intake. Concern about sodium intake is directed primarily at individuals with congestive heart failure, nephropathy, and hypertension or who are at risk for the development of these complications. Routine monitoring of blood pressure will help identify those who may benefit from a reduction in sodium intake. The recommended intake of sodium is less than 2,400 mg/day for those with mild-to-moderate hypertension and less than 2,000 mg/day for those with hypertension and nephropathy.

Patients should always be cautioned about the use of salt substitutes, which often contain potassium rather than sodium. When consumed in excess, salt substitutes can be harmful, especially for people with kidney problems. As an alternative to salt substitutes, salt-free seasoning blends are readily available.

ALCOHOL

Adults with diabetes do not have to abstain from alcohol. Indeed, the guidelines for alcohol use in individuals with diabetes mirror those for the general population. However, restrictions on or abstinence from alcohol may be necessary for those with hypoglycemic unawareness, neuropathy, poor control of blood

624 JOSLIN'S DIABETES MELLITUS

glucose or blood lipids, pancreatitis, obesity, or a history of alcohol abuse, or for those who are pregnant.

Some issues regarding the use of alcohol require attention. First, alcohol adds calories without nutritional benefit and has been shown to supplement rather than displace other calories (100). Suter et al. (101) and Flatt (102) demonstrated that, whereas carbohydrate and protein oxidation was mostly unaffected by the ingestion and metabolism of alcohol, fat oxidation was decreased by about 50%. Therefore, restriction of calories provided by ethanol is a dietary strategy that is positively related to success with weight loss. Second, excessive alcohol consumption by a person who is fasting or skipping meals can lead to hypoglycemia via inhibition of gluconeogenesis. This may pose a serious risk for those taking insulin or oral agents to control hyperglycemia. Even blood alcohol levels that do not exceed mild intoxication can result in hypoglycemia (21). Third, intoxication can impair a person's ability to follow a prescribed management plan or to recognize symptoms of hypoglycemia and obtain treatment if needed. Fourth, ingestion of alcohol increases the synthesis of lipoproteins, especially VLDL. Because some persons with diabetes are susceptible to hypertriglyceridemia, and because alcohol has the potential to raise triglyceride levels, alcohol ingestion should be discouraged. Recent studies, however, indicate that moderate amounts of alcohol have been associated with a decrease in CHD attributed to an increase in less dense HDL-C subfractions (15,103-106).

Alcohol Guidelines

- Alcohol use and abuse should be discussed as part of the education process for all persons with diabetes so that they know the facts about the effects of alcohol on glycemia.
- Excessive alcohol consumption may lead to erratic behavior, loss of consciousness, or seizures, particularly if food is not consumed with the alcohol. Alcohol should only be consumed with food or after the meal.
- For those with type 1 diabetes, alcohol should be taken in addition to their regular meal without omitting any food. Metabolism of alcohol does not require insulin.
- For those with type 2 diabetes, alcohol is best substituted for fat calories: One alcohol equivalent equals two fat exchanges (10 of fat).
- Glucagon is not effective in the treatment of alcohol-induced hypoglycemia because alcohol depletes glycogen stores.
- Alcohol should be used only when diabetes is under good control and in moderate amounts. Alcohol should be strictly avoided when driving.
- General recommendations for alcohol intake are no more than two alcohol equivalents per day for men and no more than one alcohol equivalent per day for women. An alcohol equivalent, which contains about 1 oz (15 g) of alcohol, is defined as 12 oz of beer, 5 oz of wine, or 1.5 oz of 80-proof distilled spirits (15).
- A person who ingests alcohol should always be encouraged to monitor blood glucose levels.
- Wearing identification is extremely important for individuals who choose to drink, because intoxication and symptoms of hypoglycemia can often be confused. Drinking alone should always be discouraged.

THE MICRONUTRIENTS: VITAMINS AND MINERALS

Intake of vitamins and minerals should meet recommended levels for good health. If dietary intake is balanced and adequate, there is usually no need for additional vitamin and mineral supplements for the majority of people with or without diabetes. Supplementation of vitamins and minerals should not be used in place of a varied, balanced diet to ensure adequate nutrients. However, those who may be at risk for micronutrient deficiencies and are likely to respond positively to multivitamin supplementation include (a) those who are on a very-low-calorie diet for weight reduction; (b) those who are taking medications that may alter certain micronutrients; (c) those who have documented micronutrient deficiencies such as anemia or osteoporosis; (d) those who are strict vegetarians; (e) pregnant or lactating women; (f) those who are elderly and confined or unable to eat; (g) children and teenagers who severely limit foods or whole food groups; and (h) those who have uncontrolled hyperglycemia with glycosuria, which can result in excess excretion of water-soluble vitamins.

Vitamins and minerals involved in carbohydrate and glucose metabolism that are topics of current research will be discussed briefly.

Chromium

Fortunately, most people with diabetes are not chromium deficient, and chromium supplementation is not recommended unless a deficiency is clearly documented. This trace mineral is needed to potentiate insulin action by the production of glucose tolerance factor. Chromium deficiency in both animal and human studies is associated with elevated blood glucose and lipid levels. Populations at risk for chromium deficiency include the elderly and those on long-term total parenteral alimentation. A study in China reported in 1997 (107) suggested a possible role for chromium supplementation. Individuals with type 2 diabetes were given either a 1,000-µg or 200-µg chromium picolinate supplement or a placebo. Both fasting blood glucose and glycosylated hemoglobin A1c levels were decreased in all three groups, but those taking the 1,000-µg supplement had much larger decreases in fasting and 2-hour insulin concentrations and in total cholesterol. Although the study of Anderson et al. (108) in rats showed a lack of toxicity of chromium chloride and chromium picolinate at concentrations at extremely high limits of what is estimated to be safe, other studies have demonstrated that very large amounts of chromium picolinate caused severe chromosomal damage in animals (109). Until new research can clearly demonstrate the benefits and safety of chromium supplementation, the American Diabetes Association maintains that chromium supplementation is of no known benefit except for those with chromium deficiency (15).

Magnesium

The magnesium link to diabetes involves the transport of glucose across membranes and the oxidation of glucose. Magnesium deficiency has been associated with insulin resistance, carbohydrate intolerance, cardiac arrhythmias, congestive heart failure, retinopathy, and hypertension. Probably the most common cause of magnesium deficiency among those with diabetes is loss of magnesium through chronic glycosuria or diuretic use. A deficiency may lead to increased insulin resistance or may be a result of insulin resistance (110). Several small studies have found that supplementation with magnesium can improve glucose control and insulin sensitivity (111,112). The American Diabetes Association does not recommend routine evaluation of magnesium status in healthy individuals with diabetes but recommends routine evaluations for those people at high risk for magnesium losses, such as those with poor glycemic control (diabetic ketoacidosis and prolonged glycosuria), those receiving diuretics, those with

intestinal malabsorption, those with calcium or potassium deficiencies, and pregnant women.

Antioxidants

Antioxidants have received wide attention in the past decade because of their ability to neutralize reactive free electrons and prevent toxic cellular damage. Although there are many antioxidants, including vitamins, minerals, and even plant substances, the emphasis has been on their role in reduction of cancer and cardiovascular risk. Vitamin E is receiving closer attention in people with diabetes. Vitamin E has been related to a decreased risk of cardiovascular disease. α -Tocopherol is considered the major antioxidant for LDL-C and has been reported to increase the oxidative resistance of LDL and improve nonoxidative glucose metabolism in people with type 2 diabetes (113,114). Recent research by Bursell et al. (115) demonstrated that vitamin E may reduce the risk of the development of nephropathy and eye disease. An 8-month trial evaluated 36 patients with type 1 diabetes of short duration. Patients were randomly assigned to either 1,800 IU vitamin E per day or placebo for 4 months and followed up and, after treatment crossover, were followed up for another 4 months. Oral vitamin E treatment appeared to effectively normalize retinal hemodynamic abnormalities and improve renal function without inducing a significant change in glycemic control.

Recommended dosages of vitamin E for people with cardiovascular disease should be in amounts no greater than 400 IU/day. Higher doses may increase the risk of stroke in people with high blood pressure and of bleeding for those patients receiving anticoagulants.

DESIGNING THE MEAL PLAN

Treatment rests in the hands of the patient. It is by diet and exercise as well as by insulin, and the patients with the will to win and those who know the most, conditions being equal, can live the longest. There is no disease in which an understanding by the patient of the methods of treatment avails as much. Brains count. (1)

One of the primary reasons people with diabetes have such difficulty understanding "nutrition issues" is a lack of nutrition education and counseling by qualified professionals (e.g., registered dietitians). Instead, patients may simply be told to restrict "sugar" or "cut down on calories" or may be given a "sample menu" to follow without an adequate educational foundation. The DCCT provided important insight into the role of nutrition intervention in intensive diabetes treatment and stated that registered dietitians are best qualified to match appropriate meal-planning approaches to the needs of the patient (10).

The time required by the educator and person with diabetes depends on multiple factors, such as emotional status, extended support system, preconceived ideas about the "diabetic diet," and the person's social and cultural attitudes. The consideration and involvement of the person with diabetes are considered critical to devising a successful meal plan that the person is willing and able to follow to promote positive outcomes.

A qualified registered dietitian is an important member of the diabetes team, helping patients understand the relationships among nutrition, exercise, and medication. A dietitian can gather a detailed nutrition history that includes a person's usual intake, the frequency with which he or she eats outside the home, ethnic influences on food choices, food preferences, weight history, diets followed in the past, and food allergies. Caloric needs may then be estimated and developed into a workable meal plan. Meal plans also are based on an individual's lifestyle, sociocultural and economic characteristics, activity level, food preferences, type of diabetes, medications, and other dietary restrictions. The dietitian can instruct and counsel the patient about all of the aspects of nutrition care as it relates to sick-day food management, restaurant eating, carbohydrate counting for intensive insulin therapy, exercise, snacks, and how to incorporate "treats" into the meal plan within the context of overall healthy eating.

Nutrition information is usually presented in small, sequential stages. Initially, basic "survival skills" can be taught and individualized with only general guidelines provided, such as consistency with timing, amount and types of foods, and the relationships among food, activity, and medication. This visit should lay the groundwork in nutrition basics and serve to develop a sound and trusting relationship with the patient.

In later stages, more detailed information can be provided to extend and reinforce existing knowledge and help the patients make positive improvements in nutrition behavior through continuous reviews of food and blood glucose records, laboratory values, and weight status. In recent years, the importance of tailoring nutrition programs to the individual's cultural framework to include traditional foods has been emphasized. Educators must use educational techniques appropriate to the literacy of the individual. The need for tools and techniques suitable for various ethnic groups or learning styles has led to the development of a wide variety of teaching tools, educational materials, and meal-planning approaches.

Meal-Planning Approaches

A *meal-planning approach* simply means the educational resource used by the dietitian to teach the patient how to plan meals (116). Several meal-planning alternatives are available for persons with diabetes.

CARBOHYDRATE COUNTING

Basic carbohydrate (carb) counting may be used for those receiving conventional therapy, with or without insulin. This approach assumes that one carbohydrate choice is based on the amount of food that contains 15 g of carbohydrate (Table 36.9). Patients may simply be given a "carb allowance" to aim for at each meal, while enabling them to spend their allowance based on healthy choices, weight, blood glucose levels, or lipid abnormalities. Advanced carbohydrate counting may be used for those who want to achieve near-normal glucose levels with multiple daily injections of insulin or continuous subcutaneous insulin infusion. This approach coordinates food intake (carbohydrate) by matching the peak activity of insulin with the peak levels of glucose resulting from the digestion and absorption of food. This method allows more precise adjustment of premeal rapid- or short-acting insulin using an insulin/carbohydrate ratio. The ratio is based on the assumption that carbohydrate intake is the main consideration in determining meal-related insulin requirements, together with values from self-monitoring of blood glucose and premeal blood glucose targets set by the physician and the patient. A good understanding of how carbohydrate affects blood glucose, what food groups contain carbohydrate, and which reference books provide carbohydrate content of specific foods is necessary for this approach to be effective.

THE EXCHANGE SYSTEM

This meal-planning approach is based on three main food groups: the carbohydrate group (starch, fruit, milk, vegetables, and other carbohydrates), the meat and meat-substitute group TABLE 36.9. Food Choices

Carbohydrate

Breads, Cereals, & Grains	Beans	Starchy Vegetables	(Crackers/Snacks

From Exchange lists for meal planning, with permission of the American Diabetes Association and the American Dietetic Association, \bigcirc 1995.

(protein), and the fat group (Table 36.10). Examples of the specific amounts of carbohydrate, protein, fat, or combination of these nutrients in each food group are found in Table 36.9. Foods with similar nutrient values are listed together and may be exchanged or traded for any other food on the same list (117). Portion sizes for each food are listed and are measured after cooking. Exchange lists are used to achieve consistent timing and intake of nutrients and to provide some variety when planning meals. Initially, exchange lists and a meal plan can be a starting point for those patients on conventional therapy or intensive insulin management and can help them learn the carbohydrate content of foods.

GUIDELINE APPROACHES

Another simplified guideline approach, Healthy Food Choices, was successfully used in the DCCT (10). This approach provides an introduction to diabetes meal planning and is most often used in the first stage of nutrition education. It provides guidelines for making healthy food choices with an abbreviated, simplified exchange list.

MENU APPROACHES

This simplified approach is the basis of all meal-planning approaches and illustrates how meals can be designed to accommodate the patient's food preferences and lifestyle while maintaining a healthy dietary intake. Menus may be specific or offer several choices. This method involves the patient in the concept of portion size.

COUNTING APPROACHES

Calorie or fat-gram counting may be appropriate for the obese patient with type 2 diabetes. These self-monitoring methods engage the patient in recording daily food intake and will assist the patient and the dietitian to individualize nutrition goals and achieve weight loss by the patient. These methods also provide some structure in the form of a number of calories or fat grams to strive for on a daily basis while allowing flexibility and variety in meal planning.

In summary, any of these methods can be appropriate for any given individual, but development of an individual meal plan requires that the patient be educated in both the principles of good nutrition and their effective implementation.

MEDICAL NUTRITION THERAPY FOR THE ELDERLY

The healthcare provider who takes into consideration the changes that come with age can vastly improve the nutritional status of and care given to the elderly patient. In general, the elderly have a higher percentage of body fat, a lower lean body mass, and a lower caloric requirement. The extent of the decrease in caloric needs depends on health status and activity levels.

Eating patterns in the elderly can be significantly influenced by many physical, mental, and emotional factors, such as impaired vision, smell, hearing, and/or taste; decreased dexterity and memory; loneliness and depression; dental problems; illness and multiple medications; limited financial resources; and problems of mobility and transportation. Poor teeth and gums or ill-fitting dentures are widespread problems in the elderly and commonly lead to their consumption of softer foods high in sugar and fat. Foods containing greater amounts of fiber, such as fresh fruits, vegetables, or whole-grain cereals or breads, can be more difficult to chew. Depression and physical limitations can limit their access to food or ability to prepare it.

All of these factors contribute to the increased difficulties that the elderly person has in coping with the many demands imposed by diabetes. The important first step in nutritional management for the elderly patient is a complete assessment of all factors that affect nutrition. Obtaining necessary information from some elderly persons may be difficult because of a short attention span, poor short-term memory, or a severe deficit in mental capacity. Older persons may not be able to recall their diet clearly enough to provide the educator with the information necessary for making appropriate dietary recommendations. If possible, family or caregivers or both should be present during education sessions.

In general, it is probably best to keep the meal-planning regimen of the elderly simple. Nutritional goals should aim at the provision of simple, balanced, consistent meals that fit longstanding eating habits and the physical and psychological needs of the individual. Trying to change long-standing food habits by imposing new, rigid, and/or complicated meal plans may not be successful. On the other hand, many elderly have the time and interest to get highly involved in their diabetes management and will eagerly follow instructions when given the necessary support and information.

628 JOSLIN'S DIABETES MELLITUS

Last, financial difficulties and social isolation of the elderly and the dietary problems they create cannot be neglected. The dietitian must be sensitive to these needs and be prepared with useful suggestions. Many communities have a variety of support services for elderly citizens, and all health professionals should be familiar with the resources and services available.

MEDICAL NUTRITION THERAPY AND PREGNANCY

Optimal medical and nutritional care must begin before conception to ensure a healthy pregnancy and a positive outcome. In general, the nutritional requirements of a pregnant person with diabetes are essentially the same as those of a pregnant person without diabetes. However, pregnancy magnifies the importance of adherence to nutrition management principles for those with diabetes, the rigid control of glucose levels throughout the course of pregnancy, and the avoidance of ketonuria.

Nutrition management during pregnancy should begin at the earliest possible time. Caloric intake should be evaluated as soon as possible in the first trimester and at the start of each trimester thereafter to ensure adequate intake. During the first trimester of pregnancy, daily caloric levels may vary between 30 and 38 kcal/kg of ideal prepregnancy weight. During the second and third trimesters, this level is increased to 36 to 38 kcal/kg of ideal prepregnancy weight (118). These additional calories during the second and third trimesters are needed for increases in maternal blood volume and increases in breast, uterus, and adipose tissue; placental growth; fetal growth; and amniotic fluids (15). However, individualized caloric targets, blood glucose levels, and weight goals may be recommended. In addition, pregnant women need adequate protein (0.75 g/kg per day plus an additional 10 g per day) (15). For those with preexisting diabetes in pregnancy, three meals and three snacks should be spaced no less than 2 hours apart and no more than 4 hours apart. Distribution of calories is as follows: carbohydrate, 40% to 50% of total calories; protein, 20% to 25% of total calories; and fat, 30% to 40% of total calories.

Caloric requirements are based on pregravid weight, height, age, activity level, and usual intake. Weight gain must also be measured during pregnancy. Both actual weight and BMI may be used for weight assessment. The Joslin Diabetes Center's recommendations for weight gain during pregnancy are listed in Table 36.11. Pregnant women should gain only 2 to 5 pounds during the first trimester. Thereafter, a steady gain of about 1 pound per week is recommended. However, underweight women should gain 1.1 pounds per week, and overweight women should gain only 0.7 pound per week (116). In addition, special emphasis should be placed on the following:

- Meal planning to include appropriate calcium, folic acid, and other vitamins
- Modification of the meal plan to address nausea, vomiting, heartburn, and constipation
- Risk assessment and prevention of fasting hypoglycemia
- Adequate carbohydrate, protein, and fat intake at bedtime to prevent nocturnal hypoglycemia or ketones
- Current intake of sweeteners and caffeine
- Adjustment of calories for gestational age
- Weight-gain goals during pregnancy based on pregravid weight and clinical assessment.

MEDICAL NUTRITION THERAPY FOR CHILDREN AND ADOLESCENTS

Food and feeding issues are very important in the physical and psychological growth of children. Diet education must be approached differently and be responsive to each child, his or her developmental state, and family dynamics. The child with diabetes is adding the complexities of balancing food, insulin, and activity to the already demanding needs of physical maturation and psychological, social, and cultural development. Adolescents with diabetes face unique challenges. At a time when they are attempting to separate from and become independent of parents and authority, they must follow management routines frequently in conflict with this need as well as with their need to attain peer uniformity. Special attention must be paid to these needs to achieve the young person's maximal cooperation with dietary management.

It is now possible to provide a more positive approach to what could be a potentially negative topic for children and teens: nutrition management and diabetes. Healthcare providers on the diabetes team must not lose sight of the ability of food to provide more than nutrients, especially for this group. Changes in eating should not be viewed as restrictions and losses but as a healthful way for the whole family to eat. Every attempt should be made to design a meal plan that reflects the child's food preferences and the family's social and cultural attitudes. Flexibility and graduated goal setting are important keys to success, increasing the chances of the child's achieving optimal diabetes management and decreasing the development of complications. In the attempt to maintain the "pleasures of the table," it is essential that the nutrition guidelines promote "normal" healthy eating and prevent isolating and dividing the child and family in their food choices.

For the child with diabetes, frequent assessment of diet and careful monitoring of growth are necessary. Nutritional assessment should include the regular plotting of height and weight measurement on standard growth charts in an effort to detect any

	TABLE 36.11.	Recommended	l Weight Gain Duri	ng Pregnancy

shift in growth. Meal plans will need to be adjusted on a regular basis to account for changes in growth rate and activity. There can be wide seasonal variations in caloric needs as children change activity patterns from school to home, on weekends or vacations, and from periods of sports activity to lulls between seasons. General guidelines to help develop a positive working relationship with the child or adolescent and their caretakers are as follows:

- Include children and teens in the interview to allow them to be part of the decision-making process.
- Do not refer to or label a child as a "diabetic"; these are children who happen to have diabetes.
- Interview prepubertal children separately and together with family to stimulate self-management.
- Provide reassurance that most of the child's usual foods can be included in his or her meal plan.
- Describe the meal plan as a "road map" for healthy eating, rather than a rigid diet.
- Stress healthy eating practices for the entire family rather than focusing on just the child with diabetes.
- Avoid negative words when counseling, such as cannot, do not, never, bad, restrict, and especially the word diet. In a child's mind, diet connotes deprivation, as well as a shortterm process rather than an ongoing one.
- Ask about favorite foods and avoid eliminating these foods. Instead, stress balance, moderation, and variety.
- Review the reality of special treats for special occasions and relate treat foods to extra exercise and active days.
- Advise caregivers that omitting foods because of a single high blood glucose reading is not advisable.

Continued nutritional follow-up and education are required every 6 months to 1 year as the child grows and develops and as the family works to gain expertise in the nutritional management of diabetes.

SUMMARY

Nutrition management for the person with diabetes is one of the most important factors in the attainment and maintenance of good metabolic control. Devising meal plans that provide flexibility while conforming to guidelines based on current research is a constant challenge to the registered dietitian. To translate meal plans into an action plan for patients with diabetes, a registered dietitian must have a thorough understanding of all the components of diabetes management and help each person adapt diabetes to his or her lifestyle instead of adapting lifestyle to his or her diabetes. Although a great deal of information that improves our ability to manage diabetes continues to be generated, we do not yet have the final answers about what constitutes the "ultimate" dietary maneuvers. Therefore, it is important for the clinician to stay abreast of new research and knowledge and be willing to try new approaches to nutritional management of diabetes.

CONCLUSION 644

Over the past half-century, there has been an explosion of research and clinical work focused on the central role of behavioral and psychological issues in the lives and care of persons living with chronic illness, particularly diabetes. Clinicians and researchers alike acknowledge that behavior (i.e., self-management behavior) is the most fundamental source of both the treatment and prevention of diabetes. Moreover, behavioral scientists play an important role in research focused on the prevention and cure of type 1 and type 2 diabetes. As described by Glasgow and colleagues (1), "The most compelling evidence of the complementarity of behavioral science and biology is the observation that clinical advances, such as intensive therapy, islet transplantation, or genetic testing and 'engineering,' raise rather than eliminate behavioral and psychological questions and needs." In the past decade, behavioral scientists and mental health clinicians have formed the Council of Psychology and Behavioral Medicine within the American Diabetes Association. Behavioral-science research has addressed broad-ranging issues about living with diabetes such as the impact of tight blood sugar control on the cognitive functioning and quality of life of the person with diabetes, how family members can help the person with diabetes live a healthy lifestyle, and what constitutes the most effective treatment for the person with diabetes who also has major depression. Research studies on behavioral and psychological aspects of diabetes are now published in medical journals as well as psychological journals. Most important, this attention to behavioral and psychological issues in the treatment of diabetes has refocused the field on

health promotion in living with diabetes and on prevention of the disease itself. The "behavior specialist" is now a recognized member of the multidisciplinary diabetes care team.

We are writing this chapter for clinicians who work with persons living with diabetes. We have attempted to provide an upto-date review of research progress focused on behavioral and psychological aspects of diabetes that are relevant to the professionals who care for persons with diabetes. We have divided this review into four sections. First we discuss psychosocial issues that are salient at each stage of development across the life cycle. Second, we discuss research on factors that affect adaptation to chronic illness: stress, coping, social and family environments, adherence, and "diabetes burnout." In the third major section, we focus on new paradigms of the patient-provider relationship. In the format of an "intervention table," we provide an overview of research on intervention strategies and techniques relevant to practicing clinicians. In our final section, we address special psychological problems that arise in the care of persons with diabetes, such as eating disorders, sexual functioning, and depression. To conclude, we review progress in and suggest prospects for future research on behavioral issues in diabetes.

DIABETES AND THE LIFE CYCLE

At each stage in the life cycle, the individual is confronted with a series of "developmental tasks" or goals in physical, psychological, and social domains. Within this context, diabetes presents people with unique additional demands at particular developmental stages. Persons with diabetes face the challenge of adapting to each normative developmental stage while balancing the influence of each new stage on the complex tasks of diabetes self-care and management.

The demands of diabetes self-care may exacerbate the pressures of normal development. At each stage of development, family members of persons with diabetes are confronted with the task of being sensitive to the importance of establishing a developmentally appropriate balance between the patient's need for independence and his or her need for family support and involvement in self-care tasks. This dilemma raises unique issues at different stages of child and adult development for families of patients with diabetes. The struggle to balance independence and dependence in the relationships between the person with diabetes and family members presents major coping tasks for all members of the family.

Childhood

It is well documented that the complex daily regimen of diabetes care can affect every aspect of family life and child and adolescent development (2–4).

Although diabetes is relatively rare among infants and toddlers, when it is diagnosed in this age group, the parents or caregivers are the real "patients" (5). Parents are faced initially with the challenge posed by their grief over the loss of a "healthy," "perfect" child. While still in the midst of this acute adjustment phase, parents must also learn the fundamentals of diabetes care and accommodate their family lives to include the daily tasks of disease management. Many parents, during this first phase of the disease, report increased marital conflict and feelings of depression; however, over time and with greater opportunities for diabetes education, parents report greater confidence and more flexibility in the diabetes regimen (6).

Diabetes in toddlers and children of preschool age presents parents and healthcare providers with the challenge of adapting diabetes care to the toddler's normal developmental struggle for independence. Children's natural drive toward autonomy is often reflected in refusals to cooperate when receiving injections or blood glucose monitoring and in conflicts about food. In this way, diabetes can fuel parent–child conflicts that typify this developmental stage. Parents can help foster their child's sense of independence without compromising diabetes care by allowing children to choose between two snacks, between injection sites, and which fingers to use for blood glucose monitoring. In addition, for children who are finicky eaters, administering Humalog injections after meals may help eliminate parent-child power struggles at mealtimes. Temper tantrums are common in children at this age, but they may also be indicative of hypoglycemia. Many parents identify difficulties in differentiating diabetes-related mood changes from age-appropriate behavior (6). Once hypoglycemia has been ruled out, parents need to set as firm limits as they would for their child if he or she did not have diabetes.

The transition to school is a particularly difficult time for parents of young children with diabetes. Parents struggle with anxiety about their child's safety and supervision. Parents should be encouraged to take an active role in educating daycare workers, nannies, babysitters, and teachers about signs and symptoms of high and low blood glucose levels, appropriate treatment of hypoglycemia, and the mechanics of blood glucose monitoring and insulin administration.

There is a growing body of evidence that mild cognitive deficits may result from recurrent, severe episodes of hypoglycemia in young children. Researchers using neuropsychological assessments have found significant differences in verbal intelligence, visual-motor coordination, and visuospatial abilities in comparing youths with diabetes to age-matched controls (7–10). Rovet and colleagues found that children diagnosed with diabetes before the age of 4 years had more frequent hypoglycemic seizures than did children diagnosed later in childhood, suggesting that severe hypoglycemia during the period of brain development may impair later cognitive functioning (10). In light of these findings, clinicians and caregivers of very young children with diabetes must actively avoid the trend toward intensive glycemic control advocated by the Diabetes Control and Complications Trial (11,12). Age-specific blood glucose ranges, aimed at preventing severe hypoglycemia, should be the standard of care for these young patients (13).

Because peer relationships are so important once children start school, it is important to be aware of the impact of diabetes on social functioning. Diabetes during the school-age years can affect the child's self-esteem. In fact, many studies link low selfesteem in children to poorly controlled diabetes (14,15). For this reason, children with diabetes should be encouraged to participate fully in school-based activities, sports, and clubs that can serve as sources of support for the development of positive selfesteem. For this to be accomplished, children may require individualized care plans in school (16) with changes in lunch schedules and extra time for snacks to prevent hypoglycemia. Parents may need to advocate for their child so that these safety precautions can be put in place to allow for full integration of children with diabetes into the regular school routine. Parents should be encouraged to work with school personnel to ensure that their child misses as little classroom time as possible. The overall goal of diabetes treatment during the school years should include the minimal disruption of successful experiences in school.

Adolescence

Research has consistently shown a decline in metabolic control of diabetes during adolescence-influenced partly by physiologic hormonal changes during puberty and partly by a decline in diabetes self-care during this time (17–19). The role of the peer group has been implicated in the decrease in self-care exhibited by adolescents with diabetes. Jacobson and colleagues (20) report that more than one-half of adolescents with newly diagnosed diabetes do not disclose their diabetes to their close friends and that 35% of these teens report that they believe their friends would like them more if they did not have diabetes. Other research has indicated that adolescents will skip needed insulin injections in an attempt to fit in with their peers or out of fear that diabetes self-care will draw negative attention to themselves (21,22). On the positive side, however, research on benefits of peer support for adolescents with diabetes shows that peer and family support in combination is directly associated with the integration of diabetes self-care behavior into daily adolescent routines (23,24).

A final area of diabetes management that poses a particular challenge across child development is the gradual transition of diabetes responsibilities from parent to child. The consensus is growing across research studies that children and adolescents given greater responsibility for diabetes management make a greater number of mistakes in self-care, are less consistent in adhering to their treatment plan, and have poorer metabolic control than those children whose parents remain involved in diabetes management (25–30). Results of these studies have led many clinicians to advocate a diabetes treatment approach whereby parents and teens share responsibility for the tasks of diabetes care. This involves open communication between par-

ent and child to reduce diabetes-related conflicts about out-ofrange blood sugars and to encourage a more matter-of-fact, problem-solving approach to blood sugar control. Each family needs to be encouraged to develop its own pattern of parentadolescent teamwork so that the child with diabetes can continue to feel support for the daily burden of diabetes care and be less at risk for the development of diabetes adherence problems.

Early to Middle Adult Years

In contrast to the extensive empiric literature on child and adolescent development within the context of diabetes, relatively little research has been carried out on adaptation to diabetes during early adulthood. One area of interest has focused on examining the process of transitioning from pediatric management of diabetes to management in the adult healthcare system. In a survey of patients making this transition, Pacaud and colleagues (31) report that up to 50% of the patients surveyed reported delays or loss of regular medical follow-up during this transition period. One way of understanding the barrier to transitions in healthcare providers is implicated by findings reported by Wysocki and colleagues (32) that difficulties in adjusting to diabetes during adolescence persist into adulthood. Studies of this transition period, while rare, argue for the importance of interventions aimed at smoothing the transition of care from adolescence to adulthood. This is especially important for "high-risk" patients who have already been struggling with their diabetes management during childhood and adolescence.

The developmental tasks of middle adulthood are complex and take time to master. These tasks include household and lifestyle management, childrearing, and career management. During the middle adult years, each of these tasks involves acceptance of the inevitable processes of aging, as well as an investment in external social systems. According to Newman and Newman, "The tasks of middle adulthood demand an expanded conceptual analysis of social systems and a capacity to balance individual needs with system goals. The adult not only learns how to function effectively within larger groups, s/he comes to invest energy in those groups with which s/he can most readily identify" (33).

Diabetes imposes conflicts between an adult's responsibilities for maintaining his or her own health and blood sugar levels and responsibilities for meeting the needs of other family members (34). Few studies have been done on the impact of diabetes in a parent on the family environment of children (35). Interest has centered primarily on understanding the influence of spouse support. Ahlfield et al. (36) studied the impact of diabetes on marriage and quality of daily life. They report that adults with diabetes perceived that the disease interfered with family activities and finances more than did their spouses, who did not have diabetes. Significantly more men than women with diabetes felt that the disease was a source of friction in their marriage.

Shenkel and colleagues (37) reported that the importance of the diabetes treatment regimen to the spouse who did not have diabetes was directly related to level of adherence to the treatment plan in the spouse who had diabetes. Pieper et al. (38) reported that, in a sample of patients 40 years or older who had type 2 diabetes, the higher the rating that nondiabetic spouses gave to the benefits of diet the lower they perceived their ability to help the partner with diabetes. Dietary changes were most frequently rated as the most difficult part of the diabetic treatment regimen. Pieper et al. (38) concluded, "For the married person diagnosed as having diabetes in middle age or later life, lifestyle changes, especially in regard to diet and medications, may impact on marital adjustment. A lack of understanding of the impact of diabetes on the marital relationship may allow a couple to use diabetes to negatively influence their marriage and disease control."

Pregnancy

The experience of pregnancy for a woman with diabetes is shaped by a number of forces: the development of her self-concept, sexuality, and body image during childhood and adolescence; information she has received about diabetes as it relates to her ability to become pregnant and have a "normal, healthy" baby; the quality of her diabetes control before pregnancy; the presence of any diabetes complications before pregnancy; her access to highly specialized high-risk prenatal care; her resources for coping with the physical demands of diabetes selfmanagement during pregnancy and with the emotional stress related to uncertain health outcomes for herself and the baby; and, finally, the availability of involvement and support from a partner and from her extended family and friends before, during, and immediately after the pregnancy.

Recent research documents the ability of women with diabetes to give birth to "normal, healthy" infants if they have tight blood glucose control at conception and can maintain it throughout pregnancy. More information is now available on the impact of pregnancy on the health of women with diabetes. Women with more advanced ocular, vascular, and renal complications are frequently advised not to become pregnant because of the potential for pregnancy to accelerate these physical complications and cause severe physical disability or even death of the mother. For these reasons, the decision about whether and when to become pregnant is a complex one for the woman with diabetes. Involvement and support from the partner are critical during this stressful decision-making period, especially if there are contraindications for pregnancy.

Medical management of diabetes is especially intense during pregnancy in terms of the frequency of contact with specialists and the daily diabetes self-care that is recommended. Insulin needs often decrease during the first trimester of pregnancy but increase during the second and third trimesters. Throughout the pregnancy, most women must increase the frequency of blood sugar monitoring to at least four times a day because the stabilization of blood-sugar levels is more difficult during pregnancy and because hypoglycemia and hyperglycemia present risks to the developing fetus.

Given the health risks of poorly controlled diabetes during pregnancy, it is surprising that the majority of women with diabetes do not have access to pre-pregnancy counseling. In fact, as few as 34% of women with diabetes receive conception guidance before they get pregnant (39), and fewer than half of pregnancies in women with diabetes are planned (40). Holing and colleagues (40) found that women who had unplanned pregnancies reported that their doctors had discouraged them from getting pregnant, whereas women with planned pregnancies reported that their doctors had reassured them of their ability to have a healthy baby despite their diabetes. Such research underscores the importance of positive prepregnancy education and supportive patient-doctor interactions that allow women with diabetes who are of childbearing age to feel that they can engage in family planning and work with their healthcare team to support a healthy pregnancy.

Despite the research advances and the increased likelihood of the delivery of a "healthy, normal" baby, a great deal of apprehension accompanies a pregnancy in the context of diabetes. In addition to the normal concerns that all pregnant

636 JOSLIN'S DIABETES MELLITUS

women experience, the pregnant woman with diabetes must cope with concerns about the impact of her diabetes on the health of her baby and the reciprocal impact of pregnancy on her own health. Research by Langer and Langer (41) found that pregnant women with diabetes were significantly more anxious throughout their pregnancies than were women without diabetes. This increased anxiety may be fueled by the multiple physiologic tests that women with diabetes must undergo in order to assess the health and condition of the developing fetus throughout their pregnancy. The increased work involved in managing a pregnancy in conjunction with the intense emotional experience of the pregnancy make support from the husband or partner an extremely important factor in the outcome of pregnancy in diabetes. Support from extended family and friends also is critical in helping the pregnant woman maintain the discipline and emotional stability needed for the duration of the pregnancy.

Late Adulthood

In the later adult years, the primary developmental tasks concern the redirection of energy to new roles and activities, the acceptance of one's life and the physical and cognitive changes associated with aging, and the development of a point of view about death. Retirement requires many persons to find new outlets for their intellectual capacities and social supports. Little has been written about diabetes in the later adult years. Empiric data on coping issues facing the elderly patient with diabetes are not available. Retirement can place financial constraints on patients with diabetes, who may no longer have the same access to healthcare reimbursements through private employee-based health insurance.

Compared with their functioning in middle adulthood, later adulthood is a period when the normal physical deterioration of the aging process in combination with the onset and progression of diabetes complications realistically limit the functioning of many elderly patients. Moreover, elderly patients with diabetes frequently cope with multiple medical conditions and multiple complex medication schedules simultaneously. Thus, it may be difficult for family members and elderly patients to distinguish the deterioration related to the normal aging process from the progression of diabetes complications. Worry, frustration, and alienation may result from the decline in level of functioning. Moreover, depression is a serious and underrecognized problem among the elderly. In the patient with diabetes, depression can decrease their motivation and energy for diabetes-related self-care.

Healthcare professionals caring for elderly patients with diabetes must be alert to the need to assess issues of functional status. As such, they are encouraged to assess the patient's level of manual dexterity, quality of vision and hearing, and ability to be physically active. The functional status of each patient influences his or her ability to carry out the complex tasks of diabetes management; including administering medication doses accurately, monitoring blood glucose regularly, inspecting their feet, remembering medical recommendations and appointments, preparing meals, and engaging in exercise. If self-care abilities decline, flexible arrangements need to be made for greater family or professional involvement in diabetes treatment and decision-making. Younger family members find that they must become educated in diabetes and make decisions concerning living arrangements for an elderly parent with diabetes who is no longer able to inject insulin independently, to take medications at appropriate times, or to eat reliably.

In summary, across the life span—from infancy to the later adult years—the struggle to balance independence and dependence in the relationships between the person with diabetes and family members, especially with respect to self-care, presents unique coping challenges for patients with diabetes and their families.

ADAPTATION TO CHRONIC ILLNESS

One of the most significant outcomes of the growth of the fields of health psychology and behavioral medicine has been publication of scientific evidence of the contribution of psychological and social factors to human health, particularly to adaptation to chronic health problems, such as cancer, heart disease, stroke, and diabetes (42). This has led to a wide acceptance of the interplay between psychosocial factors and biologic outcomes in both type 1 and type 2 diabetes. Three broad psychosocial factors that impact a person's adaptation to chronic illness are stress, coping ability, and the social and family environment. Although these factors interact, each will be considered separately for purposes of review.

Stress

Numerous reports have examined the influence of emotionally stressful experiences on health status. For example, Rahe et al. (43), using scaled measures of life events, found that acute medical illnesses tend to occur at times of change. Other studies suggest that stressful experiences can be important etiologic factors in the pathophysiology of disabling chronic conditions, such as coronary vessel disease (44). The course of a chronic illness such as diabetes can also be affected by stressful experiences (45). Studies often emphasize the additive effects of multiple stressful life events. In addition to the number and intensity of these life events, their particular meaning to the individual also contributes to their ultimate influence on health status (45–47).

STRESS AND DIABETES ONSET

Interest in examining the role of psychological or environmental stressors in diabetes has a long history. Early reports (48) suggested that the onset of type 1 diabetes may be triggered by psychological stress in a physiologically susceptible individual. Stein and Charles (48), using retrospective documentation, found a higher prevalence of disturbances in infant feeding patterns in a small group of diabetic children than in their siblings. Since psychological stress can alter activity in the sympathetic nervous and adrenomedullary systems, elevate plasma cortisol levels, possibly enhance the secretion of glucagon and growth hormone (49), and affect immune functions (50), a theoretically relevant set of biologic pathways are present that could mediate a relationship between psychosocial stressors and diabetes onset. Indeed, some animal studies using the BB rat as a model of type 2 diabetes have indicated that an increase in environmental stress shortens the time to onset of overt diabetes mellitus (51).

Although stress, both psychological and physical, has been shown to have major effects on metabolic activity and has long been suspected of playing a role in the onset of type 1 diabetes (52), there is no solid evidence base for this connection between stress and diabetes onset. However, recent research in genetics, immunology, and endocrinology has identified a multicomponent model of the pathogenesis of type 1 diabetes that links autoimmune destruction of insulin-producing pancreatic β cells with genetic and environmental factors. Existing studies of the role of stress in the development of type 1 diabetes have been limited by methodologic problems, including small subject samples and a reliance on retrospective accounts of major life stressors (52,53). Despite methodologic limitations, existing studies suggest that individuals with type 1 diabetes are more likely to report a major life stressor or family loss prior to the onset of symptoms of diabetes (48). A provocative recent paper by Thernlund and associates (54) reported that stressful life events during the first two years of life distinguished children who developed diabetes from matched healthy controls. The hypothesis is that major stressors, including illnesses, occurring early in the life of a genetically susceptible individual could impair immune function during this critical developmental period, which over time triggers the onset of type 1 diabetes.

Another recent line of research has examined the role of stress as a trigger for type 2 diabetes. Surwit and colleagues (56) noted the "mounting experimental evidence of altered sympathetic nervous system activity in type 2 diabetes" identified from several animal models. They have demonstrated that *ob/ob* mice differ from their lean littermates in having exaggerated blood glucose responses to environmental stressors and to the exogenous administration of epinephrine (55,56). Other research suggests that *ob/ob* mice may have enhanced adrenergic responses to environmental stress (57).

Research on obese but otherwise healthy men (58) shows that they exhibit an alteration in autonomic nervous system functioning—specifically a decrease in sympathetic and parasympathetic activity—associated with an increase in body fat. This finding indicates that a disordered homeostatic mechanism may exist that could promote excessive storage of energy by decreasing sympathetic activity but at the same time defend against weight gain by decreasing parasympathetic activity.

It is not clear whether these and other changes in neuroendocrine activity are causative, are related to the onset of hyperglycemia and/or hyperinsulinemia, or are simply chance findings without significance for the problem of type 2 diabetes. However, this is an area in which further research may elaborate the role of stress and central nervous system control in the onset and course of type 2 diabetes. There is consensus that type 2 diabetes is strongly genetically determined and most likely is polygenic and heterogeneous. Genes involved in some subtypes of type 2 diabetes have recently been identified (59): "There has been clear demonstration that obesity, physical inactivity, and other lifestyle factors are important environmental risk factors for the development of type 2 diabetes in the genetically-susceptible individual." Further research is needed to clarify the interplay between genetic factors, lifestyle factors, obesity, and stress in the onset of type 2 diabetes.

STRESS AND THE COURSE OF DIABETES

Stress has both direct and indirect effects on outcomes in chronic illness (60). It has been postulated that stress may affect the course of diabetes either directly through the stress hormones affecting blood glucose levels and insulin metabolism, or indirectly, through stress producing changes in self-care behavior (61). Stress, both psychological and physical, has been shown to have direct effects on metabolic activity (62). Physical stressors, such as illness or trauma, have been shown to cause hyperglycemia and eventual ketoacidosis in persons diagnosed with type 1 diabetes (63). Among children with type 1 diabetes, epinephrine infusion produced more elevated blood glucose levels and more rapid ketone release than among children without diabetes (64). Recent work examining negative life events among individuals with type 1 diabetes has suggested that these types of stressors have an adverse effect on glucose control (63,65). In contrast, studies of the effects of laboratoryinduced stress on glycemic functioning of individuals with type 1 diabetes have been more equivocal (66). Possibly, differences across studies in the types of laboratory stressors investigated

(e.g., noise, mental arithmetic) may have contributed to the contradictory findings, as not all subjects may find these experiences to be stressful. Indeed, studies examining the effects of stress hormones on glucose control have produced more consistent findings (62). Some research has suggested that there may be "stress-reactive" subgroups of individuals with diabetes for whom stress mainly affects metabolic control through direct physiological mechanisms (67,68).

In addition to a direct effect of stress on metabolic activity, stress has an indirect effect on metabolism by influencing the self-care behaviors of the person with diabetes, which in turn have an impact on metabolic control. Stressful events distract the person with diabetes from usual patterns of self-care. Stress causes disruptions in routines and decreases in resources and supports that are likely to result in less stable patterns of selfcare behavior for patients with diabetes and their families. Thus, to the extent that the person's self-care behaviors are influencing metabolic control, by disrupting self-care behavior, stress indirectly influences metabolic control.

In summary, there are intriguing suggestions from initial studies of animal models of diabetes that psychological and physical stress may play a role in the onset of diabetes, especially type 1 diabetes. Definitive conclusions linking stress with the onset of either type 1 or type 2 diabetes await further multidisciplinary research. The evidence is stronger that stress affects the course of diabetes, both through a direct neuroendocrine effect and an indirect behavioral effect on the metabolic control of the person with diabetes.

STRESS AS A CONSEQUENCE OF DIABETES OR DIABETES-SPECIFIC DISTRESS

Health psychologists have recognized that in addition to the possible effects of stress on the onset or course of various chronic physical illnesses, "the chronic illness itself and its required treatment also constitute stressors that the individual must confront" (60). Polonsky and colleagues at the Joslin Diabetes Center (69) led one of the first scientific efforts to identify these diabetes-specific stressors. Moreover, this group has developed and validated a measure of diabetes-specific distress—PAID (Problem Areas *in* Diabetes). Because of the innovative and important perspective that understanding diabetes-specific distress can have for healthcare providers, in this section we list the 20 sources of diabetes-specific distress that affect patients that were identified by Polonsky and associates and measured in the PAID measure (69–71).

- 1. Not having clear and concrete goals for diabetes care
- 2. Feeling discouraged with the diabetes treatment plan
- 3. Feeling scared when thinking about living with diabetes
- 4. Uncomfortable social situations related to diabetes care (e.g., people nagging about what to eat)
- 5. Feelings of deprivation regarding food and meals
- 6. Feeling depressed when thinking about living with diabetes
- 7. Not knowing if moods or feelings are related to diabetes
- 8. Feeling overwhelmed by diabetes
- 9. Worrying about low blood sugar reactions
- 10. Feeling angry when thinking about living with diabetes
- 11. Feeling constantly concerned about food and eating
- 12. Worrying about the future and the possibility of serious complications
- 13. Feelings of guilt or anxiety when off track with respect to diabetes management
- 14. Not "accepting" diabetes
- 15. Feeling unsatisfied with the diabetes physician
- 16. Feeling that diabetes is taking up too much mental and physical energy every day

638 JOSLIN'S DIABETES MELLITUS

- 17. Feeling alone with diabetes
- 18. Feeling that friends and family are not supportive of diabetes management efforts
- 19. Coping with complications of diabetes
- 20. Feeling "burned out" by the constant effort needed to manage diabetes

Weinger and Jacobson (72) have demonstrated that higher levels of diabetes-specific distress in adults with type 1 diabetes relate to poorer metabolic control as well as to lower selfreported quality of life. Future research is needed to identify strategies for preventing diabetes-related distress and for intervening with patients overwhelmed by the stresses of living with diabetes. We now address the wide variation seen in how persons handle these diabetes-specific stressors as well as the stress of chronic illness.

Coping Ability

Coping is a broad construct that generally refers to "the strategies that people use to manage and master stressful circumstances and to minimize the negative impact of life stressors on psychological well-being" (73). The concept of coping introduces the concept of "person" or "individual difference" factors that influence an individual's adaptation to the stresses of chronic illness. From a biopsychosocial model, these individual factors (such as self-esteem, health beliefs, personal models, ego strength, and personality) affect and are affected by other factors in the model (social environment, disease itself, healthcare system).

Differences in coping styles and personality types influence the appraisal of stress (74) and therefore can affect the individual's experience of what constitutes a stressful life situation. Such individual differences may affect not only the emotional and behavioral consequences of stress, as noted earlier, but also the hormonal components of the stress response in cardiovascular illness (75) and perhaps in diabetes (76). Similarly, Wolff et al. (77) found that variations in personal coping styles are associated with variations in corticosteroid levels of individuals under stress.

Clearly, individual differences color the meaning and experience of being ill as well as the specific problems posed by that illness. These differences influence the management of a complex chronic illness such as diabetes. Understanding such individual differences can contribute to the thoughtful design of treatment plans.

Studies of a pattern of individual differences in response to the diagnosis of diabetes failed to identify a "diabetic personality" and proved unproductive overall (78). This led to study of the "cognitive and behavioral" strategies patients use to manage diabetes and their emotional responses (79). First, we need to consider the major set of coping tasks that face the person diagnosed with a chronic physical illness such as diabetes. Moos and Tsu (80) identified seven fundamental "adaptive tasks" with which the person with any chronic illness must cope:

- 1. Dealing with pain and incapacitation
- 2. Dealing with the hospital environment and special treatment procedures
- 3. Developing adequate relationships with professional staff
- 4. Preserving a reasonable emotional balance
- 5. Preserving a satisfactory self-image
- 6. Preserving relationships with family and friends
- 7. Preparing for an uncertain future

Coping skills is the term used to describe those individual differences in the ways in which persons face and handle stressful tasks such as those above.

Lazarus and Folkman (81) suggested that the coping process begins when a person appraises or evaluates the stressful situation and that the person evaluates both the stressful aspects of the situation as well as his or her ability to deal effectively with these stressors. Within this theory, individuals cope with stress in one of two major ways: by attempting to change the nature of the stressful situation (problem-focused coping) or by managing their emotional reactions to the stressful situation (emotion-focused coping) (74). Emotion-focused coping is described as directing energy away from the source of stress, by avoidance, denial, or distraction. Problem-focused coping refers to efforts to resolve the problem, to focus energy and resources on solving the problem or reducing stress. Studies with adolescents with type 1 diabetes give conflicting results about the relationship between these two types of coping skills and level of metabolic control (82,83). However, in studies with adolescents, consistent associations have been reported between self-care behavior and type of coping skill, with emotion-focused coping associated with poorer levels of self-care behavior (84,85).

COPING AND THE COURSE OF DIABETES

An increasing number of systematic studies point to the influence of individual characteristics on the course of diabetes, with respect to management (adherence), metabolic control, and overall adjustment (86,87). Self-esteem is one of the aspects of personality important in adaptation to diabetes. High or robust self-esteem may serve as a protective factor in a patient's adjustment to the vicissitudes of this complicated illness and to the potentially confusing, and at times inadvertently hurtful, responses of significant others such as family members, close friends, schoolmates, and colleagues. Along these lines, Jacobson et al. (88) have found that preadolescents and adolescents with low self-esteem had lower levels of adherence at the time of diagnosis and over time than did those with higher selfesteem.

Several studies have found that other aspects of patient adjustment and coping ability are linked to adherence and glycemic control (88,89). For example, a number of investigators have considered how the patient's level of socioemotional (ego) development may bear upon his or her experience of and response to type 1 diabetes. Ego development reflects the individual's maturation along the lines of impulse control, moral development, cognitive complexity, and interpersonal relationships (90). Barglow and colleagues (91) found that ego development was the best predictor of an adolescent's responsiveness to a brief intervention designed to enhance adherence and glycemic control. In contrast, psychopathology was not associated with the response to the educative intervention. These findings and theoretical considerations suggest that the level of ego development a patient has achieved can affect the benefits of educational and medical interventions designed to improve metabolic control, adherence, or coping strategies. Researchers have suggested that a higher level of ego development may provide an individual with the cognitive and emotional maturity needed to deal effectively with the demands of having a chronic illness (92). Further research is needed to develop interventions that are either tailored to individual differences in psychosocial functioning or designed to alleviate problems in psychosocial functioning that impede adherence among patients with diabetes.

COPING WITH THE DIABETES REGIMEN: REALISTIC EXPECTATIONS AND READINESS TO CHANGE

It is well documented that most people living with diabetes find it difficult to adhere to the daily demands of the diabetes medical regimen. According to Rubin (93), coping problems are common among people with type 1 and type 2 diabetes "largely because the demands of diabetes management are so substantial and unremitting. Specifically, the regimen is demanding and unpleasant, factors outside the patient's control often affect glycemic control, and the avoidance of diabetes-related complications cannot be guaranteed." It is paradoxical that although it is widely recognized that the treatment demands placed on the person with diabetes are complex and burdensome, many clinicians, family members, and patients themselves expect "perfect" adherence to this regimen. This expectation of "perfectionism" has been documented as one of the primary causes of "noncompliance" (94) and "diabetes burnout" (95). Clearly, having realistic expectations for the patient's self-management behavior is an important aspect of the coping process.

It has recently been recognized that the patient's "readiness to change" influences the process of coping with the demands of diabetes (96). Prochaska and DiClemente (97) suggest that patients can be identified as being in one of six stages of change—from "precontemplation," in which individuals are not currently engaged in behavioral change and do not intend to change, all the way to the "maintenance" stage at which individuals have made a healthy behavioral change and have maintained it for 6 months or longer. Future studies of the link between coping style and diabetes self-care must include these dimensions of realistic expectations for self-management behavior and of patients' "readiness to change."

The Social and Family Environments

The social/family environment is the third major psychosocial mediator of adaptation to chronic illness and maintenance of health. In recent years, increased attention has been given to the role of interpersonal or social support variables in the process of adaptation to chronic illness (73). Social support is thought to have a "buffering," "mediating," or "moderating" effect on the stress of living with a chronic illness. While most of this attention has focused on support from within families, there has been some investigation of the benefits of social support outside the family for the chronic diseases of cancer, acquired immunodeficiency syndrome (AIDS), Alzheimer's disease, and cardiovascular disease (73). However, very few empiric studies have examined the social environment outside the family for adults with diabetes (98). Social support such as "worksite, neighborhood, and community factors" in adults with diabetes have received almost no examination (1).

La Greca and colleagues (99,100) have conducted research on social supports outside the family for adolescents with diabetes and reported that peers and friends serve support functions for the adolescent with diabetes specifically different from those provided by the adolescents' family. Whereas families provided more support for daily management tasks (insulin, blood glucose monitoring), friends provided more support for the "lifestyle" aspects of diabetes management (i.e., providing companionship during exercise or when eating meals away from home). Moreover, peers represented a significant source of emotional support for adolescents living with diabetes. In summary, aside from the empiric research with adolescents (23,101), there has been little investigation of social support outside the family for individuals with diabetes.

THE FAMILY AS THE PRIMARY SOCIAL ENVIRONMENT FOR LIVING WITH DIABETES

Diabetes, like several other chronic physical diseases, places demands on the patient for self-care and for clinical decisionmaking responsibilities that require major adjustments in lifestyle (102). Moreover, these lifestyle adjustments affect many components of family life—food, activity, finances, and time (34). This section focuses on how characteristics of the family environment influence self-management behavior and health outcomes in the person with diabetes. First, it is critical to point out that the relationship between family characteristics and the patient's behavior and health is a bidirectional relationship. In other words, just as family stress has been reported to produce poor diabetes control, similarly, poor control may trigger stress among family members.

CHILDREN AND ADOLESCENTS WITH DIABETES

Empiric research has documented that successful management of a child's diabetes makes it necessary for families to redistribute responsibilities, reorganize their daily routines, and renegotiate family roles (17). When a very young child is diagnosed with diabetes, the parents are, in reality, the patient (4). Golden and colleagues (103) reported that the parents of children who are diagnosed with diabetes before the age of 5 years who receive training in intensive diabetes management and are provided multidisciplinary supports report less family stress, fewer hospitalizations, and fewer episodes of severe hypoglycemia in their very young children with diabetes as compared with families receiving standard diabetes care. With respect to school-aged children with diabetes, there is consensus from empiric studies that the following family characteristics are linked to both good metabolic control and adherence to the treatment regimen: parental warmth and caring; positive parental involvement with diabetes-related tasks; low levels of family conflict; family rules that are followed by all family members; and agreement between both parents about diabetes goals (13).

Longitudinal research by Jacobson and colleagues (88,104) revealed that the child's perception of family conflict at diagnosis was the strongest predictor of poor adherence over a 4-year follow-up period. In a study by Miller-Johnson and colleagues (105), parent–child conflict was related to both adherence and glycemic control. Multivariate analyses indicated that family conflict might interfere with glycemic control by disrupting adherence to treatment (105). The most significant family characteristic of school-aged children who have the best glycemic control and who are the most adherent to the diabetes treatment regimen is the sharing of responsibility for the tasks of the treatment regimen between parent and child (25,106,107).

Certain demographic characteristics of families have also been linked to metabolic outcomes in children with diabetes. Children with diabetes from single-parent families or from ethnic minority or lower socioeconomic backgrounds have been reported to be at increased risk for problems with adherence and diabetes control (108,109).

For adolescents with diabetes, family support has consistently been linked to optimal self-care behavior. However, family support does not consistently relate directly to metabolic outcomes (61). It has been suggested that family conflict has both a direct and an indirect effect on adherence by its impact on family interactions. In a comprehensive review of the literature on adolescents with diabetes, Skinner and colleagues (61) reported that a developmentally appropriate level of parent involvement in the tasks of diabetes management is the single most important predictor of positive adolescent health and selfcare behavior outcomes.

ADULTS WITH DIABETES

In contrast to the broad range of studies of family factors and diabetes outcomes in children and adolescents, literature on the families of adults with diabetes is quite limited. The few early studies of adults with diabetes focused exclusively on the relationship of spouse support to adherence and metabolic control in the adult with diabetes. Schafer and colleagues (110) developed an objective questionnaire for assessing the frequency with which family members engage in behaviors defined as "supportive." For adults with type 1 diabetes, greater perceived negative spouse interactions were associated with poorer adherence. However, for adults with type 2 diabetes, no relationship was found between negative spouse interactions and adherence.

Recent work by Fisher and colleagues (111) has provided both a theoretical framework and empiric data on family characteristics of adults with type 2 diabetes from Hispanic and European-American ethnic backgrounds (98,111). Fisher et al. (98) identified four areas of family life that related to health outcomes for adults with type 2 diabetes (98): 1) family structure and organization; 2) family values and beliefs about the world; 3) family expression and management of emotions; 4) family problem solving. Using objective scales with excellent psychometric properties to measure the first three areas of family functioning, Fisher et al. (111) reported significant differences between characteristics of the family and disease management outcomes for Hispanic as compared with European-American families. The family's worldview and management of emotions was linked to disease management among European-American patients, whereas family structure/organization was linked to disease management among Hispanic patients. In general, optimal disease management is reported in families that are well organized, have clear and traditional gender roles, have an optimistic belief about life, and in which spouses are able to resolve differences of opinion about diabetes care.

In summary, there is a close connection between the diseaserelated coping and stress levels of the person with diabetes and his or her social environment. Especially for social influences within the family, levels of support and conflict have a significant impact on adherence and health outcomes in diabetes.

Adherence and Burnout

The Diabetes Control and Complications Trial (DCCT) proved that intensive insulin management of diabetes, aimed at achieving "near-normal" glycemia, significantly reduces the risk of medical complications of the disease (11,12). For most people with diabetes, achieving near-normal blood glucose levels means treatment with multiple daily injections of insulin, frequent blood glucose monitoring, or the use of a subcutaneous insulin infusion pump. While adherence to the diabetes selfcare regimen is believed to be the most essential ingredient in diabetes management, patients commonly have difficulty with sustaining the burden of self-care over time. This was true in the era before dissemination of the DCCT findings, but with the hopeful news for medical outcomes from the DCCT, the number of daily diabetes self-care tasks (and therefore the daily burden of the disease) has increased for most people living with diabetes.

To complicate the matter, evidence shows that adherence is not a univariate phenomenon. One patient's adherence to a meal plan, for example, may be unrelated to adherence to a prescribed regimen of blood glucose monitoring. In general, few significant correlations have been found between the different components of adherence to the self-care regimen (112–115). Therefore, healthcare providers should not assume that a patient's difficulty with adherence to one component of the regimen indicates a global disavowal of the regimen. Initial assessment must include a careful examination of patients' adherence to each aspect of the regimen.

When people become overwhelmed by the complexity of their diabetes regimen, they may feel that nothing they do or

how hard they try will have a positive impact on their disease course. This is what diabetes treatment teams are now referring to as the problem of "diabetes burnout," which Polonsky (95) has defined succinctly: "Burnout is what happens when you feel overwhelmed by diabetes and by the frustrating burden of diabetes self-care. People who have burned out realize that good diabetes care is important for their health, but they just don't have the motivation to do it. At a fundamental level, they are at war with their diabetes-and they are losing." When burnout is affecting the patient (or the diabetologist), it can be helpful to remember the words of Joan Hoover, an early diabetes advocate who was appointed to the first Congressional Advisory Committee on Diabetes in the 1970s: "Diabetes is not a do it yourself disease" (94). Diabetes management is burdensome and support of the patient is necessary. This support can include family members, friends, co-workers, and a multidisciplinary diabetes treatment team. Such a support system can help the patient set small, realistically attainable goals to help move gradually out of the struggle with burnout and toward improved diabetes management (116).

THE PATIENT-PROVIDER RELATIONSHIP

Over the last decade, empiric research has increasingly documented the importance of the patient-provider relationship to the adherence of patients with chronic disease to a particular treatment regimen and to health outcomes. The multicenter national Medical Outcomes Study demonstrated that a "collaborative relationship between patient and provider" and a "participatory decision-making style of physicians" (117) improved adherence and health outcomes in patients with chronic illnesses such as cancer, arthritis, and diabetes (118). DiMatteo and colleagues (119) reported that patient satisfaction with the interpersonal communication with their provider is related to adherence to the diabetes treatment regimen. More recently, Ciechanowski and colleagues (120) demonstrated that adherence to the diabetes regimen is associated with the type of attachment the adult patient displays in the context of the patient's perception of the quality of communication with the diabetes provider. Clearly, the behavior of the provider and the quality of the patient-provider relationship are now recognized as critical variables affecting adherence of patients with diabetes to the complex treatment regimen. Over the last decade a new paradigm of the patient-provider relationship has been described in diabetes: "patient empowerment" (121).

Patient Empowerment

As framed by R. Anderson, M. Funnell, and colleagues at the University of Michigan (122), the empowerment approach is based on three key principles: (a) More than 98% of diabetes care is provided by the patient; therefore, the patient is the locus of control and decision-making in the daily treatment of diabetes; (b) the primary goal of the healthcare team is to provide ongoing diabetes expertise, education, and psychosocial support so that patients can make informed decisions about their daily diabetes self-care; and (c) adult patients are much more likely to make and maintain behavior changes if those changes are personally meaningful and freely chosen. Perhaps the most defining characteristic of the empowerment approach is the philosophy that "the patient and the healthcare providers are equals" (123). Diabetes healthcare has benefited because the developers of the empowerment model have translated their philosophy into practical interventions and have provided empiric evidence for its effectiveness. In a randomized con-

TABLE 37.1. Office-based Interventions						
Intervention	Description	Primary source				
Blood Glucose Awareness Training (BGAT)	BGAT is a psychoeducational intervention designed for patients with type 1 diabetes. Its current version, BGAT-III, is a structured 8-week program, conducted in groups or individually, that provides patients with a systematic approach to enhance anticipation, prevention, awareness, and response to extreme fluctuations in blood glucose levels. The patients most likely to benefit from BGAT are those with poor ability to recognize/predict blood glucose extremes, on intensive insulin therapy, with reduced hypoglycemia awareness, with a history of recurrent severe hypoglycemia, with fear of hypoglycemia, with recurrent diabetic ketoacidosis, and/or with poor metabolic control.	Cox et al. (130) Gonder-Frederick et al. (131,132)				
Motivational Interviewing (MI)	MI is a counseling strategy focused on persons reluctant or ambivalent about changing their behavior. Initially formulated for changing addictive behaviors, MI has recently been applied to behavior change in patients with diabetes and other health issues. It differs from a traditional, nondirective therapeutic approach in that the counselor offers advice and helps the patient explore and resolve ambivalence to enhance motivation for change.	Miller et al. (133) Smith et al. (134)				
Stage of Change Counseling	Appropriate for use by healthcare providers not just by "counselors," this model of working with patients integrates the empowerment model and MI techniques with the transtheoretical model (Stages of Change Theory). It is a patient-centered approach that helps identify a person's readiness to change behavior and to then identify and prioritize self-management goals in diabetes. As such, it provides the healthcare provider with a framework that breaks down the process of change into a series of stages.	Doherty et al. (96) Prochaska et al. (97,135)				
Pediatric office-based interventions	Several pediatric office-based interventions have recently reported encouraging, although preliminary, results. The impact of a "care-ambassador" intervention, a trained assistant to support parents of pediatric patients in making appointments regularly, resolving insurance and billing questions, and helping schedule specialty appointments has been shown to improve medical-visit follow-up and reduce costly adverse outcomes such as diabetes-related hospitalizations and emergency department visits.	Laffel et al. (136)				
	A low-cost, family-based psychoeducational intervention aimed at sustaining parental involvement in diabetes-management tasks and reducing diabetes-related family conflict that has been used with adolescents and recently diagnosed pediatric patients. This eight-module intervention is implemented by a trained assistant at the time of the medical office visit. Preliminary results indicate that this intervention helps improve adherence, parent–child teamwork in diabetes management, and glycemic control.	Anderson et al. (137)				
Cognitive Behavioral Therapy (CBT)	CBT aims at changing patients' thoughts about diabetes and diabetes self-care tasks that interfere with diabetes management as well as actual diabetes self-care behaviors. CBT involves consciously identifying and challenging maladaptive beliefs. Behavior change in this model is achieved by working gradually toward small, achievable goals. CBT can be implemented in individualized treatment or in a group format.	Weinger et al. (72) Van Der Ven et al. (138)				
Coping Skills Training	This group-based treatment technique is aimed at helping adolescents and/or adults cope better with diabetes-related stressors and improving their treatment adherence. It has been shown to be effective when taught by a healthcare professional or a "counselor" with diabetes expertise. Coping Skills Training teaches positive coping skills to patients with diabetes through the use of role playing and active problem solving.	Grey et al. (139) Rubin et al. (140)				
Support groups	Heterogeneous support groups for patients or loved ones of patients with diabetes can include people with either type 1 or type 2 diabetes. Another support group model involves a homogeneous group in which people with the same type of diabetes are group members. Internet-based discussion groups are being used to provide diabetes support and	Tattersall et al. (141) Zrebiec et al.				
Telephone-based telemedicine technologies	education for persons unable to access support groups in-person. Telephone care is the most widely used technology as a supplement to office-based diabetes education. Telephone care has recently been extended to include "automated telephone disease management" (ATDM). ATDM involves assessment of both health and self-care problems that arose between outpatient visits, as well as education in the form of "health tips" or interactive dietary education modules. Two randomized studies showed that for patients with type 2 diabetes, ATDM as an adjunct to usual care improved glycemic outcomes, frequency of blood glucose monitoring, satisfaction with care, and self-efficacy to perform self-care activities. ATDM enhanced diabetes care for patients living at a remote distance from their diabetes provider and for non-English-speaking and illiterate patients.	(142) Piette et al. (143,144)				
Computer- and Internet- based telemedicine technologies	One of the first computer-based interventions in diabetes was pioneered by Glasgow and colleagues. This early intervention involved a 15-min touch-screen computer assessment to help patients identify personal dietary goals and barriers to achieving these goals. Responses were immediately scored and provided to patient and physician. The patient then met with a health educator to collaboratively develop an action plan that took into account the individual's barriers to adherence. This intervention was documented to be cost-effective and patients maintained improvements in diet and serum cholesterol over a 12-mo follow-up period. This work also demonstrated that older patients without previous Internet	Feil et al. (145) Glasgow et al. (146,147)				
	experiences effectively participated in Internet-based self-management support programs. A computerized system to assess patients, code and analyze data, and provide feedback to both the patient and healthcare team has also been designed. The Diabetes Psychosocial Management Aid (DPMA) has been used successfully in an inner-city hospital with patients with low literacy and computer skills.	Welch et al. (148)				
	Diabetes information has recently become available for education and support over the Internet from several Web-based sites.	www.jdrf.org; www.diabetes.org; www.childrenwith diabetes.com; www.diabetes123 .com; and www.joslin.harvard .edu				

642 JOSLIN'S DIABETES MELLITUS

trolled trial, Anderson and colleagues (124) demonstrated that a 6-week empowerment intervention program, developed by Feste (125), significantly improved diabetes self-efficacy, diabetes attitudes, and glycemic control. The empowerment model has been described by Anderson and colleagues (122) as follows: "When appropriate changes in roles are made, both the health-care provider and the patient can find themselves part of a satisfying partnership that results in improved glycemic control for the patient and an enhanced sense of self-efficacy and level of satisfaction with care for both parties." Finally, the empowerment model is directed toward physicians, nutritionists, diabetes educators, and behavioral clinicians, all the members of the multidisciplinary team that has become the recommended standard for the care of patients with diabetes.

The Multidisciplinary Team in Diabetes Care

It has long been recognized that because diabetes is such a complex disease, patients need a multidisciplinary team of health professionals for optimal care (126). The current Standards of Medical Care for Patients with Diabetes Mellitus of the American Diabetes Association (127) recommend that "people with diabetes should receive their treatment and care from a physician-coordinated team. Such teams include, but are not limited to, physicians, nurses, dietitians, and mental health professionals with expertise and a special interest in diabetes." In reality, however, most patients with diabetes do not have access to a multidisciplinary team and receive their diabetes care in the office of an internist or family practice physician (128). Appropriately, behavioral scientists have recently focused on translating interventions to improve diabetes self-care behavior and quality of life (129) for office practices that do not have a multidisciplinary team as a resource for patients with diabetes. Table 37.1 presents an overview of the most recent and empirically tested of these interventions, with information about how to access more complete information for the clinician who would like to learn more about these intervention strategies.

SPECIAL PROBLEMS IN DIABETES

Psychiatric Disorders in Diabetes

The literature examining the relationship of diabetes to psychiatric disorders continues to grow. These studies focus primarily on the relationship of diabetes to depression, anxiety disorders, and eating disorders.

With regard to the incidence and prevalence of these disorders, it now appears that patients with type 1 diabetes are at particular risk for the development of depressive disorders. The development of depressive disorders, while increasing with the duration of diabetes and the development of complications also occurs relatively early in the course of illness before the onset of complications (149–151). While there is less research on anxiety disorders, a similar trend is emerging from these studies, especially among patients with type 1 diabetes (152,153). The causal links between psychiatric disorders and diabetes are not well understood, but growing evidence from research suggests the connection described in Fig. 37.1.

Most studies looking at the relationship of diabetes to psychiatric disorders are cross-sectional in design. Directionality and causality in these relationships has yet to be fully determined. A few longitudinal studies do suggest that patients with depressive disorders and or eating disorders appear to develop worse glycemic control and greater risk for retinopathy over time (154,155). Thus, as shown in Fig. 37.1, at least in patients with type 1 diabetes, it is reasonable to assume that diabetes itself may increase the risk of developing some specific psychiatric disorders and, when present, that diabetes outcomes are influenced negatively by their presence.

Studies of type 2 diabetes are less clear with regard to the development of psychiatric disorders, as has been pointed out by Talbot and Nouwen (156). The increased rates of depression in patients with type 2 diabetes appear to occur before the onset of illness, thereby raising an entirely different hypothesis about the etiologic relationship (i.e., that depressive disorders themselves may place patients at risk for developing diabetes). Sup-

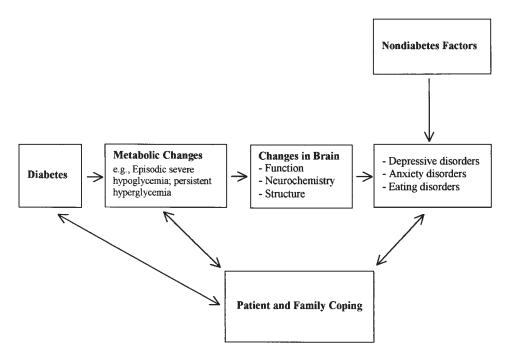

Figure 37.1. Hypothesized model of the relationship of diabetes and psychiatric disorders.

port for this hypothesis derives from the fact that patients with depression have alterations in the hypothalamic-pituitary axis, which lead to increased rates of cortisol production (157–159). Depressed patients also decrease physical activity and increase cardiovascular risk factors by smoking and eating high caloric and fatty foods, suggesting that individuals who are depressed may, because of their changes in lifestyle, develop type 2 diabetes (160–164).

Some investigators also have suggested that the metabolic problems of diabetes (increased rates of hypoglycemia and/or hyperglycemia) could themselves play a role in the development of depression. There is increasing evidence that diabetes leads to changes in the white matter of the brain (162) and that these abnormalities in the white matter, if present in the frontal lobe, may play a role in the development of depression (165). Changes in frontal white matter have been found in studies of depression in patients without medical illness and could lead to changes in the frontal–striatal tracks that regulate affect, thereby increasing risk for affect regulatory problems and consequently of depression (161,166–174). Whatever the direction of causality of the relationship, it does appear that successful treatment of depression and anxiety can lead to improved glycemic control in patients with diabetes (155).

In summary, the frequency of common psychiatric problems such as depression and anxiety disorders appears to be increased among patients with type 1 diabetes and there is now evidence that improved treatment can lead to better outcomes in terms of glycemic control. The combination of high prevalence of common psychiatric illnesses such as depression and anxiety disorders in patients with diabetes and other medical conditions and the treatability of some of these conditions means that it is critical to identify patients with these conditions early in their onset and to implement treatment strategies that are widely recognized to be successful with these patients. Based on a small number of studies, the efficacy of treatment of depression, including cognitive behavior therapy and antidepressant therapy, in patients with diabetes appears to be equivalent to the efficacy in patients without co-occurring chronic disease (175,176). Thus, attention to assessment of depression should be maintained when treating patients who are having problems adapting to diabetes, showing difficulties maintaining metabolic control, and/or other problems with adaptation and stress. These patients may well have an underlying treatable psychiatric condition. Screening measures such as the Symptom Checklist 90R (177) may be useful in identifying patients with diabetes and affective disorders. Moreover, diabetes-specific measures of quality of life, such as the Problem Areas in Diabetes Scale (PAID) (71,178) and the Diabetes Quality of Life Measure (DQOL) (179,180), may also be useful in screening patients who are at risk for these conditions.

Eating Disorders

There has been considerable interest in examining the impact of type 1 diabetes on the development of eating disorders. Although research results in this area are somewhat contradictory, the most recent controlled studies suggest an increased risk of eating disorders among female patients with type 1 diabetes. For example, Jones and colleagues (181) report that the risk of developing an eating disorder was 2.4 times higher in young women with type 1 diabetes than in age-matched women without diabetes. Some researchers have argued that diabetes-specific treatment issues, like the need to carefully monitor diet, exercise, and blood glucose may contribute to the development of eating disorder symptoms among women with diabetes (182). Researchers and clinicians have argued that the

attention to food portions, blood sugars, and weight that is part of routine diabetes management parallels the rigid thinking about food and body image characteristic of women with eating disorders. Additionally, intensive insulin management of diabetes has been shown to be associated with weight gain (183).

Researchers who do not report higher rates of eating disorders in female patients with type 1 diabetes often do not include underdosing or omission of insulin as a purging symptom. Fairburn and colleagues (184) compared 56 women with type 1 diabetes to 67 age-matched women without diabetes using a structured diagnostic interview for eating disorders, the Eating Disorder Examination (EDE). They found that the difference in the rates of eating disorders between these groups was not statistically significant; however, they also highlighted the importance of thorough assessments of disordered eating and insulin misuse in this population—especially as a potential cause of poor glycemic control. These authors found widespread insulin misuse among women with diabetes and emphasize that this behavior is not limited to women who meet formal diagnostic criteria for eating disorders. In an 8-year follow-up of this same cohort of patients with diabetes, the authors note that had they included insulin misuse in their eating disorder group, 39% of the women would have been included in the eating disorder group (185). Another study examining disordered eating among adolescents with diabetes also reported no significance between-group differences in rates of eating disorders (186). However, the teens in this study were quite young, and only one half of them administered insulin without parental supervision. It may be that insulin manipulation or omission becomes a more significant problem in older adolescents, as parental supervision of insulin administration decreases.

When symptoms of disordered eating do not meet the level of severity to warrant a formal diagnosis of an eating disorder, intermittent insulin omission and dose reduction for weight loss purposes has been found to be a common practice among women with type 1 diabetes. For example, Polonsky and colleagues (187) found that 31% of a group of 341 women with type 1 diabetes between the ages of 13 and 60 years reported intentional insulin omission. Rates of omission peaked in late adolescence and early adulthood, with 40% of women between ages of 15 and 30 years reporting intentional omission. Insulin use and tighter blood sugar management caused significant psychological distress for these women; with 42.5% reporting fears that keeping their blood glucose in good control would cause weight gain, 44.3% reporting beliefs that taking insulin would cause weight gain, and 35.9% believing that good control would cause them to become fat (187). In addition, studies show that this behavior places women at heightened risk for medical complications of diabetes. Women reporting intentional insulin misuse had higher levels of glycosylated hemoglobin A1c (HbA1c), higher rates of hospital and emergency room visits, and higher rates of neuropathy and retinopathy than did women who did not report insulin omission (187). A report by Rydall and colleagues (154) lends further support to the link between insulin misuse and medical complications of diabetes. They found that disordered eating at baseline was associated with microvascular complications of diabetes 4 years later, with 86% of young women with serious eating disorders presenting with retinopathy compared with 43% of women with moderate eating disorders and 24% of women with no reported eating disturbance.

Women with type 1 diabetes may use insulin manipulation (i.e., administering reduced insulin doses or omitting necessary doses altogether) as a means of caloric purging. Intentionally induced glycosuria is a powerful weight-loss behavior unique to patients with type 1 diabetes. As mentioned above, it is also very

644 JOSLIN'S DIABETES MELLITUS

dangerous, and places women at greater risk for developing infections, potentially fatal diabetic ketoacidosis (DKA), and long-term medical complications of diabetes. Once established as a long-standing behavior pattern, the problem of frequent insulin omission may be particularly difficult to treat. For this reason, early detection and intervention appears to be crucial. Openended questions such as, "Do you ever change your insulin dose or skip insulin doses to influence your weight?" can be helpful in screening for insulin omission, especially when patients have elevated HbA_{1c} values or unexplained DKA. Disordered eating behaviors are often well hidden, but patients should be encouraged to bring up and discuss issues such as their current level of satisfaction with their weight, their weight goals, and—if willing—their experiences with binge eating.

Neuropsychological Aspects of Diabetes

The number of studies of the potential for patients with type 1 and type 2 diabetes to develop problems in cognition and other signs of altered brain function has been growing. These studies have focused on three measures of the brain: cognitive ability; cortical evoked potentials; and magnetic resonance imaging (MRI)-based assessments of brain structure. This research suggests that patients with either type 1 or type 2 diabetes may be at increased risk for changes in brain structure, including white matter lesions and atrophy (162). Decrements in cognitive function, especially in areas of memory and psychomotor speed, have been found. Changes in cortical evoked potentials indicate the possibility of the risk for development of a central neuropathy. Older patients with type 2 diabetes appear to develop cognitive declines at earlier ages and higher rates than agematched controls without medical illness. Children with onset of type 1 diabetes before the age of 6 years who were studied during adolescence and young adulthood also appear to demonstrate subtle cognitive performance problems (188–190). It is not clear whether these cognitive differences represent developmental delays or problems that persist into adulthood. In children especially, severe hypoglycemia causing seizure, coma, and unconsciousness has been considered as an important causative factor in the development of cognitive problems (188,189,191-197). A small body of research also suggests that persistent hyperglycemia also may play a role in declines in cognitive functioning (190,198). Finally, in older individuals, the development of cerebral vascular illness has been suggested to play an important role in cognitive decline (190).

Two large clinical trials carefully evaluated the impact of intensive diabetes treatment and severe hypoglycemia on the development of cognitive problems in patients with type 1 diabetes diagnosed when they were either adolescents or adults. These studies, the DCCT and the Stockholm Diabetes Intervention Study (SDIS), did not show an effect of intensive treatment or severe hypoglycemia on the development of cognitive problems (199,200). However, both studies had relatively short follow-up periods. Moreover, because of the nature of these trials, the number of severe hypoglycemic episodes was limited. Thus, these studies may understate the problem (201,202). A few other studies of adults do suggest the possibility that severe hypoglycemia in type 1 diabetes could play a role in the development of cognitive problems (201-203). The role of severe hypoglycemia in the development of cognitive problems remains highly controversial. Recently, there have been suggestions that the demonstrated problems in cognition, brain structure, and function may also be associated with the increased incidence of depression in patients with type 1 diabetes (204). To date, no studies have explicitly examined this hypothesis.

Sexual Functioning

It is well established that men commonly develop erectile dysfunction (ED) secondary to diabetes. The prevalence of ED in men with diabetes has been estimated at 35% to 70% (205). ED has been identified as contributing significantly to decreased quality of life in men with diabetes (206).

Longer duration of diabetes, poor glycemic control, and presence of diabetes complications such as diabetic neuropathy, vascular disease, retinopathy, and nephropathy are strongly correlated with the presence of ED in men with diabetes (207,208). In addition, the reported risk of ED is greater among men who smoke cigarettes and self-report symptoms of depression, anxiety, and treatment for hypertension (208). Since the medical treatments for depression, anxiety, and hypertension can also have side effects on sexual functioning, medical interventions for men with longer-term diabetes should be recommended after these risks are taken into account.

Although the organic component in ED has been widely recognized, psychosocial factors also may contribute to the development of ED in a significant subset of men with diabetes. Indeed, some research suggests that in as many as 20% of diabetic men with reported impotence, the dysfunction may have a primarily psychogenic origin (209,210). Any evaluation of ED must therefore be sensitive both to primary psychological factors and to secondary factors that may influence sexual functioning. For example, anxiety about performance may further exacerbate a partially dysfunctional episode in organically impaired individuals. Ignorance also may contribute to such problems. Many couples do not realize and are not informed that diabetes can promote ED and may misinterpret the source of the problem, believing that it is due to loss of love or to an extramarital interest. Most frequently, organic and psychological factors coexist, so that behavioral and psychological interventions may be valuable in facilitating adjustment to the limitations posed by the organic impairment.

Little research has focused on the impact of diabetes on the sexual functioning of women. In fact, since 1971, only 16 such studies have been published (211). These studies present conflicting evidence on the existence of diabetes-associated sexual problems in women. In their comprehensive review of the literature, Enzlin and colleagues (211) attempted to draw consensus between conflicting evidence from these studies. Thus far, it appears that women with diabetes may experience diminished libido and more pain during intercourse as compared with women without diabetes. However, women with diabetes appear to be at especially high risk for decreased or slowed sexual arousal. Researchers postulate that this may relate to inadequate vaginal lubrication, which occurs in 30% of women with diabetes (twice that of the population without diabetes). There is a lack of consistent evidence that diabetes causes problems with achieving orgasm in women.

Whereas there is growing consensus that sexual problems in men with diabetes are influenced by autonomic neuropathic damage, the etiology of sexual arousal problems in women with diabetes remains unclear at this time. Further study of the impact of diabetes and the complex interplay between psychological and physical factors on female sexuality is clearly needed.

CONCLUSION

In summary, we have provided an update of the significant progress made by behavioral scientists and clinicians focused on persons living with diabetes, their families, and their health-

care teams. During the last decade, the role of psychology in diabetes care has moved from a traditionally psychiatric or medical model to a biopsychosocial model, in which behavioral interventions in the form of telemedicine technology or behavioral strategies for optimizing self-management have been shown to improve biologic, psychological, and behavioral outcomes for persons with diabetes.

Now at the beginning of the 21st century, behavioral scientists focused on diabetes are prepared to apply their skills to an even broader spectrum of factors having an impact on the quality of life for persons living with diabetes (1). Increasingly, behavioral issues are seen as critical in basic research toward finding a cure for and preventing type 1 diabetes and identifying genetic and environmental risk factors that could be modified to prevent type 2 diabetes. With the advent of new efficacious treatments and innovative technologies, basic scientists and diabetes clinicians are seeking the contributions of behavioral scientists as they collaborate on the complex biopsychosocial dilemmas in curing, preventing, and treating diabetes.

CHAPTER 38 Exercise in Patients with Diabetes Mellitus

Jeanne H. Steppel and Edward S. Horton

PHYSIOLOGY OF EXERCISE IN HEALTHY INDIVIDUALS 649

EXERCISE AND GLUCOSE METABOLISM IN PATIENTS WITH TYPE 1 DIABETES 652

EXERCISE IN PATIENTS WITH TYPE 2 DIABETES 655

CONCLUSION 656

Exercise has long been recognized as an important factor in the treatment of diabetes mellitus. Before the discovery of insulin, patients with diabetes, particular those with type 1 diabetes, were very limited in their ability to exercise, because it was almost impossible for them to avoid ketosis and dehydration. After insulin therapy was established as a mainstay treatment, exercise was no longer an elusive activity. With their ability to exercise, it became evident that hypoglycemia frequently developed both in the immediate postexercise period and during the 24 hours after exercise. It also was recognized that ketosis could be induced by exercise in patients with poor glucose control and that even patients with excellent control would sometimes develop hyperglycemia after vigorous exercise. As our understanding of exercise in the patient with type 1 diabetes has increased, the goal has been to manage glucose homeostasis and fuel metabolism so that patients can participate fully in all forms of exercise.

Exercise also plays a critical role in patients with type 2 diabetes. It can help improve insulin sensitivity and assist with reduction and maintenance of body weight in obese patients. Exercise, together with diet and pharmacologic therapies, is important as part of the overall approach to improving glycemic control and reducing cardiovascular risk factors. Indeed, exercise often is "prescribed" as a therapy for type 2 diabetes. The many benefits of exercise in these patients include improved long-term glycemic control as a result of the decrease in insulin resistance and of the cumulative blood glucose-lowering effects of individual bouts of exercise. In addition, regular exercise has been shown to improve lipid abnormalities and lower blood pressure (1-3). Finally, exercise also may be an important component of weight-loss regimens for these patients. When used in combination with dietary changes (especially calorie restriction), exercise promotes loss of adipose tissue with preservation of lean body mass (4,5). In addition, exercise may promote a beneficial redistribution of body fat. Abdominal adiposity appears to have a greater impact on insulin resistance than does fat deposition at other sites, and exercise has recently been shown to decrease abdominal fat in postmenopausal women (6). Unfortunately, there are some significant risks of exercise in the patient with type 2 diabetes, including symptomatic hypoglycemia, which can occur up to 24 hours after exercise; exacerbation of known or previously unknown cardiac disease; worsening of symptoms secondary to degenerative joint disease; and possible damage to joints in the setting of neuropathy. It is particularly important to screen patients with type 2 diabetes for existing cardiovascular disease before prescribing an exercise regimen.

There are several universal risks of exercise in patients with type 1 or type 2 diabetes. Most important, vigorous exercise can cause retinal hemorrhage or vitreous bleeding in patients with proliferative retinopathy. Maneuvers such as the Valsalva maneuver that increase intraabdominal pressure should be avoided, as should jarring head motions that might induce retinal detachment. In addition, patients with sensory neuropathy should refrain from high-impact exercise to reduce the risk of soft tissue and joint injury. The presence of autonomic neuropathy often makes performance of high-intensity exercise difficult because of decreased aerobic capacity and postural hypotension. Proteinuria tends to increase with exercise in patients with nephropathy. However, this is thought to merely be a result of a transient change in renal blood flow, as opposed to worsening of renal disease. Angiotensin-converting enzyme inhibitors have been shown to decrease this effect (7–9).

PHYSIOLOGY OF EXERCISE IN HEALTHY INDIVIDUALS

To understand metabolic regulation in patients with diabetes, it is helpful first to discuss the physiology of exercise in healthy individuals without diabetes. Several hormonal, cardiovascular, and neurologic responses that occur during exercise enable the body to respond to the increased energy demand.

In the resting fasted state, before exercise, blood glucose levels are maintained by a balance of the production of glucose by the liver and the uptake of glucose by body tissues (50% by the brain; 15% to 20% by skeletal muscle; and the remainder by kidney, splanchnic bed, blood cells, and other tissues). Glucose production by the liver early in fasting occurs predominantly via glycogenolysis, with only about 25% contributed by gluconeogenesis (Fig. 38.1). In patients with type 1 diabetes, up to 45% of glucose production during the nonexercising state derives from gluconeogenesis, even early in fasting.

GLUCOSE PRODUCTION

GLUCOSE UTILIZATION

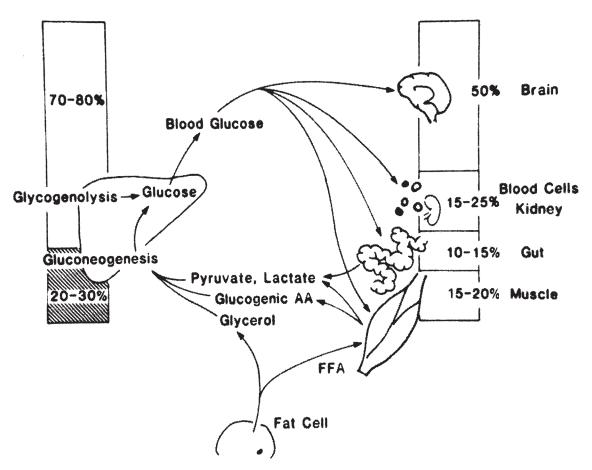

Figure 38.1. Glucose production and utilization in the resting, fasted state in normal man. AA, amino acids; FFA, free fatty acids. (Modified from Bjorkman O, Wahren J. In: Horton E, Terjung R, eds. *Exercise, nutrition, and energy metabolism.* New York: Macmillan Publishing, 1988;100–115, with permission.)

The sources of energy used by skeletal muscle vary markedly between times of rest and exercise. At rest, only 10% of the energy produced in skeletal muscle is from glucose oxidation, whereas 85% to 90% is from fatty acids and 1% to 2% is from amino acids (10). Carbohydrate metabolism increases significantly with the onset of exercise as the breakdown of glycogen in muscle increases. This is associated with the rapid generation of lactate, which enters the bloodstream. Within minutes of the onset of exercise, anaerobic metabolism switches to aerobic metabolism, and uptake of glucose and oxygen into muscle increases as the blood flow to muscle increases. The circulating glucose concentration is kept essentially constant as a result of a regulated matching of the hepatic production of glucose to the rate of glucose uptake by the muscle from the circulation. In addition to the shift in glucose metabolism during exercise, breakdown of triglycerides in adipose tissue releases fatty acids into the circulation as an alternative metabolic fuel. Glycerol released from the triglyceride backbone is taken up by the liver and used as a precursor for gluconeogenesis along with the release of amino acids from the skeletal muscle.

Once exercise stops, the increase in glucose uptake continues for a time to rebuild glycogen stores in the muscle. The rate of repletion of glycogen stores can vary dramatically, depending on intake of food. This occurs quite slowly in the fasted state; in the fed state, glycogen generally is replenished within 12 hours. Glycogen stores in skeletal muscle are repleted more rapidly than are those in the liver.

Multiple complex neurologic and hormonal responses play important roles in fuel homeostasis during exercise. These include activation of the sympathetic nervous system and a change in the ratios of insulin and the counterregulatory hormones. The shifts in the balance of these hormones, plus increased sympathetic tone, alter the metabolism of glucose, free fatty acids, and amino acids and change the body's ability to utilize oxygen and to maintain fluid status.

At the onset of exercise, the sympathetic nervous system is activated, with a resultant increase in heart rate and constriction of the blood vessels supplying the splanchnic bed, the kidneys, and muscles not involved directly in the exercise. This causes an increase in blood flow to the tissues most in need—the exercising muscles. In addition, epinephrine and norepinephrine play vital roles in stimulating breakdown of adipose tissue [β -adrenergic stimulation (11)] and suppressing insulin secretion (α -adrenergic stimulation). Catecholamines are also important in stimulating glycogenolysis during exercise.

Adjustments in insulin secretion are critical for the regulation of fuel metabolism during exercise. As mentioned above, the sympathetic nervous system suppresses secretion of insulin at the onset of exercise. Because insulin normally inhibits hepatic glucose production, the decrease in insulin allows the liver to increase glucose output. Insulin also suppresses lipolysis, and thus the decrease in insulin levels promotes the breakdown of adipose tissue triglycerides. As will be discussed later, the molecular mechanisms of glucose uptake during exercise are independent of insulin, so the decrease in serum insulin concentration does not affect the ability of the muscle to take up glucose from the circulation (12).

Glucagon is important in the regulation of glucose levels during vigorous or prolonged exercise but plays a smaller role in mild-to-moderate exercise. As the plasma glucose concentration begins to fall, glucagon acts as a counterregulatory hormone, contributing to the activation of glycogenolysis and to the increase in gluconeogenesis through accelerated uptake of amino acids by the liver (13). The role played by glucagon is generally larger in people who have not undergone physical training than in those who are trained athletes. Cortisol and growth hormone also act as counterregulatory hormones that help to block the effects of insulin during exercise. They may be especially important in antagonizing the effects of insulin in tissues that are not directly involved in exercise, thus increasing the amount of glucose available for the actively exercising muscles.

Several factors can alter fuel utilization and the extent of influence of the hormonal and neurologic regulators. These include physical training, intensity of exercise, duration of exercise, and the diet that precedes exercise. Physical training lowers the percentage of the maximum aerobic capacity ($VO_{2 max}$) that is reached when doing an equivalent amount of work. Trained individuals depend more heavily on utilization of free fatty acids than of glucose for fuel. This appears to be important in developing endurance, because muscle glycogen stores in

trained individuals do not become depleted as quickly as those in untrained individuals.

The intensity of exercise, defined as a percentage of $VO_{2 max}$, also influences fuel metabolism. As the intensity rises, the role of glucose in providing fuel to the exercising muscles keeps increasing (Fig. 38.2), with the importance of lipolysis decreasing. The use of amino acids remains roughly the same. Once the $VO_{2 max}$ is greater than 75%, carbohydrate becomes the main fuel consumed by muscle and the rate of glycogenolysis is increased.

The duration of exercise affects fuel metabolism as a consequence of a time-dependent shift from the utilization of carbohydrates to the utilization of free fatty acids. Glycogen stores become depleted after several hours of moderate continuous exercise, and lipolysis becomes the main source of fuel for exercising muscle. After depletion of glycogen stores, hepatic glucose production via gluconeogenesis is essential for maintenance of blood glucose concentrations. Sometimes in prolonged exercise such as marathon running, glycogen stores are depleted, the liver is unable to keep up with glucose requirements through gluconeogenesis, and hypoglycemia develops.

The composition of the diet preceding exercise can affect fuel metabolism during activity. A diet high in carbohydrates is associated with a greater rate of glucose oxidation and increased muscle glycogen stores. This may contribute to generally greater endurance in individuals who have had a carbohydrate-rich diet than in those with a carbohydrate-restricted diet. Some athletes therefore use a technique called "carbohydrate loading" before exercise to improve endurance.

Skeletal muscle is able to take up glucose from the circulation predominantly via the GLUT4 transporter protein (14).

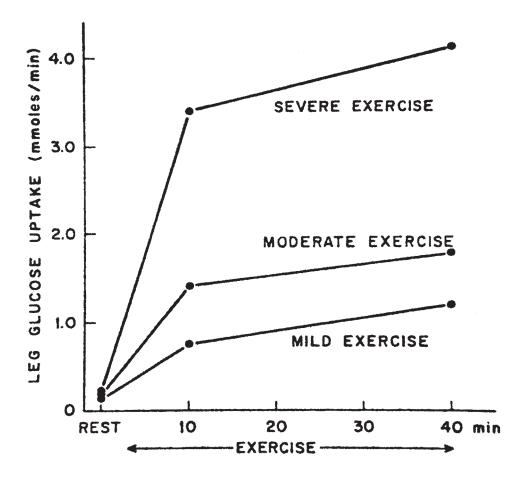

Figure 38.2. Leg uptake of glucose during bicycle ergometer exercise. Mild exercise is 25% to 30% of maximal capacity, moderate exercise is 50% to 60% of maximal capacity, and severe exercise is 75% to 90% of maximal capacity. (From Felig P, Warren J. Fuel homeostasis in exercise. *N Engl J Med* 1975; 293:1078–1084, with permission. Copyright © 1975 Massachusetts Medical Society.)

During exercise, GLUT4 is translocated from an intracellular location to the plasma membrane, similar to what occurs with insulin stimulation. There is now abundant evidence to indicate that the insulin-mediated and contraction-mediated mechanisms are distinct (15). Insulin-mediated signaling involves binding of insulin to the insulin receptor and causing its autophosphorylation and a cascade of reactions, including activation of insulin receptor substrate protein-1 (IRS-1) and phosphatidylinositol 3-kinase. Exercise-induced glucose transport does not involve either IRS-1 or phosphatidylinositol 3-kinase, although there may be activation of the signaling serine kinase Akt, which is located farther down in the insulin signaling pathway.

Numerous hypotheses have been proposed to explain the mechanism of exercise-induced glucose transport. Calcium flux in the muscle cell has been implicated, because glucose transport decreases when calcium release is blocked pharmacologically (15). Calcium is also thought to play an important role in the activation of enzymes such as protein kinase C, which are thought to be upstream of the mobilization of GLUT4. Another theory implicates nitric oxide as a potential mediator of contraction-induced glucose transport, because generation of nitric oxide increases during exercise (16). Although the uptake of glucose by muscle after contraction is not affected by inhibition of nitric oxide synthase, basal rates of glucose transport in muscle appear to be decreased (17). It is possible that nitric oxide modulates a unique pathway that affects glucose transport independent of either the insulin or the exercise pathway.

Evidence also has implicated mitogen-activated protein (MAP) kinase in the process of exercise-induced glucose transport. The MAP kinase signaling pathway contains several enzyme cascades that are activated with exercise. This appears to include both the ERK1/2 and JNK MAP kinases (18). In addition to potential effects on glucose uptake, the MAP kinase pathways likely regulate gene-transcription events that are involved in muscle growth and repair.

There currently is strong interest in the hypothesis that 5'adenosine monophosphate–activated protein (AMP) kinase serves as a metabolic "fuel gauge" and key regulator of glucose uptake during exercise. AMP kinase activity increases markedly with exercise. Studies with activators and inhibitors of AMP kinase indicate that this is causally linked to the translocation of GLUT4 transporters (19,20). Fatty acid oxidation and insulin sensitivity may also be affected by exercise via this pathway. Several excellent review articles have covered the signaling pathways implicated in exercise-induced glucose transport (15,21,22).

EXERCISE AND GLUCOSE METABOLISM IN PATIENTS WITH TYPE 1 DIABETES

Physical exercise increases insulin sensitivity in individuals with diabetes (Fig. 38.3). This increased insulin sensitivity is thought to be caused by the increase in glucose uptake via GLUT4 resulting from the effect of exercise on the expression and translocation of the transporter to the skeletal muscle plasma membrane (23). This state of altered sensitivity can last for several hours (24). Highly trained athletes have better glucose tolerance, β -cell efficiency, and glucose utilization than do untrained individuals (25). In addition, athletes may exhibit a greater glycemic response to oral glucose secondary to adaptations in glucose absorption (26). The adaptations associated with training reverse rapidly once athletes stop their exercise programs (27).

Blood glucose (mg/dl)

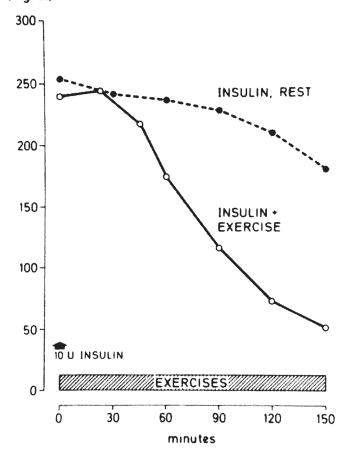

Figure 38.3. The effect of insulin on blood glucose at rest and with exercise in type 1 diabetes. (From Lawrence RD. *BMJ* 1926;1:648–650.)

In individuals with type 1 diabetes, unlike those without diabetes, regulatory events in the pancreatic islets induced by exercise cannot decrease insulin secretion, because insulin is derived by injection. Because insulin levels are sustained, the suppressive effect of insulin on the liver continues and hepatic production of glucose remains low at the same time that utilization of glucose by muscle rises. This results in a substantial risk of hypoglycemia. The risk of hypoglycemia in patients with diabetes is even greater if they have injected insulin into a subcutaneous site in an exercising limb, because increased blood flow can accelerate insulin absorption (28). This can be particularly problematic when very-short-acting insulin, such as lispro or aspart, is used (29). Because of the increased risk of hypoglycemia secondary to rapid absorption of recently administered insulin, it is recommended that vigorous exercise be avoided for 1 to 1.5 hours after injection. The site of insulin administration is also important and should be chosen with regard to the particular activity so as to avoid injecting insulin into an actively exercising area.

Because, as described above, insulin levels do not decline in response to activity in patients with type 1 diabetes, the normal upregulation of glycogenolysis and gluconeogenesis does not occur, the rate of muscle glucose uptake may not be matched, and hypoglycemia is likely to develop. This can cause problems particularly in patients who have tight glucose control, because they may have greater hypoglycemia unawareness and reduced counterregulatory responses (30). The presence of autonomic neuropathy may further contribute to a decreased counterregulatory response, as well as to a diminished ability to sense hypoglycemia.

As an approach to decreasing the risk of hypoglycemia during exercise, patients with type 1 diabetes often benefit from lowering their dose of short-acting insulin before exercise and ingesting carbohydrates before or during exercise. It often is effective to decrease the insulin dose by 25% to 50% before exercise and to avoid exercise for at least an hour after taking insulin. Patients should check their blood glucose levels before they exercise and consider a supplementary carbohydrate snack when their blood glucose level is below 100 mg/dL. The response of blood glucose to exercise may vary significantly among patients with diabetes, and thus precise adjustments in insulin and carbohydrate intake need to be individualized.

In some patients with type 1 diabetes, improved insulin sensitivity may persist for several hours after they stop exercising (Fig. 38.4), and these effects can last for up to 24 hours (31). The mechanism is not fully understood, but the increased sensitivity is thought to be due to a relatively high rate of glucose uptake by the exercised muscles and lower hepatic production of glucose as the glycogen stores are repleted (24). This may result in the development of hypoglycemia several hours after exercise. Therefore, it is often advisable to decrease doses of short- and intermediate-acting insulin before exercise (as noted above), and carbohydrate intake should be increased after exercise. As stated earlier, the treatment regimen needs to be tailored to each patient on the basis of his or her response to exercise.

It is important to recognize that different types of exercise can have distinct effects on blood glucose levels. Whereas moderate, sustained activity may lower plasma glucose concentrations and result in hypoglycemia in patients with type 1 diabetes, short bursts of high-intensity exertion can actually increase glucose levels and cause hyperglycemia (32) (Fig. 38.5). The glucose level in individuals without diabetes tends to rise modestly during brief intensive exercise, with a peak level occurring up to 15 minutes after cessation of activity. The glucose level then gradually drops during the next hour. The rise in glucose concentration is attributed to an increase in hepatic production of glucose that exceeds the rate of glucose uptake by exercising muscle. This likely reflects the dramatic stimulation of

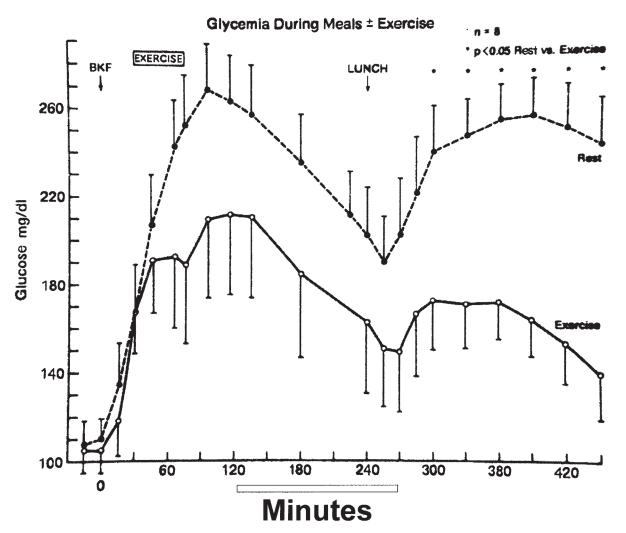

Figure 38.4. Glucose levels during breakfast (BKF) and lunch with rest and with 45 minutes of moderate exercise starting 30 minutes after breakfast in patients with type 1 diabetes. (Copyright © American Diabetes Association. From Caron D, Poussier P, Marliss EB, et al. The effect of postprandial exercise on meal-related glucose intolerance in insulin-dependent diabetic individuals. *Diabetes Care* 1982;5:364–369. Reprinted with permission from the American Diabetes Association.)

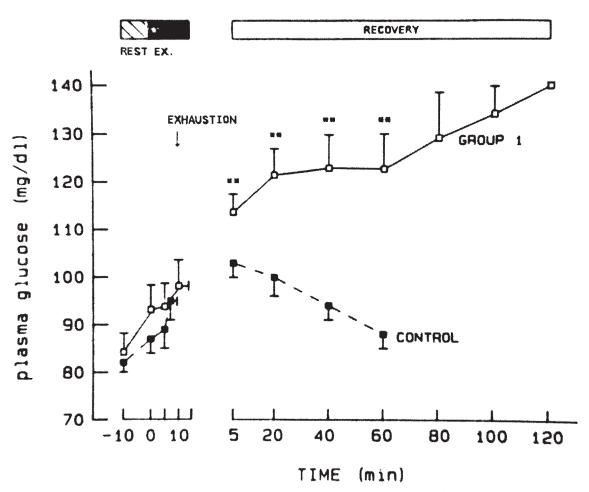

Figure 38.5. Glucose concentrations in control and diabetic subjects 10 minutes before intense exercise, then an exercise period at 80% VO_{2 max}, then 2 hours of recovery. Group 1 consists of the diabetic subjects, all of whom had plasma glucose values of 70 to 120 mg/dL before the exercise test. (Copyright © American Diabetes Association. From Mitchell TH, Abraham G, Schiffrin A, et al. Hyperglycemia after intense exercise in IDDM subjects during continuous insulin infusion. *Diabetes Care* 1988;11:311–317. Reprinted with permission from the American Diabetes Association.)

the counterregulatory hormone secretion during intense exercise, which suppresses insulin release. Once exercise is completed, there is a compensatory increase in insulin secretion.

The rise in blood glucose with intensive exercise may last longer in individuals with type 1 diabetes than in those without diabetes. One study found that the postexercise hyperglycemia reached higher levels and lasted for a full 2-hour observation period in patients with type 1 diabetes after they exercised at 80% Vo_{2max} (32). The higher glucose levels and prolonged hyperglycemia in patients with type 1 diabetes are likely due to increased hepatic production of glucose in the setting of counterregulatory hormone release. This is followed by an inability to increase insulin release after completion of exercise in response to the elevated blood glucose levels. Of note, the catecholamine response in patients with diabetes appears to be normal (33).

Although hyperglycemia can occur after intense exercise in diabetic patients with excellent glycemic control, patients with poor control who exercise often experience an even more marked increase in blood glucose levels, which can be accompanied by ketosis (Fig. 38.6). In the setting of insulin deficiency, fatty acid oxidation and glucose production by the liver are stimulated, contributing to increased ketogenesis and hyperglycemia (34). There also appears to be decreased clearance of ketones in patients with poorly controlled diabetes, because this is an insulin-stimulated response (35). It is recommended that patients with type 1 diabetes check both their blood glucose level and their urine or serum for ketones before exercising. If their serum glucose concentration is 250 mg/dL or higher and ketones are present, they should postpone exercise and administer insulin. If no ketones are present, it is generally safe for them to exercise. Indeed, moderate exercise may be helpful in improving the serum glucose level.

Recommendations for patients with type 1 diabetes should always be individualized, but there are some universal principles (Table 38.1). First, patients should always check blood glucose levels before exercise. If their glucose level is less than 100 mg/dL, they should take supplemental carbohydrate before initiating exercise. They also should exercise about 1 to 3 hours after a meal. If they take short-acting insulin with meals, they should plan to lower their dose of insulin at the meal before initiating activity. A general rule is to lower the short-acting insulin by at least 50%. If they take only intermediate-acting insulin, they may wish to lower the dose by 30% to 35% on the morning of the planned exercise. If patients are involved in high-intensity exercise with a VO_{2 max} greater than 80%, they may need supplemental insulin after exercise to counter postexercise hyperglycemia. For patients

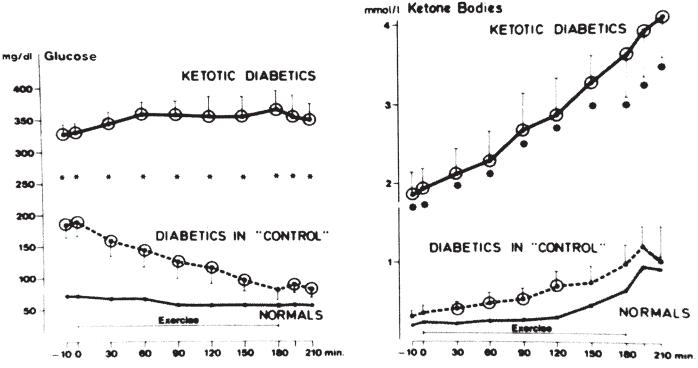

Figure 38.6. Glucose and ketone levels during exercise in patients with diabetes with good versus poor blood glucose control. (From Berger M, Berchtold P, Cuppers HJ, et al. Metabolic and hormonal effects of muscular exercise in juvenile type diabetes. *Diabetologia* 1977;13:355–365, with permission. Copyright 1977 by Springer-Verlag.)

on an insulin pump, the basal rate should be lowered and the premeal bolus decreased to avoid hypoglycemia. In addition, patients may need to take supplemental carbohydrates before exercising and at intervals during and after exercise. It is important to consider each patient's personal experience when developing an appropriate regimen and making adjustments.

EXERCISE IN PATIENTS WITH TYPE 2 DIABETES

There are many health benefits of exercise for patients with type 2 diabetes, including improvement in the circulating lipid profile and blood pressure. In addition to the benefits of acute exercise, prolonged physical training can improve insulin sensitivity and both fasting and postprandial glucose levels (36,37). It is thought that the greater insulin sensitivity from physical conditioning reflects an increase in glucose uptake by skeletal muscle rather than a decrease in hepatic glucose production. This may be linked to augmented translocation of GLUT4 glucose transporters to the plasma membrane, thus improving peripheral glucose uptake (38). Unfortunately, much of this effect disap-

TABLE 38.1. Insulin Regimen for Exercise

 Insulin pump therapy Decrease basal infusion rate Decrease or omit premeal boluses before exercise Adjust postexercise basal rate and boluses based on glucose pears once exercise training is discontinued, often within days (39,40). In a recent meta-analysis of studies focusing on the effects of exercise training on glycemic control, the hemoglobin A_{1c} level was significantly lower in the exercise group than in the control group (41), indicating that exercise is beneficial to long-term glycemic control.

Numerous studies have evaluated the effectiveness of exercise in the prevention of type 2 diabetes. Because insulin resistance plays an important role in the progression to type 2 diabetes, techniques to improve insulin sensitivity should theoretically delay or reverse this process. One study showed that Japanese persons living in Hawaii were much more likely than those living in Japan to develop diabetes. This was thought to be associated with decreased physical exercise and changes in diet in individuals who had immigrated to Hawaii as compared with those who lived in Japan (42). Subsequently, multiple studies confirmed that physical activity has a protective effect against the development of diabetes (43-46). Several important findings have emerged from these studies. First, the beneficial effect of physical activity appears to be independent of corrections in the risk factors for diabetes. In one study, the incidence of diabetes was reduced by 24% from the highest to the lowest activity group in men at high risk for developing diabetes [based on obesity, high blood pressure, and family history (44)]. In another study, women who participated in physical activity were found to have a decreased occurrence of diabetes, independent of other risk factors (45).

More recently, three important clinical trials evaluated the effects of exercise and lifestyle modification on the prevention of type 2 diabetes. The first study (the Da Qing Study) looked at 577 Chinese patients with impaired glucose tolerance. The subjects were divided into four groups according to the clinic they attended: a control group, a group treated with diet alone, a

group treated with exercise alone, and a group treated with both diet and exercise. Patients received an oral glucose tolerance test every 2 years for a total of 6 years of follow-up. All of the treatment groups had a significant drop in the incidence of diabetes compared with the control group. Interestingly, the group with only exercise as an intervention had the highest overall reduction in diabetes incidence after adjustment for baseline blood glucose and body mass index (47).

A second study (the Finnish Diabetes Prevention Study) evaluated patients with impaired glucose tolerance. The subjects were randomly divided into two groups: a treatment group offered intensive lifestyle changes, including diet and exercise, and a nontreatment group. At the end of the study (after an average of 3.2 years of follow-up), the incidence of diabetes in the treatment group was reduced by 58%. The risk reduction was most significant in those patients who exercised for more than 4 hours per week and in those who had the largest weight loss (48).

Finally, the Diabetes Prevention Program, a large multicenter clinical trial, examined the incidence of diabetes in patients with impaired glucose tolerance who were randomized to placebo, lifestyle intervention, and metformin treatment groups. The lifestyle treatment group had a 58% reduction in the incidence of type 2 diabetes compared with controls. This was significantly better than the 31% reduction achieved with metformin.

In all of these studies, it is clear that prevention or reduction of obesity plays an important role in the prevention of type 2 diabetes. Exercise must be combined with calorie restriction in order to tip the energy balance in the direction of energy expenditure.

There are several universal recommendations that should be given to patients with type 2 diabetes before they begin an exercise regimen. Individuals older than 35 should be given an exercise test to screen for potential underlying asymptomatic coronary artery disease (49). Patients should undergo an ophthalmologic evaluation to ensure that proliferative retinopathy is addressed before they start to exercise. In addition, tests for microalbuminuria and peripheral and autonomic neuropathy should be performed. Exercise regimens should then be individualized. Ideally, aerobic activity should be of a level that can be sustained for at least 30 minutes, and the maximum heart rate should not be higher than 60% to 70% above the resting heart rate. It is important to allot time for warm-up and cooldown stretching exercises to avoid muscle injuries.

For patients to achieve the health benefits of exercise, it is suggested that they partake in physical activity at least 3 days per week, and they should be encouraged to increase the frequency to 5 to 7 days per week, if possible. If patients are receiving oral hypoglycemic agents or insulin, they should be aware of the potential for developing hypoglycemia during or after exercise. They may need to ingest additional carbohydrate to prevent low blood glucose levels, and adjustments to their medications may become necessary.

CONCLUSION

It has long been known that exercise has beneficial effects for people with diabetes. In the past, it was often difficult to avoid the hazards of exercise, particularly in patients with type 1 diabetes. More recently, a greater understanding of energy metabolism and fuel homeostasis has made it possible to include exercise as a realistic goal for almost all patients with diabetes. Improvements in glucose-monitoring technology have further contributed to the feasibility of active physical exercise programs for people with diabetes. In particular, personal blood glucose monitors have allowed patients to follow their blood glucose levels closely and thus readily develop individualized exercise regimens. This has made it much easier for individuals with diabetes to participate in competitive sports or endurance activities such as marathon running. It is important to address strategies for avoiding hypoglycemia (both during and after exercise), as well as hyperglycemia and ketosis, with all patients before they embark on routine exercise.

Patients with type 2 diabetes clearly benefit from frequent exercise. Physical activity plays an important part in the treatment strategy in these patients, as it decreases obesity and lowers blood pressure while improving insulin sensitivity, longterm glycemic control, and blood lipid profiles. Because of the risk of exercise unmasking ischemia as well as causing soft tissue and joint injury or retinal hemorrhage, it is critical that all patients have a complete history and physical examination before they engage in moderate or vigorous activity.

For all patients with diabetes, physician-patient interaction is key to establishing a successful exercise program. A team approach that involves coordination among exercise physiologists, nutritionists, diabetes educators, the physician, and the patient is usually the most effective way to create an individualized exercise regimen that provides benefits to the patient while avoiding potential harm.

HISTORICAL BACKGROUND

The isolation of insulin from dog pancreas and demonstration of its biologic effectiveness by Banting, Best, Collip, and MacLeod in 1921 at the University of Toronto represents one of the greatest medical discoveries of modern medicine (1). This antidiabetic substance, initially called isletin by Banting and Best and later named insulin by MacLeod, was purified sufficiently by Collip, the biochemist member of the team, so that it could be injected into humans (2). The first injection was given to a patient with diabetes, Leonard Thompson, on January 11, 1922, at the Toronto General Hospital (3). Improvements in insulin extraction and purification followed, facilitating the widespread use of insulin for patients with diabetes.

In 1936, Hagedorn discovered that the addition of fish protamine kept insulin in suspension so that it was absorbed slowly from subcutaneous sites, thus prolonging the effect of insulin (4). Scott and Fisher (5) discovered that zinc could further extend the action of protamine insulin, leading to the development of protamine zinc insulin. In 1946, NPH insulin (neutral protamine Hagedorn), a more stable form of protamine insulin, was introduced and remains in use today (6). For the first 60 years of the insulin era, insulin was available only in bovine or porcine preparations. In the 1980s, human insulin was introduced (7), making animal insulin essentially obsolete. In the 1990s, insulin analogues with pharmacokinetics that were more appropriate for bolus (premeal) therapy were introduced and facilitated the improvement of subcutaneous insulin regimens (8). Over the last 80 years, great strides have been made to improve the treatment of diabetes with improved insulin formulations, increased ease of self-monitoring of blood glucose, and a better understanding of physiologic insulin requirements. Unfortunately, although we are much closer to the goal of physiologic insulin replacement, this goal remains elusive owing to the inherent limitations of administering insulin at a nonphysiologic site (subcutaneous tissue) (9).

TYPES OF INSULIN

The laboratory production of human insulin in the early 1980s has gradually resulted in the replacement of animal insulins as a viable therapeutic choice for patients with diabetes. Human insulins and newer insulin analogues produced by recombinant

Subcutaneous Injection				
Insulin	Onset of action	Peak of action	Duration of action	Blood glucose targets
Mealtime insulins				
Lispro	10–15 min	1–1.5 h	4–5 h	Postprandial
Aspart ^a	10–15 min	1–2 h	4–6 h	Postprandial
Regular	15–60 min	2–4 h	5–8 h	Postprandial
0				Prior to next meal
Basal insulins				
NPH	2.5–3 h	5–7 h	13–16 h	Midafternoon (for morning NPH)
				Fasting glucose next morning (for bedtime NPH)
Lente	2.5–3 h	7–12 h	Up to 18 h	Similar to NPH
Glargine ^b	2–3 h	No peak	Up to 30 h	Similar to NPH
Ultralente	3–4 h	8–10 h	Up to 20 h	Similar to NPH
Detemir ^c	2–3 h	No peak	Up to 24 h	Similar to NPH

DNA technology are becoming the main insulins used in the current treatment of diabetes in most countries. Insulins for clinical use can be characterized according to their pharmacokinetic profiles. They are available in rapid-acting, short-acting, intermediate-acting, and long-acting preparations (10). Table 39.1 shows the onset, peak, and duration of action after subcutaneous injections of the insulins used commonly in therapy. The different time-action profiles make it feasible to pursue the goal of simulating physiologic insulin secretion, as shown in Figure 39.1; however, this goal remains difficult to achieve with the current formulations. Insulin replacement should be thought of in terms of mealtime (bolus) and basal insulins. The mealtime insulins are the rapid-acting analogues or short-acting regular human insulin. These insulins have been used to attempt to simulate the high levels of insulin seen in individuals without diabetes after ingestion of a meal. The basal insulins are the intermediate- and long-acting human insulins and analogue. They simulate the basal level of insulin occurring between meals, through the night, and with fasting. Insulin is commercially available in concentrations of 100 or 500

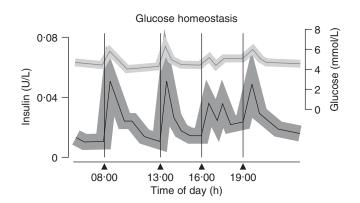

Figure 39.1 Normal insulin secretion in relation to meals and the overnight fasting state. (Redrawn from Owens DR, Zinman B, Bolli GB: Insulins today and beyond. Lancet 2001;358:739.)

units/mL, designated U-100 or U-500. The U-500 concentration, which is available only in short-acting formulations, is used only in rare cases of insulin resistance when the patient requires extremely large doses of insulin.

Mealtime Insulins

RAPID-ACTING INSULIN ANALOGUES: LISPRO AND ASPART

The time-action profile of regular human insulin is unable to adequately mimic physiologic insulin secretion. Insulin in solution self-associates and forms larger aggregates called hexamers. These large aggregates need to dissociate after subcutaneous injection before diffusion of insulin into the circulation is possible (11). Therefore, analogues of human insulin have been developed that can dissociate rapidly from hexamers to monomers or that remain less associated in solution, thus allowing faster absorption and onset of action (10,11). The first rapidly acting insulin analogue approved for human administration was insulin lispro, in which the terminal proline and lysine residues of the B chain of insulin are inverted, resulting in decreased self-association properties of the insulin (8,12). Lispro insulin is absorbed much more rapidly than regular insulin. Lispro begins acting within 15 minutes, reaches peak biologic effects in 60 to 90 minutes, and continues to act for 4 to 5 hours. In comparison to regular insulin, lispro peaks more rapidly, achieves higher blood insulin concentrations more rapidly, and has been shown to lower postprandial glucose levels and decrease rates of hypoglycemia (13-17). The impact of lispro compared with regular insulin on levels of glycosylated hemoglobin (HbA_{1c}) has been variable (18–23). However, lispro provides more flexibility for patients at mealtimes because it does not need to be administered 30 minutes before a meal and the dose can readily be adjusted for changes in the carbohydrate content of the meal. Randomized controlled prospective trials have demonstrated that lispro is one of the preferred insulins for insulin pump therapy with continuous subcutaneous insulin infusion (CSII) and results in lower HbA1c levels and less hypoglycemia (24-26). Lispro must be used with caution in patients with gastroparesis because of its rapid onset of action and the potential for early postprandial hypoglycemia. Patients with gastroparesis can delay the meal insulin injection until after they have consumed the meal to reduce the risk of hypoglycemia.

Insulin aspart is another very-rapid-acting insulin analogue. Similar to lispro, it is absorbed very rapidly after subcutaneous injection, resulting in higher peak concentrations compared with those achieved with regular insulin (27). Trials comparing insulin aspart and regular insulin in patients with type 1 diabetes show significantly reduced HbA_{1c} levels with no difference in the frequency of hypoglycemia (28-30). In type 2 diabetes, insulin aspart is comparable to regular insulin, with no significant difference in HbA_{1c} levels or frequency of hypoglycemia (31). Both insulin lispro and insulin aspart appear to be associated with a lower incidence of nocturnal hypoglycemia than regular human insulin. For these reasons, lispro and aspart are the insulins of choice for use before meals in most treatment regimens and particularly in multiple daily injection therapy (13-17,19-21,23, 28-30). The safety and efficacy of the use of aspart in CSII have also been demonstrated (31a).

SHORT-ACTING HUMAN INSULIN: REGULAR

As mentioned earlier, subcutaneously injected regular insulin, because of its relatively slow rate of absorption, is unable to mimic physiologic insulin secretion following a meal. Regular insulin has an onset of action 15 to 60 minutes after injection, a peak effect 2 to 4 hours after injection, and a duration of action ranging from 5 to 8 hours (11). Given the "short-acting" nature of regular insulin, it is used primarily as a mealtime insulin. Therefore, regular insulin should be administered approximately 30 to 45 minutes before a meal in order to match the kinetics of insulin absorption with the peak of carbohydrate absorption after the meal (11).

Basal Insulins

INTERMEDIATE-ACTING HUMAN INSULINS: NPH AND LENTE

Both NPH and lente insulins are modified into a suspension form to delay their absorption from subcutaneous sites, thereby prolonging their action. NPH insulin, first developed in 1946, has a longer duration of action than regular insulin (12). Its onset of action is within 2.5 to 3 hours of injection, with a peak action 5 to 7 hours after injection and a duration of action between 13 and 16 hours (12). Lente insulin, the other intermediate-acting insulin, was first introduced in the 1950s. Its onset of action is similar to that of NPH at 2.5 hours, its peak action is 7 to 12 hours after injection, and its duration of action is up to 18 hours (12). Given the more prolonged action of NPH and lente insulins, they are not ideal for controlling postprandial serum glucose levels. When given at appropriate times, these insulins are reasonably effective in lowering fasting plasma glucose and predinner plasma glucose levels (11). These insulins are used as the basal insulins and are necessary for adequate glycemic control in type 1 and type 2 diabetes. Currently, NPH insulin is the only intermediate-acting insulin available for the pen delivery system.

LONG-ACTING HUMAN INSULIN: ULTRALENTE

The role of long-acting insulin is to achieve basal insulin coverage with a relatively small or no pharmacologic/biologic peak action. Its onset of action is 4 hours after injection, its peak action is at 8 to 10 hours, and its duration of action is up to 20 hours (12). In clinical practice, its biologic action appears to be similar to that of intermediate-acting insulin. NPH and ultralente provide similar glycemic control when used as the basal insulin in a multiple daily injection regimen with lispro as the mealtime insulin (32). Most patients (75%) require only one injection of basal insulin per day given at bedtime (32). However, NPH seems to provide a slightly better daily glycemic profile than ultralente in those requiring two injections of basal insulin per day (32).

LONG-ACTING INSULIN ANALOGUE: GLARGINE

Glargine is a long-acting insulin analogue that was developed in an attempt to provide a more constant level of insulin than that achieved with the human intermediate- and long-acting insulin preparations (10,33–38). Glargine has a higher isoelectric point than human insulin and precipitates in the neutral environment of subcutaneous tissue, giving it its prolonged duration of action (10,33–36). Glargine is absorbed more slowly than the human long-acting insulin preparations, with no pronounced insulin peaks, decreasing the risk of nocturnal hypoglycemia (33,34,36–38). Insulin glargine has a greater affinity than human insulin for insulin-like growth factor 1 (IGF-1) receptors, and it has been suggested that this may lead to increased mitogenic potential in cell lines rich with IGF-1 receptors (39). However, the clinical significance of this hypothesis is still unknown (39).

Detemir is another long-acting insulin analogue that was developed using a different approach-binding to albumin. An aliphatic fatty acid has been acylated to the B29 amino acid, and the B30 amino acid has been removed (39a). This results in reversible binding between albumin and the fatty acid acylated to the insulin. After injection, 98% of the insulin is bound to albumin. The gradual release of the bound fraction from albumin allows for the sustained, prolonged action of detemir (39b). The time-action profile of insulin detemir is characterized by a peak activity at 6 to 8 hours after injection and prolonged 24hour duration of action (39b). Detemir has been approved for release in Europe and has received preliminary approval from the FDA in the United States. Studies to date have shown less hypoglycemia and less variation in blood glucose levels with detemir as basal insulin in intensive regimens compared with NPH (39c-e).

Premixed Insulin

Premixed preparations of short- and intermediate-acting insulins are available in a wide range of ratios (90/10 to 50/50) (11). The most commonly used premixed insulin is 70/30, which contains 30% short-acting and 70% intermediate-acting insulin. A premixed insulin of 75% NPL (neutral protamine lispro) and 25% lispro, Humalog Mix 75/25, also is available (40). Humalog Mix 75/25 provides a relatively rapid peak in insulin activity, similar to lispro alone, and the NPL provides basal coverage similar to that of NPH (40). This allows improved postprandial glycemic control compared with that offered by 70/30 insulin (41,42). A premixed insulin of 30% aspart and 70% protaminated insulin aspart (NovoLog Mix 70/30) is also available. Like Humalog Mix 75/25, NovoLog Mix 70/30 provides improved postprandial glucose control and less hypoglycemia than 70/30 insulin (42a,b).

Use of premixed insulin avoids the potential problems of self-mixing and reduces the number of steps before injection, thereby reducing the number of possible errors. The premixed insulins are preferred by elderly patients and those with visual or fine-motor impairment (43). However, premixed insulins do not permit easy adjustment of mealtime and basal insulin doses and are inappropriate for patients with type 1 diabetes. They are valuable and frequently used in the treatment of type 2 diabetes.

TABLE 39.2. Goals of Insulin Therapy

- 1. Eliminate symptoms of hyperglycemia
- 2. Prevent diabetic ketoacidosis
- 3. Arrest severe catabolic state and regain lean body mass
- 4. Reduce frequent infections
- Decrease fetal and maternal morbidity in pregnancy
 Prevent and delay microvascular and macrovascular
- complications

GOALS OF THERAPY

Type 1 Diabetes

Insulin deficiency is the hallmark of type 1 diabetes. Insulin replacement is essential for life in people with type 1 diabetes to avoid a progressive catabolic state and ketosis. When used properly, insulin can eliminate clinical symptoms of hyperglycemia, prevent diabetic ketoacidosis, restore lean body mass and exercise capacity, decrease the incidence of certain infections, and improve the patient's sense of well-being. In addition, the use of insulin in intensive treatment regimens, with the goal of achieving near-normal plasma glucose concentrations, delays the onset and slows the progression of microvascular complications in patients with type 1 diabetes (44,45). Table 39.2 itemizes some of the principal goals of insulin therapy. The Diabetes Control and Complications Trial (DCCT) was a multicenter, randomized controlled trial comparing multiple daily injection therapy or continuous subcutaneous insulin infusion (intensive therapy) to therapy with one to two injections per day (conventional therapy) in 1,441 patients with type 1 diabetes, followed for a mean of 6.5 years (44). The intensive-therapy group, who achieved significantly lower HbA_{1c} levels than patients in the conventional-therapy groups, had a relative risk reduction of 76% for developing retinopathy and a 54% relative risk reduction for progression of retinopathy (44). The intensive-therapy groups had a 39% relative risk reduction for developing microalbuminuria and a 54% relative risk reduction for progressing to albuminuria (44). The intensive-therapy group also had a 64% relative risk reduction for developing neuropathy or experiencing progression of diagnosed neuropathy (46). Thus, intensive insulin therapy, which resulted in a lower HbA_{1c} level, was associated with a statistically and clinically significant reduction in microvascular complications in the intensive-therapy group. A follow-up study of the DCCT group, the Epidemiology of Diabetes Intervention and Complications (EDIC) study, showed that the risk reduction in microvascular complications from intensive therapy persists for at least 4 years despite increasing hyperglycemia (47). However, the benefit related to macrovascular complications is less clear (48). The DCCT showed a nonstatistically significant 41% relative risk reduction for macrovascular complications with intensive therapy; however, the study was not powered to detect a difference in macrovascular events, and the number of these events in the trial was low (49). There was also a relative risk reduction of 40% for developing elevated low-density lipoprotein (LDL) cholesterol levels in the intensive-therapy group (49). A recent meta-analysis of intensive therapy in type 1 diabetes showed that intensive therapy decreased the total number of macrovascular events but showed no significant effect on the number of patients affected or on mortality due to macrovascular disease (48). The need for insulin in type 1 diabetes for survival is apparent. However, the appropriate use of insulin with the goal of achieving near-normal serum glucose concentrations has benefits beyond those of mere survival and symptom relief.

The degree of glucose lowering to be sought depends on many factors and should be individualized for each patient. In the DCCT, the mean HbA1c level achieved by the intensive-therapy group was approximately 7.2% compared with a mean of 9.0% in the conventional-therapy group (44). Therefore, the most recent clinical practice recommendations from the American Diabetes Association state that the primary treatment goal in type 1 diabetes should be blood glucose control approximating the median value achieved in the intensive-therapy group (50). Table 39.3 outlines the glycemic goals from the American Diabetes Association. In fact, any improvement in blood glucose control will slow the development and progression of microvascular complications. However, one must consider the risks of hypoglycemia when aiming for a low HbA_{1c} level. The intensive-treatment group in the DCCT had a threefold greater risk of severe hypoglycemia compared with the conventionaltherapy group, but the rate of hypoglycemia decreased with time (44). Therefore, very tight control should not be attempted in patients unwilling or unable to participate actively in their glucose management. Patients with hypoglycemia unawareness or those susceptible to permanent injury from hypoglycemia, such as children or the elderly, can be managed with intensive therapy with multiple daily injections (MDI) or CSII but should have higher glycemic targets to avoid hypoglycemia (51-53). Appropriate diabetes education and self-monitoring of blood glucose are invaluable components of reducing hypoglycemia (51,53,54). Clinical judgment and common sense are required to determine the target premeal, postprandial, and

TABLE 39.3. Target Glycemic Control for Nonpregnant Adults with Diabetes

bedtime glucose levels for individual patients without placing them at undue risk for hypoglycemia (50,51,53,54).

Type 2 Diabetes

The initial treatment for type 2 diabetes generally does not include insulin. Diet, exercise, weight loss, and oral hypoglycemic agents are initially adequate therapies for achieving glycemic control. However, insulin is indicated for patients who are unable to achieve good glycemic control with a combination of oral agents, diet, and exercise (55). The goals of insulin therapy in type 2 diabetes are similar to those for type 1 diabetes. The elimination of clinical symptoms of hyperglycemia is an important goal. In addition, maintaining good glycemic control reduces the risk of microvascular and macrovascular complications. The United Kingdom Prospective Diabetes Study (UKPDS) was a multicenter, randomized, controlled study designed to establish whether intensive blood glucose control reduced the risk of macrovascular and microvascular complications in patients with type 2 diabetes (56) and to compare the relative effectiveness and safety of different pharmacologic approaches to therapy. The UKPDS studied 5,102 patients with type 2 diabetes and followed them for an average of 10 years (56). There was a 12% reduction in diabetes-related endpoints and a 25% risk reduction in microvascular endpoints for the intensive-therapy group (56). There was no significant difference within the intensive-therapy group (i.e., no difference between insulin and sulfonylureas). A smaller Japanese study also showed significant reductions in microvascular complications with improved HbA_{1c} levels (57). Although the original analysis of the UKPDS data showed a nonstatistically significant 16% risk reduction (p = 0.052) in macrovascular complications with intensive therapy (56), a recent analysis showed a significant relationship between macrovascular complications and hyperglycemia, as measured by the updated mean HbA_{1c} (58,59). For every 1% reduction in updated mean HbA_{1c}, there was a 14% risk reduction for myocardial infarction (p < 0.0001), a 12% risk reduction for stroke (p = 0.035), and a 43% risk reduction for amputation or death from peripheral vascular disease (p < 0.0001) (58)

In the UKPDS, the intensive-therapy group achieved a median HbA_{1c} value of 7.0%, compared with 7.9% in the conventional-therapy group (56). This suggests that the primary treatment goal for patients with type 2 diabetes should be similar to that for patients with type 1 diabetes. The target HbA_{1c} should also be as close to normal as possible without placing the patient at undue risk for severe hypoglycemia (60). There is a continuous relationship between the risks of microvascular complications and glycemia, such that for any decrease in HbA_{1c} , there is a corresponding reduction in the risk of complications (58,60).

Although the UKPDS provided suggestive data to support the claim that aggressive glycemic control reduces macrovascular complications, a landmark study from Denmark provided the best evidence, thus far, that aggressive glycemic control, in the context of a multifactorial approach, can reduce cardiovascular outcomes (60a). One hundred and sixty patients with type 2 diabetes and microalbuminuria were randomized to receive intensive multifactorial treatment or conventional diabetes care by their family physician or specialist. The target HbA_{1c} level in the intensive group was less than 6.5%. In addition to intensive glycemic control, blood pressure and cholesterol levels were aggressively treated. After a mean follow-up of 7.8 years, the intensively treated group experienced a 53% relative risk reduction (p = 0.007) in the composite primary outcome of cardiovascular death, myocardial infarction, stroke, revascularization, and amputation. Microvascular complications, including nephropathy, retinopathy, and autonomic neuropathy, were also significantly reduced. This study provided further support to the recommendation for aggressive glycemic control among patients with diabetes.

Aggressive therapy with insulin in patients with type 2 diabetes appears to be particularly indicated following myocardial infarction. The Diabetes Mellitus, Insulin Glucose Infusion in Acute Myocardial Infarction (DIGAMI) trial showed that intensive insulin therapy following an acute myocardial infarction decreases patient mortality (61,62). The use of an insulin–glucose infusion for at least 24 hours after an acute myocardial infarction followed by intensive insulin therapy reduced inhospital all-cause mortality by 58% (p < 0.05) and 1-year all-cause mortality by 52% (p < 0.02) (61). The benefit persisted for several years after the event (62). Of interest, the most profound effect was seen in patients with the lowest apparent risk at the time of presentation (61).

TREATMENT STRATEGIES

The appropriate insulin regimen for an individual patient should take into account the patient's lifestyle, age, motivation, general health, self-management skills, and goals of treatment (18,63). Prior to initiating insulin therapy, the patient should receive appropriate education and support regarding the care and use of insulin, the recognition and treatment of hypoglycemia, and the management of sick days (18,63).

Type 1 Diabetes

As prescribed by diabetologists and endocrinologists, the commonly used insulin protocols for individuals with type 1 diabetes are MDI and CSII. The DCCT clearly shows that intensive therapy with MDI or CSII coupled with the appropriate education and frequent self-monitoring of blood glucose (SMBG) achieves a significant lowering of HbA_{1c} levels and reduction in the risk of microvascular complications compared with that achieved with less frequent injections (44). Unfortunately, even in the intensively treated cohort of the DCCT, after the completion of the clinical trial, glycemic control deteriorated, pointing out the necessity of continuing education and close clinical surveillance (48). Therefore, MDI or CSII, along with appropriate education, counseling, and support, is the preferred therapy for patients with type 1 diabetes.

MULTIPLE DAILY INJECTIONS

It is best to think about insulin therapy according to the pharmacokinetics of the available insulin preparations and the physiologic secretion of insulin in individuals without diabetes. Thus, we tend to think of basal insulin administration for the overnight and postabsorptive states and bolus insulin administration for mealtimes as an attempt to reproduce acute β -cell insulin release. This mealtime-basal routine usually requires at least four injections per day. A rapid-acting mealtime insulin analogue (lispro or insulin aspart) is the preferred insulin before each meal. As described earlier, the rapid onset of action of lispro or insulin aspart produces less postprandial hypoglycemia and less nocturnal hypoglycemia compared with regular insulin, which makes them ideal for an MDI regimen. NPH, ultralente, or glargine can be used as the basal insulin, classically at bedtime; however, different regimens are being used (32,37,43). It is likely that glargine (and perhaps detemir) will become the basal insulin of choice for MDI therapy because of their pharmacokinetic properties.

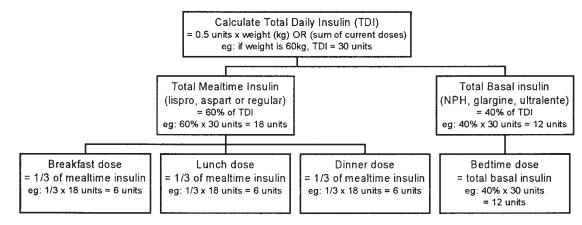

Figure 39. 2 Initiation of multiple daily injection insulin therapy (four injections per day). (From Cheng AY, Zinman B. Insulin for treating type 1 and type 2 diabetes. In: Gerstein HC, Haynes RB, eds. *Evidence-based diabetes care.* Hamilton, Ontario: BC Decker, 2001.)

Glargine, as the basal insulin in a MDI regimen, has been associated with improved fasting blood glucose levels and less hypoglycemia (36,37). The administration of a rapid-acting insulin analogue (lispro or insulin aspart) prior to each meal controls postprandial serum glucose concentrations, and the intermediate- or long-acting insulin controls fasting serum glucose concentrations. As shown in the DCCT, the risk of hypoglycemia is greater with MDI than with less frequent injections, primarily because of the tighter glycemic targets and improved control achieved (44). Therefore, patient education, self-monitoring, and a self-directed management approach are fundamental to achieving success with this therapy. Both clinician and patient have to be prepared to make adjustments to the regimen as necessary, including adjustment of glycemic targets to avoid severe hypoglycemia. Since lispro and insulin aspart are such rapidly acting insulins, a second injection of NPH or ultralente before breakfast may be required to provide basal insulin over the day and better control of predinner serum glucose concentrations. However, a controlled clinical trial (32) demonstrated that most patients (75%) required only one injection of intermediate-acting insulin. The actual doses of insulin used must be adjusted on an individual basis. However, the following is an empirical guide for choosing initial insulin doses for MDI (Fig. 39.2). The approximate total daily insulin (TDI) requirements for an individual not previously receiving insulin are 0.5 units/kg. If the patient is already receiving insulin, the TDI is the sum of all the current insulin doses. Approximately 60% should be rapid-acting mealtime insulin (lispro or insulin aspart) given before each meal. The breakfast meal usually requires a disproportionately higher dose of insulin than other meals for the calories consumed. The remaining 40% of the estimated TDI should be given as the basal insulin (NPH, ultralente, or glargine) at bedtime. Close self-monitoring of blood glucose and frequent adjustments are necessary to optimize glycemic control with the fewest episodes of hypoglycemia.

Many different MDI regimens, some outlined in Table 39.4, have been used by various individuals. However, all MDI regimens follow the same basic principles. Mealtime insulins (lispro, insulin aspart, or regular) are used in combinations with basal insulin (NPH, ultralente, or glargine) in an attempt to simulate physiologic insulin secretion.

TWICE-DAILY DOSING

Twice-daily (BID) injections are not recommended for patients with type 1 diabetes. Such a regimen provides neither optimal glycemic control nor sufficient flexibility for adjustments of insulin dose. It is important to note that NPH given before dinner increases the risk of hypoglycemia during the night; thus bedtime NPH insulin is more appropriate both to control fasting blood glucose levels and to reduce the risk of nocturnal hypoglycemia (11).

ADJUSTMENTS TO INSULIN FOR EXERCISE

Exercise is encouraged for patients with type 1 diabetes and should be prescribed on the basis of the patient's functional status and presence of complications. Patients receiving insulin may experience hypoglycemia during, immediately after, or many hours after exercise. This can be avoided by adjusting insulin therapy and nutritional intake to accommodate exercise. It is essential for the patient to collect self-monitored blood glucose data to determine his or her response to exercise. The glycemic level at the start of exercise, previously measured response to exercise, and intensity and duration of planned exercise need to be considered to make appropriate changes in insulin dose or to increase food intake as necessary (64).

Type 2 Diabetes

Insulin is indicated when adequate glycemic control cannot be achieved with diet, exercise, and multiple oral agents in patients with type 2 diabetes (55,65). Insulin can be used in conjunction with oral hypoglycemic agents or alone. Oral hypoglycemic agents include biguanides, sulfonylureas, α -glucosidase inhibitors, thiazolidinediones, and meglitinides. Studies have shown that regimens of insulin plus an oral agent are equivalent to or better than insulin-only regimens in some circumstances (55,66–70). In fact, adding metformin to insulin for

patients with poorly controlled type 2 diabetes lowers glucose and lipid levels more effectively than increasing the insulin dose alone (67). Different combinations of insulin and oral agents have been used to treat type 2 diabetes. A commonly used regimen is bedtime NPH insulin in combination with metformin with breakfast and dinner. This combination provides improved glycemic control, less hypoglycemia, and less weight gain compared with some other bedtime insulin regimens (55,66). Insulin glargine can be used in place of NPH insulin at bedtime in combination with oral agents (38). In fact, bedtime glargine causes less nocturnal hypoglycemia and provides better postdinner glucose control compared with bedtime NPH (38). Another commonly used combination regimen is BID dosing with intermediate-acting insulin given in the morning and at bedtime in combination with metformin. The thiazolidinediones also have been studied for patients with type 2 diabetes, and agents from this class of drugs are currently being used as monotherapy or in combination therapy (68–72). These drugs often are referred to as insulin sensitizers and act through the peroxisome proliferator-activated receptor- γ (PPAR γ), a nuclear receptor that regulates the expression of several genes involved in glucose and lipid metabolism (71,72). They stimulate adipogenesis, reduce plasma triglyceride and free fatty acid concentrations, and improve insulin sensitivity (71,72). In insulin-treated patients with type 2 diabetes, the addition of thiazolidinediones significantly improved glycemic control and allowed for a significant reduction of daily insulin requirements (68-70).

Insulin-only regimens can also be used in type 2 diabetes in a manner similar to that used for type 1 diabetes. It is important to note that insulin deficiency in type 2 diabetes is progressive, and the likelihood that a patient will require insulin continues to increase over time. BID dosing regimens can be used in type 2 diabetes. Frequently, premixed 70/30 insulin (consisting of 70% NPH insulin and 30% regular human insulin) is given in the morning and before dinner. This regimen is suboptimal because NPH insulin given before dinner can lead to hypoglycemia during the night. However, this regimen is simple and may be the best option for patients who have difficulty mixing insulin. Usually two thirds of the total daily insulin is administered in the morning and the remaining one third is given in the evening for BID dosing regimens. The premixed insulin analogues (Humalog Mix 75/25 or Novolog 70/30) can be used in the same fashion, but it is injected immediately before a meal, allowing a little more flexibility (41,42). This premixed insulin provides similar overall glycemic control with improved postprandial glucose control and less nocturnal hypoglycemia compared with BID dosing with 70/30 insulin (41,42). The role of insulin glargine for providing basal replacement with less nocturnal hypoglycemia has been established in type 2 diabetes (38).

COMMON DELIVERY SYSTEMS

Several insulin delivery systems are commonly used, and choices should be made on the basis of personal preferences and needs. Particular attention should be paid to individuals who have impaired vision, problems with manual dexterity, or difficulty mixing various formulations of insulin.

Syringe and Needle

The traditional insulin delivery system is the syringe and needle. This delivery system is flexible, allows dosages to be adjusted readily, and allows some of the insulin formulations to be mixed for fewer injections per day. The limitations to this delivery system are the requirement for good eyesight and finemotor skills to ensure that appropriate doses of insulin are drawn and administered. The vial, syringe, and needles need to be available whenever insulin administration might be required, and some individuals may find the apparatus cumbersome.

Pen Devices

Pen-cartridge devices are becoming more popular than the syringe-and-needle system. Replaceable insulin cartridges containing 150 to 300 units of regular, aspart, lispro, NPH, or premixed insulin are used in the pen devices. The dose is dialed into the device, and needles with a very fine gauge are used to minimize the discomfort of injection. This method of insulin administration is convenient, unobtrusive, easy to carry, and very useful for MDI regimens. However, insulins cannot be mixed, so two injections are necessary when both rapid-acting and intermediate-acting insulins are required unless premixed insulins are used (73).

Continuous Subcutaneous Insulin Infusion

External insulin infusion pumps first became available in the early 1980s and have evolved rapidly since then. Lispro or regular insulin is stored in a reservoir of the pump and is infused through a catheter into a transcutaneous catheter placed subcutaneously (73). A preprogrammed basal rate of insulin is delivered continuously. The patient can program the pump to provide more than one basal rate over a 24-hour period to best mimic the needs of the individual. There is complete flexibility in the timing of meals because the basal rate maintains glycemic control and boluses of insulin are delivered before the meal. The amount of mealtime insulin given can also be adjusted according to the preprandial blood value. As in all intensive treatment regimens, careful and frequent self-monitoring of blood glucose levels is essential. Adequate support must be provided for the patient with CSII. Although either lispro, aspart, or regular insulin can be used for CSII, there is evidence that lispro and aspart are superior to regular insulin in terms of glycemic control, postprandial blood glucose levels, and risk of hypoglycemia (24–26,31a). Therefore, lispro or aspart is the preferred insulin for CSII.

There are several advantages of the insulin pump over MDI. Patients are spared the burden of administering MDI. Also, the pump provides great flexibility with respect to meal timing and exercise programs. Insulin-pump therapy currently is the most physiologic way of replacing basal insulin, because rates of basal infusion can be changed to match different physiologic requirements.

CSII carries some patient risks and disadvantages that are not encountered with MDI. Since only short-acting insulins are used, any interruption of insulin delivery by pump malfunction, catheter blockage, or displacement of the subcutaneous catheter can result in a rapid deterioration in control and the development of ketoacidosis. However, the newer pumps with safety alarms indicating interrupted flow have dramatically decreased the incidence of this complication (73). Some studies have shown that interruption of CSII using lispro is associated with an earlier and greater metabolic deterioration than that with regular insulin (74,75). However, other studies have not shown a significant difference (76). The correction of any metabolic deterioration appears to be faster with lispro than with regular insulin (74–76). Special attention to self-care is essential to avoid subcutaneous infections. The subcutaneous catheter should be changed every 2 days. Some patients find the external pump cumbersome. Currently, the main barrier to CSII use is the substantial cost of equipment and supplies. CSII used by a well-trained patient can be an effective method of providing more physiologic insulin replacement.

PRACTICAL ASPECTS OF INSULIN USE

Storage

Insulin preparations are stable at room temperature. Insulin in use may be kept at room temperature for 30 days; however, there may be a slight loss in potency if the same vial is used for more than 30 days (77). If patients experience unexplained deterioration of their glycemic control, they should be instructed to inspect their insulin and possibly to change vials in an attempt to improve control. Vials of insulin not in use should be refrigerated. Extreme temperatures and excess agitation should be avoided. The insulin should be visually inspected before each use for changes such as clumping, frosting, precipitation, or a change in clarity or color.

Mixing Insulin

Many insulin regimens require a mixture of different insulin formulations administered at the same time. These insulin formulations either can be administered as two separate subcutaneous injections or can be mixed for a single injection. Commercially available premixed insulins may be appropriate for patients with type 2 diabetes if the insulin ratio matches the patient's insulin requirements. Pen devices do not allow for mixing insulins, so two injections are necessary. However, conventional insulin administration with syringe and needle does allow for mixing. NPH and regular insulin when mixed may be used immediately or stored for future use. Similarly, rapid-acting insulin analogues may be mixed with NPH or ultralente insulin and used without fear of significantly changing the pharmacokinetics of each component (77). Mixing regular insulin with lente or ultralente is not recommended except for patients whose glucose levels are already well controlled with such a mixture (77). The zinc present in the lente insulins can bind with the regular insulin, thereby delaying its onset of action in an unpredictable fashion (77). NPH insulin should not be mixed with lente insulins because zinc phosphate may precipitate. Insulin glargine cannot be mixed with other insulins because it is in solution at an acidic pH and will precipitate if mixed with pH-buffered insulin.

Insulin Injection Technique

The following description applies to the conventional syringeand-needle administration of insulin. The top of the insulin vial should be cleaned with an alcohol swab. If the insulin is in suspension, the vial should be gently rolled between the hands to ensure that the suspension is uniform before the syringe is loaded. Before the insulin is drawn into the syringe, an amount of air equal to the dose of insulin should be injected into the vial to avoid creating a vacuum. The proper amount of insulin is then drawn into the syringe, and the air bubbles are expelled. If two insulin types are to be mixed, air should be injected into both bottles and the clear rapid- or short-acting insulin should be drawn first. Insulin should be injected into the subcutaneous tissue. The skin should be gently pinched between the thumb and forefinger and injected at a perpendicular angle. The plunger should be pushed down, the skin released, and the needle then withdrawn. In thin people or children, the needle may need to be inserted at a 45-degree angle to avoid an intramuscular injection. Painful injections may be minimized by injecting the insulin at room temperature, making sure there are no air bubbles in the syringe before injection, keeping muscles in the injection area relaxed, penetrating skin quickly, and not reusing dull needles.

Insulin can be injected into sites with the most subcutaneous fat, which include the abdomen, anterior and lateral thigh, buttocks, and dorsal area of the arm. Within the abdomen, a circle with a 5.08-cm (2 in.) radius around the navel should be avoided. Injection into areas with little subcutaneous fat may result in intramuscular administration, which is painful and may result in faster insulin absorption (78). Insulin is absorbed more rapidly and consistently from the abdomen than from the arms, thighs, or buttocks (79) and from an extremity that is subsequently exercised, probably by increasing blood flow to the skin and perhaps by local muscle contraction (77). Massage of a local area that has been injected can increase the rate of insulin absorption, as can increased local skin temperature. Rotation of injection site is important to prevent lipohypertrophy or lipoatrophy (77). Rotation within one area is recommended as opposed to rotating to different areas within the body (77).

Blood Glucose Monitoring

All insulin-using patients should be encouraged to perform SMBG. With SMBG, patients can evaluate their goals of therapy and adjust their insulin regimens accordingly. A written or electronic record of the daily blood glucose levels is an invaluable tool for the physician and patient for guiding adjustment of the insulin regimen to accommodate fluctuations in insulin requirements. Many of the currently available glucose meters have memory, which simplifies record keeping. The frequency of monitoring depends on the insulin regimen used. The use of MDI of insulin requires multiple daily glucose monitoring, specifically before every meal and at bedtime. Specific situations, such as pregnancy and illness, may make more frequent monitoring necessary.

Implementation

One of the most critical components for successful implementation of any insulin regimen is education and support. This is especially true for implementing MDI or CSII therapy (44,50,51). All patients must be educated about the basics of insulin therapy, including all the previously discussed practical topics and about the complications and how to manage them. In addition, patients receiving MDI or CSII should learn how to self-manage their insulin therapy. They should learn about meal planning and carbohydrate counting, how to identify blood glucose patterns, potential hypoglycemic situations, and the principles of insulin dose adjustments and how to make appropriate adjustments for exercise, sick days, and travel. They should learn how to develop and adjust their own variable insulin dose scales (VIDS). These steps will empower patients and allow them to actively participate with their diabetes care team in their therapy. Education and support on a continuous basis not only improve overall glycemic control they also can decrease hypoglycemia and other adverse events (48, 50, 51, 80).

COMPLICATIONS OF INSULIN THERAPY

Hypoglycemia

Hypoglycemia is the most frequent and feared complication of insulin treatment, with potentially serious sequelae (52,81). Poor timing of meals, exercise, and insulin treatment can lead to hypoglycemia (82). Previous episodes of repeated severe hypoglycemia requiring assistance or hypoglycemic unawareness are risk factors for severe hypoglycemia (80,82). In the DCCT, the frequency of severe hypoglycemia was increased threefold in the intensive-therapy group (82). The risk of severe hypoglycemia was inversely related to HbA_{1c} levels (44,52,82). When severe hypoglycemia occurs, one should investigate the specific circumstances of that episode, potentially raise glycemic targets, and improve education to avoid future episodes (51,53,54,80). Also, a period of meticulous prevention of hypoglycemia may reverse some hypoglycemia unawareness (51). The rates of hypoglycemia in type 2 diabetes are much lower than those in type 1 diabetes (56,57,83). In the UKPDS, the frequency of major hypoglycemic episodes was 1.8% per year in the insulin-treated group (56). In the study by Okhubo et al. (57), no major hypoglycemic episodes occurred with insulinmediated intensive control over 7 years of follow-up. However, the same general principle applies in type 2 diabetes; namely, the risk of hypoglycemia is inversely related to the HbA_{1c} (84). Most patients experience symptoms when their plasma glucose levels decrease to 60 mg/dL (3.3 mmol/L). As plasma glucose levels decline further, more severe symptoms, specifically neurologic symptoms, appear (85). A complete discussion of hypoglycemia can be found in Chapter 40.

Weight Gain

Weight gain is another potential adverse effect of insulin use. In the DCCT, the incidence of becoming overweight during the median 6.5 years of follow-up was 41.5% in the intensive-therapy groups compared with only 26.9% in the conventional-therapy group (p < 0.001) (82). The risk of weight gain with insulin use in type 2 diabetes also has been well documented (56,57,82,86). In the UKPDS, the insulin group gained 4.0 kg (8.89 lb) more than the conventional-therapy group (p < 0.001) (56).

Several mechanisms have been proposed to explain the weight gain associated with insulin use. Improved glycemic control decreases glycosuria, thereby decreasing the loss of calories through the urine (87). The direct lipogenic effects of insulin on adipose tissue contribute to weight gain (87). Also, increasing insulin doses may cause recurrent mild hypoglycemia that only manifests itself as hunger. This may result in intake of excess calories. Therefore, diet therapy and weightloss programs in conjunction with appropriate glycemic targets are extremely important in the management of diabetes.

The result of weight gain in insulin-treated patients is further insulin resistance, leading to the need for more insulin and a potentially greater weight gain. Obesity is associated with decreased responsiveness to insulin in muscle, liver, and fat (88) (discussed in detail in Chapter 31).

Lipoatrophy/Lipohypertrophy

Injection of less-purified insulin into subcutaneous fat can sometimes lead to localized loss of the fat. With the current more-purified insulins, this problem is uncommon. If insulin is injected into the area surrounding the affected sites, the subcutaneous fat will be restored over several months to years.

The opposite of lipoatrophy, lipohypertrophy, may occur at sites of insulin injection. Localized areas of increased swelling of subcutaneous fat can develop with repeated injection. The sensitivity to pain may decrease in these areas, and masses of fibrous tissue may develop. Insulin absorption from sites of lipohypertrophy may be erratic and unreliable. Rotating injection sites can prevent the development of lipohypertrophy. The excess tissue will regress gradually with time.

Atherosclerosis

For a number of years, there has been a concern that insulin promotes and accelerates atherosclerosis. Some studies have shown an association between high insulin levels and macrovascular disease (89–95). Others have shown that hyperinsulinemia is not an independent risk factor for macrovascular disease (96-100). It has been suggested that hyperinsulinemia merely reflects insulin resistance, which is closely associated with other risk factors for macrovascular disease (91,92,96–100). Therefore, insulin probably does not directly promote atherosclerosis. There is clearly no evidence that exogenous insulin use is associated with macrovascular disease, and its appropriate administration should not be discouraged (60). The UKPDS showed no increase in cardiovascular events or death in either the insulin or sulfonylurea group than in the conventionally treated patients, despite higher plasma insulin levels (56). As a consequence, one can safely conclude that exogenous insulin is not a risk factor for atherosclerosis.

Alternative Routes of Insulin Delivery

The benefits of achieving tight glycemic control are well established, and the insulin analogues play an important role in meeting appropriate bolus and basal insulin requirements. However, for this goal to be achieved, MDI of insulin or CSII are required. Despite the widespread use of insulin pen devices that are less painful and use smaller gauge needles, injectionrelated anxiety remains a common problem (101). Since the 1920s, there have been many attempts to find alternative routes of insulin delivery, including oral, rectal, transdermal, nasal, and pulmonary routes.

Attempts to develop an effective oral insulin began in 1923 (102). To date, these attempts have been largely unsuccessful because of the extensive enzymatic and chemical degradation that occurs in the gastrointestinal tract (103). Researchers have tried enclosing insulin within microspheres and concurrent administration of proteolytic enzyme inhibitors, with minimal success (104). Rectal insulin has been investigated but its variable poor bioavailability and lack of patient acceptance make this route of delivery impractical (105).

Transdermal delivery of insulin is an attractive option given the easy accessibility of skin; however, success has been limited because of the relative impermeability of the skin. Methods used to try to improve the permeability of skin include iontophoresis, low-frequency ultrasound, coupling with transferomes, and the application of photomechanical waves (103,106,107). The initial observations in animals and humans have been encouraging; however, further clinical studies are required.

Intranasal administration of aerosolized insulin seemed like another attractive option. However, the disadvantages are that the surface area of the nasal mucosa is relatively small, at approximately 150 cm², and absorption must occur quickly or the drug will be removed to the back of the nasopharynx by the mucociliary clearance mechanisms and swallowed (108). Clinical studies demonstrate poor bioavailability and a rapid but short-lived hypoglycemic effect (108). Large doses are required, despite the addition of enhancers, and patients experience irritation to the nose and nasal congestion (108). For these reasons, intranasal administration does not appear to be a viable route for delivering aerosolized insulin.

Beginning as early as 1925, investigators have tried to develop an effective means of intrapulmonary delivery of insulin (108). The surface area of the alveolar region of the lung is very large (75 to 100 m²) and is highly permeable (0.1 μ m) (103,108). It is well vascularized and has minimal mucociliary clearance. All these features favor the lung as an effective and efficient means of delivering insulin. However, effective delivery of aerosolized insulin to the alveolar region of the lung requires appropriate aerosol particle size, aerosol velocity, and inspiratory flow rate (103). Current delivery systems include dry-powder inhalation systems and aqueous insulin aerosol devices.

The dry-powder insulin inhalation system uses a holding chamber to capture the insulin cloud and allow for slow deep inhalations. Comparison with subcutaneous regular human insulin demonstrated faster onset of action and time to peak effect. The duration of action was between that of lispro and regular insulin (109,110). An open-label, proof-of-concept study in 73 patients with type 1 diabetes, comparing preprandial inhaled insulin plus bedtime subcutaneous ultralente insulin and usual MDI of subcutaneous insulin, demonstrated no difference in HbA_{1c}, fasting or postprandial blood glucose levels, and frequency or severity of hypoglycemia after 3 months (111). An open-label, noncontrolled study of 26 patients with type 2 diabetes using preprandial inhaled insulin plus bedtime ultralente insulin demonstrated decreased HbA_{1c} after 3 months (112). Inhaled insulin was well tolerated in both studies, and there was no change in pulmonary function.

The aqueous insulin aerosol device is breath-activated and releases insulin when inspiratory flow rate and volume are optimal. A clear dose–response curve and a rapid onset of action as compared with that of subcutaneous regular human insulin have also been demonstrated (113,114). Both insulin formulations have relatively poor bioavailability as compared with that of subcutaneous insulin. Enhancers have been incorporated to try to improve bioavailability, and early results have been promising (115).

Improved aerosol and delivery technology, ease of use, and patient satisfaction make intrapulmonary insulin the most promising alternative route of insulin delivery at this time. Adequate patient education to ensure proper technique is critical to the success of inhaled insulin. It is important to note that clinical studies to date have been performed in patients with normal pulmonary function tests. Data are unavailable for patients with abnormal pulmonary function. In addition, smokers are known to have more rapid absorption of intrapulmonary substances, and this may affect its clinical use in this population (108). There is also concern about the potential of high concentrations of insulin in the lungs to cause pulmonary vascular disease or other effects (116). No major adverse effects have been demonstrated to date, but long-term safety and efficacy studies are required before inhaled insulin delivery systems can be routinely incorporated into clinical practice.

CONCLUSIONS

The discovery of insulin by Banting, Best, Collip, and MacLeod in 1921 represents one of the greatest medical discoveries of modern medicine. Insulin and insulin analogues remain a fundamental component of diabetes management. Insulins are now available in a wide range of time–action profiles, and a number of different delivery systems are available. MDI or CSII is considered the standard of care for type 1 diabetes. For type 2 diabetes, a number of different insulins plus an oral agent or insulin-only options may be used. Regardless of the regimen chosen, proper education and support are critical and the goal should always be to achieve the best glycemic control with the fewest adverse events. When used properly, insulin therapy effectively reduces morbidity and mortality in patents with diabetes. The challenge for the future is to continue to improve insulin replacement and to achieve the elusive goal of physiologic replacement of insulin.

Cumulative Damage from Recurrent Severe Hypoglycemia 683

SUDDEN DEATH AND HYPOGLYCEMIA 684

No definition of good glycemic control in diabetes is complete unless it includes a statement about absence of hypoglycemia. Patients with diabetes and their families are well aware of this, and healthcare professionals responsible for patients with diabetes need to be equally well informed.

Hypoglycemia-literally, a low blood glucose concentration-is rarely encountered in healthy individuals. Glucose is normally the major metabolic fuel for the brain. Because the brain stores only trivial amounts of glucose as glycogen, the brain is dependent for normal function on an adequate supply of glucose from its circulation. Both the entry of glucose into the circulation and its removal therefrom vary widely with fasting and feeding and with rest and exertion. Elaborate and sensitive mechanisms exist to maintain glucose concentrations in the plasma within narrow limits-too high a concentration upsets the water balance in tissues, causes glycosuria, and accelerates tissue glycosylation, whereas too low a concentration results in cerebral dysfunction and ultimately coma and death. In health, hypoglycemia sufficient to cause clinically significant cognitive dysfunction does not occur because of the efficiency of the endogenous mechanisms of glucose homeostasis. Once these

mechanisms are upset by diabetes *and its treatment*, clinically problematic hypoglycemia can occur.

Hypoglycemia can be defined in biochemical terms as a plasma glucose concentration below the normal range. It should be noted that glucose concentrations in plasma are approximately 10% higher than those in whole blood because red cells contain relatively low concentrations of glucose; arterial glucose levels are higher than venous levels, and capillary levels are between the arterial and venous levels. Research studies of hypoglycemia in human subjects often use arterialized venous glucose concentrations because they approximate those of the arterial system (and therefore the glucose supply to a tissue) and make arterial sampling unnecessary (1).

Fasting plasma glucose concentrations are considered normal if they are less than 6 mmol/L, although levels higher than 5.5 mmol/L are rarely seen in healthy individuals (2). The lower limit of normality is more equivocal. Healthy people rarely have a plasma glucose concentration lower than 4 mmol/L after an overnight fast, but levels of 2.8 mmol/L have been recorded in healthy people after prolonged fasting (3). Spontaneous, pathologic hypoglycemia, such as may occur in the presence of

TABLE 40.1. A Modification of Whipple's Triad for Diagnosis of Hypoglycemia in Diabetes Therapy

Presence of symptoms and/or signs compatible with a low plasma glucose concentration

Demonstrably low plasma glucose concentration (<3.5 mmol/L) Rapid resolution with restoration of plasma glucose concentration

insulin- or insulin-like growth factor (IGF)–secreting tumors, requires for diagnosis the demonstration of plasma glucose levels of less than 2.8 mmol/L or even, according to some authorities, levels less than 2.2 mmol/L in women (4). However, detailed physiologic studies show a detectable impairment of higher cerebral function at plasma glucose levels of 3 mmol/L (arterialized venous plasma) (5), and there is evidence that recurrent plasma glucose levels of 3 mmol/L damage the endogenous protective mechanisms against more severe hypoglycemia (6). Nonpancreatic counterregulatory responses to hypoglycemia start at 3.5 to 3.6 mmol/L (see below). Thus, *in the context of the treatment of diabetes mellitus*, hypoglycemia is defined as a plasma glucose concentration of 3.5 mmol/L or less.

In diabetes, hypoglycemia is also often defined by its clinical presentation. Acute hypoglycemia is symptomatic, and Whipple's triad, although defined by a surgeon interested in insulinomas, remains a useful guide for defining episodes. The triad requires (a) symptoms attributable to a low plasma glucose concentration, (b) a measurably low plasma glucose concentration (less than 3.5 mmol/L in diabetes), and (c) rapid resolution of the symptoms after correction of the biochemical abnormality (7). However, as will be described later, patients with diabetes (and indeed those with insulinomas) can lose their ability to generate and detect the symptoms of early hypoglycemia (see Hypoglycemia Unawareness), and Whipple's original triad is best modified by the inclusion of the term "and signs" in the first criterion (Table 40.1).

Perhaps the most important clinical definition of acute hypoglycemia in diabetes therapy is the division into mild and severe. Many authorities also recognize an intermediate category of moderate. Mild hypoglycemia is defined as that which is recognized and treated by the patient, and severe hypoglycemia is defined as that which the patient is unable to self-treat because of cognitive impairment. Some authorities restrict the term "severe hypoglycemia" to episodes requiring parenteral therapy (intramuscular glucagon or intravenous glucose) and/or those resulting in coma or seizure. The classification "moderate hypoglycemia" usually refers to episodes that the patient could selftreat but resulted in significant life disruption. The lack of clarity in this definition has led to its disuse. The terms "mild" and "severe" hypoglycemia are not appropriately applied to degrees of *biochemical* hypoglycemia (Table 40.2).

TABLE 40.2. Clinical Classification of Acute Hypoglycemia

Mild Moderate	Symptomatic, self-treated, no major lifestyle disruption Symptomatic, self-treated, but with significant lifestyle disruption
Severe	Often (but not always) asymptomatic, but patient unable to self-treat because of cognitive impairment1. Third-party help but not parenteral therapy2. Parenteral therapy required (intramuscular glucagon or intravenous glucose)3. Associated with coma or seizure

Commonly, the qualification concerning lifestyle disruption is omitted, leaving only "mild" and "severe" categories.

FREQUENCY OF HYPOGLYCEMIA

Formal studies of the frequency of hypoglycemic events must be compared carefully because of differences in definitions. This difficulty not withstanding, it is important to document the frequencies of hypoglycemic episodes in order to compare the effects of different therapeutic regimens and to determine clinical characteristics that put patients at risk.

Mild hypoglycemia, although often unpleasant, tends to be accepted as an inevitable consequence of glucose-lowering therapies. However, mild hypoglycemia should not be ignored, as it has the potential to increase the risk of severe episodes. In the Diabetes Control and Complications Trial (DCCT), which was conducted in patients with type 1 diabetes, the rate of severe hypoglycemia increased from approximately 20 episodes per 100 patient-years during conventional therapy to 60 per patientyear during intensified therapy (8). In contrast, the Dusseldorf group, using internally consistent definitions but different from those used in the DCCT, reported a decline in rates of severe hypoglycemia with intensified therapy from rates of 28 to 17 episodes per 100 patient-years (9).

COUNTERREGULATION: THE DAMAGED DEFENSES AGAINST SEVERE HYPOGLYCEMIA IN DIABETES

As the plasma glucose concentration begins to decrease, an orchestrated neurohumoral response acts to prevent hypoglycemia. The first component of this counterregulation is local to the pancreatic islets, with cessation of insulin secretion and stimulation of glucagon release by the pancreas. These responses promote hepatic production of glucose, which, in health, represents the most important mechanism for preventing hypoglycemia between meals. In people with diabetes, the insulin levels do not decrease as glucose levels fall, either because of persistent absorption of exogenous insulin or because of non–glucose-dependent elevation of insulin secretion by sulfonylureas. The lack of decline in plasma insulin concentration as glucose levels decrease then results in iatrogenic hypoglycemia.

In addition to their inability to modulate insulin levels as the plasma level of glucose decreases, patients with type 1 diabetes lose the ability to enhance glucagon production by pancreatic α -cells in response to hypoglycemia. Basal glucagon production and glucagon responses to other secretagogues are maintained, but the response to hypoglycemia is abrogated. This happens within 5 years of the onset of type 1 diabetes (10) and may be secondary to decreased β -cell activity. Glucagon responses are also lost late in the evolution of type 2 diabetes, and the glucagon response to hypoglycemia is reduced under experimental conditions in which β -cell activity is maintained by sulfonylureas (11,12).

In experimental studies, counterregulation (the spontaneous correction of a decreasing plasma glucose level) occurs even if the insulin and glucagon responses are inhibited (13), a consequence of secondary defense mechanisms involving the autonomic nervous system and adrenal medulla. Released epinephrine and norepinephrine stimulate endogenous glucose production and also inhibit glucose consumption by peripheral tissues. These actions occur through elevation of substrates for gluconeogenesis, including nonesterified fatty acids, which also inhibit peripheral glucose oxidation (14). Glucose is generated initially by hepatic glycogenolysis and subsequently by hepatic (and renal) gluconeogenesis (15,16). The activation of the sym-

A significant and probably growing number of patients with type 1 diabetes develop defects in the adrenal and autonomic responses to hypoglycemia. These occur independently of classical autonomic neuropathy, to which they are not mechanistically related (19) and represent an important risk factor for susceptibility to severe hypoglycemia. The defects are associated with a failure to generate the typical symptoms of autonomic activation. Affected patients, described as having *hypoglycemia unawareness*, are at greatly increased risk for severe hypoglycemia (20,21).

Growth hormone and cortisol are additional hormones with important roles in glucose homeostasis, and their absence can be associated with clinical hypoglycemia. Their roles in the response to acute hypoglycemia are less clear, and they certainly cannot compensate for defects in epinephrine secretion and autonomic responsiveness.

SYMPTOMS OF ACUTE HYPOGLYCEMIA

Early experts in diabetes, America's Elliot P. Joslin and Britain's R. D. Lawrence (22,23), divided the symptoms of acute hypoglycemia on physiologic principles into autonomic (attributable to activation of the autonomic nervous system and adrenal medulla) and neuroglycopenic categories (related to impaired glucose supply to the cerebral cortex). More recently, complex statistical packages have been used to group the symptoms reported by patients (or symptoms and signs reported by parents of children with diabetes) into related "families," with very similar results (Tables 40.3 and 40.4) (24,25). Clinically, the specific symptoms experienced are not important as long as the patient becomes aware of them at a glucose level when cognitive function is adequate to enable an effective response (i.e., ingestion of some rapidly absorbed carbohydrate). Many patients with type 1 diabetes report a greater dependence on neuroglycopenic symptoms than on autonomic symptoms over time.

The etiology of hunger, which represents a frequent symptom of hypoglycemia and most directly encourages resuscitative food intake, has not been clearly delineated. The satiety

centers lateral to the hypothalamus may be involved. Leptin does not respond acutely in hypoglycemia, and the role of orexin is uncertain (26,27).

INVESTIGATION OF RESPONSES TO ACUTE HYPOGLYCEMIA

The categorization of the symptoms of acute hypoglycemia discussed above was based on data collected from the description of symptoms and signs by patients and their family members. More detailed studies on the relationships between symptoms of acute hypoglycemia and the effect of diabetes and its therapy often have involved experimentally induced hypoglycemia. Insulin injection (i.e., the insulin tolerance test) is a high-risk procedure that results in an uncontrolled, rapid, variable, and often profound hypoglycemic challenge that will miss all but the most extreme variations in the counterregulatory response. A slow decline in plasma glucose level induced by a low-dose infusion can be useful for examining an individual's overall counterregulatory capacity (i.e., the ability to arrest or reverse a drop in glucose level) (28). However, the comparison of responses between individuals or groups of individuals may be complicated by the failure to achieve equal levels of hypoglycemia. As an alternative, controlled hypoglycemia can be induced with a modification of the euglycemic insulin clamp technique (29). In the slow-fall clamp, plasma glucose is controlled during a high-dose insulin infusion by means of an adjustable intravenous glucose infusion (Fig. 40.1). For patients with diabetes, plasma glucose often is regulated during the night preceding the study by an intravenous insulin infusion. This ensures that all subjects in a given study, with or without diabetes, are exposed to the same hypoglycemic challenge (i.e., similar initial glucose level, final glucose level, and rate of decline) (29). In some experimental protocols, the plasma glucose concentration is lowered in a series of steps, so that the glucose level associated with the onset of any one response can be determined for that individual or group of individuals. This technique first was used to determine the effect of the rate of glucose decline on the magnitude of the counterregulatory responses to a given moderate hypoglycemic challenge (29) and later to investigate the effects of intensified diabetes treatment on counterregulatory hormone responses (30). It is important to realize that the clamp technique does not exam-

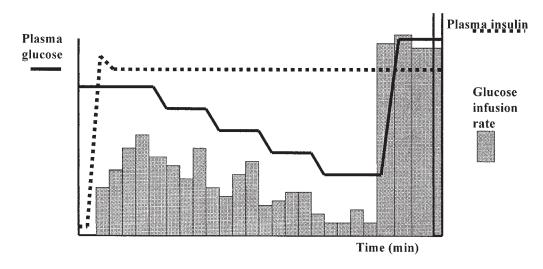

Figure 40.1. The stepped hypoglycemic clamp: a means of applying a controlled reproducible hypoglycemic challenge. A primed-continuous intravenous insulin infusion is started at time = 0 minutes, creating a predictable rapid square wave rise in circulating insulin levels (*black dotted line*). The subsequent hypoglycemia is controlled by a variable-rate glucose infusion (*bars*) adjusted according to the plasma glucose measurement made at the bedside every 5 minutes. (From Amiel SA, Simonson DC, Tamborlane WV, et al. Rate of glucose fall does not affect counterregulatory hormone responses to hypoglycemia in normal and diabetic humans. *Diabetes* 1987;36:518–522.)

ine counterregulation per se, because the glucose level is always under the control of the investigator.

Such studies show that acute hypoglycemia results in a hierarchy of responses. In healthy volunteers, epinephrine secretion begins at arterialized plasma glucose levels of 3.0 to 3.4 mmol/L, adrenergic symptoms at 3.2 mmol/L, and minor but detectable cognitive impairment (first shown as a slowing of complex reaction times) at 3.0 mmol/L (Fig. 40.2) (5,29–33). More extensive cognitive impairment has been shown at lower glucose levels (32). The hormonal and symptomatic responses occur at higher glucose levels in patients with poorly controlled diabetes (31,34). The initiation of hormonal responses, and especially of symptoms, before the onset of significant cognitive impairment during a progressive glucose decline is critical to a patient's ability to prevent severe hypoglycemia, giving a window of opportunity for recognition of the situation and for selftreatment (35).

The delineation of cognitive impairment during acute hypoglycemia is less clear. The brain is not a homogeneous organ, and specific brain functions use various brain regions that have different susceptibilities to hypoglycemia. The detection of hypoglycemia by glucose-sensing neurons and the initiation of the autonomic responses normally occur at or before the onset of cognitive changes (typically at arterialized plasma glucose levels of 3.4 mmol/L). For example, the slowing of choice reaction time occurs at glucose levels of 3 mmol/L, and the slowing of a simple motor activity such as finger tapping occurs at 2.4 mmol/L (Fig. 40.3).

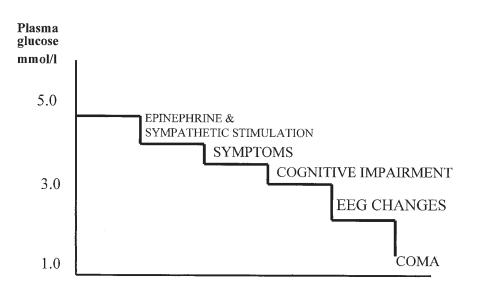

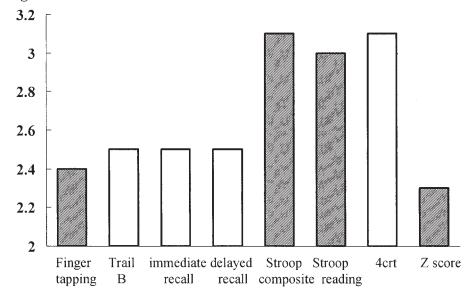

Figure 40.2. Normal hierarchy of responses to acute hypoglycemia. As plasma glucose level falls, the autonomic and symptomatic responses precede the onset of even mild cognitive impairment.

Plasma glucose level (threshold) for deterioration in cognitive function mmol/L

Figure 40.3. Glucose thresholds for onset of cognitive impairment in healthy volunteers. The data are acquired from clamp studies in which the rate of glucose decline is precisely controlled. It is important to note that different cognitive functions have different susceptibilities to hypoglycemia. Data for the two memory tests (immediate and delayed recall) and the composite Stroop score are from Cryer PE, Scott A, Segal MD, et al. Blood brain glucose transport is not increased following hypoglycemia. *Diabetes* 2000;39[Suppl 1]; the *z* scores are from Fanelli CG, Epifano L, Rambotti AM, et al. Meticulous prevention of hypoglycemia normalizes the glycemic thresholds and magnitude of most of neuroendocrine responses to, symptoms of, and cognitive function during hypoglycemia in intensively treated patients with short-term IDDM. *Diabetes* 1993;42:1683–1689; and the finger tapping, trail B, Stroop reading, and 4-choice reaction time (4crt) are from Hopkins DFC, Evans M, Lomas J, et al. Effects of antecedent control on cognitive function and symptoms during hypoglycemia in type 1 diabetes. *Diabet Med* 1998;15[Suppl]:S4. The shaded bars represent cognitive functions that have been shown to manifest a degree of resistance to hypoglycemia in patients with hypoglycemia unawareness.

HYPOGLYCEMIA UNAWARENESS

The best defense a patient with diabetes has against severe hypoglycemia is subjective awareness of an early fall in plasma glucose concentrations and the immediate ingestion of a rapidly available carbohydrate. Loss of the ability to generate and/or perceive such symptoms-the syndrome of hypoglycemia unawareness-is a serious clinical problem, increasing the risk of severe hypoglycemia by about 10-fold (20,21). Such unawareness places the patient in danger, as he or she may experience blood glucose levels low enough to impair basic cognitive processes such as reaction times (5), making common tasks such as driving or operating heavy machinery potentially lethal. Less dramatic, but equally devastating, is the sudden inability to sustain logical thought or the sudden onset of uncharacteristic aggression, which can have serious professional and social consequences for the individual. Because, by definition, a patient with hypoglycemia unawareness cannot recognize his or her state, a full assessment of a patient's experience of hypoglycemia can be completed only by interviewing the people close to the patient in everyday life: the partner, other family members, or close friends (36).

An impaired ability to decrease insulin levels in response to hypoglycemia is integral to treatment with insulin or a sulfonylurea. Failure of the glucagon response in type 1 diabetes (and late insulin-deficient type 2) is apparently universal, and early studies also showed a marked diminution of the epinephrine response to hypoglycemia in patients with long-standing (10 years or more) type 1 diabetes (10). However, most patients with long-standing type 1 diabetes do retain an ability to recognize early hypoglycemia and defend against severe episodes, at least most of the time. Loss of awareness of hypoglycemia is certainly more common in long-duration type 1 diabetes than in diabetes of shorter duration (it has not been well described in type 2 diabetes), with 25% of patients in one general diabetes clinic with a duration of diabetes of more than 15 years reporting this problem. Such patients are at much higher risk of severe hypoglycemia (20,21). Similarly, more than a decade ago, patients with a history of recurrent severe hypoglycemia were found to have defective counterregulation, with impaired hormonal responses and an inability to arrest a glucose fall during low dose insulin infusion independent of diabetic neuropathy (19).

Interest in the problems of hypoglycemia awareness increased with the recognition that both asymptomatic (37) and severe symptomatic (8) hypoglycemia were more common in patients with type 1 diabetes randomized to receive intensified insulin therapy in the large trials of prevention of chronic complications (38). Investigation showed that patients receiving intensified therapy were less able than those receiving standard therapy to produce a counterregulatory response in the face of insulin infusion (as were previously studied patients with recurrent hypoglycemia) (39). The defect was found to be a lowering of the plasma glucose level needed to initiate the adrenergic and symptomatic responses (30), closing, if not obliterating, the gap between the onset of symptomatic protective responses and of cognitive impairment (Figs. 40.3 and 40.4).

There is little doubt that the detection of hypoglycemia and the initiation of the autonomic and adrenergic responses are centrally mediated. Animal studies show that maintenance of glucose supplies in a brain region around the ventromedial hypothalamus during systemic hypoglycemia prevents the counterregulatory response (40) and, conversely, that localized intracellular glucose deprivation (by deoxyglucose) in that brain region alone can induce a peripheral hyperglycemic "counterregulatory" hormonal response in euglycemic animals (41). Neurons from these and related brain areas can be excited by changes in glucose supply (42). In an experiment of nature, a patient with a sarcoid lesion in the same region showed abnormalities of glucose homeostasis and counterregulation until his lesion regressed with therapy (43). Glucose-sensing neurons also are present in the hepatic portal tract, as shown by animal experiments in which portal perfusion with glucose ameliorates the autonomic and adrenergic responses to systemic hypoglycemia (44,45), but their role in maintaining glucose supplies to the brain glucose is unclear. One hypothesis is that these neurons monitor glucose input from the gastrointestinal tract and may be able to moderate a centrally mediated counterregulatory response to systemic hypoglycemia once eating starts (46).

There is good circumstantial evidence that the trigger for autonomic and adrenergic counterregulation is a slowing of metabolic rate in the glucose-sensing neurons. Supplying the nonglucose substrates lactate or 3-hydroxybutyrate to support metabolism during experimentally induced hypoglycemia delays (i.e., shifts to lower glucose levels) the onset and magnitude of the epinephrine response, adrenergic symptoms, and cognitive impairment of acute hypoglycemia in volunteers (47–49). One popular current theory to explain the change in hypoglycemia sensitivity of the glucose-sensing mechanism is that an upregulation of glucose transporters and of glucose uptake by the brain occurs as a result of prior exposure to hypoglycemia (50–52). A study in patients with diabetes and healthy volunteers that calculated glucose consumption by the brain from measurements of cerebral blood flow and arteriovenous differences in glucose concentrations across the brain showed no effect of hypoglycemia in diabetic patients with a history of hypoglycemia unawareness, whereas hypoglycemia was associated with a decline in glucose uptake by the brain in symptomatic diabetic and nondiabetic subjects (53). A similar apparent adaptation in the handling of glucose by the brain also was induced in healthy volunteers by exposure to 56 hours of induced moderate hypoglycemia (54). The concept that the human brain can adapt to antecedent hypoglycemia by upregulating its ability to extract glucose and thus fails to trigger counterregulation because metabolism in the cerebral glucose sensor is better maintained is an attractive one. However, recent data obtained with positron emission tomography, measuring uptake in the brain of glucose labeled with a positron emitter, have been unable to confirm the data from the studies of arteriovenous difference (55,56). The discrepancies remain to be explained. One possibility is that adaptational changes are regional-all the described studies have measured only global glucose uptake by the brain. Regional differences in sensitivity to hypoglycemia itself have already been mentioned, and regional differences within the metabolic capacity of the brain and even of just the cerebral cortex have been suggested by further studies of nonglucose metabolic substrates in acute hypoglycemia (57).

The altered sensitivity of the brain's hypoglycemia sensing mechanisms in the hypoglycemia unawareness syndrome is well documented. There is debate about the extent to which this effect occurs in the cerebral cortex. The discrepancies in the literature are almost certainly due to differences in the cognitive function tests used to assess cortical function during acute hypoglycemia-some of which adapt (i.e., do not show evidence of deterioration until a more profound hypoglycemia has been reached) and some of which do not. It is clear that, in people with counterregulatory failure and hypoglycemia unawareness, the glucose level required to initiate the symptomatic counterregulatory responses is reduced below normal to a greater extent than any change in glucose level associated with detectable cognitive malfunction, narrowing or even closing the window of opportunity between subjective awareness and confusion.

It is not known how antecedent hypoglycemia alters the response to subsequent episodes. As explained above, in connection with the mechanisms of hypoglycemia unawareness, a possible mechanism is upregulation of glucose transporters in

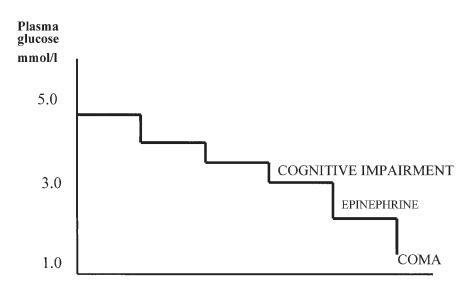

Figure 40.4. Disturbed hierarchy of responses to acute hypoglycemia after a preceding period of hypoglycemia. Counterregulatory failure is manifest as a lowering of the glucose level that induces an adrenergic counterregulatory response toward, or even below, that associated with the onset of cognitive impairment.

response to the initial hypoglycemic episodes; another is hypoglycemia-associated apoptosis of glucose-sensing cells (58). A suggested factor may be the adrenocorticotropic hormone or cortisol response to the initial insult (59,60), although how this might be involved in long-term hypoglycemia unawareness is unclear.

Whatever the mechanism, the link between the defective counterregulatory responses of hypoglycemia unawareness and hypoglycemia itself is strong. A series of research studies have demonstrated induction of counterregulatory failure and diminished symptomatic responses to experimentally induced hypoglycemia in both healthy volunteers and diabetic patients as a consequence of exposure to hypoglycemia during the day or night before the test stimulus (61-65). Such transient defects in the neuroendocrine response to hypoglycemia are very similar to those first demonstrated in intensively controlled diabetic patients with hypoglycemia unawareness: a lowering of the glucose level required to initiate the symptomatic and hormonal responses (particularly the epinephrine response) and a diminution of the hormonal response at any given glucose level. The relevance to the clinical syndrome of hypoglycemia unawareness in diabetic patients is confirmed by the demonstration that both the unawareness and the neurohumoral failure are either partially (66) or completely (67) reversible by scrupulous avoidance of hypoglycemia in daily living. It is important to note that the induction of temporary counterregulatory failure in experimental studies can be generated by modest prior decreases in plasma glucose concentrations (Table 40.5) and that reversibility in patients with diabetes can be achieved by successful avoidance of blood glucose concentrations lower than 3 mmol/L on home monitoring. This illustrates the danger of using definitions of hypoglycemia coined for the diagnosis of pathologic spontaneous hypoglycemia in the context of diabetes therapies.

It is important not to assume that counterregulatory defects induced by exposure to hypoglycemia itself are restricted to intensified insulin therapy regimens and tight glycemic control. The study by Cranston et al. (67) included six patients with

poorly controlled diabetes receiving conventional therapy who, despite high levels of glycosylated hemoglobin and generally high plasma glucose concentrations, nevertheless experienced intermittent severe hypoglycemia with no warning. These patients also recovered symptomatic neurohumoral responses to induced hypoglycemia after a period of hypoglycemia avoidance, suggesting that the etiology of their counterregulatory failure was the same as that in patients receiving intensive therapy.

The failure to generate an adequate neurohumoral response to induced hypoglycemia in diabetic patients with hypoglycemia unawareness is probably enhanced by a diminished sensitivity to adrenergic stimulation. Reduced cardiovascular responses to infused β -agonists have been demonstrated in patients with diabetes prone to recurrent episodes of severe hypoglycemia (68,69), and perhaps loss of both epinephrine secretion and its effects are required to create the full syndrome of hypoglycemia unawareness and high risk of severe hypoglycemia. The reduced sensitivity to adrenergic stimulation may be reversible; one study that attempted to correct counterregulatory failure by hypoglycemia avoidance demonstrated restoration of adrenergic symptoms but not of epinephrine responses to induced hypoglycemia (70).

Variation in adrenergic sensitivity also may explain differences in the susceptibility of patients with classical diabetic autonomic neuropathy to hypoglycemia unawareness. These patients have diminished counterregulatory hormone responses to hypoglycemia (71) and increased risk of severe hypoglycemia (72), but there is no direct link between clinical autonomic neuropathy and counterregulatory failure (19). Patients with autonomic neuropathy may be more sensitive to any adrenergic stimulation that they can achieve (73). The failure of subjective awareness of hypoglycemia in these patients can also be partially restored by avoidance of hypoglycemia (74), which does not correct the neuropathy itself.

Recent data suggest genotypic variation may contribute to the risk of severe hypoglycemia. In particular, variants of the ACE gene have been demonstrated in some populations to be excessively represented in patients with severe hypoglycemia (75).

CLINICAL CAUSES OF HYPOGLYCEMIA AND APPROACHES TO MINIMIZING RISKS

It is important to recognize that acute hypoglycemia in diabetes, whether or not complicated by hypoglycemia unawareness, is caused by excessive insulin action. There are many important differences between therapeutic exogenous insulin and endogenous insulin: exogenous insulin is delivered peripherally not portally, has variable and nonphysiologic pharmacodynamics, and is unresponsive to changes in blood glucose concentrations.

Meal-Related Insulin and Hypoglycemia

Rapid-acting (regular) insulin, designed for prandial use, has too low a peak and too long a duration of action to mimic the short, sharp, prandial burst of insulin produced by the healthy pancreas in response to eating. Thus, if enough insulin is taken to prevent an excessive increase in glucose level with a meal, too much insulin may remain in the circulation 2 to 4 hours later. The problem may be compounded if an intermediate-acting insulin is administered with the preprandial regular insulin in an effort to cover the subsequent two meals (e.g., the use of a prebreakfast mixture of regular and intermediate-acting insulin to cover breakfast and lunch). Patients trying to gain control of immediate postprandial glycemia almost invariably need

678 JOSLIN'S DIABETES MELLITUS

between-meal snacks to prevent hypoglycemia before the next meal (76). This represents one of the most troublesome aspects of such diabetes treatment regimens. The use of ultra–short-acting insulin analogues may reduce the dependence on snacks between meals (77,78), as may the use of twice-daily intermediate-acting insulin to provide basal insulin coverage and reduce the dependence on a meal-related regular insulin bolus to provide enough insulin to last from one meal to the next (9,79).

Basal Insulin Replacement and Nocturnal Hypoglycemia

Basal insulin coverage overnight often represents an even more significant problem in diabetes management. It has long been known that approximately 50% of insulin-treated patients experience nocturnal hypoglycemia (80), and this has recently been confirmed in studies in children (81-83). In one of these studies, the median glucose nadir was 1.9 mmol/L (range, 1.1 to 3.3 mmol/L) and the median duration was 270 minutes (range, 30 to 630 minutes) (82). Nocturnal hypoglycemia is often asymptomatic, possibly because it produces a much less vigorous counterregulatory hormone response during sleep than during wakefulness (84,85). This lack of a vigorous sympathetic response may explain the prolonged duration of episodes of nocturnal hypoglycemia episodes observed in children (82) and why nocturnal hypoglycemia can be profound enough to cause convulsions and seizures. It has been surprisingly difficult to demonstrate deleterious effects of nocturnal hypoglycemia on cognitive function the next day (82,86), except for the finding of a significant decline in feelings of well-being and mood. However, nocturnal hypoglycemia is capable of inducing defective counterregulation the following day (32) and should be avoided for this reason alone.

Significant difficulties result from the use of conventional intermediate-acting insulins for overnight insulin replacement in patients with type 1 diabetes. All have a marked peak-andtrough effect that does not match the physiologic pattern of nonprandial insulin secretion from the healthy pancreas. The predicted peak action is 4 to 8 hours after injection, with the subsequent decreased levels likely to leave the patient with insulin deficiency and hyperglycemia the next morning. Within the range of isophane and lente insulins, there are subtle differences in pharmacodynamics that sometimes can be exploited but the differences are not great (87). Less pure and animal insulins may last longer than the equivalent human insulins, with one study showing the lowest fasting glucose levels, dose-for-dose, with bovine insulin (87); however, a recent study specifically of nocturnal glycemic control with equivalent human and porcine insulins showed no difference in glycemic control or in the frequency of episodes of nocturnal hypoglycemia (88).

Delaying the administration of evening intermediate-acting insulin to defer the peak action into the time of the dawn phenomenon can often be useful (89), and one study showed reduced rates of hypoglycemia when nocturnal insulin replacement was by single-rate continuous subcutaneous insulin infusion (90). There is also a suggestion that the risk of nocturnal hypoglycemia may be diminished when basal insulin replacement is provided by twice-daily intermediate-acting insulins rather than by one evening dose (9,79). The new insulin analogues, glargine and detemir, which are designed to have a flatter, more prolonged, insulin action than conventional isophane and lente insulins, have been associated with reduced nocturnal hypoglycemia (91,92), although the first clinical trials have not shown a major impact on hypoglycemia in general (93). The regular insulin given before the evening meal can be a significant contributor to nocturnal hypoglycemia. This has been shown by studies suggesting that the blood glucose test before the bedtime snack may be a good predictor of nocturnal hypoglycemia (94,95), although this is not a universal finding (81). Converting to an ultra–short-acting insulin analogue for meals reduces the risk of nocturnal hypoglycemia (96), although this results in significant hyperglycemia during the early part of the night (97,98). Adjusting bedtime snacking procedures may prevent such hyperglycemia, but this has not been confirmed in controlled studies.

Bedtime snacking is a long-established component of diabetes treatment regimens that is widely accepted as an approach to preventing nocturnal hypoglycemia. It most often is used to offset the late action of the regular insulin taken before the evening meal—as food intake is not likely to have a significant effect on blood glucose levels after 3 or 4 hours. Inclusion of uncooked cornstarch in the bedtime snack has been shown to reduce rates of nocturnal hypoglycemia, but the mechanism is uncertain (99). Because the amount of cornstarch ingested is very small, it is unlikely to function as a source of carbohydrate slowly absorbed over many hours. The suggested inclusion of substrates for gluconeogenesis in the bedtime snack has a logical appeal but has not been formally tested (100). The use of β -agonists at bedtime, effective in a research setting, demonstrated no effect in a clinical trial (101).

POSTHYPOGLYCEMIC HYPERGLYCEMIA AND HYPOGLYCEMIA

Belief in the Somogyi phenomenon, literally the occurrence of ketonuria the morning after a nighttime hypoglycemic episode, as an explanation for diabetic instability and fasting hyperglycemia, has a cyclic popularity (102). As discussed previously, it is likely that morning hyperglycemia results from a waning of the insulin effect from the previous day, with the earlier peak action of that same insulin causing the prior hypoglycemia (103). Early morning ketonuria is likely to arise from the same insulin deficiency, although ketosis also is undoubtedly augmented by elevations in stress hormones. Despite the frequent importance of insulin deficiency, posthypoglycemic hyper-glycemia does occur and may explain why successful resolution of recurrent hypoglycemic episodes often is associated with lowering of glycosylated hemoglobin values and improved blood glucose control overall.

The mechanisms of posthypoglycemic hyperglycemia include a tendency to overtreat the hypoglycemic episode and the generation of insulin resistance as a result of hypoglycemia counterregulation. Contrary to traditional teaching, the effect of a single episode of hypoglycemia may be manifest as postprandial hyperglycemia the next day rather than as fasting hyperglycemia (104). The insulin resistance due to the catecholamine response is transient (105,106); a more prolonged effect appears to be attributable to growth hormone (107). This effect may be particularly pronounced in children, whose counterregulatory hormone response to hypoglycemia is greater than that in adults (108), especially when glycemic control is generally poor. The problem is compounded in adolescents, who, in addition to having a vigorous counterregulatory response, are also relatively insulin-resistant (109). No therapeutic compensation can be made for this-avoidance of the hypoglycemia is the essential therapeutic maneuver.

Paradoxically, the other change in blood glucose levels that should be anticipated following a hypoglycemic event is another hypoglycemic episode. This applies to more severe episodes of hypoglycemia and is presumably related to a counterregulatory deficit induced by the index episode (110). Patients receiving insulin should be aware of the risk of a second occurrence of hypoglycemia within 24 hours of a single severe episode.

HYPOGLYCEMIA IN TYPE 2 DIABETES MELLITUS

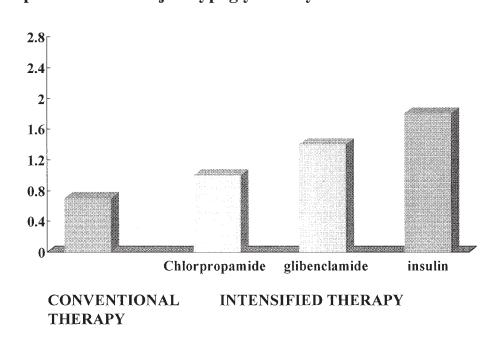

Compared with the information available about hypoglycemia in type 1 diabetes, knowledge about hypoglycemia in type 2 diabetes is limited. Severe hypoglycemia is much less common in type 2 diabetes, in which insulin resistance and residual pancreatic function presumably confer some protection. However, with progression of the disease process to an insulin-requiring state, the patient with type 2 diabetes may assume risks of hypoglycemia similar to those in patients with type 1 diabetes. The analysis of the effects of blood glucose control in type 2 diabetes in the United Kingdom Prospective Diabetes Study (UKPDS) clearly demonstrated an increased risk of severe hypoglycemia with intensification of control and the introduction of insulin (Fig. 40.5) (111).

Patients with type 2 diabetes whose therapy is limited to diet and exercise do not experience significant hypoglycemia, and it is extremely rare in those receiving metformin or thiazolidenediones, because these drugs act as an insulin sensitizer and thus do not prevent a decrease in the patient's endogenous insulin or an increase in glucagon as levels of plasma glucose decline. With insulin secretagogues, hypoglycemia can occur and can often be severe enough to produce neuroglycopenic symptoms (112–114). The long-acting sulfonylureas are particularly problematic, and the occurrence of confusion in elderly patients receiving sulfonylureas must always raise suspicion of hypoglycemia. Shorter-acting sulfonylureas and the metiglinides carry a lower risk of hypoglycemia (Fig. 40.6) (114,115).

Hypoglycemia induced by sulfonylureas can be prolonged and can recur after emergency treatment as a consequence of persistent drug action. Patients presenting with severe hypoglycemia secondary to sulfonylurea treatment should be hospitalized for observation; they often require parenteral glucose therapy.

There is controversy concerning the differences between the counterregulatory responses to hypoglycemia in type 1 and type 2 diabetes. Patients with type 2 diabetes are generally older than patients with type 1 diabetes, and normal aging has been associated with reduced counterregulatory hormone responses to induced hypoglycemia (116–118). Symptom generation and cognitive impairment in hypoglycemia occur more closely together in healthy older individuals, and this might be expected to increase the risk of severe hypoglycemia in older patients with type 2 diabetes (119,120).

There is good evidence that counterregulatory responses in patients with poorly controlled type 2 diabetes are initiated at high glucose levels, with a decrease in the levels of glucose that are associated with hormonal responses and subjective awareness as control is improved, at least with insulin (Fig. 40.7) (121). Preliminary evidence suggests that thresholds for at least some cognitive dysfunctions are not similarly mobile (121). Symptoms of hypoglycemia in patients with type 2 diabetes receiving insulin differ little from those of patients with type 1 diabetes (122), although elderly patients more readily present with neurologic symptoms such as incoordination, blurred vision, or slurred speech (122).

EXERCISE AND HYPOGLYCEMIA

Exercise is an important contributor to episodic hypoglycemia. The effects of exercise on blood glucose are immediate (as exercising muscle uses glucose), intermediate (lasting for 18 to 24 hours if the exercise is vigorous or prolonged), and chronic (in the sense that muscle is more sensitive than adipose tissue to insulin and that a fit body is more insulin-sensitive than an untrained body) (123–125).

The immediate hypoglycemic effect of exercise can be accommodated by reducing the dose of insulin that will be active at the time of planned exercise. Alternatively, rapidly available carbohydrate (fruit juice or glucose) can be taken during and after the exercise. Judicious use of home blood glucose monitoring helps the patient assess his or her own requirements for given intensities of exercise.

Vigorous or prolonged exertion will deplete liver and muscle glycogen, and the demand for glucose to restore these pools lasts at least 24 hours. People who exercise intermittently, either very vigorously or over prolonged periods, are likely to require significantly less insulin through the following night and possibly even the next day. Insulin requirements, including basal requirements, during sporting holidays (e.g., skiing) can fall by 30% to 50% (126). For a more detailed discussion of exercise in diabetes, see Chapter 38.

ALCOHOL AND HYPOGLYCEMIA

Alcoholic beverages often contain glucose, and the immediate response to alcohol ingestion, especially of beer and cider, is often hyperglycemia. The hyperglycemic effect of wine is very small. Alcohol is also an insulin sensitizer (127). It suppresses gluconeogenesis, an effect that can cause delayed hypoglycemia, as the body normally activates gluconeogenesis after several hours of fasting. This can, for example, cause significant hypoglycemia the morning after evening drinking. The effect is dose-dependent, and one or two drinks are therefore unlikely to have a major effect. However, individuals in tight glycemic control (and their friends and relatives) need to be aware of the risk. The likelihood of hypoglycemia is greatest in young people who combine alcohol intake (not necessarily excessive) with exercise—typically at overnight parties involving dancing. Young people have died as a result of this combination. Advising reduction in overnight insulin after evening or all-night parties where alcohol and/or exercise have been involved and warning relatives or friends of the risk next day should be advised.

Acutely, alcohol has been shown to diminish appreciation of hypoglycemic symptoms (128) and counterregulatory hormone responses (129) and can therefore be a contributor to severe hypoglycemia without warning signs.

DRUGS AND HYPOGLYCEMIA

The risk that β -blockers may diminish appreciation of symptoms of hypoglycemia has not been substantiated in experimental studies indicating that exaggerated sweating enhanced subjective awareness of hypoglycemia (130). The use of β -blockers in diabetic patients with cardiovascular disease should not be avoided on the basis of the risk of hypoglycemia, although it makes sense to use cardioselective agents where appropriate.

Considerable discussion about there being a significantly increased risk of hypoglycemia with the use of angiotensin-converting enzyme (ACE) inhibitors (131) was followed by evidence (in a mixed group of patients with type 1 and type 2 diabetes) that the association was with antihypertensive therapy per se (132). ACE inhibitors do appear to enhance insulin sensitivity, but the effect is small. There were suggestions that the relationship was indirect-either through comorbidity for the conditions for which the ACE inhibitors were being used or as a consequence of modern diabetes management with intensified insulin therapy and vigorous use of ACE inhibitors. A report of an association between enalapril and risk of hypoglycemia specifically in patients receiving a sulfonylurea (133) was followed by a failure to observe increased hypoglycemia rates in users of ramipril in the HOPE (Heart Outcomes Prevention Evaluation) trial (again a mixture of patients with type 1 and type diabetes) (134). The possibility that hypoglycemic effects of ACE inhibitors are drug-specific rather than class-specific has not been excluded by available studies. At present, caution is advised when introducing or increasing the dose of an ACE inhibitor in a patient with tightly controlled diabetes, with advice given to increase home glucose monitoring until the dose is established. This is good practice when making any adjustment in medication for a patient with diabetes. The data do not in any way support the avoidance of ACE inhibitors in patients with diabetes.

Thyrotoxic patients have accelerated hepatic degradation of insulin. Treatment with hypothyroid drugs may then increase the risk of hypoglycemia, especially if the patient becomes significantly hypothyroid (135).

Finally, it has been suggested that changes in the nature, and particularly the species, of exogenous insulin used by a patient with diabetes can be associated with increased risk of hypoglycemia. In particular, concerns have been raised that synthetic human insulins may carry greater risk than older animal insulins of problematic hypoglycemia. A recent systematic review of available published studies found no evidence to support this claim, although it was noted that any study may fail to pick up an idiosyncratic effect with relevance to some individuals (136). There is no evidence that various insulin species have different effects on responses to hypoglycemia (e.g., differentially disposing to hypoglycemia unawareness), but it is good practice to use an insulin species with which the patient feels most confident.

MANAGEMENT OF HYPOGLYCEMIA

The Acute Event

Acute hypoglycemia is most safely treated with 15 to 20 g of oral glucose—ideally as glucose tablets; jelly, or glucose-containing drinks such as 150 to 200 mL of fresh fruit juice, nondiet lemonade, nondiet cola, or a slightly lesser amount of Lucozade (100 to 130 mL). Chocolate is best avoided because the fat content tends to retard glucose absorption. If no meal is planned within the hour after a hypoglycemic episode, additional complex carbohydrate (10 to 20 g) should also be ingested. The parenteral route should not be used if the patient is conscious and able to swallow.

It is useful if the patient can confirm the blood glucose concentration prior to treatment, since it will help subsequent management to know the level at which the patient experiences symptoms of hypoglycemia. Treatment of nonhypoglycemic, apparently symptomatic, episodes (blood glucose higher than 3.5 mmol/L) should be avoided unless the patient needs to be sure the glucose level is not falling further or is about to drive.

If the patient is too confused to swallow safely, corrective therapy must be administered parenterally. Absorption of honey or glucose gel through the buccal mucosa can sometimes be tried if the situation is not too extreme. Intramuscular glucagon (1 mg) can be administered by trained nonprofessionals and should be effective within 10 minutes (137). The action has been said to be as rapid as intravenous glucose, although anecdotally, intravenous glucose has been reported to be faster. Administration of glucagon should be followed by oral administration of 20 g of glucose after the patient is alert enough to swallow and thereafter of 40 g of a starchy carbohydrate to maintain recovery. The action of glucagon depends on stimulation of glycogenolysis, and it therefore may not be effective after prolonged fasting or in alcohol-induced hypoglycemia.

Intravenous glucose solutions should be given with care. The old regimen of 50 mL of 50% glucose provides too much glucose in a form that is very toxic to tissues. What matters is the total quantity of glucose given, and 75 to 100 mL of a 20% solution or even 150 to 200 mL of a 10% solution of glucose is much safer. There is a report of tissue necrosis requiring amputation of a hand as a consequence of extravasation of a 50% solution of glucose administered intravenously (138).

Prevention

Aspects of hypoglycemia prevention have been discussed in the section on minimization of risk, but it is important to note the need to review the therapeutic regimen in patients with problematic hypoglycemia. This includes episodes of hypoglycemia without patient awareness; episodes that a third party had to help treat; episodes when the patient lost self-control, resulting in embarrassment, underperformance at work, or accidents with or without physical damage to the patient or another person; and episodes when the patient lost consciousness or had a seizure.

Comorbidities that might increase hypoglycemia risk (deficiencies of cortisol, growth hormone, thyroid hormone and causes of malabsorption such as coelic disease, anorexia, or gastroparesis) should be excluded. However, the principal cause of hypoglycemia is excess insulin, and adjustment of the insulin regimen or changes in insulin secretagogues must be considered in any such patient. This should be coupled with education on proper management of other risk factors, such as the timing and content of meals and snacks, management of exercise, and the effects of alcohol. Adjustment of diabetes regimens to eliminate blood glucose values of less than 3 mmol/L may help a hypoglycemia-unaware patient regain hypoglycemia warnings and can frequently be accomplished without worsening the average glucose control. Examination of a patient's "typical" day in terms of meal times and exercise patterns often can reveal easily remediable risk factors. It is often worth comparing the patient's insulin distribution with the norm and, if there is a big discrepancy, trying to redistribute the total dose in line with textbook descriptions of requirements (e.g., in multiple daily insulin regimens, 40% to 60% of a total dose should be administered as basal insulin, with the remainder divided between meals-most for breakfast, least for lunch). A schema for altering therapy to reverse problematic hypoglycemia is

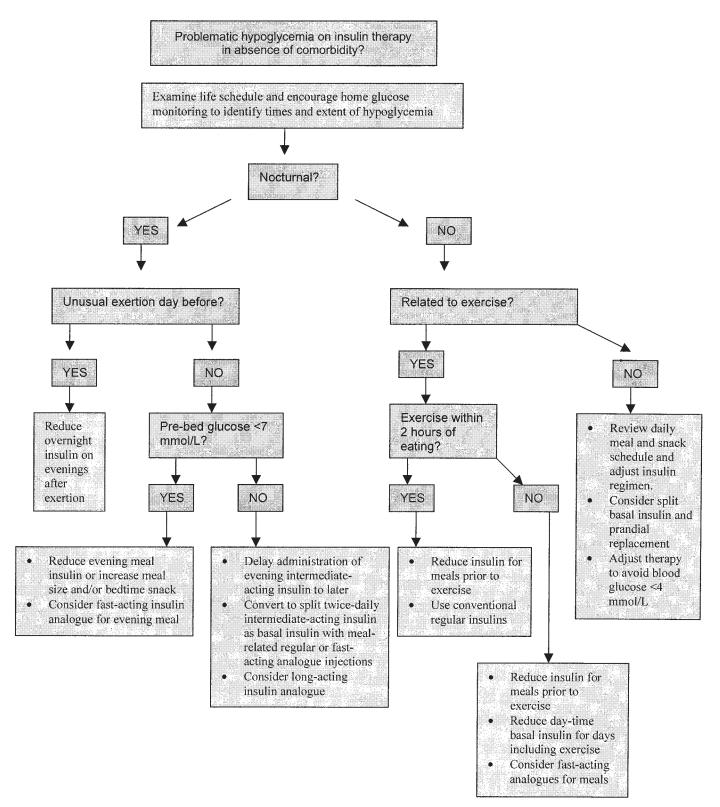

Figure 40.8. A proposed plan for the management of patients with problematic hypoglycemia.

illustrated in Figure 40.8. For patients with type 2 diabetes who are receiving sulfonylureas, reduced doses, administration of other hypoglycemic agents, and conversion to shorter-acting agents should all be considered. Ultimately, judicious use of continuous subcutaneous insulin therapy (insulin pump therapy) is effective (139,140). Islet transplantation remains a research procedure which can be effective in reducing hypoglycemia burden in insulin-sensitive type 1 patients when all else has failed (141).

Driving and Hypoglycemia

There is no clear evidence that patients with diabetes have an overall higher risk of automobile collisions than do other individuals. However, hypoglycemia is implicated as a cause of accidents (142), and it is possible that drivers with diabetes follow particularly safe driving practices to compensate. Much of the evidence on the incidence of automobile collisions was collected before the widespread introduction of intensified insulin therapy, and new studies therefore are needed (143). Ultimately, decisions about the fitness of patients with diabetes to drive must be made on an individual basis.

Patients with recurrent severe hypoglycemia and those who do not recognize hypoglycemia should not be permitted to drive. If these circumstances can be reversed by improving the mechanism of subjective hypoglycemia recognition, it is reasonable to consider the resumption of driving. It is a good strategy for such patients to verify their blood glucose level before driving and at 90-minute intervals during a long drive. The driver with diabetes should always carry glucose for rapid management of hypoglycemia should it occur. If a hypoglycemic episode develops, the patient should stop the car without delay, treat with glucose, wait 20 minutes, and recheck the blood glucose before resuming driving. This is important, because cognitive recovery from acute hypoglycemia may be delayed (144).

LONG-TERM EFFECTS OF ACUTE HYPOGLYCEMIA

Recovery from severe hypoglycemia with cognitive impairment, including coma or seizure, is generally complete. Rarely, patients suffer permanent brain damage, obvious at the time of recovery of consciousness, with slow improvement that can continue for weeks afterward. Permanent neurologic sequelae have most often been reported after massive deliberate or malicious overdosage and delayed restoration of blood glucose levels (145).

Hypoglycemic hemiplegia is an uncommon condition in which the patient wakes up after nocturnal hypoglycemia with a hemiparesis that resolves after minutes or hours. Patients may present with recurrent episodes. Although sometimes thought to indicate underlying circulatory defects, in one survey of 56 reported cases in adults, most of which involved a right-sided hemiparesis, only three of 16 who were investigated showed evidence of internal carotid artery stenosis (146). There are no data to suggest a poor prognosis. In children, there is no record of a preference for right- or left-sided neurologic signs, and one series of 44 children included 14 who underwent computed tomographic scans, which were normal in all but one (147).

Cumulative Damage from Recurrent Severe Hypoglycemia

The concern that recurrent severe hypoglycemia, *from which an apparently full recovery is made at the time*, might cause cumulative cortical damage and impaired cognitive function remains

unresolved (148). In adults, there are data to suggest a greater decline in IQ scores over time and impaired decision times on formal testing in diabetic patients with a history of recurrent severe hypoglycemia (149). These are suggestive data, but the decrement in IQ was calculated, in a rather complicated manner, as the difference between the National Adult Reading Test score (which is said to be resistant to organic brain disease) and the Wechsler Adult Intelligence Scale (revised) score, adjusted to account for the difference in the way the two tests are performed. The increased loss was approximately a doubling of the normal reduction in IQ score with age. Another study found decreased performance in a word-recall test in diabetic patients with a history of severe hypoglycemia; ultimately it was unclear whether this was associated with diabetes per se rather than with hypoglycemia (150). Similarly, diabetes was found to be associated with prolongation of the evoked potential the P300 wave on electroencephalography, with no further effect of a history of severe hypoglycemia (151). However, another study concluded that there was decreased psychomotor performance only in diabetic patients with severe hypoglycemia and neuropathy, supporting the possibility of a diabetic central neuropathy or encephalopathy (152). In evaluating the possibility of hypoglycemia-induced damage of the central nervous system, it is important to recognize that factors other than subclinical organic brain damage may affect results of formal cognitive function testing. In particular, depression can have a very major effect and is rarely factored out of the cross-sectional studies. This may explain why an early study found equally decreased cognitive performance in patients from a diabetes clinic and patients from a gastroenterology clinic (153).

Neuroimaging has not produced definitive answers. Studies have generally been small and cross-sectional. One study found leukoaraiosis in two each of 11 diabetic patients with and without hypoglycemia but found imaging evidence of cortical atrophy in 5 of the 11 with recurrent hypoglycemia only (154). It is possible that both chronic hyper- and recurrent hypoglycemia have detrimental effects on cortical function, as evidenced by delayed reaction times in both very tightly controlled (and by implication more commonly hypoglycemic) and very poorly controlled diabetes (155).

None of the changes described amount to clinical dementia, but some patients, perhaps particularly those whose habits and situations require high cognitive input and fast reaction times, may be disadvantaged. Frank dementia has been documented in five patients with severe hypoglycemia, but advanced macrovascular disease may have been of etiologic significance (156).

There is clear evidence that intensified insulin therapy, despite its association with increased prevalence of severe hypoglycemia, does not cause cognitive impairment prospectively over time (157). This does not exonerate recurrent severe hypoglycemia, because conventionally treated patients also develop hypoglycemia and not all intensively treated diabetic patients experience problematic hypoglycemia, but it provides reassurance. An exhaustive breakdown of the DCCT data, collected prospectively, showed no evidence for diminished psychomotor performance in patients with more than five episodes of severe hypoglycemia as compared with those with fewer episodes (158).

The situation is slightly clearer regarding the effects of recurrent hypoglycemia on the developing brain. In children younger than 7 years, there is evidence of impaired intellectual performance at later times if diabetes develops very early (before the age of 7 years) and if there has been recurrent hypoglycemia *with seizures* (159). In such young children, one major aim of diabetes therapy must be the avoidance of hypoglycemia. Good blood glucose control is important for the optimization of growth and for the prevention of long-term complications of diabetes. However, it is at least as important to avoid severe hypoglycemia in young children, and slightly higher glycemic targets than those appropriate for adults and older children may be indicated.

SUDDEN DEATH AND HYPOGLYCEMIA

Death from acute hypoglycemia occurs but is very rare (160,161). Hypoglycemia has been implicated in occasional unexplained deaths in young people with diabetes (162). The diagnosis cannot be made retrospectively, as it is not possible to obtain firm postmortem evidence of hypoglycemia. Typically, the patient is found in an undisturbed bed with no evidence of preceding ketoacidosis (prodromal illness, evidence of vomiting) or a hypoglycemic seizure. Recent studies have shown that acute hypoglycemia is associated with lengthening of the QT interval on the electrocardiogram, which may predispose to serious arrhythmias (163,164). It has been suggested that the combination of a catecholamine surge and a drop in potassium level associated with hypoglycemia may precipitate a fatal cardiac arrhythmia in these, fortunately rare, cases. It is not known if an "at-risk" population can be identified, as the problem is so infrequent, but the potential catastrophic complication adds to concerns about avoiding problematic hypoglycemia in the course of insulin therapy.

COMBINATION THERAPY WITH ORAL AGENTS AND ORAL AGENTS AND INSULIN 705

The management of hyperglycemia in patients with diabetes has changed significantly during the past several years as a result of numerous advances in our knowledge about the disorder and the application of this knowledge to the development of new strategies and treatments.

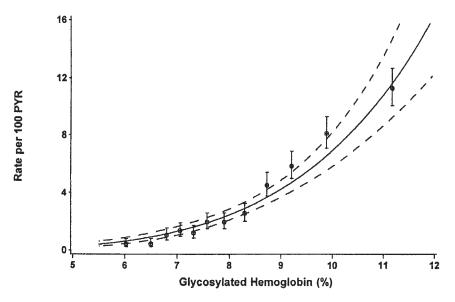

The quantitative relationship between glycemic control and the chronic microvascular, neuropathic, and macrovascular complications of diabetes have been defined by large longterm clinical studies in individuals with type 1 and type 2 diabetes (1–3). A clearer understanding of the physiologic mechanisms involved in regulating glucose metabolism has provided the basis for a more detailed analysis of the different pathophysiologic processes causing hyperglycemia (4-7). Methods for regulating fasting glycemia can be differentiated from methods for regulating postprandial hyperglycemia (8,9). New classes of antihyperglycemic agents are available that provide the means for selectively ameliorating the different mechanisms that cause hyperglycemia (10,11). Long-term follow-up data are sufficient to demonstrate that type 2 diabetes is a progressive disease and that therapy must change with disease progression (12). Combinations of oral antihyperglycemic agents or of oral antihyperglycemic agents and insulin are frequently necessary to achieve appropriate glycemic goals (13, 14). The impacts of the various classes of antihyperglycemic agents on cardiovascular risk factors have been established and are an important consideration in deciding which agents to use in a particular patient (15,16).

Effective management of hyperglycemia requires utilization of all of this new information. Initial evaluation of a patient requires establishment of the goals of therapy for that patient. Diabetes education reinforces those goals and helps the patient learn techniques and behavior that can help achieve those goals. The evaluation must include an assessment of whether the patient has the metabolic syndrome and, if so, which components of the syndrome. The selection of initial pharmacologic therapy is determined by these initial evaluations. Long-term management requires intermittent reevaluation of the progression of the disease process and modification of the therapy to adjust to this changing pathophysiology. Effective use of current therapeutic agents and techniques can result in near normoglycemic control in most patients with type 2 diabetes.

GLYCEMIC GOALS OF THERAPY

A variety of approaches are used to define the goals for glycemic control in patients with diabetes. The levels achieved and shown to decrease chronic complications in intervention studies such as the Diabetes Control and Complications Trial (DCCT) in patients with type 1 diabetes or the United Kingdom Prospective Diabetes Study (UKPDS) in patients with type 2 diabetes can define the goals (1–3). In those studies, the intensively treated patients achieved mean or median hemoglobin A_{1c} (Hb A_{1c}) levels approaching 7.0%. These levels were attainable in a large cohort of patients and significantly reduced, but did not prevent, chronic complications.

Another approach in defining the goal is to determine if there is a threshold of glycemic control only above which chronic complications occur. An analysis of the relationship between the mean HbA_{1c} and the development of retinopathy, nephropathy, or neuropathy in the entire DCCT cohort showed that there was no glycemic threshold short of normal glycemia throughout the entire range of HbA_{1c} (17). The data for sustained progression of retinopathy (Fig. 41.1) showed a constant 39% reduction in risk for each 10% reduction in absolute HbA_{1c}

values (17). The epidemiologic data from the entire UKPDS similarly showed no glycemic threshold for either microvascular or macrovascular complications (Fig. 41.2) (18).

The lack of a glycemic threshold short of normal glycemia indicates that any level of increased glycemia, as well as the duration of the increase, can result in chronic complications. These data suggest that the goal for glycemic control in patients with diabetes should be levels as close to normal as possible, provided that they can be achieved without causing unacceptable side effects. For the standard HbA_{1c} assay, normoglycemia is considered to be less than 6.0%. Obviously, other clinical factors need to be considered in determining the glycemic goal for a particular individual. The age of the individual and life expectancy are important, because the benefits of glycemic control are greatest in those who live long enough to benefit from reduced complications. The achievement of

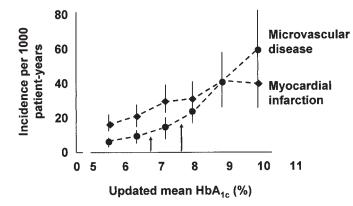

FIG. 41.2. Epidemiologic analyses of the relationships between mean HbA_{1c} over 11 years and the incidence of microvascular and macrovascular complications in the United Kingdom Prospective Diabetes Study (UKPDS). There was no glycemic threshold for either macrovascular or microvascular complications. (From Stratton IM, Adler AI, Neil HA, et al. Association of glycemia with macrovascular and microvascular complications of type 2 diabetes (UKPDS 35): prospective observational study. *BMJ* 2000;321:405–412, with permission.)

FIG. 41.1. Outcome data from the Diabetes Control and Complications Trial (DCCT) on the relationship between the risk of sustained progression of retinopathy and the mean HbA_{1c}. There is no glycemic threshold for retinopathy development and progression. Retinopathy progression decreased 39% for every 10% reduction in mean HbA_{1c} percentage. (Copyright © 1996 American Diabetes Association. From DCCT Research Group: The absence of a glycemic threshold for the development of long-term complications: the perspective of the Diabetes Control and Complications. Trial. *Diabetes* 1996;45:1289–1298. Reprinted with permission from the American Diabetes Association.)

very good glycemic control requires a motivated, educated, and cooperative patient.

Although identification of the ideal glycemic goal is nearnormal glycemia, it is equally important to recognize that any improvement in glycemic control decreases complication rates. Because the complication rate increases nonlinearly with the HbA_{1c}, a 10% reduction in HbA_{1c} from 11% to 9.9% results in a reduction in risk of progression of retinopathy of 6.57 cases per 100 patient years (17). In contrast, a decrease from 8.0% to 7.2% reduces the risk by 0.95 cases per 100 patient years (17). Table 41.1 highlights the 9-year cumulative incidence of development of retinopathy progression or microalbuminuria in patients with type 1 diabetes at mean HbA_{1c} levels ranging from 6% to 8% (17).

In summary, the glycemic goal that can be readily achieved with an acceptable level of side effects is an HbA_{1c} of 7.0%. However, in young patients and in those who are not limited by side effects, a goal of 6.0% would appear to be more acceptable. While any improvement in HbA_{1c} is worthwhile, a level in the range of 7.0% or lower should be sought.

TABLE 41.1. Cumulative Incidence Rates Among				
Patients in the Diabetes Control and Complications Trial of				
Developing Complications over a 9-year Period as a				
Function of Mean HbA _{1c} Values				

Mean HbA _{1c} value (%)	Cumulative incidence of retinopathy progression (%)	Cumulative incidence of risk of microalbuminuria (%)

FASTING VERSUS POSTPRANDIAL HYPERGLYCEMIA

Fasting plasma glucose (FPG) levels are determined primarily by hepatic and, to a lesser degree, by renal glucose production (4, 19,20). As the plasma glucose levels decrease during fasting, plasma insulin levels decrease proportionately. The decrease in plasma insulin causes an increase in adipose tissue lipolysis and skeletal muscle proteolysis and a decrease in uptake of glucose by peripheral tissue (21). At the level of the liver, the carbon skeleton from amino acids from muscle proteolysis serves as substrate and the free fatty acids from adipose tissue serve as energy source for the production of glucose. Glucose from glycogenolysis and gluconeogenesis provides the energy source for the nervous system, which has an insulin-independent requirement for glucose. Peripheral tissues use free fatty acids and ketones as their energy source. The plasma glucose level is determined by the rate of glucose production from the liver and kidney, because the rate of glucose utilization by the peripheral insulin-independent tissues is fixed. Normally, the plasma insulin level stabilizes at a level in which glucose production equals non-insulin-dependent uptake of glucose. Fasting hyperglycemia occurs when glucose production exceeds glucose utilization, as occurs with absolute or relative insulin deficiency at the level of the liver.

Postprandial plasma levels of glucose are determined in the initial phase by meal-mediated suppression of hepatic production of glucose and throughout the postprandial period by hepatic and muscle uptake of glucose (19,22). Glucose uptake requires higher plasma levels of insulin (such as those normally generated by meals) than does suppression of hepatic production of glucose. The regulation of postprandial plasma glucose therefore is highly dependent on the qualitative and quantitative aspects of meal-mediated insulin secretion, as well as by the sensitivity of muscle to insulin action (8). These phenomena account for the differential regulation of fasting and postprandial glucose that occurs in diabetes in general and in type 2 diabetes in particular.

41: ORAL ANTIHYPERGLYCEMIC AGENTS FOR TYPE 2 DIABETES 689

There are many potential consequences of the differential regulation of fasting and postprandial plasma glucose levels. Postprandial hyperglycemia occurs several years before fasting hyperglycemia and is the initial phase of glucose intolerance. Contributions of postprandial hyperglycemia to the overall glycemic control, as estimated by the HbA_{1c}, will vary with the individual and the stage of glucose intolerance (23). Some data suggest that spikes in glucose excursion may have different quantitative effects on the metabolic mechanisms involved in the pathogenesis of chronic complications (24,25). Pharmacologic agents may differentially affect fasting and postprandial hyperglycemia (10,26,27). Near-normal glycemia cannot be achieved unless both fasting and postprandial hyperglycemia are controlled.

STAGES OF TYPE 2 DIABETES

Type 2 diabetes is the end stage of a process that involves progressive loss of pancreatic β -cell function (Fig. 41.3) (12). The initial phase of this process in the majority of patients is the development of insulin resistance (28,29). Studies of low-birth-weight infants indicate that insulin resistance can be recognized in children as young as 8 years of age (30). The normal compensatory response to insulin resistance is increased insulin secretion and compensatory hyperinsulinemia. As long as the compensatory hyperinsulinemia is sufficient to overcome the insulin resistance, fasting and postprandial plasma glucose levels remain normal. If the individual with insulin resistance has the genetic predisposition to develop type 2 diabetes, the abnormalities in the pancreatic β -cell will cause a progressive loss of insulin secretory function and a loss of first-phase insulin release (31,32). This results initially in impaired glucose tolerance (IGT) and subsequently in type 2 diabetes with only postprandial hyperglycemia (23). As pancreatic β -cell function continues to deteriorate, not only does postprandial insulin secretion become inadequate, so does basal insulin secretion, and fasting hyper-

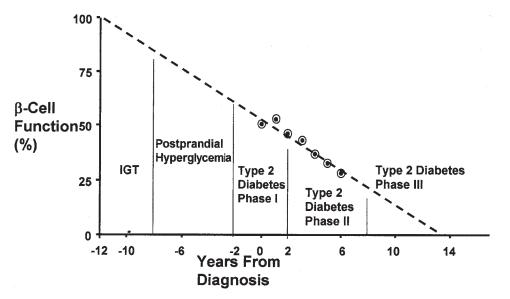

FIG. 41.3. Schematic representation of the stages of glucose intolerance as a function of pancreatic-cell insulin secretory capacity. The data points are taken from the HOMA (Homeostasis Model Assessment) calculation of percent normal-cell insulin secretory capacity as a function of time in a subset of the UKPDS population. The data are extrapolated both backward before the onset of clinical disease and forward into longer duration of disease. (Copyright © 1999 American Diabetes Association. From Lebovitz HE. Insulin secretogogues: old and new. *Diabetes Rev* 1999;7:139–153. Reprinted with permission from the American Diabetes Association.)

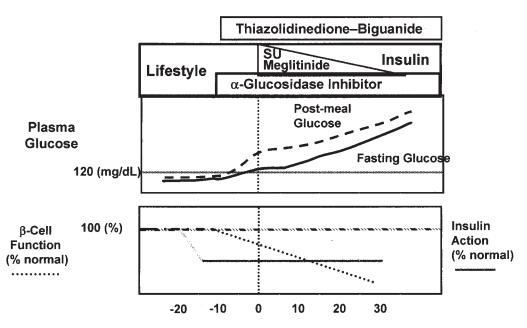

FIG. 41.4. Schematic representation of the natural history of the evolution of insulin-resistant type 2 diabetes and the matching of pathophysiology with the pharmacology of available treatments. SU, sulfonyl-ureas.

glycemia ensues. During the clinical course of type 2 diabetes, insulin secretory function continues to decrease, and finally, after a number of years of clinical diabetes, many patients become severely insulin deficient and will require insulinreplacement therapy. Treatment of the abnormal glucose metabolism is determined by the stage of the disorder (Fig. 41.4).

INSULIN RESISTANCE AND ASSOCIATED ABNORMALITIES

In the report of the American Diabetes Association Expert Committee on the Diagnosis and Classification of Diabetes Mellitus, type 2 diabetes is characterized as ranging from predominately insulin resistance with relative insulin deficiency to predominately an insulin secretory defect with insulin resistance

TABLE 41.2. Components of the Metabolic Syndrome

Insulin resistance Hyperinsulinemia Central obesity Increased systolic and diastolic blood pressure Dyslipidemia Increase in plasma triglycerides Decrease in plasma HDL cholesterol An LDL-particle pattern shifted to small, dense particles (type B pattern) Procoagulant state Increase in plasma fibrinogen Increase in plasminogen activator inhibitor 1 Vascular abnormalities Increase in urinary albumin excretion Endothelial dysfunction Hyperuricemia Non-infectious inflammation HDL, high-density lipoprotein; LDL, low-density lipoprotein. From Lebovitz HÉ. Clinician's manual on insulin resistance. London: Science

Press; 2002, with permission.

(33). In practical terms, about 85% of patients with type 2 diabetes have significant insulin resistance, which precedes the development of type 2 diabetes by many years, as noted previously. Insulin resistance is a separate entity from type 2 diabetes. Many individuals have insulin resistance and never develop type 2 diabetes because they do not have the pancreatic β -cell abnormalities (34,35).

Insulin resistance is associated with a cluster of metabolic abnormalities, and this is referred to as the *insulin resistance syndrome* or the *metabolic syndrome* (5,36,37). All of the components of the metabolic syndrome (Table 41.2) are cardiovascular risk factors. Because macrovascular disease is responsible for a large component of morbidity and mortality in patients with type 2 diabetes, their therapy must be directed at cardiovascular risk factors as well as hyperglycemia. An important issue in any antihyperglycemic treatment regimen is the effect that regimen might have on the components of the insulin resistance syndrome that are present.

PHARMACOLOGY AND USE OF CURRENTLY APPROVED ORAL ANTIHYPERGLYCEMIC AGENTS AS MONOTHERAPY

The different major classes of oral antihyperglycemic agents in current use can be divided into those that increase insulin secretion, those that decrease insulin resistance, and those that modify the rate of glucose entry from the gastrointestinal tract (Fig. 41.5). Even within these classes there are striking differences among agents. Current data on the effectiveness of newer agents on glycemic control generally are derived from the large multicenter randomized placebo-controlled phase III studies presented to regulatory agencies for approval (13,14). These studies are heavily weighted with patients who had previously received an active agent that was discontinued. In those instances, the patients randomized to placebo have a very significant deterioration of glycemic control, while the patients in the actively treated group either maintain or show improved

41: ORAL ANTIHYPERGLYCEMIC AGENTS FOR TYPE 2 DIABETES 691

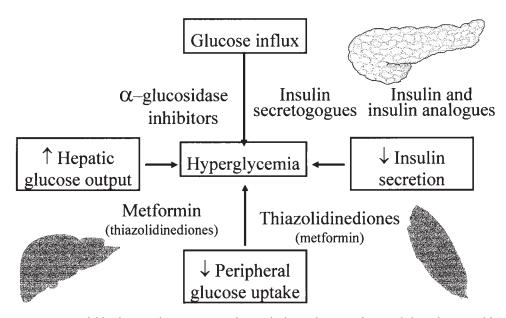

FIG. 41.5. Available pharmacologic agents ameliorate the hyperglycemia of type 2 diabetes by many different mechanisms. The antihyperglycemic effect of agents with different modes of action are additive. See Table 41.9.

glycemic control. Results are reported either as treatment effect, which is the difference between active treatment and placebo treatment, or as change from baseline, which is the difference in glycemic control at the end of the treatment period compared with that before the treatment period. The difference between treatment effect and decrease from baseline is significantly less in drug-naive patients with type 2 diabetes. Recent studies with antihyperglycemic drugs have shown that the decreases in HbA_{1c} with any treatment are directly proportional to the baseline HbA_{1c} levels (13). In drug-naive patients with type 2 diabetes in the rosiglitazone clinical trials (Fig. 41.6), it was apparent that the same dose of the same drug resulted in a 2.2%

Mean Change From Baseline HbA_{1c} at 26 Weeks (Drug-Naïve Patients)

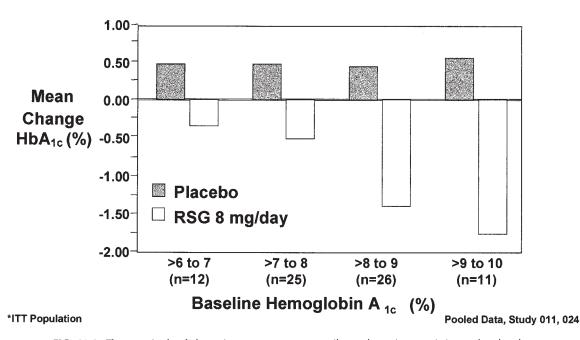

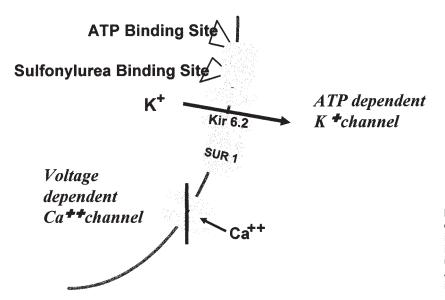

FIG. 41.6. The magnitude of glycemic response to every antihyperglycemic agent is inversely related to the baseline HbA_{1c}. The data here are from a cohort of drug-naive patients with type 2 diabetes treated in a double-blind placebo-controlled fashion with rosiglitazone at 8 mg/day. The placebo-treated patients had the same increase in HbA_{1c} regardless of their baseline HbA_{1c}.

decrease in HbA_{1c} compared with placebo treatment at a baseline of 10.0% but in only a 0.8% decrease at a baseline of 7.0%. These effects of the nature of the populations studied and the baseline HbA_{1c} levels on glycemic responses are relevant because they show that it is not possible to compare the efficacy of different agents on glycemic control unless the comparison is derived from data generated from the same randomized double-blinded study.

Insulin Secretogogues

MECHANISM OF ACTION

The insulin secretogogues currently available stimulate the secretion of insulin by causing closure of the adenosine triphosphate (ATP)-dependent potassium channel (K_{ATP}) in the plasma membrane of the β -cell (38–40). The K_{ATP} channel is composed of two different types of subunits and is assembled from four subunits of each type (Fig. 41.7). The Kir-6.2 subunits make up the inward rectifier through which K⁺ is transported from the

FIG. 41.7. The pancreatic β -cell K_{ATP} channel is open and extruding potassium ions when the plasma glucose level is low. The adjacent voltage-dependent calcium channel is closed. The K_{ATP} channel consists of two types of sub-units: the Kir-6.2 subunit, which makes up the rectifier; and the SUR-1 subunit, which regulates opening and closing of the channel.

intracellular compartment to the extracellular compartment. The SUR-1 subunit is attached to the Kir-6.2 subunit and regulates whether the KATP channel is open or closed. The SUR-1 subunit contains a binding site for sulfonylurea and related molecules, as well as binding sites for ATP and adenosine diphosphate (ADP). When the ATP:ADP ratio increases, as occurs when the plasma glucose level is elevated or when sulfonylureas or the newer insulin secretogogues bind to the SUR-1 subunit, the KATP channel closes (Fig. 41.8). When the KATP channel closes, K⁺ accumulates at the plasma membrane and causes depolarization of the membrane adjacent to the closed channels. Depolarization of the membrane causes voltagedependent L-type calcium channels in the microenvironment to open and for Ca²⁺ to enter the intracellular compartment from the extracellular compartment and increase the cytosolic Ca2+ concentration in the $\bar{\beta}$ -cell. The increase in Ca²⁺ stimulates the migration and exocytosis of the insulin granule.

All of the sulfonylureas and the newer non-sulfonylurea insulin secretogogues, repaglinide and nateglinide, act by binding to the SUR-1 subunits of the K_{ATP} channels, causing them to

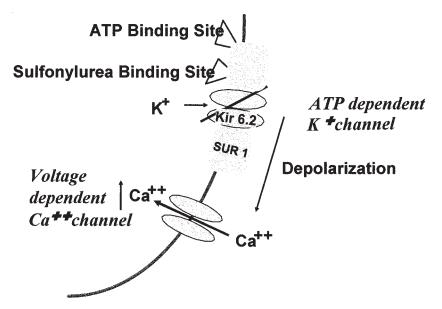

FIG. 41.8. When the plasma glucose level increases, the ATP:ADP ratio increases, causing the K_{ATP} channel to close. That initiates local depolarization of the plasma membrane, resulting in the opening of the L-type voltage-dependent calcium channels. Calcium ions enter the cell, and the rise in cytosolic calcium ion concentration stimulates insulin secretion.

close (41–43). Differences in the insulin secretory characteristics of the various insulin secretogogues are dependent on their pharmacokinetic properties and the affinity and kinetics of their binding to the SUR-1 subunit (41–43).

PHARMACOLOGY

The normal regulation of insulin secretion is tightly coupled to the plasma glucose level (44,45). Increasing plasma glucose levels, such as those that occur following ingestion of food, result in an almost immediate increase in insulin secretion. Decreasing plasma glucose levels are associated with a rapid decline in the secretion and plasma levels of insulin. Fasting is accompanied by reductions in insulin secretion sufficient to increase hepatic production of glucose to maintain glucose homeostasis. The ideal insulin secretogogue, therefore, would be one that restores to normal the defective early meal-mediated insulin secretion of type 2 diabetes, increases insulin secretion to adequately overcome the insulin resistance, stimulates insulin release only in response to elevated plasma glucose levels, and has little or no lag time in its insulin secretory response to rapidly changing plasma glucose levels. None of the available insulin secretogogues fulfills all of these properties.

Early postprandial hyperglycemia in the individual with diabetes is a consequence of delayed and inadequate early

secretion of insulin (44–46). Late postprandial hypoglycemia in these subjects with type 2 diabetes results from an increase in drug-mediated late insulin secretion that is further accentuated if there is an early exaggerated postprandial hyperglycemia. Fasting or nocturnal hypoglycemia is more likely to occur in patients with type 2 diabetes administered insulin secretogogues that have long half-lives and stimulate insulin secretion in the presence of low glucose levels (45).

The factors determining the clinical effects of the available insulin secretogogues are listed in Table 41.3 and tabulated for each secretogogue in Table 41.4 (13,47). The major factors to consider in prescribing an insulin secretogogue are the rate of onset of its action, the duration of its action, the degree to which its action is dependent on the plasma glucose level, and its spectrum of side effects, including interaction with KATP channels in other tissues. The major complications of therapy with insulin secretogogues are hypoglycemia and weight gain, both of which are manifestations of the inability of these agents to simulate normal physiologic insulin secretion (47-50). The closer a particular insulin secretogogue can restore insulin secretory physiology to normal in the patient with type 2 diabetes, the less these two complications will occur. The effectiveness of all insulin secretogogues in stimulating insulin secretion and in reducing hyperglycemia is dependent of the presence of functioning β -cells. Insulin secretogogues are ineffective in patients with type 1 diabetes, in patients with latent autoimmune diabetes of adults (LADA), and in the later stages of type 2 diabetes when pancreatic β -cell function is markedly deficient.

 K_{ATP} channels are present in many other tissues, including brain, myocardium, and vascular smooth muscle cells (38–40,51). The SUR subunit of the brain K_{ATP} channel is the same as that of the pancreatic β -cell (SUR-1), while the isoforms in myocardium and vascular smooth muscle cell are different (SUR-2A and SUR-2B). The abilities of various insulin secretogogues to interact with the different isoforms of the SUR subunit are not the same. This results in pharmacologic differences and has been postulated to produce clinical differences in sideeffect profiles.

TABLE 41.4. Characteristics of Specific Insulin Secretogogues					
Drug	Dose range (mg/day)	Peak level (hr)	Half-life (h)	Metabolites	Excretion
Sulfonylurea					
Tolbutamide	500-3,000	3–4	4.5-6.5	Inactive	Kidney
Chlorpropamide	100-500	2.4	36	Active or unchanged	Kidney

SPECIFIC CLASSES OF INSULIN SECRETOGOGUES

Sulfonylureas

Sulfonylurea drugs have been used in the treatment of type 2 diabetes since the early 1950s. Extensive literature, including many review articles, is available (13,45,47). The major new information concerning the use of sulfonylureas in the treatment of type 2 diabetes has come from the UKPDS (12,52–54), the development programs of the newer sulfonylureas such as glimepiride (55), and recent studies investigating the effects of sulfonylureas on myocardial and vascular responses to ischemia (56–59).

The sulfonylurea drugs do not appear to correct the defect in early insulin secretion characteristic of type 2 diabetes (60,61). Their primary action is to increase the late stage of insulin secretion. This increases the likelihood of late postprandial and fasting hypoglycemia. The sulfonylurea drugs do not increase insulin biosynthesis and, indeed, seem to inhibit proinsulin biosynthesis *in vitro*. There is no evidence that they are either β cytotropic or that they facilitate β -cell exhaustion (12,47). In the UKPDS, patients treated with sulfonylureas showed an increase in β -cell function for the first year but thereafter showed the same rate of loss of β -cell function as the conventionally treated group (12). Questions have been raised concerning the possibility that sulfonylureas, because of their prolonged effects on the pancreatic β-cell K_{ATP} channels, could lead to desensitization, with diminution of their pharmacologic effects. Several clinical studies showing that higher doses of sulfonylureas may be less effective than modest doses in lowering hyperglycemia provide some support for this hypothesis (62,63). Continuous in vitro incubation of β -cells with glyburide has been shown to lead to an increase in functionally deficient KATP channels (64).

Previous studies have shown that sulfonylureas can exert a variety of extrapancreatic actions in laboratory models *in vivo* and *in vitro* (47). It has been difficult to demonstrate conclusively any of these effects in humans. Some *in vivo* studies in humans have shown that sulfonylureas can lower plasma glucose levels under conditions in which the peripheral plasma insulin levels are unchanged. These studies have not excluded small changes in the portal vein insulin concentrations, which influence the liver but are not measurable in peripheral blood. Two effects of sulfonylureas that occur in humans that may result in extrapancreatic effects are interactions with K_{ATP} channels in other tissues (39) and direct effects on calcium ion–mediated exocytosis (65).

KATP channels in cardiac myocytes and vascular smooth muscle cells have SUR regulatory subunits, which differ somewhat from the SUR-1 subunit in β -cells (38–40). These different subunits change their binding characteristics such that they may have less affinity for some ligands that cause insulin secretion than for others. Brain-cell plasma membranes contain KATP channels that have the same regulatory subunit as pancreatic βcells. It is therefore possible that some sulfonylureas might interact with K_{ATP} channels in tissues other than β -cells and cause extrapancreatic effects. Another mechanism by which specific sulfonylureas might cause extrapancreatic effects is through direct enhancement of calcium-mediated exocytosis of other hormones that are stored in secretory granules. Presently, there is little evidence that sulfonylureas exert any clinically significant extrapancreatic effects in humans. The only exception may be effects on the myocardial and vascular smooth muscle responses to ischemia and hypoxia.

Chlorpropamide. Chlorpropamide is a first-generation sulfonylurea that has been prescribed extensively worldwide for almost 40 years. At dosages ranging from 100 to 500 mg once a

day, it is highly effective in reducing hyperglycemia, but because of its very long plasma half-life, it has been associated with a significant incidence of severe and protracted hypoglycemia, particularly in the elderly (47,66). Other significant side effects are water retention with hyponatremia and alcohol-induced facial flushing (45). Chlorpropamide is unique among sulfonylureas in that it stimulates secretion of antidiuretic hormones and potentiates an antidiuretic hormone effect in the renal tubules. The effect on water balance is thought to explain the observation in the UKPDS of an increase in systolic and diastolic blood pressure as well as a greater need for antihypertensive therapy in the 619 patients treated with chlorpropamide than in patients treated with insulin, glyburide, or conventional therapy (2). In the UKPDS, chlorpropamide treatment reduced HbA_{1c} significantly more than did glyburide or insulin; however, this was not accompanied by any greater reduction in risk for progression of retinopathy (2). Many previous studies have noted that hypoglycemia is a major risk of chlorpropamide treatment. Major hypoglycemic events occurred less frequently in the UKPDS in the chlorpropamide-treated cohort than in the glyburide-treated cohort (2).

Glyburide. Glyburide (glibenclamide) is currently the most widely prescribed sulfonylurea-but not because it is more effective or safer than other sulfonylureas. It is marketed as a formulation with poor and variable bioavailability (dosage 1.25-20 mg daily) and as a micronized formulation with relatively good and consistent bioavailability (dosage 1.5-12 mg daily) (45,47,67). Its efficacy in reducing hyperglycemia appears to be equal to that of other sulfonylureas, but it is associated with a high rate of serious side effects, including its long duration of action, with a rate of serious and fatal hypoglycemia that is significantly higher than that with other sulfonylureas, modest weight gain, and a relative lack of specificity on the different KATP channels (67-69). Careful evaluation of the 615 patients with type 2 diabetes treated with glyburide for a mean of 11 years in the UKPDS has clearly defined the characteristics of chronic glyburide therapy (2). It is most effective in controlling hyperglycemia in patients with newly diagnosed type 2 diabetes for the first year or 2 and then begins to lose effectiveness progressively with time (secondary failure or sulfonylurea ineffectiveness) (52-54). Glyburide treatment alone was relatively ineffective in controlling hyperglycemia after 4 or 5 years (54). The median decrease in HbA_{1c} in patients treated with glyburide as compared with patients receiving conventional (diet) treatment over 10 years was 0.7% (7.2% vs. 7.9%) (2). Weight gain occurred primarily in the first 3 or 4 years of treatment and was maintained throughout the study, so that at 10 years the glyburide-treated patients had gained 1.7 kg more than the conventionally treated patients (2). Serious hypoglycemia occurred primarily during the first few years of glyburide therapy, when it had been most effective in reducing hyperglycemia. Major hypoglycemic events were noted in approximately 1.4% of patients in year 1, 1.3% in year 2, and 0.4% in year 3 (2). These rates of serious hypoglycemic events are comparable to those reported in other large series and are greater than those with other sulfonylureas (Table 41.5) (68, 70-72).

Glipizide. Glipizide is a sulfonylurea that is available in both a short-acting formulation and in an extended-release formulation (glipizide-*g*astro*i*ntestinal *t*herapeutic *s*ystem, or glipizide-*GITS*) (45). The short-acting form is rapidly absorbed and is completely bioavailable. It is metabolized by oxidative hydroxylation and is eliminated with a half-life of 2 to 4 hours

Study	Sulfonylurea	Rates of serious hypoglycemia (per 100 person-years)

---------------	------------------------	-------------------	-----------------------

(45). Its elimination is not affected by mild to moderate renal insufficiency (creatinine clearance \geq 30 mL/min) (45). Glipizide is administered once or twice a day. Its efficacy is equal to that effects. Some

condition requiring the assistance of another person.

Is administered once or twice a day. Its efficacy is equal to that of glyburide in controlling hyperglycemia, but because of its metabolism and more rapid elimination, therapy with glipizide is associated with less hypoglycemia (45). The official maximum dosage of glipizide in the United States is 40 mg per day, although available clinical studies show little or no benefit in giving more than 15 or 20 mg per day. Glipizide should be administered before meals, as its absorption may be mildly delayed by food ingestion.

The extended-release formulation of glipizide provides once-a-day dosage of 5 to 20 mg (73,74). Plasma levels of glipizide 24 hours after doses of 5 mg and 20 mg of glipizide-GITS (Glucotrol XL) are 54 ng/mL and 310 ng/mL, respectively. The decreases in HbA1c in clinical trials with glipizide-GITS were 1.50% and 1.84% compared with placebo treatment. The decrease in HbA1c was maximal at 5 mg per day. FPG level was reduced 57 mg/dL to 74 mg/dL compared with placebo treatment. The extended-release form appears to have glucose-lowering effects similar to those of immediate-release glipizide, as measured by the improvement in HbA_{1c}. In a study comparing glipizide-GITS to immediate-acting glipizide, the authors concluded that the glipizide-GITS formulation at dosages of 5 mg and 20 mg have an improved metabolic profile compared with that of immediate-acting glipizide; however, the design of the study makes such a conclusion tenuous. No increase in hypoglycemia was noted with the extended-acting form.

Glimepiride. Glimepiride is the newest of the sulfonylureas to be approved for use. It is said to be more selective for the β cell K_{ATP} channel than for the cardiovascular tissue K_{ATP} channel (75). It appears to bind to a slightly different part of the sulfonylurea-binding site than does glyburide, although the two sulfonylureas displace each other from their respective binding sites. Glimepiride associates 2.5- to 3.0-fold faster and dissociates 8.0- to 9.0-fold faster than glyburide from its β -cell K_{ATP}-binding site (75,76). Insulin release is therefore more rapid and of shorter duration than that with glyburide. Hyperglycemic and euglycemic-hyperinsulinemic clamp studies in patients with type 2 diabetes demonstrated that glimepiride does not restore first-phase insulin secretion and that it increases second-phase insulin secretion, wholebody glucose uptake, and increases insulin sensitivity (61). Some studies have suggested that glimepiride reduces hyperglycemia with less insulin secretion than that required by other sulfonylureas, and this has led to the claim that glimepiride has an insulin-sparing action (57,77-80). The data are marginally significant, and additional studies are required

to substantiate this claim. For glimepiride, as for all other sulfonylureas, there are claims that it has extrapancreatic effects. Some of the effects described are an increase in glucose uptake and utilization by an increase in the translocation of the GLUT4 transporter protein in adipose and muscle cells, an effect on the regulation of the intracellular routing of the insulin receptor complexes toward degradative pathways, and an increased association of the insulin receptor with protein kinase C isozymes (76,79). These extrapancreatic effects have been demonstrated in *in vitro* systems, and their relevance to glimepiride effects in humans is debatable.

Glimepiride is administered once daily at dosages ranging from 1 to 8 mg. The recommended starting dosage is 1 to 2 mg daily, and the average maintenance dosage is 1 mg to 4 mg daily (57,77–80). Glimepiride is absorbed quickly and achieves maximal blood glucose lowering within 2 to 3 hours, but its bloodglucose-lowering effect is still evident at 24 hours. Like most sulfonylureas, glimepiride is metabolized by the liver and its metabolites are excreted via the kidney. In a 1-year comparative clinical trial, glimepiride and glyburide were equivalent in controlling glycemia; however, fasting plasma insulin and C-peptide values were statistically significantly lower in patients treated with glimepiride than in patients treated with glyburide (77). Glimepiride reduced HbA_{1c} 1.2% to 1.9% and mean FPG 54 mg/dL to 76 mg/dL compared with placebo treatment in studies of monotherapy (57,78).

Glimepiride treatment is associated with lower rates of documented hypoglycemia than is glyburide treatment (1.7% vs. 2.4%) and with rates that are equivalent to those with glipizide (0.9% vs. 1.2%) (57,79,80).

Repaglinide

Repaglinide is a non-sulfonylurea insulin secretogogue. It is a member of the meglitinide family (Fig. 41.9) (81–83). The mechanism of action of insulin release for repaglinide is slightly different from that of sulfonylureas (44). Repaglinide interacts with a specific binding site on the SUR-1 subunit that is distinct from the glyburide sulfonylurea-binding site but still causes closure of the KATP channel. Repaglinide, unlike sulfonylureas, does not directly stimulate exocytosis of insulin granules (65). Repaglinide is rapidly absorbed orally, with the C_{max} occurring 45 to 50 minutes after ingestion and plasma levels returning to baseline in 3 to 4 hours (47,83). The pharmacokinetic and K_{ATP} channel interactive properties of repaglinide result in the more rapid release of insulin and for a shorter duration than with sulfonylureas. The insulin-releasing action of repaglinide commences within 30 minutes and facilitates early meal-related secretion of insulin. Its major insulin secretory effect subsides in approximately 4 hours. Because repaglinide is a short-acting

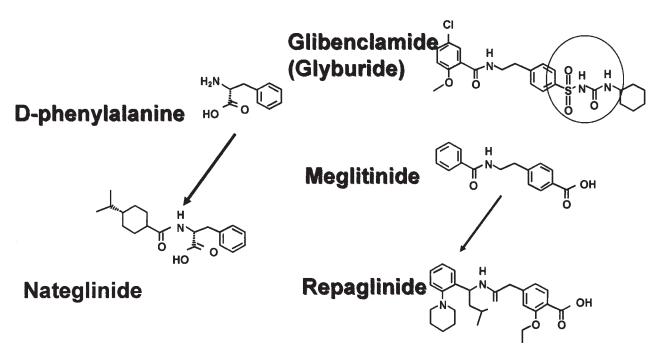

FIG. 41.9. Structure of the new rapid insulin secretogogues compared with a sulfonylurea such as glyburide.

insulin secretogogue, it must be taken within 30 minutes of each meal. When a meal is skipped or delayed, the administration of repaglinide should be altered similarly (84). The ability to alter the time and dose of repaglinide administration to match meal ingestion more closely reduces the likelihood of postprandial or fasting hypoglycemia. This is an advantage over traditional sulfonylurea treatment, although multiple doses of repaglinide per day are necessary. Repaglinide is administered as 0.5 mg to 4.0 mg before each meal, and the dose can be adjusted on the basis of the estimated calories and content of the meal (83,85).

Monotherapy with repaglinide in patients with type 2 diabetes was found to reduce mean HbA_{1c} by 1.7% and mean FPG by 62 mg/dL as compared with placebo treatment. One-year trials showed that the antihyperglycemic effects of repaglinide and glyburide are equivalent (86). Although repaglinide-treated patients experience hypoglycemia and weight gain, the magnitude is significantly less than with glyburide.

Repaglinide is metabolized by the liver, and 90% of the dose is excreted in the bile. Therefore, repaglinide is not contraindicated in patients with type 2 diabetes who have impaired renal function. The dose of repaglinide should be reduced in patients with clinically significant liver disease.

Nateglinide

Nateglinide is a D-phenylalanine derivative (Fig. 41.9) that does not contain a sulfonylurea moiety, is rapidly absorbed, and binds to the SUR-1 subunit of the K_{ATP} channel with binding characteristics quite different from those of sulfonylureas (43). When nateglinide is administered 10 minutes before the meal, its peak plasma level is achieved at a mean time of 0.92 hours and its mean half-time disappearance rate in plasma is 2.14 hours (10,87). Oral bioavailability is estimated to be 72%. The drug is metabolized by the mixed-function oxidase system of the liver (CYP3A4 and CYP2C9) before excretion (87). The drug and its metabolites are eliminated rapidly and completely. If nateglinide is taken after the meal, its rate of absorption is decreased, resulting in a 22% increase in the time to maximal plasma levels.

Binding and displacement studies with nateglinide and the β -cell K_{ATP} channel indicate that it dissociates very rapidly. Inhibition of the K_{ATP} channel current by the patch-clamp technique and its reversal confirm the rapid and short duration of nateglinide action on the channel. Nateglinide selectively binds to the K_{ATP} channel of the β -cell and binds relatively little to the K_{ATP} channel of vascular smooth muscle (relative binding, 45- to 311-fold relative selectivity) (51). It has a 1.6-fold selectivity for inhibition of the β -cell K_{ATP} channel current as compared with the cardiac K_{ATP} channel current. These properties of nateglinide are predictive of a rapid and short duration of stimulation of insulin secretion with little or no potential for effects on cardiac or vascular tissues.

Clinical data are consistent with what would be predicted from the pharmacologic properties. Administration of nateglinide to fasted patients with type 2 diabetes caused a small increase in plasma insulin levels (4–5 μ U/mL), which peaked within an hour and caused a small decrease in plasma glucose over the 4-hour period following dosing (10,88,89). In contrast, when nateglinide was given to the same individuals 10 minutes before a meal, the plasma insulin levels increased by 30 minutes, peaked at 2 hours, and declined at 3 hours to those levels seen following treatment with placebo (88). Nateglinide increased meal-mediated plasma insulin levels in a dose-dependent manner, with a maximum effective dose of 120 mg.

When administered as monotherapy for 12 weeks to patients with type 2 diabetes whose glucose levels were inadequately controlled by diet and exercise (mean HbA_{1c} 8.4%; mean FPG 182 mg/dL), a dose of 120 mg administered 10 minutes before meals resulted in a decrease in HbA_{1c} of 0.55% and in a reduction in FPG of 21 mg/dL (10). A large randomized double-blind study in patients with type 2 diabetes, with washout of their previous treatment for 4 weeks, compared 24 weeks of treatment with 120 mg of nateglinide before each meal to 500 mg of metformin three times a day and to a combination of metformin

and nateglinide (89). Placebo treatment resulted in a 0.5% increase in HbA_{1c}, whereas metformin treatment resulted in a 0.8% decrease and nateglinide treatment resulted in a 0.5% decrease. Combination nateglinide-metformin therapy resulted in greater improvement in glycemic control (1.4% decrease in HbA_{1c} and 40 mg/dL decrease in FPG) than did either drug alone. The major benefit of nateglinide treatment is a reduction in the postprandial glucose excursions.

The potential side effect of nateglinide is hypoglycemia. In the clinical studies completed to date, hypoglycemia appeared to be relatively uncommon and mild.

INSULIN SECRETOGOGUES AND CARDIOVASCULAR EFFECTS

Starting with the report of the results of University Group Diabetes Program in 1970, there has been an ongoing concern about whether sulfonylureas have a detrimental effect on the cardiovascular system (90). In that study, the authors noted that chronic treatment of patients with type 2 diabetes with tolbutamide for 8 years was associated with a statistically significant 75% increase in cardiovascular mortality as compared with the mortality in the placebo-treated controls. The design and results of that study were extensively criticized throughout the 1970s, and several subsequent studies failed to confirm their findings.

In the 1980s, K_{ATP} channels were found to be present in the plasma membranes of myocardial and vascular smooth muscle cells and in pancreatic β -cells, and ischemic preconditioning was discovered (91,92). Ischemic preconditioning is the phenomenon whereby a short period of ischemia followed by reperfusion transiently protects the myocardium from a subsequent more severe and prolonged ischemia and reduces the area of infarction in the ischemic region by as much as 75% to 80%. Information has accumulated that indicates that the mechanism responsible for ischemic preconditioning involves an opening of the myocardial and coronary artery KATP channels by the metabolic consequences of ischemia (93). The effects are an increase in K⁺ efflux and a reduction in Ca²⁺ influx into the cells. The consequences are a shortening of the duration of the myocardial action potential, a reduction in contractility, energy conservation by the myocardium, and vasodilatation by the coronary artery. Another consequence of the K⁺ changes, however, is a possible increase in ventricular arrhythmias.

When it was recognized that the primary action of sulfonylureas is to close the K_{ATP} channels in the pancreatic β -cells, the question arose as to the possible effects of sulfonylureas on cardiovascular K_{ATP} channels and whether sulfonylurea treatment might interfere with the protective effects afforded by the opening of K_{ATP} channels by ischemia in cardiovascular tissues (94). A series of studies were carried out, first in animal models and subsequently in humans, that have demonstrated that doses of glyburide in the range of the maximal prescribed doses can block ischemic preconditioning, presumably by closing the K_{ATP} channel (95,96).

The clinical significance of these observations is not clear. A retrospective study from the Mayo Clinic reported that patients with diabetes undergoing angioplasty for acute myocardial infarction had a risk of early mortality 2.77 times greater than patients receiving no therapy or receiving insulin (97). The Bypass Angioplasty Revascularization Investigation reported that patients with diabetes had greater long-term mortality following angioplasty than did patients without diabetes, but the two groups had similar mortality following bypass surgery. The sulfonylurea-treated patients in particular had greater mortality 4 to 7 years after the angioplasty (98). In contrast, Klamann et al. (99) have reported no increase in mortality or infarct size in a cohort of 245 patients with type 2 diabetes taking glyburide

who were admitted with an acute myocardial infarction and followed for a mean of 6.5 years as compared with those not taking a sulfonylurea. Some investigators have indicated that patients with diabetes treated with glyburide may have a lower rate of ventricular arrhythmias.

All of the clinical and animal studies showing effects of the sulfonylureas on ischemic preconditioning have used glyburide as the sulfonylurea. The binding affinities of glyburide for the K_{ATP} channels in cardiovascular tissues and for those of the β cell are almost equal (51). Tolbutamide has virtually no binding activity to the SUR-2 subunits (those in $K_{\mbox{\scriptsize ATP}}$ channels in cardiovascular tissues). Glimepiride had no effect on blocking ischemic preconditioning in human studies in which glyburide abolished it (77). The non-sulfonylurea insulin secretogogues have very little binding affinity for the SUR-2 subunits and have a very high specificity for the SUR-1 (β -cell subunit) (51). Summarizing the data, one can make the following conclusions: (a) it is likely that insulin secretogogues with relatively equal specificity for the SUR-1 and SUR-2 subunits could affect cardiovascular responses under specific conditions; (b) the only condition under which a drug that closes the KATP channel might interfere with normal cardiovascular responses is one in which there is transient ischemia followed shortly thereafter by more prolonged ischemia; (c) the effects would be manifest as a greater area of infarction; (d) maximum doses of glyburide are most likely to interfere with the cardiovascular responses to ischemia; and (e) the new non-sulfonylurea insulin secretogogues are much less or not at all likely to produce those effects. Despite all of the studies, the question of whether sulfonylurea treatment has detrimental cardiovascular effects in humans remains controversial. There are currently no clinical data that unequivocally demonstrate an adverse effect of glyburide on outcomes related to cardiovascular events.

Insulin Sensitizers

The majority of patients with type 2 diabetes have insulin resistance and the metabolic disease syndrome as a component of their disorder. The normal compensatory response to insulin resistance is a sufficient increase in insulin secretion to overcome the insulin resistance and maintain normal glucose metabolism. Glucose intolerance is an indication that the individual's β-cells are not secreting enough insulin to overcome the insulin resistance adequately. The evolution of glucose intolerance in these individuals progresses from normal glucose tolerance with insulin resistance and compensatory hyperinsulinemia, to IGT with insulin resistance and decreasing compensatory hyperinsulinemia, to type 2 diabetes with insulin resistance and frankly inadequate secretion of insulin. A reduction in insulin resistance at each and every stage of the evolution of type 2 diabetes in such individuals will improve glucose metabolism by allowing their endogenous insulin to be more effective (77.100)

Additional benefits to be accrued from reducing insulin resistance are amelioration of some components of the metabolic syndrome (insulin resistance syndrome). These components increase macrovascular disease risk, and reduction of the components of the metabolic syndrome are as important to the health of the individual with type 2 diabetes as is the treatment of the hyperglycemia (101–103). Treatment of insulin resistance at the stage of IGT with metformin can slow the progression to type 2 diabetes by 31% over 3 years, although this effect is not as great as that with intensive lifestyle modification, which slows progression by 58% over 3 years (104). Thiazolidinedione treatment may also be highly effective in delaying or preventing the development of type 2 diabetes in insulin-resistant individuals, as troglitazone treatment of women with previous gestational diabetes decreased the development of diabetes by 56% over 30 months (TRIPOD study) (100). It has been postulated that treatment of insulin resistance itself in the absence of glucose intolerance may slow the development of atherosclerosis and macrovascular disease (36,101,103). Clinical trials to evaluate this possibility are under way.

The high prevalence of insulin resistance worldwide and its impact as a contributor to the development of so many diseases has made the discovery of drugs for the treatment of insulin resistance a very high priority for the pharmaceutical industry. Currently, two classes of oral agents, the biguanides and thiazolidinediones, are available to treat insulin resistance, and both are important agents for the treatment of type 2 diabetes. Metformin is the only widely available biguanide. Rosiglitazone and pioglitazone are the currently available thiazolidinediones. Troglitazone, which was the first thiazolidinedione to be marketed, was withdrawn from the market because its treatment was associated with rare cases of idiosyncratic liver toxicity with liver failure and death.

METFORMIN

Mechanism of Action

Metformin, a biguanide, has been used in the treatment of type 2 diabetes since the 1960s. Its mechanism of action has been studied extensively, and although many metabolic effects have been described in in vitro systems and animal models, the molecular and biochemical sites of action have eluded discovery (105–107). Metformin exerts several physiologic effects that contribute to its ability to decrease hyperglycemia in patients with type 2 diabetes. Patients taking metformin frequently complain of a metallic taste and often have some degree of anorexia (108). Treatment of patients with type 2 diabetes is usually associated with a mean weight loss of 2 to 3 kg, which is due primarily to a decrease in adipose tissue (52,109). This effect has been obscured in some studies by confounding weight gain associated with improved glycemic control and a reduction in glycosuria. Though not well documented, the weight loss usually is associated with a decrease in appetite. Recent studies show that the percent reduction in the visceral adipose tissue depot is significantly greater than that in the subcutaneous or total adipose tissue pool (110). The ability of metformin to increase insulinmediated glucose disposal in skeletal muscle appears to be at best quite modest. Studies in the 1980s using the euglycemic hyperinsulinemic-clamp technique demonstrated that metformin significantly increased insulin-mediated glucose uptake by muscle. Those studies, however, did not control for weight loss or reduction in glucose toxicity resulting from improved glycemic control. Several subsequent studies in which weight loss was not a factor failed to show a significant effect of metformin on insulin-mediated glucose uptake in peripheral tissues. Two more recent studies, which were specifically designed to eliminate changes in weight and differences in glycemic control, found no effect and a small increase in insulin-mediated peripheral glucose uptake, respectively (9, 111). In contrast, all well-designed studies have shown marked effects of metformin in decreasing the elevated hepatic glucose production that is associated with fasting hyperglycemia (20, 109,112). The decrease in hepatic glucose production by metformin appears to be due primarily to a decrease in gluconeogenesis, although there is some contribution from a decrease in glycogenolysis (112). Administration of metformin has been shown to lower plasma levels of free fatty acids and to increase lipid oxidation in some, but not all, studies. The effects on lipid metabolism are modest and not likely to play a major role in

decreasing hepatic glucose production (20,109,112,113). Metformin has no direct effects on pancreatic β -cells and does not influence insulin secretion directly but only through its influences on changing plasma glucose levels.

Pharmacokinetics and Metabolism

Metformin is incompletely and slowly absorbed from the small intestine, with a bioavailability of 50% to 60% from a 500-mg tablet taken in the fasting state (114). Absorption decreases with increasing dose, and administration with food decreases the extent of and slightly delays absorption. Peak plasma concentrations reach 1 μ g/mL to 2 μ g/mL 1 to 2 hours after an oral dose of 500 mg to 1,000 mg. Metformin is not bound to plasma proteins, has a plasma half-life of 1.5 to 4.9 hours, is not metabolized, and is rapidly cleared by the kidney (90% within 12 hours). These properties of metformin are quite important, since the drug does not accumulate in the body, and excessive plasma levels are unlikely to occur in the presence of normal renal function. These properties are in contrast to those of phenformin, a biguanide that is no longer available in most countries because of its occasional association with the development of lactic acidosis. Dose-response studies of the effect of metformin on glycemic control in patients with type 2 diabetes indicate that maximal effects occur at dosages of 1,750 to 2,000 mg per day (115). Metformin is administered twice or three times a day with meals, because that minimizes the gastrointestinal side effects.

Metformin is now also marketed as a long-acting preparation (metformin hydrochloride extended-release tablets). The peak plasma level following oral administration of this preparation occurs at 4 to 8 hours and is 20% lower than that following a comparable dose of the regular formulation of metformin (114). The extended-release formulation is administered at dosages of 500 to 2,000 mg given once daily with the evening meal. The peak plasma level attained with 1,000 and 2,000 mg were 1.1 μ g/mL and 1.8 μ g/mL, respectively.

Clinical Use

Administration of metformin to patients with type 2 diabetes results in a decrease in hepatic insulin resistance. The consequence is an increase in the effectiveness of endogenous portal vein insulin and a resultant decrease in hepatic glucose production and fasting hyperglycemia (9,109,112). Fasting plasma insulin levels are either unchanged or modestly reduced. A reduction in insulin resistance of muscle is a less consistent and relatively minor effect of metformin. Metformin treatment generally reduces hyperglycemia by approximately the same magnitude as sulfonylurea treatment, even though their mechanisms of action are entirely different (52,116).

While many clinical studies measuring the effects of metformin treatment in patients with type 2 diabetes have been published, relatively few have been randomized, been placebo-controlled, included large numbers of subjects, had treatment periods extending for more than a few months, and had adequate assessments of glycemic control. The registration studies done for metformin approval in the United States (116) and the UKPDS provide the best data relative to the clinical effectiveness of metformin (3). In the registration studies, metformin monotherapy in obese subjects with type 2 diabetes (mean baseline HbA_{1c} and FPG 8.3% and 240 mg/dL, respectively) for 29 weeks lowered mean HbA_{1c} 1.8% and mean FPG 58 mg/dL compared with placebo-treated controls. The glucose-lowering effect was greatest in subjects with the highest HbA_{1c} and FPG values and the least in those with the lowest HbA_{1c} and FPG values. The effect of metformin on glycemic control was due primarily to a decrease in FPG, as there was

41: ORAL ANTIHYPERGLYCEMIC AGENTS FOR TYPE 2 DIABETES 699

no significant reduction in the postprandial glucose excursions. Fasting plasma insulin and C-peptide levels were unchanged. Body weight did not change significantly. Metformin treatment resulted in small decreases in serum total cholesterol, low-density lipoprotein (LDL) cholesterol, and triglycerides.

In the UKPDS, 342 obese patients with newly diagnosed type 2 diabetes were randomized to metformin treatment and followed for a median duration of 10.7 years. The median HbA_{1c} for the first 5 years of metformin treatment was 6.7%. For the same time interval, the conventional control group had a value of 7.5%. For the second and third 5-year periods, the median HbA_{1c} for the metformin-treated group was 7.9% and 8.3%, respectively. Throughout the study, the median difference between the metformin and conventionally treated groups was 0.6%. Metformin treatment was associated with no weight gain, with a decrease in fasting plasma insulin levels, and with no significant incidence of hypoglycemia.

Studies comparing the effects of metformin and sulfonylureas on glycemic control in patients with type 2 diabetes consistently show equivalence, even though their modes of action are entirely different. The practical consequence of this finding is that replacement of sulfonylurea treatment by metformin or metformin by sulfonylureas does not improve glycemic control (116). There are, however, differences in effects on body weight and the incidence of hypoglycemia. In a 1-year study in which patients of normal weight were randomized to metformin or chlorpropamide, glycemic control in the two groups was remarkably the same, but the chlorpropamide-treated patients gained a mean of 4.6 kg while the metformin-treated patients lost a mean of 1.5 kg (117). Hypoglycemia does not occur with metformin monotherapy (105-107). Combining the two oral agents, however, is additive because they lower glycemia equally but by different mechanisms.

Metformin treatment has beneficial effects on many aspects of the insulin resistance syndrome (metabolic disease syndrome): it decreases obesity and particularly central obesity; has a small beneficial effect on decreasing serum triglycerides and LDL cholesterol; improves fibrinolysis by decreasing plasminogen activator inhibitor 1 (PAI 1); and frequently decreases plasma insulin levels (105,109,113). The metabolic disease syndrome is associated with an increase in clinical macrovascular disease. A drug that improves some or all of the components of the metabolic disease syndrome would be expected to decrease macrovascular disease. One of the major findings of the UKPDS was that treatment of the overweight patients with type 2 diabetes with metformin reduced the risk of myocardial infarction by 39% and of diabetes-related deaths by 42% (3). Those were highly significant reductions when compared with conventional treatment, but not when compared with the other intensive treatments, which were associated with small but statistically insignificant reductions even though they reduced HbA_{1c} to a degree equivalent to that with metformin.

While the data from the metformin primary prevention arm of the UKPDS appear valid, a substudy in the UKPDS comparing the effect of adding metformin to the regimen of patients poorly controlled with sulfonylureas showed a statistically significant increase in cardiovascular mortality when compared with those randomized to added placebo (3). A further analysis of the data compared with the results of the entire study suggested that the results were due to an unexplained decrease in mortality in the sulfonylurea-plus-placebo group rather than an increase in mortality in the sulfonylurea-plus-metformin group. Two recent retrospective studies have reported that diabetic patients treated with sulfonylureas plus metformin have a higher mortality than those treated with diet or sulfonylureas alone. A study of 2,275 patients with diabetes and coronary disease in Israel who were followed for a mean of 7.7 years found an increase in mortality in patients who received metformin in combination with glyburide compared with those on dietary or glyburide management alone (118). A Swedish study reported an increase in mortality in 169 patients taking sulfonylureas in combination with metformin as compared with 741 patients taking sulfonylureas alone (119). The major flaws in these studies are the lack of randomized cohorts, which means the groups are not comparable, and the retrospective analysis, which implies dissimilar care during the follow-up period. The substudy and two retrospective studies suggest that a definitive long-term study of the safety and efficacy of combination sulfonylurea and metformin therapy would be useful.

Side Effects

The major complications associated with metformin treatment are gastrointestinal symptoms (105,106,116). In general, the symptoms are dose-related and transient. They have been reported to occur in 5% to 20% of patients. The most common gastrointestinal symptoms are metallic taste, anorexia, nausea, abdominal pain, and diarrhea. Gastrointestinal symptoms can be minimized by starting therapy with low doses of metformin (500 mg) and increasing the dose slowly. Taking the drug with meals decreases the symptoms, and it is useful to initiate drug therapy with the evening meal.

Lactic acidosis is the most frequently discussed complication, although it is extremely rare and almost always occurs in clinical situations in which metformin is contraindicated (105,106,120). The reported incidence of lactic acidosis in patients receiving metformin is 3 per 100,000 patient years; the fatality rate is 50%. Almost all cases of lactic acidosis during metformin therapy have occurred in patients with impaired renal function or those who have illnesses that predispose to impaired renal function. Metformin is contraindicated in those patients (Table 41.6).

TABLE 41.6. Contraindications for Metformin Treatment Decreased renal function: plasma creatinine ≥1.5 mg/dL for men and ≥1.4 mg/dL for women or a creatinine clearance <60 mL/min</td> Patients with congestive heart failure requiring pharmacologic management Patients ≥80 years of age unless a creatinine clearance demonstrates adequate renal function Liver disease Chronic alcohol abuse Sepsis or other acute illness with decreased tissue perfusion During intravenous radiographic contrast administration From Glucophage; Glucophage XR prescribing information. Bristol-Myers Squibb Co. Revised October 2000, with permission.

Vitamin B_{12} malabsorption was found in 30% of patients with diabetes during long-term treatment with metformin. In the large U.S. registration studies, serum vitamin B_{12} levels were decreased 29% during metformin treatment. Megaloblastic anemia during metformin treatment is very rare and can be treated by administering vitamin B_{12} . The mechanism of the malabsorption is unknown.

THIAZOLIDINEDIONES

Mechanism of Action

The thiazolidinediones were discovered in the late 1970s during screening for lipid-lowering agents. Ciglitazone, which was the original compound, was noted to reduce hyperglycemia, hyperinsulinemia, and hypertriglyceridemia in rodent models of insulin-resistant diabetes. During the 1980s, many derivatives containing the glitazone structure were synthesized and evaluated. The three thiazolidinediones eventually approved for clinical use were troglitazone, rosiglitazone, and pioglitazone (Fig. 41.10). Troglitazone was the first to be marketed and had reasonable efficacy in reducing insulin resistance and improving hyperglycemia in type 2 diabetes (121). Its use, however, was associated with the rare development of idiosyncratic liver toxicity, which could progress to hepatic failure and death, and troglitazone was removed from the market in March 2000 (122, 123). Rosiglitazone and pioglitazone have been approved for the treatment of type 2 diabetes since mid-1999. No evidence of significant liver toxicity has been found with either rosiglitazone or pioglitazone after almost 2 years of use and the treatment of more than 2 million patients (124).

The mechanism of action of the thiazolidinediones was discovered after their clinical effectiveness had been established. The thiazolidinediones were found to be ligands for an orphan receptor known as the peroxisome proliferator–activated receptor (PPAR) (125-127). This receptor is a member of the nuclear receptor superfamily of ligand-activated transcription factors. It is a heterodimer consisting of two subunits: one that binds thiazolidinediones and one that binds retinoids (Fig. 41.11). There are three subtypes of PPARs: PPAR- α , PPAR- δ , and PPAR- γ . The three subtypes have distinct actions. All three bind to specific response elements of genes that have central roles in the storage and catabolism of fatty acids. PPAR- α is present at high concentrations in the liver and is activated by fibrates, which are pharmacologic ligands for the receptor. PPAR- δ is ubiquitous, and its activation by specific pharmacologic ligands has a profound influence on lipoprotein metabolism. PPAR-y is the receptor to which thiazolidinediones bind. The natural ligands for each of the PPARs are unknown, and the physiology of each is being studied actively. The three-dimensional structures of the PPAR class of receptors, as well as the sites involved that characterize each of the subtypes, have been defined, and it is now possible to design molecules that activate a single specific subtype or several subtypes simultaneously.

When thiazolidinediones bind to the PPAR- γ heterodimer, the heterodimer becomes activated and attaches to the PPAR- γ response elements of genes that contain such an element (Fig. 41.11). Binding to the response element is followed by incorporation of activator and inhibitor molecules, and gene transcription is either activated or inhibited. The specific genes that are PPAR γ responsive are numerous (e.g., lipoprotein lipase, fatty acid–binding proteins, PEPCK) and involve the regulation of lipid metabolism, insulin action, and adipose tissue differentiation.

The major pharmacologic actions of thiazolidinediones *in vivo* are to increase insulin-mediated glucose uptake (decrease in insulin resistance) in muscle and to increase adipogenesis (37,128–131). Considerable controversy exists concerning the mechanism of both of these actions. PPARγ receptors are

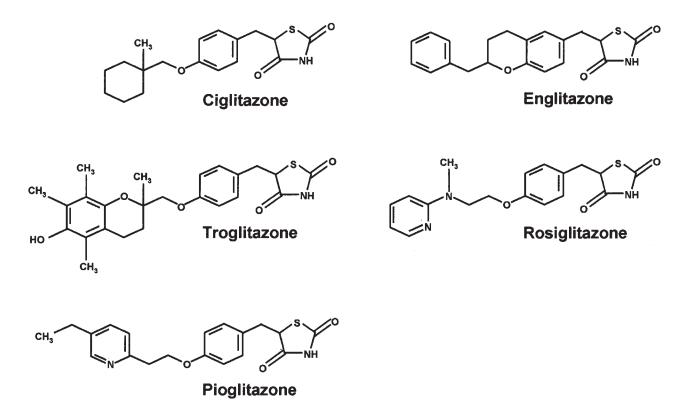

FIG. 41.10. Structure of commonly studied and currently available glitazones.

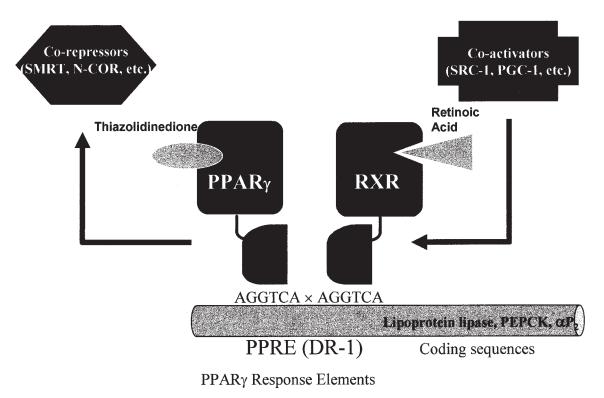

FIG. 41.11. Mechanism of action of thiazolidinediones. Thiazolidinediones bind to the PPARy receptor of a heterodimeric intranuclear transcription factor. The activated transcription factor binds to genes with a PPARy response element and, after interactions with appropriate coactivators and coinhibitors, either activates or inhibits transcription of the genes. (Adapted from Forman BM, Tontonoz P, Chen J, et al. 15-Deoxy-delta 12,14 prostaglandin J2 is a ligand for the adipocyte determination factor PPARy. *Cell* 1995; 83:803–812.)

expressed primarily in adipose tissue (>10-fold higher than in muscle), yet the major quantitative effect in improving total body insulin sensitivity occurs in muscle. One strain of genetically engineered mice that lack adipose tissue (A-ZIP/F-1 phenotype) fail to respond to troglitazone or rosiglitazone therapy by a reduction in insulin resistance and hyperglycemia (132). In contrast, another genetically altered mouse (aP2/DTA) that has little or no white or brown adipose tissue responds to troglitazone with the expected improvement in insulin resistance and hyperglycemia (133). The latter data plus muscle cell culture studies showing that troglitazone increases glucose uptake suggest the possibility that the small number of PPAR-y receptors in muscle and liver might mediate the insulin-sensitizing effects of thiazolidinediones. Recent studies, however, have emphasized that products released from adipose tissue such as free fatty acids and their metabolic derivatives rather than adipose tissue itself mediate the insulin resistance in muscle (7,134), and these products are elevated in the mice without peripheral adipose tissue (132). Other studies show that thiazolidinediones act on adipose tissue to decrease not only the circulating levels of free fatty acids but also protein factors such as tumor necrosis factor- α , resistin, and leptin that are released from adipose tissue and that can cause insulin resistance in muscle (135,136). Thiazolidinediones also stimulate the release of an adipose tissue hormone, adiponectin, which is associated with increased hepatic insulin sensitivity (137). Thus, whether the improvement in insulin action is secondary to a primary action on adipose tissue, is a specific effect on free fatty acid metabolism, or is a direct effect on muscle has not yet been resolved (125-127, 129). The second major unresolved issue is how a drug that increases the quantity of adipose tissue can decrease insulin

resistance. In rodents, thiazolidinediones increase the number of small adipocytes and decrease the number of large adipocytes (138). The smaller cells are more sensitive to insulin and have a lower rate of lipolysis. In humans, thiazolidinediones increase adipogenesis in subcutaneous adipose tissue but have no effect on visceral adipose tissue (139,140). Thus, thiazolidinediones appear to facilitate adipogenesis but in a way that improves insulin sensitivity.

PPAR- γ receptors are present in moderate concentrations in macrophages, colonic epithelium, and endothelial and vascular smooth muscle cells. Their functions in these tissues are being investigated actively, as is the therapeutic potential of these drugs for the treatment of inflammatory bowel disease and the early lesions of atherosclerosis.

Pharmacokinetics and Metabolism

Rosiglitazone and pioglitazone are rapidly and well absorbed orally (141,142). Both are extensively metabolized in the liver by the CYP450 isoenzymes—rosiglitazone by CYP2C8 and CYP2C9 and pioglitazone by CYP2C8, CYP3A4, and several other CYP isoenzymes. Approximately two thirds of the rosiglitazone dose is excreted in the urine and approximately one third in the bile, whereas two thirds of the pioglitazone dose is excreted in the feces and one third in the urine. The plasma half-life of rosiglitazone is 3 to 4 hours and that of pioglitazone and its active metabolites is 16 to 24 hours. Both drugs can be administered safely to individuals with impaired renal function.

Clinical Use

Rosiglitazone is administered in doses of 4 to 8 mg given once or twice daily (130,141). Pioglitazone is given in doses of 15 to

45 mg administered once daily (131,142). These differences in effective doses reflect to some degree the differences in binding affinities of these two drugs for the human PPAR-y receptor. When administered to patients with type 2 diabetes who are inadequately controlled with diet and increased physical activity, rosiglitazone at 4 and 8 mg daily decreased HbA1c and FPG 1.2% and 58 mg/dL and 1.5% and 76 mg/dL, respectively. Pioglitazone at 15 and 45 mg daily decreased HbA_{1c} and FPG 1.0% and 39 mg/dL and 1.6% and 65 mg/dL, respectively. These data reflect comparisons to placebo treatment in the same studies. Of the patients treated with rosiglitazone at 4 mg twice a day, 59% achieved a HbA1c level of less than 8% and 30% achieved a level less than 7%. The data on glycemic control with monotherapy indicate that the two thiazolidinediones are similar in efficacy. Because the patient populations studied had somewhat different clinical characteristics (patients treated with pioglitazone had poorer baseline glycemic control, were more obese, and were hypertriglyceridemic than those treated with rosiglitazone), any subtle differences noted in the responses to the two drugs may have been due to differences in the responsiveness of the different populations rather than any true differences of the effects of the drugs. Any presumed differences need to be substantiated by a comparison of comparably effective doses of the two drugs in the same randomized controlled study.

In addition to improving glycemic control, both pioglitazone and rosiglitazone improve many of the components of the insulin resistance syndrome (29,127–129). Both improve insulin sensitivity and decrease plasma insulin levels. Both improve the dyslipidemia characteristic of insulin resistance, that is, they both consistently increase plasma HDL cholesterol and have some effects on lowering plasma triglycerides. Differences in the effects of pioglitazone and rosiglitazone on dyslipidemia have been reported (143). Rosiglitazone produced a small increase in plasma concentrations of LDL cholesterol and reduced plasma triglycerides only if they were elevated. Preliminary data indicate that these changes may be due to a shift in the characteristics of the LDL particles from small, dense, very atherogenic particles to large, buoyant, less atherogenic ones and not to an increase in the number of particles. Pioglitazone treatment has been associated with a general reduction in plasma triglycerides and no increase in plasma levels of LDL cholesterol. As noted previously, a comparison of the effects of the two drugs on dyslipidemia in the same randomized study is necessary to clarify whether these drugs do indeed have somewhat different effects on serum lipids and lipoproteins.

The thiazolidinediones decrease plasma levels of PAI-1, which reduces the inhibition of fibrinolysis that is characteristic of insulin resistance (144). One of the more striking effects of treatment of patients with type 2 diabetes with thiazolidinediones is a 20% to 25% reduction in plasma levels of free fatty acids (130). Several studies have shown that thiazolidinediones reduce rates of urinary excretion of albumin independent of their effects on improving glycemia (145). The thiazolidinediones cause an increase in subcutaneous adipose tissue (~5%–8%) but either have no effect or slightly reduce visceral adipose tissue (128,146). Preliminary data indicate that thiazolidinediones improve the endothelial dysfunction that is characteristic of insulin resistance (16).

The decline in β -cell function characteristic of type 2 diabetes has been postulated to be related in part to detrimental effects of insulin resistance (147). Insulin resistance increases β -cell secretory function and as such increases the metabolic activity of the β -cell and also increases the secretion of amylin. Increased secretion of amylin can result in increased amyloid deposits within the islets and in destruction of β -cells. Increased metabolic activity of genetically programmed β-cells could lead to increased rates of apoptosis. It has been postulated that thiazolidinediones, by reducing insulin resistance, might decrease the rate of β -cell loss in patients with type 2 diabetes. Controlled studies comparing glyburide treatment with rosiglitazone for 1 year show better preservation of glucose control with rosiglitazone. One-year studies are inadequate to prove β-cell preservation and need to be followed up by 3- to 5-year studies. Studies in two rodent models of insulin-resistant diabetes have shown that rosiglitazone treatment does preserve β -cells in that setting (148). Recently reported studies (TRIPOD study) have shown that the administration of troglitazone to women who had previously had gestational diabetes decreases the rate of β -cell loss and can prevent the development or progression of type 2 diabetes (100). This effect is likely due to its reduction in insulin resistance, an effect shared by the two available thiazolidinediones, rosiglitazone and pioglitazone.

Side Effects

The major side effects observed with rosiglitazone and pioglitazone have been fluid retention with peripheral edema and, in unusual circumstances, congestive heart failure, and weight gain (37,128,141,142). Idiosyncratic liver toxicity with liver failure developed in a few people treated with troglitazone who then died. The clinical trials with troglitazone showed some changes in liver function that in retrospect were probably signals of potential hepatotoxicity (130). Serum alanine aminotransferase (ALT) levels greater than three times the upper limit of the reference range (ULRR) were recorded in 1.9% of the patients with type 2 diabetes treated with troglitazone compared with 0.6% of those who received placebo (Fig. 41.12). As many as 0.68% of the troglitazone-treated patients had serum ALT values 10 times or greater than the ULRR, and jaundice developed in two patients that reversed on drug withdrawal. In contrast, neither rosiglitazone nor pioglitazone showed any signal of hepatotoxicity during their clinical trials, and after approximately 2 years on the market, no significant severe hepatotoxicity has been associated with either drug.

A small increase in plasma volume appears to be related to activation of the PPAR-y receptor, as judged by a small decrease in hemoglobin and hematocrit values (0.6 g/dL and 2.8%, respectively) (130,131). This change was not accompanied by any alteration in red blood cell mass in any patients with diabetes treated with any of the thiazolidinediones. Mild-to-moderate peripheral edema is observed in 3% to 5% of patients treated with a thiazolidinedione as monotherapy (37,128,130, 131). This increases to approximately 15% in patients treated with the combination of pioglitazone and insulin (128). The mechanism for the development of edema is presently unknown. The edema responds poorly to loop diuretics and inhibitors of angiotensin-converting enzymes. Rarely, severe edema can develop that is reversed with discontinuation of the drug. It is unclear to what extent thiazolidinedione treatment might precipitate heart failure in a susceptible patient, as there are no controlled data. It might be anticipated that an individual in borderline congestive heart failure would develop clinical failure if the plasma volume were expanded significantly. There is no evidence in 1- and 2-year studies of cardiovascular function that the thiazolidinediones have any detrimental effect on myocardial function (149).

The weight gain associated with thiazolidinedione treatment is due to a combination of fluid retention and an increase in adipose tissue. A primary action of thiazolidinediones is the differentiation of stem cells into adipocytes (126,127). In humans, PPAR- γ agonists differentiate subcutaneous adipose tissue stem cells into small adipocytes but appear to have no effect on the

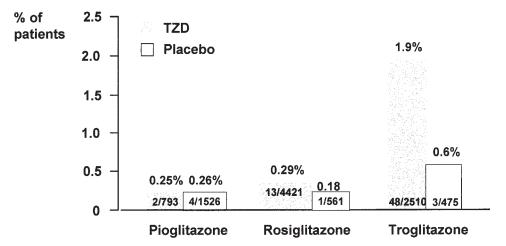

FIG. 41.12. The results of monitoring alanine aminotransferase (ALT) levels in the phase three clinical trials of troglitazone, rosiglitazone, and pioglitazone. The percentage of subjects with any ALT that is greater than three times the upper limit of the reference range (ULRR) is reported. Troglitazone treatment was associated with a significantly higher rate of abnormal values than was the placebo control. Neither rosiglitazone nor pioglitazone treatment showed any differences in abnormal values from their placebo controls.

differentiation of visceral adipose tissue stem cells (140). Several studies have examined the effect of either troglitazone or rosiglitazone on weight gain and adipose tissue distribution. All studies show a significant increase in total body fat and subcutaneous adipose tissue mass. Mass of visceral adipose tissue is usually not changed (128,146,150).

The effects on expansion of plasma volume usually are seen in the first 12 weeks of treatment and probably stabilize by 6 months. The few long-term studies on weight gain show increases that tend to slow down and stabilize after 12 months of treatment. Careful long-term studies of both edema and weight gain are needed to clarify these issues.

Potential Cardiovascular Benefits

Thiazolidinediones ameliorate many of the components of the insulin resistance syndrome, and one might anticipate that such actions would decrease the cardiovascular complications of type 2 diabetes (128,151). At the present time, clinical outcome studies are limited to a few preliminary observations that thiazolidinedione treatment preserves the patency of coronary artery stents by slowing the proliferation of the cells of the intima and media. There are many observations of improvement of endothelial function in vivo. The improvement of the dyslipidemia by increasing plasma high-density lipoprotein cholesterol, lowering elevated plasma triglycerides, and shifting LDL particles from small-dense to large-buoyant particles are significant and consistent effects of thiazolidinediones, as is the improvement in the procoagulant state. Although the current data are insufficient to recommend thiazolidinediones as primary treatment for improving macrovascular outcomes in patients with type 2 diabetes, one needs to be aware of the potential of these agents. Outcome studies are under way to determine the effects of these agents on clinical cardiovascular events.

α -GLUCOSIDASE INHIBITORS

The recognition of the importance of controlling postprandial hyperglycemia began when pharmacologic agents specifically targeted at postprandial plasma glucose levels became available. The first group of these agents were oral agents specifically designed to delay postprandial carbohydrate digestion and lower postprandial plasma glucose excursions. The α -glucosidase inhibitor acarbose is a pseudotetrasaccharide of microbial origin that was isolated and purified in the late 1970s and approved for the treatment of type 2 diabetes in the early 1990s (152). It acts exclusively on the gastrointestinal tract and specifically lowers postprandial glucose excursions.

Mechanism of Action

The digestion of complex carbohydrates involves initial cleavage by amylases in the small intestine into oligosaccharides (11, 153). Oligosaccharides are poorly absorbed and have to be cleaved into monosaccharides before absorption through the intestinal mucosa. The cleavage of oligosaccharides into monosaccharides occurs in the brush border of the enterocytes and is carried out by a variety of α -glucosidase enzymes (glucoamylase, sucrase, maltase, dextrinase, and isomaltase). The monosaccharides generated are absorbed rapidly. The digestion of complex carbohydrates normally occurs in the distal duodenum and proximal jejunum.

The cleavage of the oligosaccharides by the α -glucosidase enzyme involves binding of the oligosaccharides to a binding site on the enzyme, followed by hydrolytic cleavage. The α -glucosidase inhibitors compete with the oligosaccharides for the binding site. They bind to the site but cannot be hydrolyzed. They are classic competitive inhibitors. The mechanisms of action of the different α -glucosidase inhibitors are similar though not identical. Acarbose binds to glucoamylase, maltase, sucrase, and dextrinase. It binds to intestinal sucrase with a binding affinity 10⁴ to 10⁵ greater than that to sucrose. Acarbose has minimal effects on isomaltase and no effect on lactase, which is a β -glucosidase enzyme. Acarbose is also an inhibitor of pancreatic amylase. Voglibose inhibits most α-glucosidase enzymes but is weaker than acarbose at inhibiting sucrase and has little effect on pancreatic amylase. Neither acarbose nor voglibose interferes with glucose absorption through the intestinal sodium-dependent glucose transporter. Miglitol is an effective α -glucosidase inhibitor and has greater activity than acarbose on isomaltase. Miglitol has no effect on pancreatic amylase but does mildly interfere with glucose absorption by interacting with the intestinal sodium-dependent glucose transporter.

704 JOSLIN'S DIABETES MELLITUS

The consequence of administering an α -glucosidase inhibitor with the meal is that oligosaccharide cleavage is only partially accomplished in the upper small intestine. The rest of the oligosaccharides go into the middle and distal small intestine, where they are cleaved if the enterocytes contain sufficient enzyme. If enzyme is insufficient, the oligosaccharides go into the large intestine, where the bacteria ferment the carbohydrate and produce short-chain fatty acids, hydrogen gas, methane, and carbon dioxide.

Since carbohydrate digestion and absorption normally are complete in the upper jejunum, the amount of α -glucosidase enzyme in the middle and distal small intestine is low and insufficient to digest the carbohydrate load presented to it during the initiation of α -glucosidase treatment unless the therapy is initiated with a very low dose and the dose is increased very slowly over time.

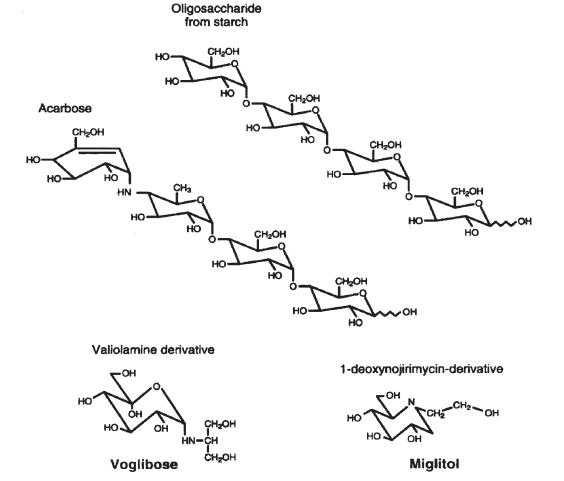

Pharmacokinetics and Metabolism

Three α -glucosidase inhibitors are available: acarbose, voglibose, and miglitol (Fig. 41.13). Acarbose is a pseudotetrasaccharide that contains a nitrogen in place of an oxygen. Voglibose is a valiolamine derivative, and miglitol is a synthetic deoxynojirimycin analogue (11). The primary site of action of both acarbose and voglibose is at the enterocytes, since neither is significantly absorbed (acarbose <2%; voglibose 3%–5%). Miglitol is absorbed rapidly and excreted unchanged by the kidney. Although acarbose is not absorbed, it is metabolized in the colon by bacteria to several intermediates and 4-methylpyro-

gallol, which are absorbed, conjugated, and excreted as sulfates or glucuronidates. Because the α -glucosidase inhibitors are competitive inhibitors of the binding of oligosaccharides, they must be administered at the start of each meal.

Clinical Use

α-Glucosidase inhibitors must be given at the start of each meal. They are effective only if the diet contains at least 40% and preferably 50% carbohydrate. As noted previously, therapy must be initiated with very low doses and the doses titrated up quite slowly. For acarbose and miglitol, therapy should be started with 25 mg with the evening meal (153). After 2 weeks or so the dose can be increased to 25 mg with the start of breakfast and 25 mg with the start of the evening meal. After another several weeks, the dose can be increased to 25 mg at the start of each of the three major meals. Increasing the dose to 50 mg with each meal should also be done in incremental steps. If at any stage, gastrointestinal side effects become a significant problem, the dose should be reduced for several weeks and then the titration continued. Most patients will initially obtain a maximal effect on glycemia at 50 mg with each meal. Some, however, may need to have the dose increased slowly to 100 mg with each meal. The primary clinical effect of the α -glucosidase inhibitors is to decrease the postprandial glucose excursion in patients with either type 1 or type 2 diabetes. The mean decrease in the peak postprandial rise in plasma glucose level during acarbose monotherapy in diet-treated patients with type 2 diabetes is approximately 54 mg/dL and is associated with a

mean decrease in HbA_{1c} of 0.9% (11,154). The mean decrease in FPG is approximately 24 mg/dL, and that is probably due to a reduction in glucose toxicity as a result of improved postprandial hyperglycemia. Voglibose is given at a dose of 0.1 to 0.2 mg with each major meal. There are no comparative data for voglibose and acarbose, but the few reported studies suggest that voglibose lowers mean HbA_{1c} between 0.3% and 0.7%

 α -Glucosidase inhibitors are extremely effective for the treatment of severe hypoglycemia following gastrointestinal surgery and other forms of reactive hypoglycemia. Several studies have shown that α -glucosidase inhibitors given with the evening meal can reduce the incidence and severity of nocturnal hypoglycemia in patients with insulin-treated type 1 diabetes.

Other effects of α -glucosidase inhibitors are a slight reduction in mean weight (<1.0 kg), a decrease in postprandial plasma insulin levels, a small decrease in postprandial plasma triglycerides, and a modest increase in plasma levels of glucagon-like peptide-1 (11).

Side Effects

The major side effects of α -glucosidase inhibitor therapy are gastrointestinal and include abdominal discomfort, flatus, and diarrhea, which are due to an excessive amount of carbohydrate reaching the colon and undergoing fermentation (11,155). Rare cases of jaundice with cholestasis have been reported in patients in Japan treated with acarbose and voglibose. However, studies of acarbose administration to individuals with liver disease have not shown any significant worsening of the hepatic problems.

Hypoglycemia does not occur with monotherapy with these agents. The addition of an α -glucosidase inhibitor to a sulfonylurea, another insulin secretogogue, or insulin, may improve glycemic control such that hypoglycemia may occur. In such cases, the hypoglycemia must be treated with glucose because the digestion of sucrose and complex carbohydrates will be delayed.

COMBINATION THERAPY WITH ORAL AGENTS AND ORAL AGENTS AND INSULIN

Although all of the oral antidiabetic agents are reasonably effective as monotherapy in improving glycemic control and reducing HbA_{1c}, they are rarely able to restore glycemia to near

normal and HbA_{1c} levels to less than 6.5% in patients with type 2 diabetes who present with fasting hyperglycemia and HbA_{1c} levels of 7% or greater (13). This is probably because the hyperglycemia is caused by the combination of metabolic defects that have caused the diabetes and the marked deficiency of βcell function that has occurred by the time an individual has developed symptomatic hyperglycemia (12). Oral medications such as sulfonylureas and metformin that predominately lower FPG will decrease HbA_{1c} values 2.0% to 3.0% in patients with type 2 diabetes who have HbA_{1c} values 10% or greater by a combination of their specific pharmacologic actions and the resultant decrease in glucose toxicity (13,14,128). The same agents will lower HbA_{1c} only 0.5% to 1.0% when the baseline HbA_{1c} is between 6.0% and 8.0%. The same types of results are obtained with oral agents that lower both fasting and postprandial plasma glucoses, such as repaglinide and thiazolidinediones. Oral agents that primarily decrease postprandial plasma glucose levels will have a lesser absolute effect on HbA_{1c} levels (decrease of 0.5%–1.0% at a baseline HbA_{1c} of 8.0%-9.0%), but again their effects decrease as the baseline HbA_{1c} level decreases (13).

It appears that there is a limited benefit to improving glycemic control by ameliorating any one specific mechanism that accounts for the hyperglycemia in patients with type 2 diabetes. Generally, replacing an oral agent with one mechanism of action by another with a different mechanism of action does not result in better glycemic control (116,156). Combining agents with different modes of action, as depicted in Figure 41.5, produces additive effects on glycemic control; allows the use of submaximal doses of the agents, thereby decreasing unwanted side effects; and provides for complementary benefits on cardiovascular risk factors (13,14). Tables 41.7 and 41.8, which are from one of the author's recent reviews, illustrate these advantages (13). Table 41.9 summarizes the results of most of the published U.S. Food and Drug Administration registration studies that have examined the effects of combination oral antihyperglycemic agent therapy on glycemic control in patients with type 2 diabetes (13).

The main principles that underlie combination therapy (Table 41.10) start with the assessment of a patient's specific pathophysiology at the time of initiation of therapy. The assessment should determine (a) the presence or absence of significant insulin resistance; (b) the components, if any, of the insulin resistance syndrome that are present; (c) the stage of

TABLE 41.10. Guidelines for Developing Combination Therapy Strategy for Patients with Type 2 Diabetes

Assess patient's specific pathophysiology

- Is insulin resistance present? Are there any components of the insulin resistance syndrome?

- What is the stage of β -cell function? How abnormal are the fasting plasma glucose levels? What is the magnitude of postprandial hyperglycemia?
- Evaluate the patient for subclinical or clinical diabetic complications
- Estimate the patient's life expectancy
- Define the goals of treatment
- Select the appropriate insulin sensitizers
- Select a method of increasing insulin availability
- Insulin secretogogue
- Insulin preparation
- Decide if an α -glucosidase inhibitor has any advantage
- In patients in whom glycemic control has been elusive, consider 48- to 72-hr continuous blood glucose monitoring or pattern testing with home glucose monitoring
- Monitor HbA_{1c} every 3 mo

 β -cell dysfunction; (d) the magnitude of both fasting and postprandial hyperglycemia; (e) the presence of subclinical and/or clinical complications of diabetes; and (f) the likely life expectancy of the patient. After the assessment, the goals for the planned therapeutic intervention should be defined. The choice of an insulin sensitizer needs to be made. Metformin and the thiazolidinediones have major differences in their effects. Rather than regarding them as competing agents, one might consider them as complementary agents. Frequently, there is a rationale for prescribing them in combination. The next choice is to decide whether β -cell function is sufficient to warrant the use of an insulin secretogogue or whether insulin or an insulin analogue should be used. If an insulin secretogogue is chosen, it is necessary to decide which one to use. Sulfonylureas are inexpensive and can be given once a day. Rapidacting insulin secretogogues are expensive and must be administered with each meal. Weight gain and hypoglycemia are less with the rapid-acting insulin secretogogues. They also partially restore early postprandial insulin secretion and provide a much more flexible lifestyle. If insulin is elected, a choice of a basal, bedtime, or meal-related insulin or a combination of them must be made (see Chapter 39). If postprandial hyperglycemia is the major unresolved issue, the use of an α -glucosidase inhibitor as part of the therapeutic program might be desirable. Combinations of two and sometimes three oral antihyperglycemic agents may be necessary to reach the target glycemic goal.

The availability of devices that allow for continuous blood glucose monitoring for 48 to 72 hours has revolutionized our understanding of the individual variability that occurs in glucose regulation in patients with diabetes. These devices may assist in planning and modifying combination therapy in patients who are not achieving target goals with their current regimen, although the advantage of these devices over traditional home blood glucose monitoring four to seven times a day has not been determined.

Among the unanswered questions concerning combination therapy is whether it should be started at the time of clinical diagnosis or only after a trial of monotherapy has failed to achieve the target glycemic goal. The recent clinical trial comparing the efficacy of glyburide alone, metformin alone, and a combination of submaximal doses of glyburide and metformin

707 41: ORAL ANTIHYPERGLYCEMIC AGENTS FOR TYPE 2 DIABETES

on glycemic control in patients with type 2 diabetes inadequately controlled by diet and exercise showed better glycemic control with initial combination therapy than with monotherapy with either agent alone (157). It was unclear from that study whether the improved benefit resulted from some potentiating of effects or from a limitation of the dose of the monotherapy because of side effects.

The combination of one or more insulin sensitizers with an insulin secretogogue will result in target glycemic goals only if there is sufficient β -cell function remaining to allow endogenous insulin secretion in the presence of improved insulin sensitivity to regulate glucose and lipid metabolism appropriately. In many instances, and particularly after several years of clinical diabetes, β-cell function is so reduced that insulin secretogogues either need to be replaced by or supplemented with exogenous insulin preparations. An effective strategy is to administer either intermediate-acting insulin or glargine at 10:00 p.m. to regulate overnight hepatic glucose production, resulting in an FPG less than 110 mg/dL, or either an oral insulin sensitizer or a short-acting insulin secretogogue, or a combination of both, to regulate prandial glucose control (158,159). This type of program will decrease HbA_{1c} between 1.8% and 2.5% when the baseline HbA_{1c} with two oral agents is approximately 9.5% (Table 41.11). In the instances where β -cell insufficiency is so advanced that the patient with type 2 diabetes requires full insulin replacement therapy, it is also important to treat the insulin resistance (either effective lifestyle modification or insulin sensitizers), as it will decrease the quantity of insulin (160-162) that has to be administered and will improve the components of the insulin resistance syndrome, most of which are known cardiovascular risk factors (3,128,147, 163)

Therapy for type 2 diabetes with oral medications has become more complicated because of the availability of several new classes of drugs, particularly the insulin sensitizers. These drugs appear to be increasing the number of patients who can achieve target glucose values with oral therapy. In addition, these new drugs, used singly or in combination, may prolong the responses of improved glycemic control by improving β -cell function directly or indirectly. The long-term results of these combinations on clinical diabetes outcomes remain to be established by long-term intervention trials.

TABLE 41.11. Effects of Bedtime NPH Insulin and Daytime Oral Agents or Morning NPH Insulin on Glycemic Control in Patients with Type 2 Diabetes with Previous Poor Control with Oral Agents (Treatment Duration 1 yr)

Parameter	Glyburide	Metformin	Glyburide + metformin	Morning NPH insulin
Number of patients	22	19	23	24

DIABETES IN THE SCHOOL AND DAY-CARE SETTING 732

Diabetes in childhood is a chronic metabolic disorder that results in hyperglycemia. In children, as in adults, energy metabolism is altered as a result either of inadequate insulin secretion or of inadequate insulin action, causing aberrant fuel homeostasis, which affects carbohydrate, protein, and fat metabolism. Diabetes is classified into four types: type 1, type 2, gestational, and other types, including secondary diabetes. The approaches to type 1 and type 2 diabetes in children and adolescents will be reviewed. Gestational diabetes does not generally occur in the pediatric population. Many forms of other types of diabetes, due to causes such as pancreatic hypoplasia or pancreatectomy (secondary to hyperinsulinemia or chronic pancreatitis), behave like and are treated similarly to type 1 diabetes. Another common form of secondary diabetes, cystic fibrosis-related diabetes, appears clinically like either type 1 or type 2 diabetes; readers are referred to recent reviews on this subject (1-5).

DIABETES IN CHILDREN AND ADOLESCENTS: INCIDENCE AND PREVALENCE

Although detailed information on the epidemiology of diabetes appears in Chapter 20, we will summarize fundamental statistics about the occurrence of diabetes in youth, because such information is helpful to practicing clinicians in their work with families and the community. In the United States, the incidence rate of type 1 diabetes is approximately 18 per 100,000 (6,7). The age of peak incidence of type 1 diabetes is gender-specific and coincides with the increased insulin demands of puberty (8). In general, the highest incidence is in the 10- to 14-year-old group and the lowest is in the 0- to 5-year-old group for both genders (8,9). Type 1 diabetes is most likely to develop in girls between the ages of 10 and 12, and boys between the ages of 12 and 14. The prevalence of type 1 diabetes is estimated to be 1.7 cases per 1,000 children and adolescents younger than 20 years old.

712 JOSLIN'S DIABETES MELLITUS

While the prevalence is lower with 1 in 2,500 children up to 5 years, it is about 1 in 400 children by 5 to 18 years of age. This translates to approximately 123,000 children and adolescents in the United States who have type 1 diabetes (6,7). In children of all age groups, the overall occurrence of type 1 diabetes has been increasing over the past few decades (9). Estimates of the numbers of youth with type 2 diabetes are less clear. Of the approximately 18,000 children in the United States diagnosed with diabetes each year, 8% to 45% appear to have type 2 diabetes in reports from urban centers in the United States during the last decade (10-13). The Diabetes SEARCH Study, currently supported by the Centers for Disease Control and Prevention (CDC) and the National Institute of Diabetes and Digestive and Kidney Diseases (NIDDK) aims to provide national data on both type 1 and type 2 diabetes in children and adolescents (7; http://www.searchfordiabetes.org).

Type 1 Diabetes

Type 1 diabetes is a multifactorial immune-mediated disease characterized by destruction of the pancreatic β -cells by Tcells, leading to a state of insulin deficiency. Type 1 diabetes has long been identified by its previous name, "juvenile diabetes," implying its common, although not exclusive, occurrence during childhood. Current understanding of its etiology includes an interaction between a genetic predisposition to autoimmunity coupled with an external, environmental trigger leading to autoimmune destruction of the insulin-producing β -cells, resulting in total or near-total deficiency of insulin production (see Chapter 23). Environmental factors, including foods (14-17), toxins, and viruses, have been suggested as triggers of the autoimmune process in genetically susceptible persons (18,19). Markers of autoimmunity include the presence of circulating autoantibodies to the β -cells, such as cytoplasmic islet cell antibodies (ICAs), insulin autoantibodies (IAAs), glutamic acid decarboxylase (GAD) antibodies, and 64-kilodalton (IA-2) autoantibodies to tyrosine phosphatases (IS-2 and IA- 2β) (20–28). With improvements in the antibody assays, it has been possible to identify antibodies in the sera of more than 90% of patients with newly diagnosed type 1 diabetes. However, these antibodies are neither necessary nor sufficient for the diagnosis of type 1 diabetes. Identifying the presence of these autoantibodies may be helpful in clinical situations in which it is unclear whether the child has type 1 or type 2 diabetes, particularly with the current epidemic of childhood obesity and type 2 diabetes in youth. Screening for pancreatic autoantibodies in family members of patients with type 1 diabetes also is used as a research tool in studies of the prevention of type 1 diabetes (see Chapter 23). Several human leukocyte antigen (HLA) class II genes have been linked to susceptibility to type 1 diabetes, and some have been linked to a reduced risk of diabetes (29-32). It is clear that genetic factors, like environmental factors, do not exclusively account for the pathogenesis of type 1 diabetes. In fact, 80% of families of children with newly diagnosed type 1 diabetes do not report any family history of the disease, and the concordance rate in identical twins is only 30% to 50%. The complex interplay of genetics, environment, and autoimmunity as it relates to the etiology, pathogenesis, and possible prevention of type 1 diabetes is the subject of ongoing research.

With the destruction of the majority of β -cells, insulin deficiency results in the onset of the classic symptoms of type 1 diabetes: polyuria, polydipsia, and polyphagia with accompanying weight loss. The stages are outlined below.

 Onset: Symptoms such as increased thirst, increased urination, weight loss despite increased appetite.

- Honeymoon: Once insulin therapy is initiated, the residual β-cells regain functional capacity, producing some insulin for a short time.
- **Intensification:** Destruction of β-cells continues, and control of blood glucose becomes more difficult.
- Total diabetes: All of the insulin-producing β-cells are destroyed, resulting in total insulin deficiency.

Treatment of type 1 diabetes begins at diagnosis and includes insulin therapy, the development of a meal plan, an activity/exercise plan, training in the use of a blood glucose monitor, and family support. Initial self-management training aims to provide the child or adolescent who has diabetes and his or her family with the knowledge, skills, and problem-solving abilities to manage diabetes on a daily basis. This initial education is followed up by ongoing education evolving with duration of diabetes and the growth and development of the child and adolescent (33–35).

Type 2 Diabetes

Type 2 diabetes in children and adolescents was identified in the late 1970s and has become a growing medical and public health problem as a result of the burgeoning epidemic of childhood obesity (10-13,36,37). Like type 2 diabetes in adults, the increase in youth is the direct result of greater caloric intake with decreased caloric expenditure. Youth commonly have poor eating habits, eating high-calorie, high-fat, "super-sized" fast foods; spend an increased amount of time watching television or using computers or playing video games; and are victims of a reduced emphasis on physical education in schools and physical activity in general (38). Almost all youths with type 2 diabetes are overweight and have a positive family history of type 2 diabetes (10,12,37,39). The increasing prevalence of type 2 diabetes has been most marked in ethnic minority groups, including African Americans, Mexican Americans, Asians, Hispanics, and Native Americans (10,12,13) (see Chapter 29).

The first data on type 2 diabetes in youth are from the Pima Indians, the group with the world's highest prevalence of type 2 diabetes (6). In 1979, the prevalence of type 2 diabetes was 1 in 1,000 children 5 to 14 years of age and 9 in 1,000 youths 15 to 24 years of age (40). By 1996, the prevalence had increased to 22.3 per 1,000 in the 10- to 14-year-old age group and 50.9 per 1,000 in the 15- to 19-year-old group (13). In Northwest Ontario, between 1978 and 1984, the prevalence of type 2 diabetes in Native-American children under the age of 16 years was 2.5 per 1,000, a prevalence higher than that for type 1 diabetes in the white population (11,13,41). In Manitoba, the prevalence of type 2 diabetes among Native-American children studied between 1984 and 1990 was 0.53 per 1,000 children 7 to 14 years of age (11,13,42). In Japanese junior-high-school children, the incidence of type 2 diabetes was recently found to be seven times higher than the incidence of type 1 diabetes (13.9/100,000 vs. 2.07/100,000) and increased more than 30-fold over the past 20 years (43,44).

A study from Cincinnati, Ohio, was the first to document incidence rates of type 2 diabetes in the pediatric population over an extended time (45). One-third of all new cases of diabetes diagnosed between 1982 and 1995 in the 10- to 19-year-old age group were classified as type 2, giving an age-specific incidence of 7.2 per 100,000 per year. In 1992, type 2 diabetes accounted for only 2% to 4% of all newly identified cases of diabetes in patients younger than 19 years of age, but by 1994, 16% of all new cases in children were type 2 diabetes. In the Cincinnati report, 70% of the children with type 2 diabetes were African American, whereas only 10% of the children with type

TABLE 42.1. Risk Factors Associated with the Development of Type 2 Diabetes in Children and Adolescents

- · Family history of diabetes
- Body mass index \geq 27 kg/m²; weight for height >85th percentile; >120% ideal body weight
- ≥ 10 y of age (in mid or late puberty)
- African-American, Hispanic, Asian, and American Indian descent
 Acanthosis nigricans in 41%–92%
- Signs of insulin resistance such as hypertension, hyperlipidemia, and polycystic ovarian syndrome (PCOS)

From the American Diabetes Association Type 2 diabetes in children and adolescents. Diabetes Care 2000;23:381-389.

1 diabetes and 14.5% of the general population were African American (45).

In contrast to the similar gender ratio for children with type 1 diabetes, more girls than boys are reported to have type 2 diabetes in studies of type 2 diabetes in children. The ratio of females to males in the Pima Indian population is 2:1; in Ontario Indians, 6:1; in Manitoba Indians, 4:1; and in the predominantly African-American population in Cincinnati, 2:1 (11). Furthermore, diabetes is consistently related to two important variables, obesity and puberty: both states are associated with insulin resistance. Indeed, markers of insulin resistance have recently been identified in 5- to 10-year-old overweight African-American children (46).

Several risk factors are associated with the development of type 2 diabetes: ethnic background, family history of type 2 diabetes, increased blood pressure, increased lipid levels, and obesity (10,12,20,37,45,47,48) (Table 42.1). In addition, acanthosis nigricans, thought to be a cutaneous manifestation of hyperinsulinism, is present in 60% to 70% (vs. the 7% normally seen in this population) of children with type 2 diabetes. These factors are quite similar to the risk factors for type 2 diabetes in adults (10).

A recently convened task force from the NIDDK, CDC, American Diabetes Association (ADA), and the American Academy of Pediatrics recommend testing for diabetes in youth beginning at 10 years of age or at the onset of puberty if earlier. This recommendation includes testing for type 2 diabetes in children and adolescents if they are overweight (defined as weight >120% of ideal body weight, body mass index [BMI] > 85th percentile for age and gender, or weight for height > 85th percentile), and have any two of the following:

· Family history of type 2 diabetes in first- or second-degree relative

- Race/ethnicity: African, Hispanic, Asian/South Pacific, and Native-American descent
- Signs of insulin resistance such as hypertension, hyperlipidemia, or polycystic ovary syndrome (PCOS) (10).

Determination of the fasting plasma glucose is the preferred means of testing, with a positive diagnosis when fasting plasma glucose is 126 mg/dL or higher. Testing should be repeated every 2 years (20). The initial treatment of type 2 diabetes in youth is dictated by clinical presentation. Diabetic ketoacidosis (DKA) or severe hyperglycemia with nonketotic hyperosmolar hyperglycemic syndrome (NKHHS) requires emergency management per a DKA protocol. Insulin will likely be needed as therapy in these patients even after their recovery from the acute condition. Others who are not ill at diagnosis can initially be treated with medical nutrition therapy and physical activity (see sections below). Unless there is successful weight loss, most patients will require some form of drug therapy. Previously, insulin was the only drug approved by the U.S. Food and Drug Administration (FDA) for use in children and adolescents. Recently, metformin has been approved for use in adolescents 12 years of age and older. Nonetheless, most pediatric endocrinologists use some of the anti-diabetes oral agents to treat children with type 2 diabetes (10,12). The study of metformin in children and adolescents has recently been published, while investigations of other oral hypoglycemic agents in youth are currently under way (10,49). Markers that aid in the differential diagnosis of type 1 and type 2 diabetes in children and adolescents are outlined in Table 42.2.

While it is apparent that type 2 diabetes is developing in an increasing number of children, as in adults, the prevalence of this disorder is likely underestimated, given the typical lack of symptoms early in the course of the disease. Thus, the emerging epidemic of type 2 diabetes in children and adolescents presents a challenge not only to the diabetes specialist but also to the primary care provider, who plays a pivotal role in screening for risk factors for development of this disease in the general pediatric population (10,50). There are currently NIH-funded multicenter clinical trials under way to examine treatment and prevention strategies of type 2 diabetes in youth.

Maturity-Onset Diabetes of the Young

An important category of other forms of diabetes is maturityonset diabetes of the young (MODY). MODY is a monogenic (51,52), autosomal dominant, heterogeneous form of diabetes. It is related to a defect in insulin secretion by the β -cells in the pancreas rather than to an impairment of insulin sensitivity (52,53). It is estimated that about 1% to 3% of people with diabetes have MODY. MODY is characterized by early age of onset (10-30 years of age, although it can be as early as 2 to 3 years of

TABLE 42.2. Differential Diagr Diabetes in Children	nosis of Type 1 and Type 2 and Adolescents

714 JOSLIN'S DIABETES MELLITUS

age), treatment with oral anti-diabetes medications versus treatment with insulin, usually an antibody-negative status, and a diagnosis of diabetes in three or more family generations, often with multiple individuals within those generations. The majority of individuals with MODY are not overweight. This diagnosis should be entertained in children and adolescents with a strong family history of diabetes in multiple generations (54). MODY is reviewed extensively in Chapter 26.

THE TEAM APPROACH

In this current era of intensive diabetes control following the release of the Diabetes Control and Complications Trial (DCCT), the team approach to diabetes care remains central to the successful treatment of children and adolescents with diabetes (55–57). Care of youth with either type 1 or type 2 diabetes is complex and time-consuming. In this age of managed care and cost-containment, few primary care physicians, including pediatricians, possess the time to care for these patients and keep up with evolving therapies or new technologies.

The expertise required to deliver the numerous components of the diabetes treatment program resides within a multidisciplinary team that works with the child's family, primary care physician, and school (55,58). The physician-led pediatric diabetes team should be trained in all aspects of pediatric diabetes management and includes a diabetes nurse educator, a dietitian, and a mental health professional-either a social worker or a clinical psychologist. In addition, the team may include an exercise physiologist and subspecialists such as ophthalmologists, podiatrists, nephrologists, gastroenterologists, and others as needed (55). Each team member should appreciate the goals of therapy, the complexities of pediatric diabetes care, the need for individualization, the complications of diabetes, prevention of and early intervention for deteriorating glycemic control, and the impact of the disease on normal childhood and adolescence, as well as on family dynamics.

The process of educating parents and children in diabetes care should begin at the time of diagnosis. Initially, many parents and children or adolescents are overwhelmed and unable to assimilate the extensive body of information of diabetes selfmanagement training. Therefore, it is recommended that selfmanagement training and education be carried out in stages (33–35,59,60).

PATIENT AND PARENT EDUCATION

Today, the child with newly diagnosed diabetes is usually treated as an outpatient or during a very brief inpatient admission. Therefore, education goals need to be tailored to the needs of the individual child or adolescent, the family, and the resources of the healthcare team. These initial goals become an important part of the ongoing process of diabetes follow-up care. Central to successful management and attainment of treatment goals are the child or adolescent with diabetes and his or her family, whose needs should receive priority in planning and implementing the treatment program. The child's primary care provider must be included as a member of the diabetes healthcare team. In addition, caregivers such as day-care providers, teachers, school nurses, coaches, grandparents, and babysitters are integral to successful outcomes (Fig. 42.1). This collaborative approach helps the patient receive optimal diabetes care, taking into account his or her age, day-care or school schedule, eating patterns, personality, temperament, family structure, cultural background, and other medical conditions.

Initial goals are limited to imparting an understanding of the fundamental nature of diabetes and how it is treated. Next, diabetes treatment routines need to be integrated into school, sports activities, day care, and family activities. This occurs through practical experience at home and by frequent contact with the diabetes healthcare team. As time passes, most families are ready to learn the intricate details of diabetes self-management necessary for maintaining optimal glycemic control, while coping with the challenges imposed by such things as physical activity, "picky" or selective eating habits, intercurrent illnesses, and other normal variations in a child or adolescent's daily routine. In addition to imparting facts and teaching prac-

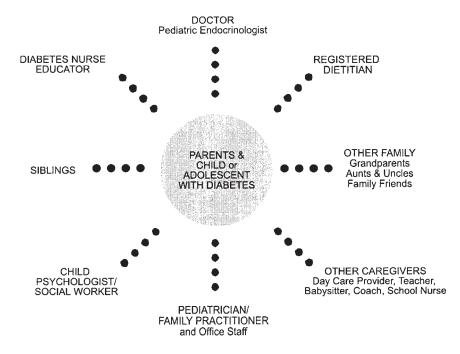

FIG. 42.1. The diabetes healthcare team for the child or adolescent with diabetes.

42: TREATMENT OF THE CHILD AND ADOLESCENT WITH DIABETES 715

tical skills, diabetes self-management training and education should attempt to promote desirable health beliefs and attitudes in the young person who has to live with a chronic and incurable disease (33–35).

For the child, this is often best accomplished in an educational setting such as age-appropriate peer education/support groups or summer camps for children with diabetes. The educational program must match the child's level of cognitive development and be adapted to the learning style and intellectual ability of the individual child, adolescent, and family (35,61-63). We urge that parents be fully involved, and we encourage the diabetes healthcare team to supervise, when appropriate, a gradual and flexible transfer of responsibility from parents to the adolescent, facilitating the normal process of separation and attainment of independence that occurs during the teenage years (64–67). Ideally, we encourage cooperation around diabetes tasks between the teen and parent with the goal of developing interdependence, because parent involvement has been consistently associated with better medical and behavioral outcomes for youths with diabetes (64-66,68).

Continued education is necessary during transitions between developmental stages of childhood, such as at school entry, between the school-age years and adolescence, when the adolescent leaves home for college or for independent living, as well as throughout the lifespan. Some families benefit from reinforcement of teaching skills at home with the help of visiting nurse services, either shortly after diagnosis or during challenging family times. We have established a developmental model of care, education, and psychosocial support through our agebased multidisciplinary clinics.

Beginning with the most vulnerable group of youth and their families, the Pediatric and Adolescent Unit of the Joslin Diabetes Center has implemented a comprehensive, familyfocused outpatient program of care for children with type 1 diabetes younger than 8 years of age called the Young Children's Program (69,70). It is offered once each month, and approximately 400 families with young children have participated to date. Through a systematic assessment of initial needs, we documented that parents of preschool and early school-age children with diabetes are concerned about the following: collisions between diabetes treatment and normal childhood behavior; differentiating symptoms of hypoglycemia from normal behavior and mood swings; and the impact of diabetes on family relationships (69,70). Fear of hypoglycemia surfaced as a primary concern. One of seven of these very young children experienced severe hypoglycemia (70). Thus, families of young children become extraordinarily reliant upon blood glucose monitoring in these young patients who are unable to identify and communicate hypoglycemic symptoms.

We have implemented a similar comprehensive program for school-age children, 8 to 13 years of age, and their families. This group also meets monthly, with the provision of individualized medical care followed by simultaneous separate support groups for parents and for the youth. Similar to the Young Children's Program, the parent group is facilitated by members of the mental health team, either a child psychologist or social worker, and by members of the medical team, including a physician, a pediatric diabetes specialty nurse, or registered dietitian. Major topics of discussion include transition to middle school, impact of puberty on glycemic control, and review of new technologies along with research updates. An early childhood educator, who coordinates developmentally appropriate activities to insure positive clinic encounters that encourage routine follow-up, supervises the group of youth. Diabetesspecific educational curricula are not routinely discussed.

These comprehensive programs encourage positive interactions between the diabetes healthcare team and the patients along with their families. The positive result of these interactions is evident in our assessment of the Young Children's Program (70). The program evaluation yielded improved follow-up attendance at diabetes care visits for families who participated in the comprehensive Young Children's Program compared with infrequent program attendees (70). In addition, the group of patients with improved follow-up care had significantly fewer children with poor control (glycosylated hemoglobin A_{1c} [HbA_{1c}] >9.9%) than the group with infrequent program attendance and follow-up care (P < .05) (70).

Adolescents with diabetes and their families receive multidisciplinary diabetes care as well as medical care and psychosocial support. The program for teens at the Joslin Clinic helps teens and their families devise individualized management programs that fit their lifestyles. Families are helped in the negotiation of acceptable parental involvement in the tasks of diabetes management to sustain adherence to insulin injection routines and blood glucose monitoring (66,71). To provide additional support for the parents as they try to help their adolescents, we initiated a bimonthly evening parent support group facilitated by the multidisciplinary pediatric team. In an initial needs assessment, fear of complications surfaced as a concern in 50% of families, while fear of hypoglycemia was noted by 19%. We stress the importance of continued medical follow-up and frequent blood glucose monitoring for these families to help them overcome these concerns.

We have recently launched a professionally monitored Discussion Board for Teens on the Joslin website. Parents of adolescents also can participate in a Discussion Board specifically for them, as well in the bimonthly discussion group. Parents of adolescents require ongoing help in developing realistic expectations for adolescent blood glucose levels and monitoring behavior, as well as in negotiating an acceptable level of involvement in the diabetes management tasks of their teen. Adolescents with diabetes also require help in developing realistic expectations for blood glucose monitoring and in negotiating with their parents about acceptable levels of involvement in monitoring and insulin routines. The team approach to pediatric diabetes care promotes these goals and remains the accepted standard of care throughout childhood and adolescence (55).

GOALS OF THERAPY

In 1993, the results of the DCCT heralded intensive management or so-called tight control as the standard of care for most patients with type 1 diabetes (56). With scientific evidence showing a marked decrease in the risk of microvascular complications of the eyes, kidneys, and nerves with intensive management, the post-DCCT era emerged (56). Although the study did not enroll patients younger than 13 years of age, there were 195 youth, between the ages of 13 and 17 years old, at entry in the study sample. As a result, diabetes care today utilizes intensive management in the diabetes treatment plans for the majority of children and adolescents with diabetes (72). The theoretical goal of treatment is to restore metabolic function to as near normal as possible while avoiding serious complications of therapy, especially symptomatic hyper- and hypoglycemia. However, the approach to care also incorporates more global goals, such as the normalization of childhood and adolescent development and the maintenance of successful family functioning (34,55,59) (Table 42.3).

TABLE 42.3. Goals of Therapy of the Pediatric and Adolescent Unit of the Joslin Diabetes Center

- Avoidance of symptomatic hyperglycemia and hypoglycemia
- Early intervention for increasing hemoglobin A_{1c} levels
- Prevention of parent/child burnout and isolationPrevention of metabolic deterioration of adolescence
- Identification and treatment of behavioral/adjustment dilemmas
- Provision of positive medical experiences
- Provision of realistic expectations for diabetes management
- Integration of diabetes routines into school, day care, and family activities
- · Maintenance of normal growth and development

Glycemic goals vary for children and adolescents and reflect developmental differences. Since hypoglycemia can have more of an impact on the neurocognitive function of young children (73–80), the ADA position does not support tight glycemic control for children under the age of 2 years and advises caution for children 8 years old and younger (55). Table 42.4 shows the glycemic control goals for youth with diabetes.

Several studies indicate that children who develop diabetes during infancy and early childhood may be at increased risk for the subsequent development of cognitive impairment (75, 81-84). Such impairment is presumed to be the result of multiple episodes of severe hypoglycemia, which may be more frequent in very young children because of their hypoglycemic unawareness (85–87). Therefore, maintaining very tight control of glucose levels in children with very-early-onset diabetes may be harmful, given the risk of causing recurrent, severe, and potentially debilitating episodes of hypoglycemia that have the potential for neurocognitive sequelae (78,88–90). Care must also be taken to avoid poor glycemic control, as one wants to limit the hyperglycemic exposure that is associated with future complications (91). One report raises the question of a correlation between high long-term HbA1c values and intellectual impairment in boys diagnosed below the age of 6 years (92). Furthermore, fear of hypoglycemia among parents who have witnessed severe hypoglycemia in their young children becomes a major deterrent both to achieving optimal control in these children as they mature and in allowing them to experience many normal activities of childhood that require separation from parents (93–95). A recent publication reports increased parenting stress, in general and in relation to mealtimes, in families with young children with diabetes, which underscores parental fears of hypoglycemia (96).

The prepubertal child may be relatively protected from microvascular complications, although this is still controversial. Signs of eye or kidney disease are extremely rare in the prepubertal child (97). Diabetic nephropathy, for example, with microalbuminuria used as an index of renal glomerular damage, is significantly less prevalent in children younger than 12 years of age than in those older than 12 years of age matched for duration of diabetes (98). Indeed, it is extremely rare to uncover clinically significant microvascular complications in children younger than the age of 10 years (97-99). However, debate continues about the contribution of glycemic control during the prepubertal years to the development of future complications (100). Thus, current clinical care should approach this dilemma by aiming for safe and realistic glycemic targets that limit the occurrence of significant hyperglycemia and hypoglycemia and that match the patient and family's particular needs.

In children and adolescents, as in adults, individualization of the treatment program is important. In highly motivated families, close monitoring of blood glucose and administering multiple insulin injections or utilizing insulin pump therapy using dosage adjustment algorithms are fairly routine. In other families, simplification of the regimen may be the only key to successful management. Thus, while keeping the general therapeutic principles in mind, the diabetes healthcare team must tailor the goals of treatment to the needs and capabilities of each individual child or adolescent with diabetes and his or her family (33–35,59,60).

TYPE 1 DIABETES: GLYCEMIC CONTROL IN THE PEDIATRIC POPULATION AND THE DCCT/EDIC STUDY

Despite multidisciplinary specialty care, glycemic control remains suboptimal in many pediatric diabetes centers worldwide, including our own center. In a recent sample of 300 children with type 1 diabetes, the mean HbA_{1c} was $8.7\% \pm 1.2\%$, with 33% achieving an HbA_{1c} level below 8.1% (101). Glycemic control in our population appears quite similar to that reported in other large, cross-sectional studies of pediatric populations (Table 42.5). A multicenter cross-sectional study involving 22 pediatric departments in 18 countries in Europe, Japan, and North America enrolling 2,873 children with type 1 diabetes, reported a mean baseline HbA_{1c} of $8.6 \pm 1.7\%$, with 34% of patients achieving an HbA_{1c} <8.0% (105). Three years later, the mean HbA_{1c} from these centers remained $8.7\% \pm 1.7\%$ (111). Similarly, a recent cross-sectional nationwide study of 2,579

 TABLE 42.4. Goals for Glycemic Control for Children, Adolescents, and Young Adults with Diabetes

French children with type 1 diabetes reported an overall mean HbA_{1c} of 8.97% \pm 1.98%, with 33% of patients achieving an HbA_{1c} less than 8.0% (105). In the DCCT, 83% of the intensively treated patients achieved HbA_{1c} values of 8% or less, compared with only 20% of the patients receiving standard care. Fewer than 5% of the intensively treated patients achieved HbA_{1c} values <6.05% (56).

Intensive insulin therapy, compared with conventional therapy, in the DCCT delayed the onset and slowed the progression of long-term complications in both the adolescent and adult cohorts. The subset of the 195 adolescent patients, ages 13 to 17 years at study entry, randomized to intensive therapy experienced a similar reduction in risk for complications to their adult counterparts (112). In contrast to the adolescent cohorts from the DCCT, the adults in both conventionally and intensively treated groups achieved lower HbA_{1c} values both during the DCCT and during the follow-up Epidemiology of Diabetes Interventions and Complications (EDIC) study (56,112-114). During the DCCT, intensively treated adults achieved HbA_{1c} values of 7.1% compared with values of 8.9% in conventionally treated adults (Fig. 42.2). Among the 195 adolescents, both intensively and conventionally treated adolescent patients had HbA_{1c} values about 1% higher than those of their older counterparts. At the end of the DCCT, all study patients were encouraged to use intensive insulin therapy. During the EDIC follow-up, both groups of adult patients experienced a change in their glycemic control, with HbA1c values in intensively treated adult patients increasing to 7.9% and HbA_{1c} values in the conventionally treated adults decreasing to 8.1%. Nonetheless, the intensively treated adult patients benefited from their initial exposure to intensive insulin therapy, with a sustained risk reduction in the occurrence of retinopathy and nephropathy during the first 4 years of follow-up in the EDIC study (114). This risk reduction has been confirmed after 7 years of followup in EDIC (115).

This significant reduction in risk for microvascular complications was sustained in the intensively treated adolescents when they were followed 4 years after the end of the DCCT (113). One hundred seventy-five of the 195 adolescents initially enrolled in the DCCT participated in the follow-up EDIC Study (115). After the release of the results of the DCCT, the conventionally treated patients were invited to receive intensive insulin therapy. During the first 4 years of follow-up, 50% of conventionally treated adolescents selected multiple daily injections, approximately 17% selected insulin pump therapy, while the remainder continued to receive conventional insulin therapy (113). Among the intensively treated youth during the DCCT, 90% elected to continue intensive insulin therapy during the 4 years of follow-up. Despite the difference in diabetes management between the two groups, glycemic control was identical 4 years after the end of the DCCT, with the group assigned to intensive insulin therapy in the DCCT maintaining a mean HbA_{1c} of 8.4% while those who received conventional insulin therapy achieving a mean HbA_{1c} of 8.5%. Despite this equivalence of glycemic control between the two groups, the previous exposure to intensive insulin therapy was associated with a sustained risk reduction for the occurrence of retinopathy and diabetic nephropathy (113,114).

These differences in glycemic control between adult and adolescent patients during the DCCT and EDIC studies underscore the challenges associated with the management of type 1 diabetes in adolescents. This suggests that adolescents and young adults may have particularly challenging metabolic and behavioral factors that warrant additional study in order to devise suc-

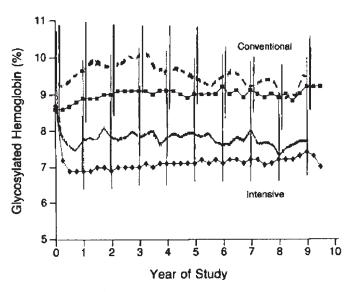

FIG. 42.2. Levels of glycosylated hemoglobin (HbA_{1c}) achieved in the Diabetes Control and Complications Trial. The conventionally and intensively treated (first and third curves from top, respectively) adolescents had higher HbA_{1c} values and more overlap than did their adult counterparts (second and fourth curves, respectively).

cessful treatment programs that can optimize their glycemic control. Issues related to pubertal growth and development, as well as behaviors, likely contribute to these challenges.

Furthermore, achievement of optimal glycemic control remains challenging for most centers caring for youth with type 1 diabetes. A recent follow-up to a large multinational study examining glycemic control reported wide differences in mean glycemic control among specialty centers and values significantly higher than targets achieved in adult population (111). In addition to the long-term risks of late complications that follow long periods of uncontrolled diabetes, youth with poorly controlled diabetes experienced significantly more hospitalizations and emergency room visits compared with youth who achieve HbA_{1c} values of 8% or less (101). For 2 years, we prospectively observed 300 youth, ages 8 to 16 years, with type 1 diabetes. There was a threefold increase in the rate of hospitalizations and emergency room visits among those with average HbA1c values of greater than 9% compared with those with HbA1c values of 8% or less. In addition, the frequency of hypoglycemia was equally high among those with poorly controlled diabetes and those with lower HbA_{1c} values. Despite the lack of optimal control, the occurrence of hypoglycemia in the group with poor control most likely results from the lack of attention to diabetes management tasks (71). Repeatedly, achievement of optimal glycemic control has been found to be significantly related to the frequency of blood glucose monitoring (65,66,71,101). (See section on behavioral factors).

Puberty

Puberty is a challenging period for diabetes management from both physiologic and behavioral standpoints. The hormonal milieu of puberty sets the stage for significant insulin resistance due to increases in the production of growth hormone and sex steroid hormones (115). Amiel and colleagues performed elegant studies of glucose disposal using a hyperinsulinemic clamp in prepubertal, pubertal, and postpubertal individuals (116) (Fig. 42.3). Their investigation confirmed that, despite similar levels of circulating insulin, individuals in the midst of puberty displayed significantly lower (by 30%) glucose disposal than did prepubertal and postpubertal individuals (116). The diminution in glucose disposal was evident in pubertal youth with type 1 diabetes as well as in pubertal normoglycemic control individuals matched for age and gender with the youth with diabetes. Thus, it is quite common for insulin requirements to increase by 50% during pubertal growth and development (116).

An observational study of more than 900 persons at our center who were 15 to 45 years of age, all of whom were diagnosed with type 1 diabetes before the age of 40 years, found significant relationships between HbA1c and age of diabetes onset and attained age (Fig. 42.4). The patients who were the youngest at onset of diabetes had the poorest glycemic control, as expected by the greater severity of their deficit in insulin-producing β cell capacity (authors' unpublished data). On the other hand, HbA_{1c} was the highest during the late adolescent years, ages 16 to 20, likely reflecting the period of greatest behavioral adjustment and the time when patients experience difficulties with adherence to the diabetes treatment program. These findings suggest that particular attention needs to be focused on older adolescents and young adults, as their glycemic control appears to be deteriorating. Furthermore, patients of this age may be changing their care from pediatric to adult providers and, as a result, may be at great risk for being lost to follow-up. The combination of deteriorating glycemic control and loss to follow-up care places these patients at high risk for the start of microvascular complications (117,118). Together physiologic demands of puberty and behavioral issues add to the challenges of diabetes during this developmental stage (65,66,110,111). The period of adolescence is notable for the need for the rapidly growing and developing youth to experiment and push the limits of his or her environment. These youth are often encouraged to take over much, if not all, of their diabetes tasks. However, with the recognition that puberty is a challenging period for glycemic control, additional parental support and guidance are imperative to prevent excessive glycemic deterioration at this stage. Furthermore, newer studies have confirmed the importance of continued parental guidance to help adolescents avoid deterioration of their schoolwork, to reduce the use of drugs and alcohol, and to reduce the occurrence of teen pregnancy (110). Thus, we promote interdependence between family members and the teen with diabetes that encourages teamwork to support the rigors of diabetes management. This is particularly important in light of the physiologic demands of puberty occurring at a time when the youth is striving for more independence. To help maintain adherence to diabetes tasks, especially to blood glucose monitoring, caregivers must reward the act of monitoring

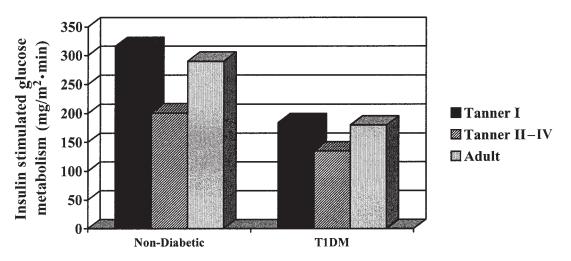

FIG. 42.3. Effect of puberty on insulin-stimulated glucose metabolism in nondiabetic and diabetic subjects. Tanner 1, prepubertal; Tanner 2–4, pubertal; Tanner 5, postpubertal. (Adapted from Amiel SA, Sherwin RS, Simonson D, et al. Impaired insulin action in puberty. A contributing factor to poor glycemic control in adolescents with diabetes. *N Engl J Med* 1986;315:215–219. Copyright © 1986 Massachusetts Medical Society. All rights reserved.)

rather than punish unfavorable blood glucose results (121). (See section on behavioral issues and family studies.)

INSULIN THERAPY

Only the number of insulins currently available and the tools with which to deliver them limit insulin regimens utilized in the management of diabetes in children and adolescents. These regimens can range from the use of a single intermediate- or long-acting insulin (NPH [neutral protamine Hagedorn], lente, ultralente, or glargine) to an intensive program of multiple types of insulins administered through three or four daily injections or aspart/lispro/regular insulin through continuous subcutaneous insulin infusion (CSII) (Table 42.6). The selection of an insulin regimen depends upon many factors, such as type of diabetes, age, glycemic goals, and personal choice. The use of insulin in type 1 diabetes is the main focus of this section.

	TABLE 42.6. Insulin Actions	by Type of Human Insuli	ns
Insulin type	Onset	Peak	Duration
Insulin aspart	5–10 min	1–3 hr	3–5 hr
Insulin lispro	<15 min	30–90 min	2–4 hr
Regular	30–60 min	2–3 hr	3–6 hr
NPH	2–4 hr	4–10 hr	10–16 hr

50/50	30 min	2–3 hr	10–24 hr
75/25	15 min	1.5–3 hr	16–24 hr

^a70/30 (70% NPH/30% regular), 70/30 (Novolog Mix) (70% insulin aspart protamine suspension/30% insulin aspart); 50/50 (50% NPH/50% regular); 75/25 (75% insulin lispro protamine suspension/25% insulin lispro. From American Diabetes Association. Health Care Products. Diabetes Forecast. Available at: http://www .diabetes.org/main/community/forecast/jan_2002_insulin.jsp#relative insulins, with permission. Available insulins are listed by their onset, peak, and duration of action in Table 42.6.

Although there is no one established formula for determining a child's insulin requirement, experience has shown that children with newly diagnosed type 1 diabetes require approximately 0.5 to 0.75 U/kg per day. For children diagnosed before the development of ketonuria, the initial insulin doses may be lower than the 0.5 U/kg per day. With diminished insulin sensitivity associated with DKA, steroid use, puberty, or infection, the initial doses may be as high as 1.0 U/kg per day or more to achieve reasonable glycemic control. Usual subcutaneous daily insulin dose calculations are summarized in Table 42.7. Children younger than 8 years old, often in direct contrast to adolescents, are exquisitely sensitive to insulin. The small insulin needs of infants and toddlers may require insulin diluted to U10, U25, or U50 as opposed to the standard U100 preparations (100 U/mL) to allow for more precise dosing and measurement of insulin in less than 1-unit increments. Diluents are available for specific types of insulins from the insulin manufacturers. Insulin can be diluted either in a pharmacy or at home after parents are taught to dilute the U100 insulin using the diluent specified by the manufacturer for the insulin type.

Although the theoretical goal is to normalize the premeal blood glucose levels to values between 80 and 120 mg/dL and to maintain the middle-of-the-night blood glucose level at 80 mg/dL or above, a number of variables must be considered when establishing individual target blood glucose goals. These variables include, but are not limited to, the stage of diabetes, issues of growth and development (e.g., chronologic age or Tanner stage), activity level, child temperament, family infrastructure, school support, and family fear of hypoglycemia or longterm complications. Adjustments in insulin doses are based on the evaluation of patterns of blood sugars attained over a 3-day period, taking into account the effect of the level of activity as well as the frequency and amount of carbohydrate intake. If there is an emerging pattern of out-of-target blood glucose levels at a consistent time of day, the insulin most responsible for insulin action at that time should be adjusted by 10%. Once that adjustment has been made, ideally it should remain fixed for 2 to 3 days to see the impact of the change before further adjustments are made.

It is not unusual within a period of several weeks after the initiation of insulin therapy for a child's diabetes to enter the honeymoon phase with residual insulin production. During this phase of diabetes, insulin requirements may fall well below the 0.5 U/kg per day generally required to maintain blood glucose targets in the setting of β -cell failure. Children may require only minimal amounts of intermediate- or long-acting insulin, possibly combined with small amounts of aspart, lispro, or regular insulin. Given the autoimmunity of type 1 diabetes, β -cell

destruction continues in spite of this honeymoon phase. With the progressive loss of β -cell function, the need for increased exogenous insulin will become readily apparent in the form of increased blood glucose levels. These insulin needs may continue to rise over the ensuing weeks, months, and years as a result of declining β -cell function but also with growth of the child-in both height and weight. Insulin requirements may rise to as much as 1.5 U/kg per day during puberty. As diabetes intensifies, the ability to manage glycemia with a single dose of insulin or with less than 0.5 U/kg becomes virtually impossible. Inadequate overnight dosing of insulin will result in an overproduction of hepatic glucose, resulting in fasting hyperglycemia, occasionally with ketonuria. Most children with diabetes will require, at minimum, a mixture of rapid- and intermediate- or long-acting insulin administered two to three times a day—before breakfast, before the evening meal, and/or at bedtime-to remain free from persistent hyperglycemia and to achieve reasonable 24-hour glucose control. In the adolescent population especially, it is not uncommon for the afternoon snack to consist of more than 15 to 30 g of carbohydrate. That snack may coincide with the waning of the morning NPH. The use of aspart or lispro to cover the added calories of a mid-afternoon snack may be needed to improve the pre-supper blood glucose level.

The newest insulins are called insulin analogues. These "designer" insulins arise from the biochemical alteration of the human insulin molecule. Modifications to the insulin molecule alter its onset, peak, and duration of action, with the goal of creating insulin preparations that mimic insulin action produced by the human β -cells within the pancreatic islets. Clinical trials have shown that these analogues are safe and effective; their advantages include more optimal management of blood glucose levels by the close mimicking of normal physiologic function (123).

The FDA approved the first insulin analogue, lispro (Humalog), in 1996. Lispro has a rapid onset-within 15 minutes of administration-but a duration of action shortened to 2 to 4 hours. The onset, peak, and duration of action of lispro were designed to match the postprandial increase in blood glucose that follows the intake of food. Its rapid onset makes it ideal for administration just before eating. Studies have demonstrated the feasibility of administering lispro after meals in very young children (124). Dosing with lispro after meals allows a care provider to more accurately titrate the insulin doses for an erratic eater, with the goal of matching food intake and insulin more closely and minimizing the potential for hypoglycemia. A diluent for lispro is available, allowing for accurate lispro administration in, for example, 0.1- or 0.25-U increments, making this preparation extremely useful in very young children. Clinical studies have shown that, compared with regular

TABLE 42.7. Usual Subcutaneous Daily Dosages of Insulin in Children and Adolescents with Diabetes

Туре	Non-DKA presentation	DKA presentation
Type 1 diabetes Child, prepubertal Adolescent, pubertal Type 2 diabetes	0.25–0.5 U/kg per day 0.5–0.75 U/kg per day	0.5–0.75 U/kg per day 0.75–1.0 U/kg per day
Adolescent	20–40 U/day ^a	_

DKA, diabetic ketoacidosis.

^aOften administered as intermediate-acting insulin as starting dosage. Depending on level of hyperglycemia at presentation, insulin needs can be significantly higher.

insulin, lispro improves HbA_{1c} values, improves postprandial blood glucose levels, results in fewer episodes of hypoglycemia, and enhances hypoglycemia awareness (123,125).

A second rapid-acting insulin, aspart (NovoLog), was recently approved by the FDA and is available for use. Although the onset of action very closely mimics that of lispro, its duration is between 4 to 6 hours. Rapid-acting insulins such as aspart and lispro allow for maximal flexibility of injections at meals versus that of regular insulin, which for maximal effectiveness must be injected 30 to 45 minutes before eating. In a clinical trial comparing the frequency of nocturnal hypoglycemia in an insulin program of regular insulin or a program of aspart, the aspart group had fewer episodes of low blood glucose levels at night, as well as lower HbA_{1c} values (126). Currently, insulin aspart is not approved by the FDA for use in persons younger than 18 years of age. Insulin aspart recently received FDA approval for use in insulin pumps (127). Additional pediatric studies evaluating the effectiveness of aspart are ongoing (126,128).

The third FDA approved insulin analogue is glargine (Lantus). Glargine is the first long-acting insulin analogue to have achieved FDA approval. It appears to be an almost peakless insulin, with a duration of 24 hours or longer. Its pharmacologic action most closely mimics the basal insulin produced by the β cells when the body is in the fasting state, that is, during the overnight hours. Glargine, a clear U100 insulin preparation, must be injected alone which is unlike the other intermediateor long-acting insulins, which can be mixed with rapid-acting insulins. The acidic pH of glargine prevents it from being mixed with other insulin preparations. Clinical studies of premeal lispro or regular comparing glargine administered at bedtime with NPH administered either once or twice daily demonstrated that the glargine group experienced lower fasting blood glucose levels with less nocturnal hypoglycemia than the NPH group (129). Glargine has not been approved for use in pediatric patients younger than 6 years of age. Ongoing clinical studies in the pediatric population will define the level of efficacy of this insulin preparation.

Another category of insulin preparations is the group of premixed insulins. One mixture of insulins contains an analogue of lispro with an intermediate-acting insulin called NPL. NPL is a lispro protamine insulin suspension creating a monomeric insulin with an activity profile like that of NPH insulin. The mixture consists of 75% NPL and 25% lispro. There may soon be available a 70/30, as well as a 30/70, preparation of intermediate-acting NPH and insulin aspart.

The use of premixed insulins, i.e., 70/30 (70% NPH/30% regular), 50/50 (50% NPH/50% regular), and 75/25 (75% NPL and 25% lispro), provides ease of administration, but these mixtures are not commonly used in the pediatric population. Premixed insulins are not recommended in the pediatric population unless all other insulin programs have failed. The premixed insulins do not allow for the independent adjustment of either the rapid- or intermediate-acting insulin, as they are in fixed, pre-set ratios that cannot be altered independently of one another. This does not allow a response to increased blood glucose levels or activity without altering the entire insulin program. Premixed insulin may be advantageous for adolescents whose psychosocial needs impair their ability to handle yet one more diabetes related task, that is, the mixing of insulins. Families in which the primary insulin-giver has a learning disability or cannot master the sequencing of steps needed to mix insulins or add together the clear and cloudy doses may benefit from the use of premixed insulins.

A mixed dose of rapid-acting and intermediate-acting insulins administered before breakfast will provide insulin cov-

erage for breakfast and the midday meal, as well as provide early afternoon insulin effect. Because the prebreakfast intermediate insulin effect will have sufficiently waned by late afternoon, the need for a second dose of insulin to provide coverage for the evening meal and overnight hours will become obvious. The peak action of presupper intermediate insulin will occur between midnight and 3 a.m., increasing the risk for nocturnal hypoglycemia. Fasting blood glucose levels may be increased as a result of increasing overnight hepatic production of glucose and overnight release of growth hormone. Increasing the level of presupper intermediate-acting insulin to compensate for the fasting hyperglycemia without monitoring the insulin effect between midnight and 3 a.m. may trigger severe nocturnal hypoglycemia. If the middle-of-the-night blood glucose is 100 mg/dL or less, it is unwise to raise the supper intermediate-acting insulin to correct the fasting hyperglycemia, as the risk for nocturnal hypoglycemia increases. In such instances, a safer approach to managing the fasting hyperglycemia is to administer the rapid-acting insulin alone at dinner and the intermediate- or long-acting insulin at bedtime (approximately 9 p.m.), thus providing more insulin coverage in the hours just before dawn when it is needed. The use of ultralente insulin before supper as a substitute for a bedtime injection in the prepubescent child, maintaining a twice-daily injection program, can occasionally be quite successful (130). The success of this insulin regimen fades rather dramatically with the exuberant hormonal changes in the adolescent, necessitating a multiple daily injection program.

In a common insulin regimen, two thirds of the total daily insulin dose is given before breakfast and the remaining one third, before dinner and/or bedtime. Rapid-acting insulin usually makes up one third of the morning dose, with the remaining two thirds composed of the intermediate-acting insulin. One third to one half of the evening dose is devoted to the rapid-acting insulin, and the remainder is administered as either the supper or bedtime intermediate-acting insulin. Finetuning of doses is accomplished through the use of blood glucose monitoring to determine the effectiveness of the insulin program. Families should be encouraged to become active participants in evaluating and self-adjusting insulin doses based on blood glucose levels, anticipated carbohydrate intake, and planned-for activity levels.

Over the past 10 years, since the release of the DCCT results, practitioners worldwide have recognized and accepted the value of aiming to normalize glycemia (56). To achieve this goal, regimens should attempt to mimic the function of the β -cells, using a basal-bolus approach to diabetes management. To date, this is accomplished through either multiple daily injections (using either ultralente or glargine as the basal insulin and lispro, aspart, or regular insulin as the bolus insulin) or through CSII using an insulin pump. Both of these programs have demonstrated advantages over the more conventional insulin programs but are not without distinct disadvantages as well (56). Advantages include greater flexibility around food, with respect to both the timing and amounts; lower risk of hypoglycemia, as the variable peaking of intermediate-acting insulins is eliminated; the ability to "sleep in" without the risk of significant waning of insulin effect by morning with hyperglycemia or the risk of hypoglycemia from lack of calories; and the ability to improve blood glucose levels and glycemic control. Clearly, disadvantages include the need to increase the frequency of blood glucose monitoring to four or more times per day, the required attention to the carbohydrate content of meals/snacks, and the potential for weight gain. The DCCT experience showed that those participants in the intensively managed group were, on average, 10 pounds heavier than those

722 JOSLIN'S DIABETES MELLITUS

in the conventionally treated group (56). Successful management of diabetes with an intensive insulin program requires a demonstrated comfort level with blood glucose monitoring tools as well as with insulin delivery systems, increased family and school support, proficiency with carbohydrate counting, record-keeping, and more frequent contact with a diabetes healthcare team that can provide 24-hour support. It has been demonstrated that the success of such an insulin program requires that both the child/adolescent and family want this approach and communicate well with each other. Families with major stress, such as conflictual child-parent relationships, major mental illness, or poor adherence to a more conventional treatment program, should defer intensive insulin therapy programs until there has been some resolution to the psychosocial or medical tensions.

INSULIN DELIVERY SYSTEMS

Options for the delivery of insulin are many and varied. They include syringes, pens, pumps, and air injectors.

Traditionally, most pediatric patients receive their insulin by injection with syringes to provide mixing of insulins and flexibility in dosing of both short- and long-acting insulin preparations. Syringes are calibrated to 3/10 cc, 1/2 cc, or 1 cc and have either 29-gauge, 1/2-inch needles or 30-gauge, 5/16-inch needles.

The use of insulin pens with disposable needle tips has long been the delivery system of choice in Europe. The advantage of the insulin pens is that they offer a discrete, rapid way of administering insulin accurately for those children who object to or who feel unsafe carrying a vial of insulin and a syringe. Pens are available as disposable devices holding 300 U of a specified type of insulin or as more-durable equipment that requires replaceable cartridges of either 150 or 300 U of various types of insulins. Currently, it is possible to purchase insulin pens or cartridges of aspart, lispro, NPH, 75/25, or 70/30. The disadvantage of the pen system is that it is not possible to mix insulins together for a single injection with the exception of the above premixed insulin preparations.

Healthcare providers appreciate the challenges associated with intensive insulin therapy. The pharmacokinetics of injected insulin hamper spontaneity of lifestyle and increase the risk of hypoglycemia or hyperglycemia. Since the 1970s, physicians and scientists have investigated alternative insulin delivery systems in an attempt to improve glycemic control and quality-of-life for patients. The use of insulin pumps or CSII therapy provides one approach to intensive insulin therapy that can optimize glycemic control, reduce hypoglycemia, and maintain quality of life (131). Pump use is growing rapidly in the pediatric population. Insulin pumps offer a continuous infusion of insulin over the course of the day in an effort to replicate basal insulin production by the pancreas. Boluses of insulin are administered at the time of meals or snacks to mimic the normal physiologic peaks of insulin release in response to food intake. Four companies currently make insulin infusion pumps: MiniMed (http://www.minimed.com), Disetronic (http://www.disetronic.com/), Animas (http://www.animascorp.com/), and Deltec (http://www.delteccozmo.com). Although each has individualized features designed to set it apart from its competitors, they have many similarities. See Chapter 39 for additional information on insulin pump therapy.

Each of these battery-run, computerized insulin pumps is about the size of a beeper. They hold a reservoir of insulin and are worn externally, either on a waistband or in a pocket. The pumps are connected by an infusion set of thin plastic tubing that contains most commonly an introducer needle within a Teflon catheter at its end. The catheter, with the aid of the introducer needle, is inserted into the subcutaneous tissue of the abdomen, thigh, or buttocks and is left in place after removal of the introducer needle. Insulin is delivered through the tubing throughout the course of the day and night. The child or adolescent with diabetes or a parent must replace the manually inserted infusion set and the insulin supply every 2 to 3 days.

The ADA's Position Statement on CSII provides recommendations on provider aspects, patient selection, insulin pump choice, and safety (132). Issues related to the use of insulin pumps in the pediatric and adolescent populations are not addressed specifically in the position statement; however, the recommendations have been helpful in the development of center- or practice-specific pump protocols and education programs supporting assessment, initiation, and continued use of CSII in the pediatric population. Table 42.8 presents the advantages and disadvantages of insulin pump therapy. The success of these current insulin delivery systems revolves around the following factors:

- Intensive blood glucose monitoring minimally four to six times a day: none of the available insulin pumps are closedloop systems able to monitor blood glucose levels and deliver insulin automatically; all pumps must be manually programmed.
- Comfort with and utilization of carbohydrate counting: matching insulin and activity with carbohydrate intake.
- Adult support both at home and in school.
- Access to a diabetes team offering 24-hour/7-day-a-week problem solving and support. The number of decision-making points through the course of the day around fluctuations in blood glucose levels, carbohydrate intake, activity variables, illness, and the presence/absence of ketones makes it imperative that there be adult support in determining insulin doses.

TABLE 42.8. Advantages and Disadvantages of Insulin Pump Therapy		
Advantages	Disadvantages	
 Greater flexibility around timing of meals Greater flexibility with portion size of food Ability to intensify glycemic control Fewer severe hypoglycemic episodes Fewer injections Immediate access to insulin 	 Increased frequency of blood glucose and ketone monitoring Increased chance of hyperglycemia and DKA due to crimped infusion sets, air bubbles, and dislodged cannula Potential for skin abscess Change in hypoglycemic symptoms Constant attachment to the pump 	

There is no best, predetermined age to initiate insulin pump therapy. As with all diabetes management issues, individualized treatment plans, after considering the needs of the patient, as well as those of the family, are best. Presently, there are fewer young children than pre-adolescents and adolescents using insulin pumps. Use of insulin pump therapy at nighttime for young children along with daytime insulin injections has been shown to improve glycemia, counterregulatory hormone response, and awareness of hypoglycemia in certain pediatric populations (133,134). We have evaluated pump use in 170 youth with type 1 diabetes. While glycemic control improves after 3 months of pump use, HbA_{1c} values appear to return to baseline by 1 year (135). The worsening of glycemic control after the initial improvement stems from diminished blood glucose monitoring and missed insulin boluses.

At present, there are no clinically approved implantable pumps for children. All of the current pumps are open-loop systems, meaning that the pumps are not able to discern blood glucose levels and automatically deliver insulin. Clearly, the goal of all pump manufacturers is to develop a closed-loop system an artificial pancreas.

Inhaled insulin therapy may soon be available. Recent reports describe short-term safety and efficacy of inhaled insulin use in patients with type 1 or type 2 diabetes during a 12-week trial (136–138). In addition to receiving inhaled insulin before meals, the experimental group received injected ultralente insulin at bedtime. Additional pediatric studies, as well as long-term trials, are needed to confirm the safety and efficacy of inhaled insulin.

Children should never be forced to self-draw or self-administer insulin before they are either emotionally or physically ready for this responsibility. Although there is no one "right" age at which all children should be taught to prepare and inject insulin or insert pump sets, there are good studies to support the theory that, developmentally, many children may express interest and desire to participate in this responsibility around the age of 10 to 12 (63). Until that time, insulin administration is the responsibility of an adult care provider. All insulin drawnup and self-administered by a child should be supervised by an adult for accuracy of dosage and technique of injection.

THERAPY FOR TYPE 2 DIABETES IN YOUTH

The treatment goal for youth with type 2 diabetes, similar to that for type 1 diabetes, is normalization of blood glucose values and HbA_{1c}, with a major emphasis on lifestyle change around nutrition and physical activity. Management of related conditions such as hypertension and hyperlipidemia in pediatric patients with type 2 diabetes also is indicated. The overall goal of treatment is to reduce the risk of acute and chronic complications of diabetes. Treatment is aimed at lowering blood glucose levels to near-normal values in all patients with diabetes to avoid (a) acute metabolic decompensation due to DKA or NKHHS; (b) symptoms of polyuria, polydipsia, fatigue, weight loss with polyphagia, blurred vision, recurrent vaginitis/balanitis; (c) the development or progression of complications involving the eyes, kidneys, and nerves; and (d) failure to maintain normal growth and development and a near normal lifestyle.

The initial treatment of type 2 diabetes in youth depends on the clinical presentation (10). Severe hyperglycemia with NKHHS syndrome requires emergency management similar to that for DKA. Insulin will likely be needed as therapy in these patients even after recovery from the acute condition. Others who are not ill at diagnosis can be treated initially with medical nutrition therapy and physical activity (see sections below). Unless there is successful weight loss, most patients will require some form of drug therapy. Insulin was previously the only drug approved by the FDA for use in children. Metformin has recently been approved for the treatment of type 2 diabetes in youth age 12 years and older (139). Nonetheless, most pediatric endocrinologists use some of the oral anti-diabetes agents to treat children with type 2 diabetes, even while there are ongoing studies of many of these agents (46,49).

As with type 1 diabetes, the goal of treatment for youth with type 2 diabetes is normalization of blood glucose values and HbA_{1c}. Management of comorbid conditions such as hypertension and dyslipidemia should be initiated. Macrovascular risk factors such as hypertension and dyslipidemia, when found in a younger individual, have potential for significantly shortening life if diabetes complications begin in early adulthood (140).

Patients who present with DKA or NKHHS should be treated per protocol (see Chapter 53). Indications for initial treatment with insulin include dehydration, ketosis, and acidosis. After stabilization and follow-up, re-evaluation is necessary, as insulin may be tapered and an oral anti-diabetes agent introduced following improvement in metabolic control. Other patients may begin oral anti-diabetes agents along with diet therapy and exercise at diagnosis when the presentation suggests type 2 diabetes and the patient is stable. The consensus statement of the ADA published in March 2000 (10) recommends that metformin be the first oral agent used in pediatric patients with type 2 diabetes. Metformin should not be used in patients with known renal disease, hepatic disease, hypoxemic states, severe infections, or alcohol abuse or with radiocontrast material. In addition, patients of childbearing age should be made aware that metformin may normalize anovulatory cycles in patients with polycystic ovary syndrome, a common condition in adolescent females with type 2 diabetes (49,141,142). Thus, adequate birth control should be addressed in sexually active teens.

If monotherapy with metformin fails to accomplish glycemic goals within 3 to 6 months, additional therapy should be added to the treatment regimen. Supplemental agents include insulin, as well as other oral agents such as a sulfonylurea, other insulin secretagogues such as repaglinide and meglitinide, insulin sensitizers such as thiozolidenediones, or α -glucosidase inhibitors. Insulin can be started either at bedtime alone or twice daily. Frequent blood glucose monitoring should be encouraged, especially aimed at achieving fasting blood glucose levels of less than 126 mg/dL. Frequency of contact with the primary care provider or healthcare team will depend on the therapeutic response to treatment but should occur at least quarterly and more often when therapies are being altered.

MEDICAL NUTRITION THERAPY: NUTRITION EDUCATION

Dissemination of the results of the DCCT brought with it changes in a variety of diabetes self-management tools and recommendations (56,72). Most recently, the ADA's 2002 revision of the Evidence-Based Nutrition Principles and Recommendations increases flexibility in terms of food and meal plans for the child and adolescent with diabetes (143). As a member of the diabetes healthcare team, a registered dietitian provides medical nutrition therapy (MNT) through nutrition assessment, education, and counseling. Patients/families with newly diagnosed type 1 diabetes begin MNT as soon as the patient is medically stable following the diagnosis, and they continue MNT every 3 to 6 months in very young children and every 6 to 12 months in older children and adolescents. Patients with type 2 diabetes also begin MNT at diagnosis and continue as needed to attain weight loss goals. This enables appropriate, ongoing changes to the meal plan reflective of changes in growth and development, and based on family lifestyle and cultural food values.

MNT provides information, motivation, and problem-solving techniques for meal planning and family nutrition for children and adolescents with diabetes. Not surprisingly, children and adolescents with diabetes and their families, as well as professionals, often identify food as the most difficult part of diabetes self-management (100,144). Thus, MNT is an integral component of any successful diabetes self-management plan (143,145).

MNT must be individualized, provide appropriate nutrition, and match the lifestyle of the child or adolescent with diabetes and his or her family. A meal plan is not a diet; it is a guide to choosing healthy, age-appropriate foods in a way that contributes to various positive medical outcomes, such as blood glucose levels, lipid levels, blood pressure, renal function, and normal growth and development in children (143).

Appropriate meal planning should enable patients and families to optimize glycemic control by matching the insulin dose with food and activity. Meal planning is successful when the child or adolescent's meal plan provides flexibility, satiety, satisfaction, and inclusion for the picky eater, partygoer, fast-food lover, and school-lunch or college-cafeteria eater and promotes a sense of normalcy.

MNT provides an individualized prescription of calories and macronutrients for the child or adolescent, which is commonly known as a meal plan. It starts with a nutrition assessment and generates treatment goals (60). The assessment also collects clinical data, dietary history, nutrient intake, and a social history (60). The assessment generates goals for therapy. Goals should be age appropriate, attainable, socially appropriate, and clearly stated. General nutrition goals (143) for children and adolescents with diabetes follow:

- Reach and maintain optimal blood glucose levels
- · Achieve optimal lipid and lipoprotein levels
- Maintain normal blood pressure levels
- Prevent and/or treat the complications of diabetes
- Improve general overall health through healthy food choices and an active lifestyle
- Develop a meal plan that takes personal and cultural issues into consideration reflective of the individual/family's wishes and willingness to change
- Provide adequate calories for maintaining or attaining acceptable weight for adolescents and normal growth and development rates for children and adolescents
- For children and adolescents with type 2 diabetes, facilitate lifestyle changes in eating and physical activity.

A team approach by the registered dietitian, physician, nurse educator, and family and child with diabetes is required to achieve nutrition-related goals (145). For children and adolescents who are intensively managed, personal algorithms for therapy adjustment need to be developed (59). Use of blood glucose monitoring results allows for adjustments to the selfmanagement plan. Postprandial blood glucose values help in determining if the present algorithm is working. Knowledge of the child or adolescent's insulin-to-carbohydrate ratio, as well as insulin-sensitivity correction factor, can be important information in calculating the personal algorithm (see Chapter 36).

There are several distinct meal planning systems, such as the exchange system and carbohydrate counting. The DCCT showed that many different approaches to meal planning can be successful (56,72). The outdated "no-concentrated-sweets" approach is very restrictive. The 2002 Nutrition Recommendations offer an expert consensus stating that sucrose (table sugar) and sucrose-containing foods may be eaten but in the context of a healthy diet (143). The no-concentrated-sweets approach ignores important facets of MNT, such as the timing and consistency of meals and snacks. The four general approaches to medical nutrition therapy are (a) general guidelines (146); (b) meal planning (sample menus); (c) exchange lists; and (d) carbohydrate counting.

Both the exchange-list and carbohydrate-counting approaches incorporate flexibility and individualization and strive for optimal glycemic control. The exchange lists have six different exchange groups: bread/starch, protein, milk, fruit, vegetable, and fat. The carbohydrate counting method arises from the 1994 ADA Nutrition Recommendation guidelines, which consider that the total amount of carbohydrate, not the type of carbohydrate, impact on glycemic control (60,145). This allows for the incorporation of all carbohydrate sources, including sucrose, into the meal plan, providing maximum flexibility to patients of all ages. Counting "carbs" is the most common meal planning approach used with pediatric and adolescent populations with diabetes (see Chapter 36 on nutrition for more information on these meal-planning approaches).

MNT requires a caloric and macronutrient prescription. Nutrient requirements for children and adolescents with diabetes appear similar to those for their peers without diabetes. Table 42.9 gives general guidelines for calculating daily calories (60).

The 2002 Nutrition Recommendations allow for the carbohydrate, protein, and fat contents of meal plans to be individualized to achieve optimal metabolic goals. Protein intake of 15% to 20% is adequate for the general population (143). The Recommended Dietary Allowance (RDA) for protein ranges from 2.2 g/kg per day for infants to 0.9 g/kg per day for adolescent males age 15 through 18 years (60). As per the ADA recommendations, carbohydrate and monounsaturated fats combined should make up 60% to 70% of the meal plan (143).

The amount of fat in a meal plan for the child or adolescent over the age of 2 years should not exceed 30% of the total calories, with less than 10% from saturated fat, less than 10% from polyunsaturates; and 10% to 15% from monounsaturates. Dietary cholesterol should be limited to less than 300 mg/day.

Those patients who are of normal weight and have normal lipid levels are encouraged to follow the recommendations of the National Cholesterol Education Program (http://www .nhlbi.nih.gov/about/ncep/). Healthy fat intake can be encouraged by the consumption of lean cuts of red meat, more chicken and turkey without skin, fish and seafood, skim and low-fat milk and milk products, and vegetable proteins (legumes). The results of the Dietary Intervention Study in Children show that there are cholesterol-lowering benefits to a diet reduced in fat

TABLE 42.9. General Guidelines for Calculating Daily Calorie Requirements for Children and Adolescents

Age	Calorie requirements
0–12 y 12–15 y	1,000 kcal for 1st year + 100 kcal/y over age 1 y
Female Male	1,500–2,000 kcal + 100 kcal/y over age 12 y 2,000–2,500 kcal + 200 kcal/y over age 12 y
15–20 y Female Male	13–15 kcal/lb (29–33 kcal/kg) desired body weight 15–18 kcal/lb (33–40 kcal/kg) desired body weight

and cholesterol in children with elevated lipid levels. The study shows that a diet low in saturated fat and cholesterol is safe for children and is not a risk for altered growth, nutritional status, or sexual maturation (147). It is important that children and families know the value of a healthy meal plan that incorporates fat and cholesterol in appropriate amounts. As for the use of fat replacers, more research is needed on their role in a child's meal plan. Attention should be directed to the nutrition facts label for any products containing fat replacements, since many such products tend to be higher in carbohydrates than their fatcontaining counterparts (143). Following the ADA Nutrition Recommendations becomes important with the epidemic of childhood obesity and type 2 diabetes (11,12,39). Strategies to successfully decrease fat and total calories for children and adolescents with type 2 diabetes need to be developed.

Dietary fiber is a carbohydrate found in such foods as whole grains, breads, cereals, legumes, fruits, and vegetables. Fiber helps in the digestion process, provides satiety, and reduces levels of serum cholesterol and triglycerides. The recommended five-a-day servings of fruits and vegetables is a good guideline to use. Serving children and adolescents foods that provide a source of fiber provides essential vitamins and minerals for health and growth. Grams of fiber are listed on the nutrition label under *Total Carbohydrate*. When calculating the dose of rapid- or fast-acting insulin based on carbohydrate intake, if the serving to be eaten contains 5 or more grams of fiber, the numbers of fiber grams are subtracted from the grams of total carbohydrate. Use of foods containing a large amount of fiber for the treatment of hypoglycemia is *not* recommended.

Sweeteners, such as sucrose, fructose, or aspartame, can all be incorporated into the meal plan of a child or adolescent with diabetes. An individual assessment must be made as to the glycemic impact of these sweeteners. The carbohydrate content of nutritive sweeteners (e.g., sucrose, fructose, and sugar alcohols like sorbitol) must be calculated into the meal plan (143). Ingestion of large amounts of foods containing sugar alcohols like sorbitol, mannitol, and xylitol may cause gastrointestinal upset with flatus or diarrhea, particularly in young children. Choosing nutrient-rich foods is preferable to choosing "sweets" such as cakes and candy that tend to be foods with basically "empty" calories. However, it is important for children and adolescents with diabetes to "fit in" with their peers and share in the food aspects of celebrations, holidays, and parties that tend to include these "treats."

Nonnutritive sweeteners, commonly called "sugar substitutes," are often used in the meal plans of children and adolescents with diabetes. They include saccharin, aspartame, acesulfame potassium, and sucalose. The acceptable daily intake has been determined by the FDA for sweeteners in terms of safety of consumption, with a 100-fold safety factor (145,148). Use of packets and bulk forms of these products, as well as consumption of products such as diet sodas, sugar-free gelatins, and ice pops, will have little effect on blood glucose levels. The major problem is that patients and parents often ignore other components of foods and drinks containing these sweeteners and consume them liberally without calculating their calorie and carbohydrate contents into the meal plan. It is possible to calculate carbohydrates, protein, and fat in such foods from the nutritionfacts label based on the portion size eaten.

What, when, and how much food is eaten by children and adolescents with diabetes are all important. So, too, is where they eat. School is where all children spend the majority of their time; school is where all children have lunch more than 150 times a year. The child or adolescent with diabetes can eat "school lunches." Most school systems post the weekly or monthly school-lunch menu in the newspaper, on community bulletin boards, and, increasingly, on the Internet. School-lunch menus can be calculated to fit the child or adolescent's meal plan as needed for reasons of convenience, sociability, or cost.

Another important issue for the child or adolescent with diabetes is fast food. There are a variety of fast-food guides that provide nutrition information for menu items from most of the major fast-food restaurants. The child or adolescent with diabetes and his or her family benefit from knowledge of the content of carbohydrate, fat, protein, and total calories in fast foods so that they may best match insulin dosage or activity to the meal eaten. Paper copies or information from the Internet can provide this important fast-food nutrition information.

The self-management plan may call for the delivery of a rapid-acting insulin (lispro or aspart) at the end of a meal for some children. Food struggles are not new to parents nor are they specific to diabetes. Post-meal protocols utilizing rapidacting insulin can help to eliminate some of the food struggles and provide a better match of insulin dose to the food eaten.

Children and adolescents with type 1 diabetes have a slightly increased risk of celiac disease, a common cause of malabsorption in children (149-151). Celiac disease is an autoimmune-mediated disorder that occurs in genetically susceptible individuals. Immune-mediated damage to the mucosa of the small intestine occurs after exposure to the gliadin moiety of gluten, leading to destruction of the absorptive surfaces of the villi of the small intestine. Gluten is found in wheat, rye, barley, and possibly oats (152). Symptoms of celiac disease include diarrhea, weight loss or poor weight gain, growth failure, abdominal pain, chronic fatigue, irritability, an inability to concentrate, malnutrition due to malabsorption, and other gastrointestinal problems (152). Diabetes-specific symptoms may include unexplained hypoglycemia. Diagnosis is based on the results of a blood test [most specific-IgA to tissue transglutaminase (ttg) followed by small bowel biopsy]. At present, the only treatment for celiac disease is a gluten-free diet with the avoidance of the foods listed previously. Children and adolescents with diabetes who also have undiagnosed celiac disease or those diagnosed who do not follow a gluten-free diet often have unpredictable blood sugars with hypoglycemia and deterioration in glycemic control (151). It is very important for families of children with diabetes and celiac disease to work with a registered dietitian who has experience with both diabetes and celiac disease, as gluten-free foods are often very high in carbohvdrates.

Eating disorders constitute a challenge in the adolescent population, particularly in females. It is reported that adolescent females with diabetes are twice as likely as adolescent females in general to have an eating disorder or subthreshold eating disorder (153). Insulin omission with the goal of weight loss is the hallmark of eating disorders in the diabetes population (153,154). The resultant adverse health outcomes, such as high HbA1c values, increased hospitalizations, episodes of DKA, and eye and kidney complications, call for identification of and clinical intervention for eating disorders in this population (155-157). Use of such questionnaires as the General Survey of Eating Problems (EAT-26), Eating Disorder Examination (EDE), Children's Eating Disorder Examination, or the Diabetes Eating Problem Survey (DEPS), which is diabetes specific (155), provide tools for screening. As with the general population, more youths with diabetes have subthreshold eating disorders than have DSM-IV-classified eating disorders (158). Little in the literature addresses the problem of eating disorders in the pediatric or adolescent male population; however, practices such as weight gain during football season or weight loss during wrestling season, by way of manipulating insulin doses and food, have been seen in many pediatric and adolescent

endocrinology practices. In general, food can be a source of conflict for children and parents. Theories in the literature suggest that those youths with type 1 diabetes who have eating disorders have other underlying psychiatric disorders (159). The emphasis placed on food issues for youths with type 1 diabetes may increase the occurrence of eating disorders in this population (160).

In summary, MNT must be individualized to the family of the child or adolescent with diabetes. The measure of success of the meal plan within the self-management plan is optimal glycemic control with prevention of frequent episodes of hyperglycemia and hypoglycemia.

EXERCISE/PHYSICAL ACTIVITY

All children and adolescents need to be physically active! The Surgeon General's Report on Physical Activity and Health emphasizes the fundamental role of physical activity in promotion of health and prevention of disease (38). Physical activity is necessary for the optimal health for all children and adolescents.

For children and adolescents with diabetes, physical activity plays an added role as a tool in the diabetes treatment plan. For the child or adolescent with type 1 diabetes, a balance of exercise, insulin, and food, using information from blood glucose monitoring, enhances the attainment of optimal blood glucose control. The benefits of exercise for the child or adolescent with type 1 or type 2 diabetes are substantial. With the rise in childhood obesity and sedentary lifestyle, leading to an epidemic of type 2 diabetes in children and adolescents, an increase in physical activity and exercise is necessary. The Kaiser Family Foundation Study reports that the average American child uses electronic media outside of school more than 38 hours a week and that 53% of children 2 to 18 years old have a television in their bedrooms (161).

For the child or adolescent with type 2 diabetes, changes in lifestyle, including aerobic exercise, can result in improved outcomes in terms of glycemic control, weight loss, lipid abnormalities, and hypertension. The benefits of exercise for the child or adolescent with diabetes include:

- Improvement in blood glucose control
- Reduction in dosage of insulin
- Reduction in long-term health risks, including obesity, osteoporosis, hypertension, arteriosclerosis, and cardiovascular disorders
- Appropriate weight gain, weight maintenance, or weight loss
- Improvement in skeletal growth and strength
- Enhancement of muscle development
- Development of self-esteem and social and team building skills
- Development of lifelong healthy habits
- Psychological well-being and improved quality of life
- Stress reduction.

The child or adolescent must enjoy the physical activity, have access to the activity on a regular basis, and find it convenient and fun so that it becomes part of his or her lifestyle. Children and adolescents with diabetes should, like their peers who do not have diabetes, be able to profit from the physical and social benefits of physical activity.

It is important for physical activity to be a part of the family's lifestyle. The child or adolescent with diabetes should not be the only family member encouraged to incorporate physical activity into daily activities: father, mother, and siblings should also be active. Since children and adolescents spend the majority of their time in school and at school-based activities, school personnel and coaches must be aware of the beneficial nature of exercise for all students. Students with diabetes should participate fully in recess, gym classes, and sports. Education and preparation are important. Education for teachers and coaches should include an understanding of signs and symptoms of hypoglycemia and appropriate treatments. Preparation for the student with diabetes would include access to the appropriate supplies for the treatment of hypoglycemia.

The role of physical activity for children and adolescents with type 2 diabetes is paramount. Physical activity uses calories, decreases insulin resistance, and is a tool for weight maintenance or loss (162). Physical activity and dietary modifications are necessary lifestyle changes to improve short- and long-term outcomes for the child or adolescent (10–12,48).

Physical activity can increase the risk of hypoglycemia for children and adolescents who take insulin (163–166) or for those patients with type 2 diabetes who take blood-glucose-lowering oral medications (167). However, the occurrence of hypoglycemia during, immediately following, or hours after physical activity can be minimized. Remember that the child or adolescent is at maximal risk for hypoglycemia for up to 6 to 12 hours following physical activity (168)-the so-called lag effect. Newer management tools such as insulin analogues, insulin delivery devices, and blood glucose monitors can help to prevent and/or manage hypoglycemia. Since physical activity can increase the risk of hypoglycemia, it is necessary to develop individualized exercise/physical activity guidelines for the child or adolescent with type 1 or type 2 diabetes who is treated with insulin. This requires being in tune with individual responses to physical activity, insulin, and carbohydrate intake, arrived at empirically. Checking the blood glucose level before, sometimes during, and after physical activity should be encouraged. Use of blood glucose monitoring is necessary to make appropriate adjustments for physical activity as part of the diabetes treatment plan. These adjustments can decrease the frequency of hypoglycemia.

Children and adolescents with diabetes should always wear diabetes identification—a bracelet, necklace, or shoe tag—in case of hypoglycemic episodes and for a variety of other safety concerns. If the athletic association requires players to remove the identification during practices or games, it is imperative for the coach to be aware of who on his or her team has diabetes, to develop some form of plan (58) to identify when his or her player feels a need to be removed from the game because of symptoms of hypoglycemia, and to have available a source of rapid-acting carbohydrate. Depending on the intensity of the sport and the amount of water lost through dehydration and perspiration, many athletes will prepare their water bottle with a dilute form of fortified sports drink (50% water/50% sports drink) to replenish fluids, electrolytes, and glucose expended during the activity.

Adequate fluid intake is extremely important to avoid dehydration. Dehydration can have an adverse affect on blood glucose levels. Fluid intake before, during, and after exercise is recommended (169). Environmental factors—extremes of heat, humidity, cold, and altitude—can affect blood glucose levels during exercise, and precautions should be taken when exercise or any kind of physical activity is done in any of these environments (169).

Issues of oxygen consumption, muscle uptake, glycogen stores, triglycerides, and free fatty acids affect glycemic control. Maintenance of euglycemia during physical activity in the person with and without diabetes is for the most part hormonally mediated. In the person with type 1 diabetes who is insulindeficient, excessive release of counterregulatory hormones during physical activity may result in hyperglycemia and the formation of ketone bodies, which can lead to DKA (169).

Physical activity can lower blood glucose levels of patients with diabetes who begin with either normal blood glucose levels or moderate hyperglycemia. With extreme hyperglycemia, physical activity can exacerbate an insulinopenic state, and blood glucose levels may actually increase. It is best to avoid physical activity if ketones are present and/or if the blood glucose level is greater than 300 mg/dL and to treat the ketonuria/hyperglycemia first. If the blood glucose level is less than 100 mg/dL before physical activity, patients should take a carbohydrate snack to avoid hypoglycemia. Patients should be alert to the symptoms and signs of hypoglycemia during physical activity and for several hours thereafter. Patients should have a source of "sugar" (such as glucose tablets or glucose gel) readily available during and after physical activity to treat hypoglycemia. The risks and benefits of physical activity are specific to the individual child or adolescent with diabetes. It is highly recommended that an exercise physiologist, with experience in diabetes, set the physical activity prescription. Necessary adjustments to food and insulin must consider blood glucose levels at the time of physical activity, the type of activity, and the intensity and duration of activity in addition to the timing and dose of insulin, as well as the timing and amount of carbohydrate intake.

A variety of snack bars supply effective carbohydrate sources for the prevention and/or treatment of hypoglycemia. It has been hypothesized that foods containing resistant starch (cornstarch) or foods modified with resistant starch (high amylose cornstarch) may have an effect on postprandial glycemic response, including prevention of hypoglycemia. Thus, a variety of energy bar products are now available that contain resistant starch: uncooked cornstarch. People with diabetes may eat the bars at bedtime to help prevent nocturnal hypoglycemia. Conventional snack bars or energy bars, which contain 15 to 30 g of sugars, are designed to raise blood glucose levels before or during exercise. Some research findings support the utility of both types of products for the prevention of exercise-induced hypoglycemia (170–172). However, there are no published, evidence-based longitudinal studies in subjects with diabetes to prove benefits from the use of resistant starch (143).

The sole use of carbohydrate to treat or prevent an episode of hypoglycemia during physical activity is no longer recommended. For the child or adolescent striving to improve glycemic control or lose weight, the use of additional carbohydrate for physical activity can sabotage desired outcomes. Intensive insulin therapy, either by multiple daily injections or CSII, permits appropriate adjustments in the insulin dose for various activities. Newer insulin analogues and insulin delivery systems coupled with blood glucose monitoring tools allow for adjustments of both insulin and carbohydrates. The amount of adjustment necessary varies from patient to patient and is highly individualized. Individualized physical activity algorithms can be developed from exercise guidelines. In general, however, mild-to-moderate exercise may require that pre-exercise doses be decreased by about 20% for lispro, aspart, or regular insulin and by 10% for intermediate-acting insulin. Heavy exercise may require decreases of 30% to 50% for rapid-acting insulins and 20% to 35% for intermediate-acting insulins. It is difficult to make adjustments in ultralente or glargine insulin for physical activity because of their long duration of action. For patients who use an insulin pump and anticipate 60 minutes or more of exercise, a temporary basal rate may be set by decreasing the current basal rate by 25% to 40%. After the exercise, the pump user may continue with a diminished basal rate, by 25%, for 2 to 4 hours, depending on the intensity of exercise and past experience (59). If activity is strenuous, additional carbohydrates may also be needed. Young children with diabetes often

42: TREATMENT OF THE CHILD AND ADOLESCENT WITH DIABETES 727

have unpredictable levels of activity, so snacking is often the preferred adjustment, especially for play. Thus, prevention of hypoglycemia due to physical activity necessitates adjustments in both insulin and food. These preventive strategies must take into consideration the type, amount, and duration of the activity, in combination with such variables as the child's age, fitness level, and body mass (173). Although there is no evidence that physical activity in itself can significantly lower HbA_{1c} values, there is evidence of overall health benefits.

A standard recommendation for physical activity includes a 5- to 10-minute warm-up, followed by exercise, followed by a 5- to 10-minute cool-down period (169). This pertains to sports training and other exercises for children, adolescents, and young adults. Most physical activity for young children is spontaneous and is called "play"; for most of this type of physical activity, warm-ups and cool-downs are not necessary. Young individuals in good metabolic control can usually participate safely in most physical activities, including weight training (169). However, the older adolescent and young adult should have formal ophthalmology assessment before unrestricted participation in impact exercises or weight lifting. In addition, cardiac stress testing should be considered for the young adult.

For the most part, children and adolescents with diabetes follow the recommendations for physical activity as stated by the ADA (169). However, children and adolescents with diabetes often experience greater variability in blood glucose levels than do their adult counterparts.

For children, there needs to be a balance between glycemic control and the appropriate tasks of childhood and adolescence. This necessitates planning by parents, school personnel, athletic coaches, other adults, and sometimes even peers. Diabetes selfmanagement training and education on the causes, symptoms, and treatments of hypoglycemia and hyperglycemia; insulin adjustments; nutrition; and physical activity, can make a physically active lifestyle a safe and rewarding experience for children and adolescents with type 1 or type 2 diabetes (169).

MONITORING

The Position Statement of the ADA on tests of glycemia in diabetes stresses the importance of monitoring glycemic status (174). This includes self-monitoring of blood glucose (SMBG) and ketones as well as laboratory measurement of HbA_{1c} and, in certain situations, glycosylated serum protein. The HbA_{1c} has become the standard for assessing glycemic control over a period of approximately 2 to 3 months. The HbA_{1c} should be measured at diagnosis and every 3 months thereafter (174). Goals of therapy using HbA_{1c} data were discussed earlier in this chapter.

As a component of comprehensive self-management training, all children and adolescents with diabetes and their families should receive training in SMBG (33,34). SMBG is necessary for achievement of any of the treatment goals outlined previously. Frequency and timing of monitoring should be individualized to the patient's needs. During periods of acute illness, monitoring frequency should be increased to at least four to six times daily to avoid decompensation (175).

SMBG has made a tremendous impact on how diabetes is managed. Insulin doses, hypoglycemic treatments, physical activity, and general treatment behaviors are based on up-tothe-minute blood glucose results. Intensive therapy, as defined by the DCCT, with its adjustments to treatment regimens, is possible only by utilizing SMBG (56). Widely introduced in the 1980s, blood glucose monitors have become smaller, faster, more accurate, more available, more affordable, and less tech-

728 JOSLIN'S DIABETES MELLITUS

nique-dependent. Today, more than 30 different monitors are available for home use (176). Healthcare teams make recommendations for monitor use based on the needs of individual patients and families. There are some common features that better accommodate the needs of a pediatric population, such as small size, small blood sample requirement, and short time for results (69). Meter memory and computer download capacity are also important features. "Alternative-site" blood glucose monitors, which allow the use of alternative sites, such as the forearm, upper arm, thigh, calf, and places on the hand, are recent advances in meter technology. Patients report less pain with the use of such alternative sites. However, there have been reports of a lag in the detection of hypoglycemia when using alternative sites compared with fingertips (177). Thus, the FDA has encouraged manufacturers to recommend fingerstick as opposed to alternative-site blood glucose monitoring when hypoglycemia is suspected, in patients with hypoglycemic unawareness, or in very young children who are unable to communicate symptoms. Blood glucose monitoring strips have also been improved for easier blood sampling through capillaryaction strips (176).

It is important to note that blood glucose monitoring, whether on fingertips or forearms, with new or old monitors, is about the person with diabetes. It is important to remind patients and their families that they use blood glucose monitoring to provide data and inform management, rather than to criticize diabetes control (175). The diabetes healthcare team can help remove the "blame and shame" of diabetes by reinforcing to children and their parents that blood glucose levels are not "good" or "bad" but instead are "high," "in-range," or "low"; that blood glucose is "checked" not "tested"; and that levels always vary in a person with diabetes so expect some out-ofrange results (121). If patients feel blamed by their out-of-range numbers, if they think that blood glucose monitoring takes too much time, or if they do not know what to do with the information, the best and newest technology will not be of clinical value.

Another new monitoring technology involves blood ketone testing rather than traditional urine testing. Recent clinical trials have begun to evaluate the clinical utility of measuring blood ketones (β -hydroxybutyrate) with a home-based monitor (179,180). It is hoped that ongoing clinical research will determine how to use blood β -hydroxybutyrate measurements to better manage sick days, prevent metabolic decompensation, and decrease the economic and human burden of DKA (175). For additional discussion, see section on sick day rules.

Children with type 1 diabetes require monitoring for other diseases, as they are at increased risk for other autoimmune disorders. Clinical management should dictate the frequency with which thyroid function, adrenal function, and laboratory studies to assess gastrointestinal disorders such as celiac disease or inflammatory bowel disease should be monitored. Unexplained glycemic excursions or changes in growth should trigger investigation.

For additional discussions of hypoglycemia, see Chapter 40. Hyperglycemic emergencies and DKA are discussed in Chapter 53.

PREVENTION OF DIABETIC KETOACIDOSIS: SICK-DAY RULES

The cornerstones of sick-day management are (a) never omit insulin, (b) prevent dehydration and hypoglycemia, (c) monitor blood glucose frequently, (d) monitor for ketosis, (e) provide supplemental fast-acting or rapid-acting insulin doses according to guidelines, (f) treat underlying trigger(s), and (g) have frequent contact with the diabetes healthcare team to review clinical status.

Never Omit Insulin. Illness presents specific dilemmas for children and adolescents with diabetes and their families. Insulin must always be administered during illness, even if the child or adolescent is not eating. Infection induces insulin resistance, thereby often necessitating increased or supplemental doses of insulin. Generally, the usually prescribed insulin dosage is supplemented by rapid- or short-acting insulin in the form of lispro, aspart, or regular. The additional or supplemental dose is needed to manage the hyperglycemia and ketosis. The optimal supplemental dosage of insulin is calculated from the blood glucose level and the presence or absence of ketones. Ketones are detected in urine by semiquantitative measurements or with athome blood monitors that measure β -hydroxybutyrate (3HB). Additional studies are needed to help create and refine sick-day algorithms according to blood 3HB measurements (175,180,181). In general, supplemental insulin dosages, generally 10% to 20% of the total daily insulin dosage, are based on the blood glucose level and the urinary (or blood) ketone results (see Table 42.10 and section on supplemental insulin). Supplements of lispro or aspart may need to be repeated every 2 to 3 hours while regular insulin may need to be administered every 3 to 4 hours. Finally, if the blood glucose level is low, the patient's insulin dosage may be decreased by 20%. Examples of sick-day algorithms using either urine or blood ketone results are shown in Table 42.10.

Prevent Dehydration and Hypoglycemia. Fluid intake to prevent dehydration must be encouraged. Oral hydration is preferred but may be impossible at times of nausea and vomiting. In fact, the presence of vomiting and the inability to hold down orally administered fluids may be the limiting factor for the continued home management of a sick day. If vomiting persists, the healthcare team must be called immediately. Nonetheless, attempts at oral hydration with frequent, small quantities of "clear fluids" are recommended.

The blood glucose level determines whether sugar-containing or sugar-free fluids are used. When the patient is anorexic and usual solid food intake is curtailed or absent, sugar-containing drinks such as regular soda, clear juices, flavored sugarcontaining gelatin, or other glucose containing drinks are suggested to provide for usual carbohydrate intake, especially when blood glucose is under 180 to 200 mg/dL. Volumes of 3 to 8 ounces per hour or, for children, 2 mL per pound of body weight per hour or 3 L/m² per day should be encouraged. Fluids containing salt and potassium are helpful when gastrointestinal losses from vomiting or diarrhea occur. Fluids such as bouillon, broth, soda, and fruit juices, often in combination, are useful.

Sugar-free drinks are recommended when the patient is able to follow a usual meal plan or take in solids that provide adequate carbohydrates and calories. We suggest that families keep a "sick-day" cupboard stocked with nonperishable items such as gelatins that come as sugar-free and sugar-containing varieties. Antipyretics are important at times of fever in order to reduce any additional insensible fluid losses; in addition to antipyretics for oral use, antipyretics in suppository form are particularly useful at times of nausea and vomiting. Use of antiemetics should be individualized and usually only after consultation with the healthcare team.

Reassessment of hydration status is important to avoid decompensation. Evidence of dehydration such as weight loss, sunken eyes, or dry tongue indicates a need for prompt medical assessment.

Monitor Blood Glucose Frequently. Self- (or family) monitoring of blood glucose should be performed at least every 2 to 4 hours for sick-day management. More frequent monitoring is recommended if the glucose level is low. Maintaining careful records is helpful for tracking progression of illness and detecting early signs of decompensation prior to progression to frank DKA. Patients and families should be comfortable with the accuracy of their blood glucose meter by utilizing the "check strip" or control solutions periodically and insuring that their supplies are up to date.

Monitor for Ketosis. Traditionally, urine tests for ketones have been an important aspect of monitoring for sick-day management. Recommendations for urine testing for ketones have included testing at 2- to 4-hour intervals during illness, with stress, or whenever the blood glucose is consistently greater than 300 mg/dL (>16.7 mmol/L) (174). However, with the advent of blood monitors that can quantitate blood 3HB, the weaknesses inherent in urine ketone testing become apparent. Blood measurement of 3HB may be a better guide to insulin therapy in the home management of ketosis. A separate, larger issue is whether home use of the 3HB blood test can prove useful in the daily management of type 1 diabetes. Patients and medical staff must be taught how to deal with the new volume of information

that they will be collecting. In cases in which both serum glucose levels and ketone levels are elevated or normal, it will be reasonably clear what is required. But what should be done when there is some degree of discordance in the findings, for example, if 3HB levels are elevated in the setting of normal or near-normal glucose values? Clearly, more studies are necessary, and perhaps guidelines for patient self-management of 3HB levels need to be created that are based on the findings of empiric studies. A recent, randomized trial comparing sick-day management using blood 3HB measurements with urine ketone testing suggests reduced need for hospitalization or emergency department assessment with blood ketone versus urine ketone testing (182).

Reinforcement of ketone testing during illness, appropriate storage of supplies, and the use of insulin algorithms based on blood glucose and ketone results are necessary. Supplies for ketone testing must be stored according to the manufacturer's recommendations and replaced at the recommended intervals. Administration of supplemental insulin and hydration are generally adequate interventions for successful treatment of ketosis. If the patient fails to clear ketones within 12 hours, the diabetes healthcare team must be contacted for assessment.

Provide Supplemental Fast-Acting or Rapid-Acting Insulin. During any intercurrent illness, the frequency of monitoring blood glucose and ketone levels should be increased to every 2 to 4 hours. When the blood glucose level is greater than 300 mg/dL on two or more consecutive occasions, patients and families should always monitor for the presence of ketones. Ketones, in general, are markers of insulin deficiency and the need for supplemental insulin (Table 42.10). However, in the setting of gastrointestinal illness with vomiting, diarrhea, increased transit time, and malabsorption, hypoglycemia may prevail in the presence or absence of ketones. Under such circumstances, especially when the blood glucose level is less than 80 mg/dL in the setting of positive ketones, increasing fluid intake with the provision of 10 to15 g of carbohydrates should be encouraged until the blood glucose level increases. Recommendations include the continued administration of fluid until the ketones clear.

Supplemental doses of rapid-acting (lispro or aspart) or fastacting (regular) insulin should be administered in addition to usual insulin dosages whenever hyperglycemia and ketosis are present. The degree of hyperglycemia and the presence or absence of ketones determines the amount of supplemental insulin. Dosages of supplemental insulin are generally calculated according to weight (0.1-0.3 U/kg), as a percentage of total daily insulin dosage (usually between 10% and 20% of the total daily insulin requirement in the baseline state), or according to team-derived algorithms (Table 42.10) (60). Special algorithms may be required for patients treated with CSII (59). Multidisciplinary team involvement can help to individualize the approach, as particular needs vary according to the patient's insulin sensitivity, the severity and duration of the illness, and the presence of anorexia. If blood glucose levels remain elevated, with or without positive ketones, additional supplemental doses of regular insulin may be needed every 3 to 4 hours. If lispro or aspart insulin is given as the supplemental insulin, dosages may need to be repeated at 2- to 3-hour intervals. Patients (or family members) should continue to monitor blood glucose and urinary or blood ketones every 2 to 4 hours and keep careful records.

Treat Underlying Triggers. Any acute infectious process needs to be evaluated and treated accordingly. Intercurrent viral illnesses, not requiring any specific prescriptive therapy, may still produce elevated glucose levels and ketosis and require sick-day management. Symptomatic treatment with antipyretics and analgesics is beneficial. Patients with a history of recurrent DKA, with known eating disorders or psychosocial problems, and with poor glycemic control are at risk for decompensation and should be advised to call their healthcare team at the earliest symptoms and signs of illness or decompensation (101,183). It is advisable that patients always have access to a phone and transportation for follow-up care.

Frequent Contact with the Medical Team. Patients and family members should be advised to look out for signs that medical attention is needed. These include vomiting that continues for more than 2 to 4 hours; blood glucose levels that exceed 300 mg/dL or persistence of ketones for more than 12 hours; signs of dehydration such as dry mouth, cracked lips, sunken eyes, weight loss, or dry skin; or symptoms that DKA may be developing, such as nausea, abdominal or chest pain, vomiting, ketotic breath, hyperventilation, or altered consciousness. The latter suggests the need for immediate medical attention. If recognized early, milder forms of DKA can be treated in the ambulatory setting, obviating the need for hospitalization (184).

Illness and stress are common. For the child or adolescent with type 1 diabetes, these can be triggers for counterregulation and subsequent metabolic deterioration if no attention is paid to diabetes management tasks. Sick-day management requires increased monitoring of blood glucose and assessment for ketosis. Extensive experience has shown that by assiduously following the guidelines outlined in this protocol, families can successfully manage most intercurrent illnesses in children at home without recourse to a hospital emergency department.

BEHAVIORAL ISSUES

Diabetes care should include careful attention to the educational, developmental, and behavioral issues of childhood and adolescence. (See Chapter 37 for additional discussion.) Since diabetes treatment and self-management training for the child, adolescent, and family with diabetes is time-intensive, copious in content, and evolves over the course of childhood, adolescence, and into adulthood, a team of diverse health providers best accomplishes the goal of optimal diabetes management. This, too, is the position of the ADA's Standards of Medical Care, which calls for a multidisciplinary team approach to the care of the child or adolescent with diabetes (55).

Treatment of diabetes with training in self-management needs to address the overall issues of child and adolescent growth, development, temperament, and behavior, as well as the issues of the natural course of diabetes itself-diagnosis, adaptation, ongoing disease progression, and potential complications. What distinguishes diabetes from many other chronic diseases of childhood are the incessant demands made on patients and families for self-management and the clinical decision-making responsibilities given to parents almost immediately after diagnosis (185). To meet these demands, families need to make adjustments in their lifestyle. The role of the diabetes healthcare team is to help the child or adolescent and his or her family learn, practice, and revise diabetes self-management skills to succeed in balancing the complicated requirements of insulin injection/infusion, meal planning, and physical activity, using the information from frequent blood glucose monitoring. The development of the treatment plan is based on the commonalities of childhood and adolescence and the individualization that takes into account family factors, age, developmental stage, and issues of temperament. As is clear from the preceding discussions in this chapter, diabetes self-management affects many components of family life—eating, physical activity, finances, and time management. One main goal of the diabetes healthcare team is to prevent, predict, or manage behavioral and family complications that arise in response to the pediatric diabetes.

The Psychosocial Therapies Working Group reports that children and adolescents with type 1 or type 2 diabetes face unique demands in dealing with diabetes both because of the nature of their being children and adolescents and because of the chronicity of the disease. The psychosocial challenges include an increased risk for psychiatric disorders, including depression, adjustment and adaptation problems, and eating disorders. All of these disorders can result in poor metabolic control (89). A variety of psychosocial interventions have been shown to be effective in improving metabolic outcomes. As noted previously, this is evident from the outcomes from pediatric behavioral studies and clinical programs carried out at the Joslin Diabetes Center.

Behavioral Risk Factors: Uncontrolled Diabetes and Family Studies

Coping with the unrelenting demands of this chronic incurable disease, for which treatment is complex, difficult, and impacts

on the lifestyles of the patient and his or her family, is stressful. It is not surprising, therefore, that emotional difficulties are common. Consequently, an important goal of therapy is the prevention and the identification and treatment of emotional problems and the provision of continuous psychosocial support and encouragement to patients and their families. Despite the previous general description of the goals of therapy, it is critically important to tailor the goals of treatment to the capabilities of the individual patient and family.

Various diabetes treatment tools can significantly help manage and improve glycemic control (186,187). In particular, blood glucose monitoring is central to the successful management of diabetes (65,101,188). However, data suggest that only about 60% of patients with type 1 diabetes routinely perform blood glucose monitoring (189). In a series of studies in the Pediatric and Adolescent Unit at the Joslin Diabetes Center, we have systematically investigated behavioral and family factors that optimize glycemic control and adherence to blood glucose monitoring and other diabetes management tasks in children and adolescents with type 1 diabetes (65-67,101,189a). In summary, frequent blood glucose monitoring is related to better glycemic control; increased family involvement improves adherence to diabetes management tasks; and diabetes-specific family conflict, commonly related to food issues and blood glucose monitoring, hinders control.

Frequent Blood Glucose Monitoring Predicts Better Glycemic Control. In a cohort of young adolescents 10 to 15 years old with type 1 diabetes, the frequency of blood glucose monitoring was significantly associated with HbA_{1c} values, after controlling for gender, duration of diabetes, and pubertal development (Fig. 42.5). This significant association was recently confirmed in a study of 300 youth 7 to 16 years of age with type 1 diabetes at the Joslin Diabetes Center (101).

Parent Involvement in Diabetes Management Tasks Is Related to Increased Monitoring. Parent-adolescent teamwork supports increased adherence to blood glucose monitoring and does not increase family conflict (65). Previous studies have revealed that adherence to diabetes management tasks decreases over the early adolescent years (66,67). This coincides with the predictable decrease in parent involvement during adolescence (64–66). We developed a low-intensity, office-based intervention for 10 to 15 year olds and their parents aimed at maintaining parent involvement in diabetes management tasks over the early adolescent years without the triggering of increased diabetesrelated family conflict. This trial demonstrated sustained involvement, diminished family conflict, and better glycemic control. The intervention focused on new ways of communicating about blood glucose monitoring in families that avoided "shame and blame" and promoted realistic parental expectations for blood glucose levels in growing and developing adolescents (65,66).

Realistic Expectations and Blood Glucose Monitoring. We have developed materials focused on blood glucose monitoring for patients of all ages and their family members (121). The *Blood Glucose Monitoring Owners Manual* reviews the importance of monitoring, provides realistic expectations of blood glucose levels for patients and their families, and reinforces the increased flexibility in lifestyle that is possible with increased monitoring. This manual provides a new vocabulary around monitoring that includes the need to *check* (not test) blood glucose and that glucose levels can be *high* or *low* (not bad or good). In a study of 200 at-risk adults with baseline HbA_{1c} 8% or higher, use of this educational tool was significantly associated with more monitoring (P < .05) and less-negative attitudes (P < .05) (190).

Blood glucose results appear to trigger both negative and positive responses within families. We uncovered from surveys administered to youths ages 8 to 16 years multiple sources of conflict within families around diabetes management tasks. More than half the respondents endorsed conflict around blood glucose monitoring, insulin, and food issues (67) (Fig. 42.6). Decreased conflict within families was associated with increased frequency of blood glucose monitoring. Thus, education focused on positive communication within families around blood glucose results is important and will likely play a critical role with the introduction of the new technologies for frequent or near-continuous monitoring.

Intensive Insulin Therapy and Blood Glucose Monitoring. Our recent experience with insulin pump therapy (CSII) in youth with type 1 diabetes, the fastest-growing group of new pump users, confirms the importance of blood glucose monitoring for

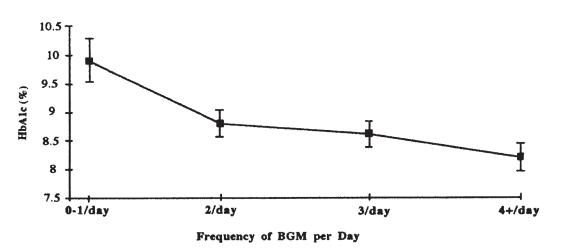

FIG. 42.5. Relationship of frequency of blood glucose monitoring (BGM) and glycemic control (HbA_{1c}) in young adolescents 10 to 15 years old at the Joslin Diabetes Center. (Reprinted from Anderson BJ, Ho J, Brackett J, et al. Parental involvement in diabetes management tasks: relationships to blood glucose monitoring adherence and metabolic control in young adolescents with insulin-dependent diabetes mellitus. *J Pediatr* 1997;130:257–265, copyright 1997 with permission from Elsevier.)

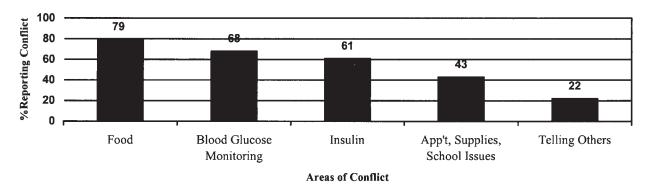

FIG. 42.6. Areas of family conflict reported by youth with type 1 diabetes (personal data).

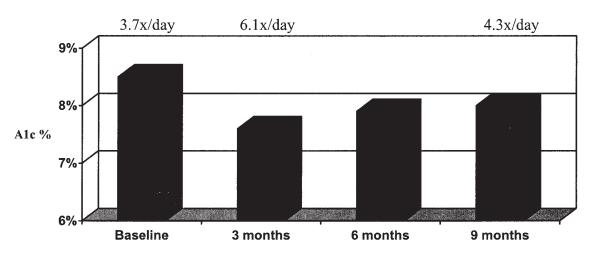

sustained improvement in glycemic control (191). Evaluation of 109 patients undergoing CSII showed improvement in HbA_{1c} results of about 1% after the first 3 months of pump use (192) (Fig. 42.7). This improvement was associated with a significant increase in blood glucose monitoring, from 3.7 times a day at 3 months. After 9 months of pump use, there was a decrease in the frequency of monitoring to 4.3 times a day. The decrease in monitoring was associated with a significant increase in HbA_{1c}. Thus, successful pump therapy requires sustained monitoring. With increasing numbers of pediatric patients beginning CSII, there is a need to incorporate family teamwork programs aimed at increasing and sustaining adherence to blood glucose monitoring with pump use (192).

DIABETES IN THE SCHOOL AND DAY-CARE SETTING

Children and adolescents with diabetes are not unlike their peers without diabetes—they spend the majority of their waking hours in school. Because of the need for optimal glycemic control for youth with diabetes, the tasks of diabetes self-management become a necessary part of the school day. The successful integration of diabetes management into the school setting is built on a foundation of good communication between the parent(s), child, school, and healthcare team. Knowledge, understanding, and skill building are necessary for the successful management of diabetes at school.

Laws protect the rights of children with diabetes in the United States, particularly Section 504 of the Rehabilitation Act of 1973, the Individuals with Disabilities Act of 1991, and the Americans with Disabilities Act-ensuring safe and full participation in all school activities. Because diabetes is classified in these laws as a disability, it is illegal to discriminate against a child or adolescent because of diabetes. These laws ensure that the child or adolescent with diabetes is able to monitor blood glucose, inject insulin, follow a meal plan, and participate in physical activities at school, both during the school day and during after-school extracurricular activities. Although children with diabetes are at risk for discrimination at school, great efforts have been made to ensure appropriate care and accommodation in the least restricted environment possible. To this end, the ADA has developed a position statement, "Care of Children With Diabetes in the School and Day Care Setting" (58).

The goal of the position statement is to provide direction for the care of children and adolescents during school. An individ-

Blood glucose monitoring frequency

FIG. 42.7. Relationship of frequency of blood glucose monitoring and glycemic control (HbA_{1c}) after the initiation of insulin pump therapy (CSII) in 109 youth with type 1 diabetes. (From Laffel L, Loughlin C, Ramchandani N, et al. Glycemic challenges of pump therapy (CSII) in youth with type 1 diabetes (T1DM). *Diabetes* 2001;50:A66–A67(abst).

ualized care plan provides the framework for addressing the needs of the child with diabetes in a school or day-care environment and states needs, responsibilities, and expectations of the school, the parents, and the child or adolescent during the school day and during school-related extracurricular activities. The development of an individualized diabetes healthcare plan should provide information on the needs of the child or adolescent with diabetes and instructions for blood glucose monitoring, meals and snacks, symptoms and treatment of hypoglycemia, administration of glucagon, symptoms and treatment of hyperglycemia, measurement of ketones, and sick-day rules (58).

School personnel, parents, the diabetes healthcare team, and the child or adolescent with diabetes all have the same goal: to have a healthy, happy student. Through accommodation and support of diabetes self-management tasks at school, the student with diabetes will be afforded the opportunity to safely succeed in diabetes management, academics, and development of evolving social skills.

In summary, pediatric behavioral studies and clinical programs have consistently documented the challenges of achieving optimal metabolic control in youth with diabetes. While new technologies provide hope to our patients and their families, they also increase the burdens placed upon them to achieve a new pattern of normalcy while integrating the rigors of diabetes management into their daily lives. To this end, support from a multidisciplinary diabetes team is important.

EPIDEMIOLOGY AND DIAGNOSIS OF DIABETES IN OLDER ADULTS 737

CHANGES IN CARBOHYDRATE METABOLISM WITH AGING 738

DIABETES AND THE PHYSIOLOGY OF AGING 738

TREATMENT OF THE OLDER ADULT WITH DIABETES 739

Determining Treatment Goals 739

- Despite the continual expansion of knowledge about diabetes, including the importance of control of risk factors and glycemia in decreasing the complications of diabetes, much of this knowledge does not specifically address issues in older adults, even though about 50% of people with diabetes in the United States are 60 years and older (1). For example, in the United Kingdom Prospective Diabetes Study (UKPDS), the mean age of participants was 53, although a few older people were enrolled and their number increased during the study. People with significant complications or comorbidities at diagnosis were excluded (2). Therefore, the implications of the results of the UKPDS for the millions of older people with prevalent as well as incident diabetes, many of whom have multiple comorbid conditions, are not yet clear (3).
- Clearly, diabetes in older adults is a major health problem (Table 43.1), and older patients with diabetes face major health problems. Those who develop diabetes during middle age will face its debilitating complications as they age or will die prematurely. Those who develop diabetes later in life face an increase in co-occurring risks and complications and comorbidities as they become very old. These older patients and their physicians have no clear clinical guidelines for diabetes management; recommendations must be extrapolated from studies of other age groups. Clinicians confronted with great heterogeneity in the older population and with rapidly changing knowledge about diabetes and its management must understand the similarities and differences in the pathophysiology and management of diabetes in older versus middle-aged adults.

EPIDEMIOLOGY AND DIAGNOSIS OF DIABETES IN OLDER ADULTS

tion Examination Survey (NHANES III), conducted by the National Center for Health Statistics from 1988 through 1994, provided the most recent estimates of the prevalence of diagnosed and undiagnosed diabetes mellitus in the United States among individuals 20 years and older. Among those 60 to 74 and those 75 years and older, respectively, 12.6% and 13.2% had previously diagnosed diabetes and 6.2% and 5.7% had newly diagnosed diabetes according to the criterion for fasting glucose levels established by the American Diabetes Association (ADA). An additional 5% to 6% of people age 60 to 74 met diabetes criteria based only on an oral glucose tolerance test (OGTT) value of more than 200 mg/dL at 2 hours. An overall prevalence of diabetes of approximately 25% among people age 60 to 74 years was confirmed in the Cardiovascular Health Study of older people in the United States and extended to the population over age 75 years. In addition to the high prevalence of diabetes, 20% had impaired glucose tolerance (IGT) by the 1997 ADA diagnostic criteria (4). The incidence of new diagnosis of diabetes mellitus also increased with age until about age 75 and then stabilized. The incidence rate was approximately two per 1,000 among those individuals aged 25 to 44 and increased to approximately five per 1,000 among individuals older than 45 (5).

Most individuals with diabetes who are older than 65 years have type 2 diabetes. However, type 1 diabetes occurs in this age group as well, including some with newly diagnosed diabetes (6). In addition, a small percentage of older individuals who initially have type 2 diabetes become insulin-dependent over time. While the HLA-DR3 allele is more common in older adults who require insulin treatment than in those who do not require insulin, the frequency of antibodies to islet cells in this group is not increased (6).

As in patients with type 2 diabetes in general, atherosclerotic complications are the most significant cause of morbidity and mortality in older patients with diabetes. Observational studies of older adults have suggested that poor glycemic control in

TABLE 43.1. Diabetes: A Key Problem in Older Adults

More than 20% of nursing home residents have diabetes

older people with diabetes contributes to excess risk of stroke and cardiovascular events (7,8). Atherosclerotic macrovascular disease accounts for 75% of the mortality among people with diabetes in the United States (9). In the UKPDS, 20% of patients with newly diagnosed diabetes developed macrovascular complications after 9 years, whereas only 9% developed microvascular complications (2).

Microvascular complications are also a significant problem in older adults. In the United States, diabetes is the major cause of renal failure and dialysis in people older than 65 years (10). Diabetic retinopathy is a major cause of visual loss in older adults, and even if it does not lead to blindness, it is associated with disability and depression (11,12). Peripheral neuropathy and peripheral vascular disease are particularly prevalent in older age groups (13). The prevalence of amputations increases with age, as do balance problems, mobility impairment, and chronic pain related to diabetic nerve disorders (14).

The prevalence of disability and functional impairment is greater in older people with diabetes than in older people without diabetes. Older adults with diabetes are about two to three times more likely to have physical limitations (15) and 1.5 times more likely to have ADL (activities of daily living) disability (16) than are those without diabetes. Much of this excess disability is a direct result of complications of diabetes, such as eye disease, stroke, cardiovascular disease, neuropathy, and peripheral vascular disease (15).

Because the hyperglycemia cutoff points for risk of diabetes complications appear to apply similarly to older and younger populations, the ADA diagnostic criteria for diabetes in adults are not modified by the patient's age. Recently, several studies comparing the groups identified by the previous criteria of the World Health Organization (17) versus the ADA fasting glucose criteria (18-21) have been published. Most have found a decreased prevalence of diabetes with the ADA criteria (19,22), although effects have varied in different populations (21). Although this difference in prevalence is small in middle-aged people, it increases with age because older people are more likely to have an elevated 2-hour postchallenge glucose level than an elevated fasting blood glucose level. In addition, the two criteria identify different groups who may have different risks for complications and different outcomes. Studies have suggested that fasting glucose levels may not predict progression to cardiovascular disease or mortality as well as an abnormal postchallenge glucose level (20). Similarly, the ADA category of impaired fasting glucose (IFG) may not predict progression to type 2 diabetes as well as IGT as defined by an OGTT (23). Again this discrepancy may be more pronounced in older adults.

Regardless of the effect of the current diagnostic criteria on determinations of diabetes prevalence in older adults, it is far more common in routine clinical practice to obtain a fasting glucose level than an OGTT. The clinician can use the results of the fasting glucose determination along with a 2-hour glucose level if IFG or other diabetes risk factors are present. It is important to have a high index of suspicion because of the high prevalence of known type 2 diabetes, previously undiagnosed diabetes, and IGT in older people, all of which are associated with excess risk for atherosclerotic disease and mortality. Therefore, *any* elevated fasting blood glucose should be evaluated, and if present on more than one occasion, should mandate the start of patient education regarding glucose intolerance and diabetes, management of associated risks for atherosclerotic disease, and if frank diabetes is present, management of hyperglycemia.

CHANGES IN CARBOHYDRATE METABOLISM WITH AGING

The prevalence of diabetes and glucose intolerance increases with advancing age. These abnormalities in carbohydrate metabolism have features in common, and the glucose intolerance associated with aging increases the risk for development of overt diabetes (24). There is no evidence to suggest that the pathophysiology of type 2 diabetes is any different in older adults than in younger adults. However, physiologic changes that appear to accompany the aging process produce alterations of glucose metabolism even in very healthy older individuals (25). These changes are manifested primarily as an elevation in postprandial blood glucose levels, which may increase by as much as 15 mg/dL (0.8 mmol/L) per decade after the age of 30. The tendency for older adults to have increased postchallenge glucose levels relative to fasting glucose levels has implications for prevalence of diabetes in older adults as defined by the 1997 ADA diagnostic criteria (discussed in previous section).

The pathophysiology of the changes in glucose tolerance associated with aging has been reviewed (25). Glucose absorption following glucose ingestion may be slowed with increasing age, and suppression of hepatic glucose production is delayed (most likely as a result of delayed insulin secretion). A number of age-related changes in regulation of insulin secretion and insulin action have been described.

In addition to intrinsic changes of aging, extrinsic factors may contribute to glucose intolerance. Both the decline in lean body mass and the increase in body fat that accompany aging may contribute to insulin resistance. Levels of physical activity decline with age, and such changes may precipitate or accelerate changes in body composition. Studies of both master athletes and older nonathletes suggest that some of these changes can be either prevented or modified with exercise. Drugs commonly used by older individuals, including diuretics, estrogen, sympathomimetics, glucocorticoids, niacin, phenytoin, and tricyclic antidepressants, can adversely affect glucose metabolism, exacerbating glucose intolerance. Stress states such as myocardial infarction, infection, burns, and surgery can worsen glucose intolerance and precipitate fasting hyperglycemia.

DIABETES AND THE PHYSIOLOGY OF AGING

Many effects of diabetes appear to accelerate age-related physiologic changes. For example, the presence of diabetes confers on diabetic women a risk of cardiovascular disease equal to that for men at the same age (26). Some of the mechanisms presumed to underlie this accelerated vascular aging include effects of diabetes on platelets, increased glycosylation of vascular tissues, and lipoprotein alterations associated with diabetes (27–29).

Changes that occur with diabetes and changes that occur with aging may interact, especially with respect to the general age-related decrease in physiologic reserve in many organ systems. Although most physiologic systems (cardiovascular, renal, pulmonary, central nervous system) in older people function appropriately under normal stable conditions, they may be unable to cope with the increased demands posed by acute illness or injury. Complications of diabetes leading to end-organ damage may further accelerate this loss of physiologic reserve. In addition, the clinical manifestations of diabetes may stress physiologic systems even in the absence of frank pathology. For example, even a mild increase in urine volume in an older diabetic patient with poorly controlled hyperglycemia may exacerbate bladder dysfunction and lead to urinary incontinence. Glycosuria, even without polyuria, can lead to electrolyte imbalance and cardiac arrhythmias.

TREATMENT OF THE OLDER ADULT WITH DIABETES

Determining Treatment Goals

The goals of diabetes management for older patients are not different from those for other patients, and as with patients with diabetes of any age, include far more than treatment of hyperglycemia. These goals are summarized in Table 43.2.

It is important to consider the similarities and differences between older and younger people with diabetes and their impact on diabetes management. Like younger people with diabetes, most older people with diabetes are highly functional and active and deserve the same attention to diabetes management as do younger patients. For both age groups, macrovascular complications are the major causes of morbidity and mortality related to diabetes. For both age groups, co-occurrence of other atherosclerotic risk factors are frequent, and the management of such associated risk factors has been shown to have a favorable impact on morbidity and mortality (30). Finally, the management of diabetes for most people with diabetes, regardless of age, has been shown to be inadequate, with poor physician and patient adherence to published guidelines and recommendations (31–35).

Some key differences between older and younger patients with diabetes can affect management. The older population is very heterogeneous both with respect to their diabetes and their general health status. An older patient with "newly diagnosed" diabetes may truly be a new diabetic patient, with no evidence of diabetes complications and comorbidities; may have had IGT or undiagnosed diabetes for years with complications present at diagnosis; or may have none or many related or unrelated comorbid diseases and disabilities. Some older patients may be more symptomatic from hyperglycemia than are younger patients but are also more prone to complications of treatment. Finally, special evaluation and treatment goals must be devised for frail elderly patients (i.e., those who have multiple comorbidities and disabilities and a significantly impaired physiologic reserve).

43: TREATMENT OF OLDER ADULTS WITH DIABETES 739

Because of this complexity and heterogeneity, selecting appropriate management goals for older patients with diabetes should be based on a detailed evaluation. A complete history and physical examination should be done at the time of diagnosis, when control of hyperglycemia and risk factors is inadequate, or when a reassessment of the patient's status is needed. Diabetes complications and the presence of risk factors for diabetic complications, as well as co-occurring diseases and disorders and general functioning, must be assessed.

A key component of the medical history for all patients with diabetes, but especially older patients, is a thorough evaluation of their medications, including prescription and over-thecounter drugs, "alternative medications," and dietary supplements. Older patients commonly take several medications, and drug–drug interactions, drug–disease interactions, and increased expense can be problematic in patients taking multiple drugs.

Laboratory evaluations and subspecialty referrals recommended for older patients with diabetes are not substantially different from those for middle-aged patients with type 2 diabetes, except in unusual circumstances such as severe debilitation or advanced dementia. Laboratory evaluation should include determinations of fasting serum glucose level, glycosylated hemoglobin (HbA_{1c}) (to assess previous level of control and to be used as a baseline), fasting lipid profile, and serum creatinine; urinalysis with examination for proteinuria or microalbuminuria; and an electrocardiogram. The ADA recommends ophthalmologic evaluation at the time of diagnosis and yearly for all patients with type 2 diabetes (12), a recommendation that applies to elderly patients as well, who are at high risk for ocular diseases other than retinopathy.

Recently, the American Geriatrics Society and the California Healthcare Foundation convened a multidisciplinary expert panel to develop evidence-based guidelines to improve diabetes management in older adults (36). A major recommendation was that management be individualized according to health status and preferences of the older diabetes patient. They also recommended that an evaluation of an older diabetes patient include screening and management of geriatric syndromes: polypharmacy, cognitive impairment, depression, falls, urinary incontinence, and pain. Geriatric syndromes are more common in older adults with diabetes than in those without diabetes. (See referenced guidelines for details.)

For many older patients with diabetes, especially those with several comorbid conditions and "geriatric syndromes" and/or problems managing their diabetes, a comprehensive geriatric evaluation, sometimes also referred to as a geriatric or functional assessment, is indicated (36a,37). This is a multifaceted assessment of the patient's capabilities for self-care, including ADL (bathing, grooming, dressing, feeding, toileting, and transferring) and instrumental ADL (e.g., shopping, telephoning, finances, and housework), and indicates the amount of assistance, if any, that the patient needs. It also includes assessment of nutritional status, evaluation for possible depression or cognitive impairment, and evaluation of the patient's social support systems, financial and insurance status, and advance medical directives. Nursing and social-work assistance is invaluable for both geriatric assessment and diabetes teaching and self-management support. These health professionals can help patients and their families access support services available in the community. For some patients, referral to a geriatrician may be necessary.

Symptomatic Hyperglycemia in Older Patients

Aging-related changes and increased comorbid conditions make older patients with diabetes particularly vulnerable to

740 JOSLIN'S DIABETES MELLITUS

symptoms of hyperglycemia, even if those symptoms are not the "classic" symptoms. Symptoms such as falls, fatigue, dizziness, and increased incontinence may often be traced back to hyperglycemia-associated polyuria. Glycosuria may also be associated with weight loss caused by the loss of calories in the urine. Older people may be at increased risk for depletion of trace nutrients and minerals caused by osmotic diuresis. Magnesium and potassium deficiencies can have deleterious effects on cardiac conduction. Glycosuria can also increase phosphate excretion, which can accelerate calcium loss from bone (38). An impaired central thirst response in older people may contribute to the volume depletion due to osmotic diuresis from hyperglycemia. Clearly, elimination of glycosuria is an important therapeutic goal (blood glucose level approximately 200 mg/dL or 11 mmol/L) in older people with diabetes.

Weight loss caused by uncontrolled hyperglycemia can be a significant problem. Patients with weight loss may be in a constant catabolic state, which can lead to loss of muscle mass, weakness, and potentially to falls and injury. Older patients may not perceive increased hunger, in some cases exacerbating poor nutritional status. The associated catabolic state may predispose to infections and other complications of malnutrition.

An increased concentration of glucose or its metabolites in the lens and aqueous humor of the eye can lead to visual problems. Hyperglycemia may predispose patients to bacterial and fungal infection and increased pain perception (39) and may alter platelet adhesiveness, worsening intermittent claudication. Lipid abnormalities also worsen with poor glycemic control, and high triglyceride levels can predispose to pancreatitis. A careful search for such symptoms of hyperglycemia is clearly indicated in elderly diabetic patients.

In many older patients, symptoms associated with diabetes and hyperglycemia may be atypical. For example, hyperglycemia does not usually lead to dramatic polyuria and polydipsia; more often there will be increased incontinence, a urinary tract infection, or increased lethargy or mental confusion. Similarly, undiagnosed or unmanaged diabetes may manifest as increased bacterial or fungal infections of the skin, unexplained weight loss, increased fatigue, or slow wound healing. Increased paresthesias and weakness, orthostatic hypotension with falls, or decreased vision also should raise suspicion for undiagnosed or inadequately managed diabetes.

The most severe complication of diabetes in older individuals is hyperglycemic hyperosmolar nonketotic coma. This condition is seen almost exclusively in older patients with diabetes. It is often precipitated by a catastrophic event, such as myocardial infarction or stroke, and can sometimes occur in people not previously known to have diabetes. Details of inpatient management are discussed elsewhere in this volume (Chapter 65).

Management of Atherosclerotic Risks and Complications

Findings from the UKPDS and other studies have made it clear that treatment of associated risks for atherosclerotic disease is a major goal of diabetes management (40). A higher proportion of older than younger patients with diabetes have associated hypertension, hyperlipidemia, and atherosclerotic arterial disease (41–45). Although fewer older than younger people smoke cigarettes, smoking-cessation programs should be encouraged for those who do smoke (46). Older patients with diabetes have been shown to benefit as much as or more than patients without diabetes from treatment of hypertension (47). Meta-analysis has shown aspirin use to be beneficial in older patients with diabetes who are at risk for atherosclerosis or have atherosclerosis (48). Treatment of hyperlipidemia in diabetic patients with cardiovascular disease has been shown to be beneficial and may decrease mortality among those who may develop cardiovascular disease; no age limit has been defined (3), although the data available on people older than 75 years are limited. Peripheral vascular occlusive disease and amputations increase with age; therefore, monitoring and evaluation for circulatory problems are indicated. Preventative treatment and monitoring for complications are not appropriate for the few older patients who are in a preterminal state or have advanced dementia. Most older people, even those with comorbidities and disability, will benefit from interventions shown to prevent or slow an increasing burden of illness over a period of several years.

Management of Microvascular Risks and Complications

Many dialysis patients older than 60 have diabetic renal disease, and because of the increasing prevalence of diabetes, the number of older people who have diabetic renal disease is increasing. Currently, treatment of hypertension and hyperglycemia are the major recommended interventions for preventing end-stage renal disease due to diabetes (10). These interventions are appropriate for most older patients with diabetes.

Peripheral neuropathy leading to pain, neuropathic joints, wounds, mobility problems, and amputations contributes to disability and poor quality of life in older patients. The little evidence available suggests that foot care and monitoring may be associated with better outcomes.

Although macular degeneration is the major cause of blindness after age 65, poor vision due to macular edema or other diabetes-related eye disease is highly prevalent among older people with diabetes. Simulations have suggested that few older persons with new-onset diabetes will become blind because of diabetes (49). However, it is important to remember that most older people do not have new-onset diabetes, many have had diabetes for 10 years or more, and the true duration of diabetes is not known for many others. Eye disease either due to or related to diabetes is prevalent in such patients. Therefore, yearly ophthalmologic referral is warranted for most older people with diabetes.

Treatment of Hyperglycemia

While there is broad agreement that symptomatic hyperglycemia should be treated in all older patients regardless of health status, there is much more controversy regarding the benefits of aggressive control of asymptomatic hyperglycemia in older patients. The UKPDS demonstrated that lowering glucose levels reduced risk of microvascular disease (50). Observational studies in older people also suggest that improved glycemic control is associated with improved outcomes-both macrovascular and microvascular. Thus, although the benefits of glycemic control in older diabetes patients have not been demonstrated conclusively, the weight of available evidence suggests it is beneficial. The physician and the older patient must decide when tight glycemic control for potential prevention of long-term complications of diabetes is a reasonable therapeutic goal. If the decision is made to attempt, glycemic goals would be exactly the same as those for middle-aged people.

Several arguments have been made against choosing an aggressive management program for older adults with diabetes. One such argument is that some elderly patients may be less capable than younger patients of carrying out activities requiring the high levels of skill, commitment, and diabetes education necessary to achieving an aggressive treatment goal. However, while methods of learning and memory do change with age, most older individuals are fully capable of learning complicated concepts and tasks (51). To the extent that older adults lead a less hectic, more ordered life than younger adults, it may actually be easier for them to make the type of adjustments in lifestyle necessary for adherence to a good diabetes treatment program. In fact, recent evidence from NHANES III (52) and a community population in Michigan (53) suggest that, on average, glycemic control in older adults may not be any worse than that in younger people with type 2 diabetes.

A common argument against aggressive diabetes management in older adults is based on inaccurate estimates of life expectancy (i.e., why try to prevent complications in someone who is likely to die soon?). However, the median remaining life expectancy for individuals aged 65 is more than 17 years; for those aged 75, 10 years; and for those aged 85, 6 years (54). Furthermore, these median estimates will be exceeded by approximately 50% of the people in a given age cohort. Thus, there is substantial time for the development of diabetes complications in patients whose diagnosis is made during their 60s or 70s.

It is also clear that elderly individuals are susceptible to virtually all of the chronic complications of diabetes. Age and diabetes frequently interact to worsen the risk for many of these complications. For example, creatinine clearance declines with normal aging (55), and age is an independent risk factor for the development of peripheral neuropathy (56,57). Until studies are available demonstrating that the risks of tight glycemic control outweigh the benefits in older adults or that glycemic control does not prevent the development of complications, many elderly patients deserve the same consideration as younger adults regarding aggressive management of their disease.

Some older patients who have a limited life expectancy, multiple chronic diseases, functional or cognitive impairments, poor social support, or who take multiple medications, are clearly not candidates for aggressive management of hyperglycemia (see Frail Older People). For these patients, treatment of symptomatic hyperglycemia and monitoring and managing complications and comorbidities are indicated. One proposed way of deciding about tight glycemic control for a given patient is to consider whether it would be of either no benefit or high risk (30). For older patients, characteristics such as frequent hypoglycemia or severe cognitive impairment would suggest high risk, whereas a preterminal state or advanced disability would suggest that it would not be beneficial.

Once the level of care is decided, subsequent management of older adults becomes clearer. In short, the treatment regimen chosen is the one necessary to achieve treatment goals. The four standard modalities of diabetes therapy—diet, exercise, oral hypoglycemic agents, and administration of insulin—all merit consideration for older adults.

DIET

The role of medical nutritional therapy has been substantially redefined by the ADA (58), and there is no uniformly recommended ADA diet. In general, dietary therapy must be individualized to support the goals of diabetes management; this is true for older as well as younger patients with diabetes. While weight loss in overweight patients with diabetes has many benefits (improved short-term glycemic control, improved blood pressure and lipid profile, and improved glucose tolerance), it has proven difficult for people of any age. Therefore, the goal of dietary therapy is not specifically weight loss. Rather, nutritional therapy should be designed to contribute to optimal glycemic, lipid, and blood pressure management. In obese patients, this may include hypocaloric diets, but it is important to remember that up to one third of older patients with diabetes are not obese and some are undernourished. In these undernourished patients, caloric supplementation and reversal of a catabolic state would be important. The ADA has recognized this fact with special recommendations for institutionalized patients with diabetes that include an increase in caloric intake when appropriate (58).

Older patients with diabetes often have multiple issues to be considered in a nutritional prescription. These include appropriate caloric targets, micronutrient assessment, and the role of dietary management for associated hypertension, hyperlipidemia, and renal disease if present. In addition, older patients may have problems with shopping, finances, or meal preparation that may become evident only during a dietary assessment. Therefore, dietary education and support in nutritional selfmanagement remain important.

EXERCISE

Exercise has been shown to improve glucose tolerance and to be useful in chronic glycemic control in persons with type 2 diabetes (59). However, a much broader consensus regarding the benefits of exercise is emerging—unfortunately without specific clinical recommendations regarding exercise prescriptions for older patients with diabetes. A decrease in the levels of physical activity in the population has been linked to an increase in the prevalence of obesity and type 2 diabetes; the role of exercise as part of lifestyle intervention in the prevention of type 2 diabetes is currently under study (60). In other chronic conditions, including hyperlipidemia, hypertension, atherosclerotic heart disease, and even heart failure, exercise appears to confer therapeutic benefits, although more specific information is needed. Even in frail older patients, resistance and aerobic exercises have been shown to have objective and subjective benefits (61), although such benefits may be short-lived.

Currently, exercise recommendations must be individualized for patients with type 2 diabetes regardless of age. In older patients for whom the goals of treatment include prevention of diabetes complications and glycemic control, an exercise program is part of a diabetes self-care regimen. Clinical judgment is needed regarding exercise recommendations if clinical or preclinical cardiovascular disease is suspected. In frail elderly patients, some forms of exercise may be appropriate and may be directed at conditions other than their diabetes. Unfortunately, despite the many proven or suspected benefits of exercise, there is no clear consensus on precisely what exercise recommendation or what preexercise evaluation is appropriate for any patient with type 2 diabetes, regardless of age or health status.

ORAL MEDICATIONS

Several different classes of medications that work by different mechanisms are currently available for the treatment of hyperglycemia. Most have been tested to some degree in older patients, so benefits and concerns about their use in older people with diabetes have been identified. In older patients with diabetes, combination therapy for hyperglycemia that is based on complementary actions of different drugs can be used. In general, the potential benefit of improved control of hyperglycemia without the use of insulin must be balanced against potential risks associated with a higher prevalence of contraindications to some drugs, polypharmacy, decreased compliance with multidrug therapy, and increased financial burden. At this time, there is no consensus on what constitutes the best approach to pharmacologic therapy for hyperglycemia in older adults.

Sulfonylureas

The sulfonylureas have many advantages for the management of hyperglycemia in older patients with diabetes. First, they are efficacious, with proven ability to decrease HbA_{1c} levels by up to 3% to 5%, and there is no evidence suggesting that these drugs are any less effective in older adults than in younger adults. These drugs have been available for many years, so physicians and patients are familiar with them. They have a good safety profile, an easy dosing schedule, and are much less expensive than newer oral agents. They remain first-line agents for any older patient with diabetes for whom the decision has been made to treat hyperglycemia with medications.

The major risk for older adults treated with sulfonylureas is hypoglycemia. Although hypoglycemic attacks are relatively rare, with attacks leading to hospitalization reported to occur with a frequency of 1.23 cases per 1,000 patient treatment years (62), age alone is a significant risk factor for hypoglycemia. There are multiple factors associated with aging that might increase the risk for hypoglycemia. These include age-associated impairments in hepatic and renal function that alter drug metabolism and excretion. The impairment of hepatic oxidative pathways associated with aging may increase the half-lives of sulfonylureas, which are metabolized extensively by the liver. Renal function, as measured by creatinine clearance, declines with age (55), and insulin clearance has been shown to be reduced (63). Aging also is associated with impairments in the autonomic nervous system (64,65) and reductions in α -adrenergic receptor function (66), suggesting that the sensation of glycemia may not be as acute in older adults as in younger adults. The elderly are frequent users of drugs that are known to increase the risk for hypoglycemia, including α -adrenergic blockers, salicylates, warfarin, sulfonamides, and alcohol. The longer-acting sulfonylureas, glyburide and chlorpropamide, have been reported to cause more episodes of hypoglycemia (67). Hyponatremia has also been seen in older diabetes patients using chlorpropamide, a development that may be related to a drug interaction with thiazide diuretics (68) and intrinsic changes in water metabolism with aging.

Biguanide

Metformin, the only biguanide currently available in the United States, has both advantages and disadvantages for treatment of older patients with diabetes. Chapter 41 has reviewed its characteristics in detail and its proven benefit in obese type 2 diabetes patients (69). A major advantage of metformin for older patients is that, because of its mechanism of action, it does not produce hypoglycemia when used as a single agent. In addition, its association with weight loss is potentially beneficial to obese older patients, especially the frail elderly and/or those in nursing homes, are not obese and may not be good candidates for metformin. Older patients with hyperlipidemia may benefit from the favorable effects of metformin on lipid profiles.

The major disadvantage of metformin in older patients is its interaction with comorbid conditions, many of which are prevalent in older patients. It is relatively contraindicated in the presence of congestive heart failure, liver disease, and especially renal disease. It should not be used if the serum creatinine exceeds 1.4 mg/dL (124 μ mol/L) (women) or 1.5 mg/dL (133 μ mol/L) (men). Since the serum creatinine value will overestimate the creatinine clearance in an older patient who has decreased muscle mass, an even lower serum creatinine level may be a cause for concern in such a patient. Therefore, the presence of these conditions, even if asymptomatic, must be carefully assessed in older patients.

Another potential disadvantage of metformin is its gastrointestinal (GI) side effects, generally bloating and flatulence, which may affect older adults more than younger adults. However, it is not known whether older people are more likely than younger people to discontinue metformin because of GI symptoms.

Metformin costs more than the sulfonylurea medications and insulin but less than other oral agents used for treating diabetes.

α-Glucosidase Inhibitors

Acarbose and miglitol are α -glucosidase inhibitors, which delay absorption of sugars through the GI tract. Because postprandial hyperglycemia is particularly common in older people, these agents may merit consideration. They lower HbA_{1c} levels by about 1% (on average) (70). Because of their mechanism of action, they do not cause hypoglycemia, but their use in combination with another hypoglycemic agent may make it more difficult to treat hypoglycemia. The most common side effects are GI. Although they do not cause symptoms of malabsorption, they potentially can lead to weight loss. These drugs are currently more expensive than sulfonylureas or insulin. Although their safety makes them attractive for elderly patients, the potential for weight loss and GI side effects limits their use for older patients with diabetes who are undernourished. These agents can be used as part of combination therapy. Their use in combination with metformin may worsen GI discomfort.

Thiazolidinediones

The thiazolidinediones improve insulin sensitivity and thus could be of particular benefit to older patients with diabetes, who in addition to having diabetes, may have aging-associated insulin resistance. These drugs have moderate potency, lowering HbA_{1c} by up to 2% to 4% (71), although it is not known if this is different in older patients with diabetes. Two thiazolidinediones, pioglitazone and rosiglitazone, are now available. The drugs are currently very expensive, limiting their use for low-income elderly patients. They may be used as part of combination therapy when one agent alone is insufficient to achieve desired control of hyperglycemia.

Meglitinides

Repaglinide is the first of a new class of oral hypoglycemics that enhance insulin secretion, but by a mechanism different from that of the sulfonylureas. Repaglinide acts rapidly to enhance insulin secretion, so it is designed to be used immediately before meals. It is of moderate potency and is currently expensive. No specific information is yet available regarding its use in older patients. If used as additive therapy with sulfonylureas, repaglinide presumably could increase the risk of hypoglycemia. The role of repaglinide in older patients with diabetes awaits further clinical and testing.

D-Phenylalanine Derivative

Nateglinide is the first of a new class of hypoglycemic agent that is a derivative of the amino acid D-phenylalanine. It became available for clinical use in 2001. Nateglinide acts directly on pancreatic β -cells to rapidly stimulate insulin secretion. Because of the rapid onset and short duration of action, it was developed to address mealtime needs for insulin secretion. It is to be taken shortly before a meal at a standard dose of 120 mg, although a 60-mg dose also is available. Because of the glucose-level dependency of its effect on insulin secretion and its short duration of action, its use has been associated with a low rate of hypoglycemia when used alone or in combination with other agents such as metformin. There are currently no known drug interactions, and nateglinide can be used in patients with renal insufficiency.

Older Patients: Advantages and Disadvantages			
Advantages		Disadvantages	
	Improved glycemic control Potential metabolic benefits due to different drug mechanisms May be easier than multidose insulin May be safer than multidose insulin	Cost Increased hypoglycemia risk May worsen gastrointestinal symptoms Risk of adverse drug effects due to polypharmacy and comorbidity	

TABLE 43.3. Combination Oral Therapy of Hyperglycemia in Older Patients: Advantages and Disadvantages

Combination Oral Agent Therapy

The many oral hyperglycemic drugs now available have complementary mechanisms of actions, thereby providing a rationale for multidrug therapy to attempt to achieve the desired level of glycemic control in patients without resorting to insulin. In addition, the availability of newer agents brings into the clinical arena physiologic considerations about type 2 diabetes that previously were considered primarily in research settings. However, the clinical importance of specifically targeting insulin resistance, hyperinsulinemia, or "glucose toxicity" remains to be determined. Some advantages and disadvantages of combination oral agent therapy are summarized in Table 43.3.

As with other diabetes management decisions, the choice to use combination therapy to achieve improved glycemic control in older patients requires some special considerations. It is important to reevaluate the glycemic target to see if combination therapy is still appropriate. In those healthy older patients with diabetes in whom the goal is control of hyperglycemia for its potential benefits to decrease future risks, combination oral agent therapy must be carefully monitored to make sure it achieves the treatment goal. In some older patients with diabetes, especially the frailest, problems and difficulties with insulin use are likely, and insulin-induced hypoglycemia may be a greater risk. The use of combination oral agent therapy may be easier and safer for some of these patients, although some oral agent regimens may also cause hypoglycemia.

Several other considerations are especially pertinent to older patients. First, they are much more likely to have a condition or conditions that may be contraindications to the use of some of the drugs in the combination. Second, older patients with comorbidities and diabetes-related complications are likely to be receiving many other medications. Polypharmacy and drug–drug interactions are a major concern, even if all the drugs being used are indicated. Finally, except for insulin and the sulfonylureas, these drugs are very costly and patients may not be able to afford them. Financial considerations can lead to problems in patients either with these medications or with necessary medications for other conditions. Research is clearly needed to assess the safety and efficacy of specific oral-agent combination therapy in older patients with diabetes.

Although the initiation of insulin therapy is sometimes considered to be a difficult and momentous step for an older patient,

INSULIN

insulin is indicated for any patient when treatment goals are not being met without it. No studies have demonstrated that elderly patients are unable to use insulin effectively and safely. Insulin therapy can result in euglycemia in those patients for whom this is the goal and should also be used for elderly patients with symptomatic hyperglycemia whose glucose levels cannot be controlled with diet and oral agents. Some advantages and disadvantages of insulin therapy in the population are summarized in Table 43.4.

No special insulin regimens have been identified as being more or less efficacious in older patients. As in younger adults, it is probably difficult to achieve normoglycemia with a single dose of intermediate-acting insulin. Therefore, when aggressive management is indicated, a split-mixed regimen is usually necessary. New rapidly acting insulin analogues offer an opportunity to target postprandial hyperglycemia, which is particularly prevalent in older people. A single dose of insulin may be appropriate, however, to prevent symptomatic hyperglycemia when this is the treatment goal.

Insulin therapy does require some special considerations when used in older adults. Aging alone, or complications secondary to diabetes, may impair vision and the fine-motor skills necessary for insulin administration. Blood glucose monitoring, indicated for patients treated with insulin, requires additional skills that may also be impaired with aging or disease processes. Hyperglycemia and poor diabetes control may be associated with subtle impairments of cognitive function in older adults (72,73). Such impairments, combined with the high prevalence of cognitive disorders in older populations, may adversely affect the ability of an older individual to adhere to a complicated insulin regimen. Older patients with diabetes who live alone without adequate family or support services may be at increased risk for serious sequelae of insulin administration (i.e., hypoglycemia). However, none of these considerations is an absolute contraindication to insulin therapy. If problems are recognized before or at the time of institution of insulin therapy, solutions can usually be found for each. Family members are frequently the most valuable resource. Community support services such as Meals on Wheels, visiting nurse services, and home health aides or homemaker services may be able to provide primary assistance or fill in the gaps.

Hypoglycemia is a potential concern for older patients treated with insulin. Some risk factors for hypoglycemia in this

TABLE 43.4. Insulin Therapy in Older Adults		
Advantages	Disadvantages	
Glycemic control goals achievable Relatively inexpensive Decreases possible polypharmacy Avoids gastrointestinal symptoms with multiple pills	Requires home blood glucose monitoring Injections, often multiple/day Overall complexity of regimen Risks of hypoglycemia	

TABLE 43.5. Risks for Hypoglycemia

Visual impairment Impaired manual dexterity Inability to do blood glucose monitoring Impaired cognitive function Poor family support

population are summarized in Table 43.5. Hypoglycemia counterregulatory mechanisms are generally intact in otherwise healthy older adults with diabetes mellitus. However, older people on complex medical regimens, who eat meals irregularly, or who have a significant cognitive disorder are likely to be at significant risk. The strategies for prevention of hypoglycemia include appropriate selection of patients for insulin treatment; frequent monitoring of blood glucose levels; adequate diabetes education, with special emphasis on the recognition and treatment of hypoglycemia; dietary assessment and instruction; and the intervention of family, friends, or support services to provide frequent (at least daily) contact for the insulin-treated older adult with diabetes.

Insulin Combined with Oral Agents

A single insulin dose, possibly administered at bedtime, combined with one or more oral agents, may be useful in achieving desired glycemic control in patients with type 2 diabetes (71). As in middle-aged people with diabetes, such a regimen may be reasonable in otherwise healthy and high-functioning older patients with diabetes. However, there is little specific information available about such combination regimens in older adults.

Self-Management Education and General Health Status Counseling

Because diabetes is associated with atherosclerotic risks, comorbidities related to macrovascular and microvascular complications, and increased disability, all of which increase with age in people with and without diabetes, improvement in general health status is an important component of diabetes management in older patients. For older people who may have multiple other conditions associated with their diabetes, it is important to understand how all these conditions affect everyday functioning at home and in society. Key to this is a comprehensive evaluation, as previously discussed. Besides appropriate medical management of diagnosed diseases, it is important to assess an older patient's nutritional status, affective and cognitive status, mobility, and functioning because diabetes has been shown to be associated with impairments in all these conditions. Although approaches to prevention and management of such disabling conditions and disabilities associated with diabetes are in their infancy, it is becoming increasingly important for physicians to learn to identify disabling conditions and functioning difficulties and to apply available management techniques.

Diabetes is fundamentally a self-managed disease. The healthcare provider must educate the patient and family, guide appropriate management choices, manage risks and comorbid conditions, and support the patient's efforts at self-management. Unfortunately, very little is known about self-management in older patients with diabetes. Many older people have other chronic conditions, have friends and family members with chronic conditions, and have retired from work and thus may have the inclination, time, and knowledge base to handle diabetes self-management better than do middle-aged patients with diabetes. However, because some older people may have very poor health and/or be cognitively impaired, the success of diabetes "self-management" will depend on the availability and skills of a caregiver. Future research is urgently needed to clarify the relationships of health status and diabetes self-management in older adults. It is clear, however, that many functioning older people can be expected to manage their diabetes as well as any younger patients with diabetes and should have similar access to education and self-management support.

Management of Older Patients with Diabetes in Special Situations

FRAIL OLDER PEOPLE

The health status of some older patients with diabetes is very poor because of preterminal illnesses, advanced dementia, or significant comorbid problems and functional difficulties. Many such patients also have decreased physiologic reserve and are often termed "frail." Most frail elderly patients live in the community with caregivers, in assisted living facilities, or sometimes alone; others are in nursing homes. For these frail older patients with diabetes, management of their diabetes will be one aspect of the coordinated, multidisciplinary management of their multiple problems. For such patients, a basic diabetes management program may be most appropriate (74). This program would include treatment of symptomatic hyperglycemia, attention to nutritional status (these patients may be malnourished and catabolic), and treatment of diabetes complications and comorbidities directed toward patient comfort, maintenance of function, and prevention of further decline when possible. It is important to remember that findings attributable to hyperglycemia may be substantial and may include infections, worsened mental status, blurred vision, falls, and worsened incontinence. Such patients benefit from geriatric evaluation and multidisciplinary management, and referral to a geriatrician is often appropriate. Research is needed concerning the contribution of diabetes to the frailty syndrome and on the appropriate management of diabetes in this group of patients.

NURSING HOME RESIDENTS

Approximately 3% to 5% of the population over the age of 65 are residing in nursing homes at any given time, and up to one fourth of older people will experience an extended nursing-home stay. The prevalence of diabetes in the nursing-home population is about twice that in the general population. According to the 1987 National Medical Expenditure Survey, diabetic patients in nursing homes had a significantly higher prevalence of diseases associated with diabetes, such as heart disease, hypertension, and kidney failure, than elderly nondiabetic patients in nursing homes; were also more limited in all ADL except feeding; and were more likely to be blind. The frequency of amputations was higher among the diabetic patients in nursing homes, although the difference was not statistically significant (75).

The approach to most nursing-home patients with diabetes should be that of providing basic care with control of hyperglycemia to prevent symptoms and associated acute complications. Tight glycemic control for the prevention of chronic complications may not be appropriate because of the poor health status and reduced life expectancy of most nursing-home patients. Control of hyperglycemia in patients in nursing homes is achieved primarily through the use of diet and medications. Exercise will probably not play a major role in the management of diabetes in these patients. However, patients who are capable of an exercise program should be encouraged to participate to enhance mobility and functional status. Diet is an important therapeutic option, but weight maintenance may be more important than weight reduction for many elderly patients with diabetes who are in nursing homes. One study found that over 20% of patients with diabetes in nursing homes were more than 20% underweight (76), a finding that raises the concern about malnutrition in this population. Thus, a dietitian should evaluate all patients with diabetes at the time of admission to the nursing home. Adjustments in recommended caloric intake should be made for wounds, infections, and level of activity. Patients should be weighed at least monthly, and further dietary adjustments should be made as needed.

As in other situations, the decision regarding use of medications or insulin should be based on the level of glycemic control desired. Often an oral agent is preferred both by the patient and the nursing-home staff, but insulin is needed for those patients for whom glycemic goals cannot be achieved with oral agents. Glucose control may be more easily obtained in the patient with diabetes who is in a nursing home because medications and meals are delivered on a regular schedule. In the nursing-home setting, glucose monitoring may be done more frequently and the response of the physician may be more immediate than in the outpatient setting. In fact, Mooradian et al. (76) found that patients with diabetes in the nursing home had lower levels of HgA_{1c}, fewer episodes of hypoglycemia, and were thinner than a younger group of outpatients with diabetes.

In addition to glycemic control, particular attention should be paid to the prevention of conditions that may be related to, or are exacerbated by, diabetes mellitus. Infections, particularly skin and urinary tract infections, are more common in nursinghome patients with diabetes than in other nursing-home patients. The incidence of urinary tract infections may be reduced by limiting the use of indwelling bladder catheters and by ensuring good urinary output through adequate hydration. Skin infections may be prevented by strict precautions against the development of decubitus ulcers, such as frequent turning of immobilized patients; the use of adequate bed and wheelchair cushioning; and the use of heel protectors. The prevalence of all infections is reduced with good staff hygiene, particularly by the enforcement of strict hand-washing regimens. The use of annual influenza vaccination and one-time pneumococcal vaccination for all nursing-home patients will provide population immunity and protect against epidemics of these illnesses in the nursing home. Immunization and PPD (purified protein derivative) status should be verified and documented for all patients newly admitted to the nursing home. Patients with diabetes who have a positive PPD reaction should be considered for prophylaxis with isoniazid if they have not been treated previously for tuberculosis.

Preventative medicine appropriate for all nursing-home residents, including regular ophthalmologic, dental, and foot care, is especially important for those with diabetes. Many institutions offer these services in the nursing home itself. These interventions will maintain quality of life and, in some circumstances, may serve to detect and ameliorate potentially life-threatening events.

HOSPITALIZED OLDER PATIENTS

The rate of hospitalization among elderly patients with diabetes is 1.7 times the rate among elderly people without diabetes. These include hospitalizations both for diabetes and for other reasons. Regardless of the reason for hospitalization, an appropriate goal for glycemic management should be established for each patient. In general, efforts should emphasize minimizing the likelihood of insulin deficiency, which can contribute to a catabolic state. If this is the primary goal, tight glycemic control is not necessary. Reasonable goals would be a mean plasma glucose level lower than 250 mg/dL (14 mmol/L) and minimal

43: TREATMENT OF OLDER ADULTS WITH DIABETES 745

glycosuria. Stressful illnesses such as myocardial infarction, pneumonia, influenza, and stroke or conditions associated with a decline in renal function can exacerbate hyperglycemia and may even precipitate hyperosmolar hyperglycemic nonketotic coma in a patient who is already hospitalized. Thus, older patients with these conditions (including patients previously managed with oral agents or diet alone or even patients not previously recognized as having diabetes) may need to be treated temporarily with insulin. Attention must also be given to fluid status, with the use of appropriate intravenous fluid therapy to prevent dehydration and worsening of hyperglycemia. Frequent glucose monitoring is recommended to prevent wide perturbations in blood glucose levels. Sliding scales of regular insulin can be useful for the acutely ill patient or postoperative patient who is unable to eat. However, once oral intake is adequate, most hospitalized patients are better managed with splitmixed dosing of insulin with adjustments made as needed on the basis of the results of frequent glucose monitoring.

An important risk for the hospitalized older adult with diabetes is hypoglycemia. In general, hypoglycemia in the hospital results from decreased caloric intake or inappropriate changes in insulin dosage (77). Hypoglycemia may be prevented by frequent glucose monitoring, with careful adjustments in the insulin dose as the patient's medical condition changes, and with the establishment of appropriate in-hospital goals for glycemic control.

The basic principles of geriatric medicine apply to the management of hospitalized elderly patients with diabetes. Some general recommendations include strict decubitus precautions, restriction of the use of indwelling catheters, and judicious use of psychoactive drugs [their administration should not be on a "prn" (as required) basis]. Mobility should be encouraged, and physical therapy should begin early in the hospital course, as indicated. Planning for discharge should begin at the time of admission, with input from the social-work service. Involvement of a consultant in geriatric medicine should be considered, particularly if the patient has multiple medical problems and is taking multiple medications, is functionally impaired, and requires or may require home care or nursing-home placement at the time of discharge.

SUMMARY 760

Several aspects of the female reproductive life cycle are influenced by insulin and the metabolic effects of diabetes. From puberty through childbearing to menopause, women with diabetes may need to make special adjustments in their regimens to maintain optimal control as the reproductive hormones change. Conversely, poor diabetic control can impair normal reproductive function. The waning of reproductive hormones at menopause raises special issues in decisions about hormone replacement therapy in women with diabetes, as well as additional risks for osteoporosis and endometrial cancer.

Most investigations into the effects of diabetes on reproductive function have focused on type 1 insulin-dependent diabetes because this is the most prevalent form in women of reproductive age. Insulin resistance also has reproductive consequences, both in severe forms such as type A insulin resistance and in milder forms as in polycystic ovary syndrome. The changing epidemiology of diabetes in the United States, with an increasing prevalence of obesity and an earlier onset of type 2 diabetes, makes the reproductive consequences of insulin-resistant diabetes more significant. Studies of diabetes in postmenopausal women have focused largely on women with insulin-resistant diabetes. Although issues of cardiovascular disease, hyperlipidemia, and endometrial cancer are important in this population, another classic postmenopausal issue, osteoporosis, is of greater concern for women with type 1 diabetes. Thus, this chapter will review both type 1 and type 2 diabetes and their metabolic effects in women. In many studies, the type of diabetes has not been defined by strict standards such as C-peptide, autoimmune antibodies, or insulin levels; thus, subjects described as insulindependent may include persons with either type 1 or type 2 diabetes. In these situations the descriptions "insulin-dependent diabetes mellitus" or "non-insulin-dependent diabetes mellitus" are used as specified in those studies, as the heterogeneity of the populations may help reconcile the results.

MENSTRUAL CYCLES

Menarche

In 1925, Dr. Eliot Joslin observed that "unaided by insulin, no girl in our series developed menstruation after the onset of diabetes" (1). By the mid-20th century, a major series by Bergqvist reported delay in menarche of 15 months associated with diabetes (2). More recently, this observation has been contested by studies showing normal menarche in series of clinic patients (3–6). However, subanalyses in several of these studies showed

that those girls with the onset of diabetes before 10 years of age or before menarche still had a delay in menarche, as well as more irregular menses (3,6). The major complications of diabetes have now been shown to correlate with glucose control, as these studies would suggest for age of menarche. Most of these studies, however, did not specifically investigate degree of control in relation to onset of menarche. One indirect clue is available from a study by Yeshaya et al. (6), who found that, among women with diabetes, those with diabetic complications were older at menarche and more likely to have amenorrhea than those without complications, but a direct relationship between menarche and glycemic control has not been established.

Menstrual Dysfunction

Beyond menarche, menstrual periods are often disrupted by diabetes. The major problems are absent menses (amenorrhea) or infrequent menses (oligomenorrhea), but overly frequent menses (polymenorrhea, or more commonly called "dysfunctional uterine bleeding") have also been described. Some type of irregular menses has been reported in 22% to 47% of women with diabetes (3,7). These high prevalence rates likely reflect various definitions of irregularity, as the corresponding incidence in controls ranged from 11% to 35%. The lower figures come from one of the most thorough studies of menstrual cycles in insulin-dependent diabetes by Kjaer et al. (3), using an epidemiologic study of an entire county in Denmark. Kjaer and others (3,8) also have found that the incidence of irregularity correlated inversely with diabetic control and with body weight. Specifically, two groups have shown that the incidence of menstrual disturbances increases with the hemoglobin A_{1c} concentration (HbA_{1c}) and becomes statistically significant with HbA_{1c} values above 10% (3,9).

Regular menstrual function requires the integration of neuronal and hormonal signals between the hypothalamus, the pituitary, the ovaries, and the uterus. Neuronal signals in the hypothalamus trigger the pulsatile release of gonadotropinreleasing hormone (GnRH), which causes the pituitary to release follicle-stimulating hormone (FSH) and luteinizing hormone (LH), which in turn stimulate the development of eggs, estrogen, and progesterone in the ovary. The estrogen fosters proliferation of the endometrium and feeds back to the hypothalamus and pituitary to control its own production. No single mechanism of impairment in diabetes has been established, but abnormalities from the hypothalamus to the ovary have been described.

The most clearly described syndrome of menstrual dysfunction in diabetes is a form of hypothalamic amenorrhea. Hypothalamic amenorrhea (HA) results from lack of stimulation by the hypothalamic GnRH to the pituitary LH and FSH. In HA, serum levels of LH and FSH are low, and studies using frequent sampling show that LH and FSH pulses are decreased or absent and insufficient to stimulate ovulation; thus menses do not occur (10). Women with insulin-dependent diabetes and amenorrhea have been found to have low LH and FSH levels, and decreased LH pulses (8,11) (Fig. 44.1). Various investigators have tried to assess GnRH responsiveness of the pituitary gonadotroph cells by administering a single dose of GnRH to women with diabetes, but results are conflicting and not as informative as those from pulse profiles of LH (12). However, a study by South et al. (11) that showed decreased LH pulses in amenorrheic, diabetic women (as compared with normal cycling nondiabetic women), also noted an increased LH response to GnRH. Both decreased pulses and an increased LH response to GnRH are seen in other forms of hypothalamic amenorrhea. The clinical features of HA in diabetic women are similar to those in the general population. As in women with

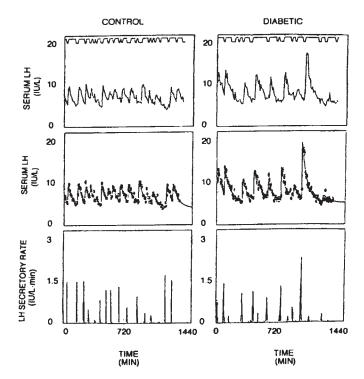

Figure 44.1. Serum luteinizing hormone (LH) pulses in diabetic amenorrhea. Representative profiles of LH concentration versus time series obtained from a eumenorrheic nondiabetic women (*left*) and an amenorrheic diabetic woman (*right*). (Reprinted from South SA, Asplin CM, Carlson EC, et al. Alterations in luteinizing hormone secretory activity in women with insulin-dependent diabetes mellitus and secondary amenorrhea. *J Clin Endocrinol Metab* 1993;76:1048–1053, with permission. Copyright 1993. The Endocrine Society.)

poorly controlled diabetes, hypothalamic amenorrhea also occurs in nondiabetic women who have inadequate nutrition, frequently as a result of excessive exercise or anorexia nervosa (13). Severe illness can also suppress levels of LH and FSH, as seen in patients hospitalized for other diseases (14). In diabetes, HA may reflect a combination of these factors. Diabetic women with hypothalamic amenorrhea tend to be underweight and/or to have poor glucose control. In the series of HA in diabetes by South et al. (11) and O'Hare et al. (15), women were selected for normal body weight but had elevated mean glycosylated hemoglobin of 12.8% and HbA1c of 11.8%. Djursing et al. (8) included both normal and underweight subjects but did not find a correlation between amenorrhea and glycemic control. An obvious approach to these patients is to improve diabetes control. Unfortunately, after 6 months of improved metabolic control decreasing HbA_{1c} levels from 11.8% to 8.5%, with a concomitant mean weight gain of 4.2 kg, none of six amenorrheic subjects in the series of O'Hare et al. (15) resumed menses, suggesting additional processes contributed to the observed amenorrhea. Women with hypothalamic amenorrhea have an increased risk for estrogen-deficiency osteoporosis (16) and need treatment to restore or replace (i.e., oral contraceptive pills) menstrual cycles to ensure adequate estrogen supplies (17). Although the bonedensity response to oral contraceptive pills has not yet been specifically evaluated in diabetes, treatment must be considered because of the additional increased risk of osteoporosis in type 1 diabetes (see discussion below). Other causes of HA, such as eating disorders, which have an increased prevalence in women with diabetes (18), must also be addressed. Even without meeting the full psychiatric DSM III-R criteria for anorexia nervosa or bulimia, 15% to 40% of young women with diabetes disclose

disordered eating and underdosing their insulin as a tool for weight loss (19,20). In addition to worsened glycemic control, diabetic patients with eating disorders have an increased incidence of diabetic complications (21,22).

Oligomenorrhea has also been associated with poor glucose control and low body weight in insulin-dependent diabetes (3,8). Some cases of oligomenorrhea in women with diabetes may represent a form fruste of hypothalamic amenorrhea. For research purposes, these studies define hypothalamic amenorrhea as 3 or 6 consecutive months of missed periods and oligomenorrhea as irregular periods occurring nine or fewer times per year. In diabetic women, as in nondiabetic women, the causes of oligomenorrhea are diverse. Oligomenorrhea specific to diabetes has received very little study. Most investigations of oligomenorrhea and diabetes have focused on polycystic ovary syndrome (PCOS) and type 2 diabetes rather than type 1 diabetes. PCOS is defined by oligomenorrhea and hyperandrogenism (such as hirsutism or acne) or hyperandrogenemia (such as elevated serum testosterone concentration or DHEAS). It is often associated with obesity and insulin resistance and carries a high incidence (30%–50%) of subsequent type 2 diabetes (23,24). PCOS is rare in type 1 diabetes with negative C-peptide levels (25). Prelevic et al. (26) found that oligomenorrheic patients with insulin-dependent diabetes who were negative for C-peptide had low androgens and low LH/FSH ratios, while those who were positive for C-peptide had more classic features of PCOS, with elevated and rogen levels and LH/FSH ratio and histories of obesity and oligomenorrhea before the diagnosis of diabetes. One recent paper has contested these views, finding a 39% prevalence of PCOS in a group of Spanish patients with insulindependent diabetes (27). However, this group did not test Cpeptide levels, and controls were excluded if they had signs of hyperandrogenism (hirsutism or acne)-important because normal body hair varies by ethnicity, so higher hirsutism scores are normal in Hispanic women with or without diabetes. Treatment with insulin-sensitizing medications ameliorates the hyperandrogenism of PCOS and has been shown to restore ovulatory cycles (28). Weight loss has also been found to restore regular menses and ovulation, as well as insulin sensitivity in PCOS (29). Because insulin augments LH-driven ovarian androgen synthesis, an elevation in androgens that induces insulin resistance (30) is difficult to distinguish from the elevated insulin levels of insulin resistance that induce hyperandrogenism (31). Blockade of this loop in either direction, by treating the hyperandrogenism (i.e., with the antiandrogens estrogen, flutamide,

or spironolactone) or treating the insulin resistance (i.e., with metformin or troglitazone) is effective for PCOS (32).

Oligomenorrhea also is seen in the syndromes of severe insulin resistance. Type A insulin resistance, which is mediated by insulin-receptor defects, and type B insulin resistance, which is mediated by antibodies, share symptom patterns including hirsutism, oligomenorrhea, and hyperandrogenism. Treatment of these syndromes includes the use of antiandrogens, as well as GnRH analogues, to block LH production (33). A defect in the insulin receptor has also been found in some women with PCOS (34).

Ovarian dysfunction is suggested by increased levels of the androgens, including testosterone and androstenedione, in women with insulin-dependent diabetes (35). However, these levels are increased in normally cycling women with insulindependent diabetes and are not usually associated with clinical signs of hyperandrogenism such as hirsutism or acne, and the free androgen levels are normal (36). Rather than an ovarian problem, these androgen levels are likely due to the elevated levels of sex hormone–binding globulin (SHBG) stimulated by insulin. This is further supported in a study by Djursing et al. (36) that found that SHBG levels were decreased in the amenorrheic women both with and without diabetes. Thus, hypothalamic, pituitary, and ovarian factors may contribute to menstrual disruption in diabetes.

Carbohydrate Metabolism

Even with regular menstrual cycles, many women with diabetes note changes in their home monitoring of blood glucose results during the cycle. In observational series of women with diabetes, 61% to 70% of patients reported cyclic glucose changes (7,37). Three fourths of these women described higher glucose levels in the luteal phase, especially during the week before menses. A consistent but smaller set report hypoglycemia at the beginning of menses (Fig. 44.2). In Lunt and Brown's study (37), 36% of the women adjusted their insulin to accommodate perimenstrual glucose changes, but this subset did not have better control and even showed a trend toward slightly higher levels of glycosylated hemoglobin. This study did not assess carbohydrate intake or exercise levels but did note that the insulin-adjusting group reported more perimenstrual changes in appetite.

The mechanism behind menstrual glucose changes has been a source of controversy, perhaps because of the heterogeneity of

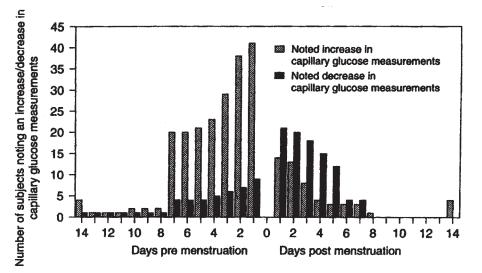

Figure 44.2. Number of subjects noting a perimenstrual change in self-reported capillary glucose measurements. (Reprinted from Lunt H, Brown LJ. Self-reported changes in capillary glucose and insulin requirements during the menstrual cycle. *Diabet Med* 1996;13:525–530, with permission.)

individual responses. In normal cycling, nonobese, nondiabetic women, some (38,39) but not all (40-42), studies of oral glucose tolerance have shown a decline in glucose tolerance during the luteal phase of the menstrual cycle. Progesterone, which increases during the luteal phase, has been implicated as the cause of worsened glucose tolerance because of its ability to induce insulin resistance (43). Intravenous glucose tolerance tests have not, however, shown consistent changes across the menstrual cycle (44). Euglycemic, hyperinsulinemic clamp studies in normal subjects showed no differences in basal levels of glucose, insulin, or glucose turnover during the follicular or luteal phase (45,46). In contrast, in hyperglycemic clamp studies, impaired glucose metabolism is seen in the luteal phase (47). When these same investigators performed hyperglycemic clamp studies in women with insulin-dependent diabetes, they found a heterogeneous response, with no cycle phase differences in some women, and a decrease in luteal-phase insulin sensitivity in others (48). The women who showed cyclic decreases in insulin sensitivity in clamp studies were those who noted premenstrual hyperglycemia; however, they were not different from women without cyclic differences with regard to duration or control of diabetes, age, or body weight. The worsened premenstrual insulin sensitivity was associated with a greater increase in estrogen from the follicular to luteal phase.

The presence or absence of premenstrual syndrome did not affect carbohydrate metabolism assessed by oral glucose tolerance testing in normal subjects across the cycle (41). Premenstrual symptoms in women with diabetes have been correlated only with depression (specifically not hypoglycemia) and do not differ (except the perception by women with diabetes that they were less severe) from those in women without diabetes (7).

SEXUAL DYSFUNCTION

Some surveys have found a high incidence of complaints of sexual dysfunction in women with diabetes, whereas others have reported a similar incidence in women with and without diabetes [reviewed in reference (49)]. The specific components of sexual dysfunction in women are poorly understood. In women as compared with men, sexual function is more variable within an individual and across the life cycle, has a less predictable response to hormones, and is more susceptible to social influences (50). These issues and others have limited research on sexual dysfunction in women, particularly in women with diabetes (51). Extrapolating from research on male sexual dysfunction is not necessarily relevant because of the gender differences in sexual function. For instance, in contrast to studies in men, the first study of sildenafil in women showed no improvement in sexual function (52), although one later study did show some improvement in sexual fantasy and satisfaction (53). Also in contrast to the findings in men, two studies of sexual function in women with diabetes found no correlation between sexual function and glycemic control (with the caveat that the sexual dysfunction predated the diabetes in many of the subjects) (54,55). One study of xerostomia noted that complaints of vaginal dryness were more common in diabetic women who had abnormally low salivary flow rates than in other diabetic women (56). The low salivary flow correlated with higher HbA_{1c} but not with cardiovagal autonomic dysfunction. Thus, although poor diabetic control and extensive vascular and neurologic complications are known to contribute to sexual dysfunction in men (57), few data exist to support parallels in women.

It is important to exclude other comorbid illnesses that can inhibit sexual function. Vulvovaginal candidiasis, which can

cause dyspareunia, occurs more frequently in women with poorly controlled diabetes (58,59). Depression, which has an increased prevalence in people with diabetes (60), is also a major cause of sexual dysfunction (61). Treatments for comorbid conditions, particularly depression and hypertension, also can have an impact on sexual function. Treatments for depression, especially selective serotonin reuptake inhibitors, may inhibit sexual function as a side effect but also improve sexual function as the depression is treated (62). Many antihypertensive medications have been implicated in male sexual dysfunction. In women, thiazide diuretics and spironolactone have been noted to decrease vaginal lubrication (49). In summary, diabetes has not yet been shown to be a direct cause of sexual dysfunction in women, but knowledge of the common issues associated with diabetes offers potential therapeutic approaches.

FERTILITY

In women with diabetes who have regular menstrual cycles, the ability to conceive is not affected. Among women with insulindependent diabetes diagnosed prior to pregnancy, the cumulative rates of pregnancy (85% in the first year) and of involuntary infertility (17%) were the same as in the control Danish population (63) (Fig. 44.3). In women with menstrual irregularity such as amenorrhea or oligomenorrhea, missed periods represent missed ovulations and therefore decreased opportunity for fertilization. Thus, women with PCOS and diabetes may have decreased fertility (32). Fertility in women with PCOS (studied in nondiabetic patients) is enhanced by weight loss (29) and insulin sensitizers (28). The results of in vitro fertilization in a small series of women with insulin-dependent diabetes, in good control as part of the therapy, were not different from the results in women without diabetes (64). Poor glycemic control does not impair the ability to conceive but does impair fertility because of an increase in spontaneous abortion in proportion to the

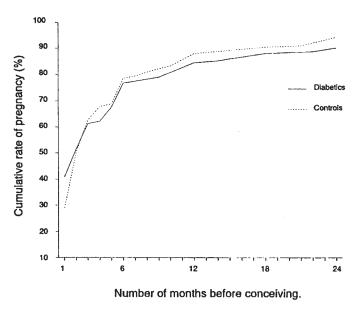

Figure 44.3. Cumulative rate of pregnancy (time to conception) over months for 139 pregnancies in women with diabetes and 199 pregnancies in controls (1959–1989). (Reprinted from Kjaer K, Hagen C, Sando SH. Infertility and pregnancy outcome in an unselected group of women with insulin-dependent diabetes mellitus. *Am J Obstet Gynecol* 1992;166: 1412–1418, copyright 1992, with permission from Elsevier Science.)

increase in HbA_{1c} (65). For women seeking fertility, the first approach should be optimization of glucose control, not only to improve ovulation and decrease the risk of spontaneous abortion but also to decrease the risk of birth defects. The prevalence of fetal malformations is increased when glycemic control is poor during early pregnancy (66) (see Chapter 61).

CONTRACEPTION

Contraception is an essential issue in the care of women with diabetes. Pregnancies must be planned because poor glycemic control during pregnancy leads to an increase in maternal and fetal complications, and good glycemic control reduces that risk (65,66). Nevertheless, most pregnancies in women with diabetes are still unplanned (63). Because of the medical importance of good compliance with the contraceptive regimen in this population, logistical issues are as important as medical effects and side effects associated with various contraceptives (Table 44.1).

For some women with advanced complications of diabetes, contraceptives are necessary for the protection of their own health. Pregnancy may worsen retinopathy (67) and nephropathy (68) and is associated with increased maternal mortality, especially if nephropathy or coronary artery disease is present. For women with these complications who have completed their families, surgical sterilization by tubal ligation should be considered. Women with diabetes need careful counseling on the risks of planned and unplanned pregnancy (see Chapter 61).

Combination Oral Contraceptive Pills

Oral contraceptive pills (OCPs) are the most popular form of reversible contraception and are associated with one of the lowest rates of unintended pregnancy. OCPs combine supraphysiologic doses of estrogen and progesterone and work by several mechanisms, principally by suppressing the hypothalamic and pituitary stimulation of the ovary. A common concern is the potential to worsen glycemic control with OCPs. This stems from reports in which early OCP formulations were used at much higher doses than are currently used. Worsened glucose tolerance was first reported by Waine et al. in 1963 (69), who noted that nondiabetic women treated with a high-dose OCP (containing 100 μ g of mestranol) developed impaired glucose tolerance. Women with a history of gestational diabetes mellitus (GDM), a first-degree relative with diabetes, or who are obese or older are at higher risk for the development of impaired glucose tolerance while receiving higher-dose OCPs (70). The impaired glucose tolerance usually reverses within 6 months of discontinuation, except in women with a history of GDM.

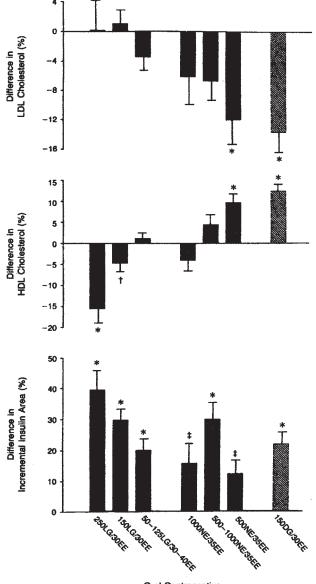

Most OCPs currently in use are "low dose" (<50 µg of estradiol) OCPs, which also contain up to a 25-fold lower dose of progesterone and have minimal to no effect on glucose tolerance, even in women with a history of GDM (71–73). In women with pre-existing insulin-dependent diabetes, OCPs can also decrease glucose tolerance, but significant adverse effects on glucose control are very unusual (74). The low-dose OCPs maintain the same contraceptive efficacy as the high-dose OCPs but are associated with a lower risk of some of the other doserelated side effects, such as stroke and cardiovascular disease, effects that have deterred physicians from using OCPs in women with diabetes (75). Not only do changes in the estrogen and progestin doses impact glucose tolerance, so do differences in the particular progestin. The gonane-derived progestins (e.g., norgestrel) produce more hyperinsulinemia (71).

Various OCP formulations can have minor or marked effects on lipids, changes particularly important in women with diabetes who already are at increased cardiovascular risk. In a large study of nine different OCPs used by 1,040 women (without diabetes), compounds with desogestrel increased high-density lipoprotein (HDL) cholesterol and decreased low-density lipoprotein (LDL) cholesterol, compounds with levonorgestrel decreased HDL and increased LDL, and norethindrone had an

^aOutside the context of breast-feeding, progestogen-only contraceptives are somewhat less effective than combined oral contraceptives. Adapted from World Health Organization. *Improving access to quality care in family planning medical eligibility criteria for contraceptive use,* 2nd ed. WHO/RHR/002. Geneva: World Health Organization, 2000. intermediate effect (76) (Fig. 44.4). Petersen et al. (77) examined the effects of OCPs with norethisterone, levonorgestrel, and gestodene in 30 diabetic women and found no adverse changes in plasma lipids from any of the compounds. In rare cases, OCPs can induce severe hypertriglyceridemia. This is mostly a risk for women with baseline triglycerides greater than 600 mg/dL (78). Estrogens are contraindicated in patients with any of the familial hypertriglyceridemia syndromes because of the increased risk of pancreatitis. Women with diabetes who are receiving estrogen therapies should have their lipid profiles monitored because poor glycemic control also results in elevated triglycerides. This effect is secondary to the decrease in lipoprotein lipase activity caused by relative insulin deficiency.

Oral Contraceptive

Figure 44.4. Lipid changes in women taking oral contraceptives. Percent differences in HDL and LDL cholesterol levels between women taking one of seven combination oral contraceptives and those not taking oral contraceptives. Hypertension, another infrequent side effect of OCPs in normal women (79), merits careful attention in the diabetic population. Studies of the use of high-dose OCPs in healthy women demonstrated new hypertension in 4% to 5% and worsening in 9% to 16% of women with pre-existing hypertension (80). This effect may be due to both the estrogen and the progestin components and is reversible with cessation of the OCP. Angiotensinogen production is increased by ethinyl estradiol (81), and progestins may have mineralocorticoid agonist or antagonist effects. Sudden development or worsening of hypertension after starting OCPs should be considered a complication of the medication and mandates discontinuation of the OCP. Few data exist for women with diabetes, except for the lack of problems noted in studies looking at other aspects of OCPs in carefully selected populations. A large (384 women with type 1 diabetes) and reassuring cross-sectional study by Klein et al. (82) showed no association between current or past use of OCPs and severity of hypertension or retinopathy or level of current glycemic control. Another smaller retrospective study also showed that the use of OCPs in women with a mean age of 22.7 years but a mean duration of diabetes of 13.8 years did not increase the risk of their developing early retinopathy or nephropathy (83).

Concern about increased risk of macrovascular complications stems in part from early retrospective observations in a series of diabetic women who were taking high-dose formulations, among whom cerebrovascular thromboses developed in three and myocardial infarction in one of 120 women who used OCPs compared with no such events in the control group who used nonhormonal contraception (84). This increased risk has been supported by subsequent studies demonstrating relative risks from 1.8 to 6.9 in women with diabetes versus nondiabetic OCP users (85,86). However, neither of these studies assessed the relative risk of cerebral or myocardial infarction in women with diabetes not taking OCPs. Another study showed an increased relative risk of stroke in women with diabetes that was the same in users and nonusers of OCPs (87). The risk for cardiovascular events is likely based on thrombotic events, which were increased in women taking OCPs (88), and may be related to the increased clotting factors (factor X, factor II, plasminogen, PAI-1) and decreased platelet aggregation that occur with OCPs (89) and with hyperinsulinemia and hyperglycemia (90,91). Older studies also showed some increased risk among nondiabetic OCP users as compared with nonusers, but the newer (low-dose estrogen and second- and third-generation progestins) OCPs are actually associated with the same or lower risk of cardiovascular disease in nonsmoking, nondiabetic OCP users (88,92,93). It is controversial whether these studies can appropriately account for the excess risk of cardiovascular disease due to smoking, which is high and accounts for the majority of myocardial infarctions in young women (94,95). In nonsmoking women with well-controlled, uncomplicated diabetes, there is probably not an excess risk of cardiovascular disease associated with OCP use, but this has not yet been confirmed in prospective studies. A large retrospective study by Klein et al. (96) did not show any excess mortality in diabetic OCP users. Thus, in otherwise healthy women with diabetes, OCPs decrease health risks by decreasing the risks associated with unintended pregnancy. For women with complications of diabetes, especially vascular disease, or who smoke, these additional risks of estrogen-progestin-based OCPs must be weighed in comparison to the additional risks of pregnancy.

Newly available transdermal forms of estrogen-progestin contraceptives offer the possibility of a lower thrombotic risk based on extrapolation from lower-dose transdermal hormone replacement therapy (97). Another recent therapy is the use of

DMPA, depot medroxyprogesterone acetate; HDL, high-density lipoprotein; IUD, intrauterine device; LDL, low-density lipoprotein; OCPs, oral contraceptive pills.

Adapted from Diab KM, Zaki MM. Contraception in diabetic women: comparative metabolic study of Norplant, depot medroxyprogesterone acetate, low dose oral contraceptive pill and CuT380A. *J Obstet Gynaecol Res* 2000; 26:17–26.

OCP tablets taken in extra doses as emergency postcoital contraception. This approach provides higher acute but less chronic exposure to estrogen and progesterone and is more convenient. Unfortunately, it is often poorly tolerated and not as effective as regular OCP use (98). Data are not yet available on the use of these newer contraceptive options in women with diabetes.

Progesterone

A major advantage of progesterone-based contraceptives is the lack of thrombotic or hypertensive effects (75,81). Weight gain and irregular bleeding are, however, common side effects. Progesterone contraceptive options include daily pills, short-term depot injections lasting 3 months (e.g., Depo-Provera), and long-term implants in silastic capsules lasting 5 years (Norplant). Intrauterine devices also may be coated with progesterone. Progesterone-only "mini-pills" are not as effective at suppressing ovulation as are combined OCPs, but they effectively decrease the volume of cervical mucus and increase its viscosity to block implantation (98). Progesterone-only pills have not been studied for their effects on glucose control in women with diabetes, but their high risk of failure is a concern (98). Depot formulations of progesterone do not fail as frequently, but they may increase insulin resistance slightly (99) and are associated with weight gain in some individuals (98). Subdermal levonorgestrel (Norplant) offers the advantage of long-lasting contraception (up to 5 years), which is suitable for many younger women, but requires a minor surgical procedure for insertion. Long-acting progesterone formulations offer good contraception for patients who are unable to comply with daily pills. Emergency contraception can also be accomplished with progesterone alone, using two doses of levonorgestrel ("Plan B"), which would have little metabolic impact on diabetes but is less effective than chronic use (98).

Progesterone contraceptives all worsen glucose tolerance to some degree, which is an issue especially for women at high risk of progressing to type 2 diabetes, such as those with a history of gestational diabetes or PCOS. Kim et al. (100) performed a case-control study of depot medroxyprogesterone acetate (DMPA) users compared with OCP users among Navaho women, a group at very high risk for development of diabetes. They found that the risk of diabetes doubled in women who used DMPA compared with the risk in women with no history of contraceptive use and that the risk increased with longer use. Women gained approximately 3 kg during the first year of use, but the excess risk of developing diabetes persisted even after adjustment for body mass index (BMI) ([weight (kg)]/[height (m)²]). Interestingly, the risk of developing diabetes was lower in the OCP group than in either the control or DMPA groups. In women with preexisting diabetes, changes in glucose tolerance

due to progesterone contraceptives, which were greatest with norgestrel, did not necessitate an increase in insulin doses (71). Use of continuous subdermal levonorgestrel was found to increase insulin resistance progressively to a plateau after the first 6 months of use (101). Lipid profiles in women with diabetes showed increased LDL cholesterol and decreased HDL cholesterol with DMPA but decreases in both LDL and HDL with subdermal levonorgestrel or IUD (99) (Table 44.2). Concerns have also been raised about possible decreased bone density in women using DMPA. Prospective studies (in women without diabetes) have now shown that, compared with women using OCPs, women using DMPA lose bone (17,102), but whether this is reversible on cessation of therapy has not been assessed.

Nonhormonal Contraception

Nonhormonal methods, including condoms, IUDs, rhythm methods, and sterilization, have no systemic effects and provide safer contraception for women at high risk for vascular or clotting problems. However, except sterilization, they are associated with high failure rates (98). Male condoms are the only form of contraception offering protection from infectious disease. IUDs, which act principally by a mechanical effect to block implantation, often are coated with progesterone to increase their efficacy. They do not have any disadvantages specific to women with diabetes except for the high rates of unplanned pregnancy at 3.5% and of discontinuation—after 24 months of use, only 57% of women were still using the IUD (103). In studies of IUDs in women with diabetes, side effects were frequent and included expulsion and removal for bleeding or pain but were not different from results in nondiabetic women (103,104). Contraception based on either coitus interruptus or timing of ovulation ("rhythm method") is highly ineffective and is not recommended.

DIABETIC MASTOPATHY

Diabetic mastopathy is a rare complication unique to diabetes. It is a fibro-inflammatory disease of the breast that presents as a firm, nontender breast lump (or lumps) and may be difficult to distinguish from malignancy on physical examination. It occurs mostly in premenopausal women but has been described in men (105). Nearly all reported cases have been in patients with type 1 diabetes; the few patients with type 2 diabetes were taking insulin (106). Diabetic mastopathy is described in women with an average duration of diabetes of 13 (106) to 18 years (107) and occurs in the setting of other diabetic complications, including retinopathy, neuropathy, and nephropathy (106). On mam-

mograms, diabetic mastopathy appears as dense parenchymal changes, while ultrasound also shows nonspecific changes with acoustic shadowing (108). Pathologic specimens show keloidal fibrosis with mononuclear perivasculitis and mononuclear ductitis or lobulitis (106,109). These lesions are benign and are not associated with an increased incidence of neoplasia. In the largest series of 19 cases, four were bilateral and six recurred, highlighting the need for awareness that could spare these women repeated biopsies (110).

MENOPAUSE

Menopause is defined as the permanent cessation of menstrual periods and represents the loss not only of ovarian follicles but also of the elevations of estrogen and progesterone that accompanied the monthly maturation of those follicles. In addition to the loss of menses, the immediate effects of the loss of the steroid hormones are hot flashes and vaginal dryness. In the longer term, the hypogonadism of menopause is associated with increased cardiovascular risk and osteoporosis, both of which are increased in women with diabetes even before menopause.

The age of menopause in women with type 1 diabetes (111) and type 2 diabetes (111,112) has been shown to be the same as that in other women in the same populations. However, the possibility of extensive complications of diabetes secondarily terminating ovarian function was not evaluated in these studies, which included subjects with a mean duration of disease of 9 and 17 years and did not assess complications. One recent report did describe an earlier age of menopause associated with diabetes. In the Familial Autoimmune Diabetes Study, women who were diagnosed before 1964 and had a mean duration of disease of 34 years were a mean of 6 years younger at natural menopause than were their contemporaries who did not have diabetes (113). However, this study includes only 15 women who have reached menopause, five of whom had premature ovarian failure and another autoimmune disease, which can be part of the polyglandular autoimmune syndrome. Data from further follow-up of this cohort will be very interesting.

Premature ovarian failure (POF), defined as menopause before the age of 40, is a component of several uncommon syndromes that also include diabetes (Table 44.3). One of the more frequent of these is polyglandular autoimmune disease, type II. Polyglandular autoimmune syndromes are the associations of multiple destructive autoimmune diseases in endocrine tissues.

Syndrome	Type of diabetes	Type of hypogonadism	Other clinical features	Etiology
Polyglandular autoimmune syndrome	Autoimmune	Primary	Primary hypothyroidism, Addison disease, celiac sprue, pernicious anemia	Destructive lymphocytic infiltration
Hemochromatosis	Insulin resistant or deficient	Primary or secondary	Bronze pigmentation, cirrhosis, dilated cardiomyopathy, loss of body hair	Autosomal dominant defects causing iron overload
Turner's syndrome	Insulin resistant or autoimmune	Primary	Short stature, webbed neck, hearing loss, shield-chest, low hairline, thyroiditis	45 XO karyotype
Down syndrome	Insulin resistant	Primary	Mongoloid facies, cardiac structural abnormalities, mental retardation, shortened phalanges	Trisomy 21
Pseudohypoparathyroidism	Insulin resistant	Primary (resistance to LH, FSH)	Short stature, short metacarpals, round facies, parathyroid hormone resistance	Gαs-inactivating mutations
Crow-Fukase (POEMS) syndrome	Insulin resistant	Primary	Polyneuropathy, organomegaly, endocrinopathies, M-proteins, skin disorder	Plasma cell dyscrasia
Ataxia telangiectasia	Insulin resistant	Primary	Early ataxia, oculocutaneous telangectasia, immunodeficiencies, dysgenetic gonads	Autosomal recessive defect in DNA repair (in ATM helicase)
Fanconi anemia	Insulin resistant	Primary	Short stature, bone marrow hypoplasia, radius malformations, abnormal pigmentation	Autosomal recessive proximal renal tubule dysfunction due to DNA-repair defect
Werner syndrome	Insulin resistant	Primary	Premature aging, atrophic skin, cataracts, early osteopenia, atherosclerosis	Autosomal recessive defect in DNA repair (in Wrn helicase)
Myotonic dystropy	Insulin resistant	Primary or secondary	Muscular dystrophy, mental retardation, premature balding, hypothyroidism	Autosomal dominant trinucleotide repeat in protein kinase DMPK
Prader-Willi syndrome	Insulin resistant	Secondary	Infantile hypotonia, mental retardation, short stature, morbid obesity	Chromosomal deletion in SNRP gene
Kearns-Sayre syndrome	Insulin deficient	Secondary	Ocular myopathy, pigmentary retinopathy, cardiac conduction defects, ataxia	Chromosomal deletions in mitochondrial DNA

FSH, follicle-stimulating hormone; LH, leutenizing hormone.

Type II polyglandular autoimmune disease, or Schmidt syndrome, includes the constellation of autoimmune thyroid disease and Addison disease in association with autoimmune diabetes as redefined by Carpenter in 1964 (114). POF occurs in less than 10% of these patients; other infrequent manifestations are pernicious anemia, celiac sprue, lymphocytic hypophysitis, and vitiligo (115). Schmidt syndrome has incompletely penetrant, autosomal dominant inheritance with onset usually in the 20s or 30s. The individual components may occur in any order. Therefore, in patients with autoimmune diabetes and amenorrhea, thyroid disease and adrenal insufficiency must be considered as reversible causes of menstrual dysfunction. The diagnosis of POF is made by amenorrhea with an increased FSH before the age of 40 years. After the exclusion of other causes (chemotherapy, radiation, or karyotype abnormalities), antiovarian antibodies are present in 27% of patients with POF (116). POF is not reversible, but some ovarian follicles may still be present at diagnosis. For women seeking fertility, careful monitoring may reveal these rare ovulations, and pregnancies have occurred (117,118). Once the diagnosis of premature ovarian failure is established, it is important to screen for thyroid and adrenal failure.

Turner syndrome, which may be less evident in its mosaic form, can include insulin-resistant diabetes and POF due to primary gonadal failure. Hemachromatosis, associated with iron overload in various organs, including the pancreas, liver, and pituitary, may present with diabetes and secondary gonadal failure. Menstrual bleeding reduces the incidence of iron overload in women. Crow-Fukase syndrome (POEMS) is a plasma cell dyscrasia with polyneuropathy, organomegaly, endocrinopathy, M protein, and skin changes. This disease usually has an onset in the sixth decade, so the gonadal failure may not be recognized if a woman is already peri- or postmenopausal. Several more rare diseases such as Kearns-Sayre syndrome (with myopathy) and myotonic dystrophy can present with POF and diabetes. Also, syndromes with impaired DNA repair and/or metabolism such as Werner syndrome (with premature aging), Fanconi anemia (with proximal tubular defects), and ataxia-telangiectasia, are associated with diabetes and gonadal failure. In these entities, other features of the syndrome will signal the diagnosis.

Perimenopausal Symptoms

Despite the various influences of diabetes on menstrual function, little research has been done regarding symptoms at the cessation of menses. No increase in hot flashes is seen in women with diabetes (112). The incidence of vaginal dryness may be increased in relation to HbA_{1c} (56), but genitourinary atrophy at menopause has not been specifically studied. One would expect no differences in short-term hormone replacement therapy for treatment of these symptoms, but this also has not been formally studied. In one study of uncomplicated type 2 diabetes, the incidence of postmenopausal anxiety and depression was slightly increased and was associated with duration of disease and premenopausal depression (119). It is well documented that depression in general is about twice as common in the diabetic population as in the nondiabetic population and that depression is more prevalent in women with diabetes than in men with diabetes (60).

Hormone Replacement Therapy

Estrogen replacement therapy is the prescription of low-dose estrogen in postmenopausal women with the intent of reversing the changes of menopause. In women who have not undergone

44: WOMEN'S HEALTH ISSUES IN DIABETES MELLITUS 755

hysterectomy, the use of progesterone with estrogen is necessary to prevent endometrial cancer. The combination of estrogen and progesterone is termed hormone replacement therapy (HRT). Before the need for progesterone was recognized, most women received estrogen alone, and higher doses were used; thus, some older studies of estrogen replacement therapy (ERT) show side effects that may be different from those expected if the studies were done with HRT. ERT using the same estrogen doses as HRT is currently appropriate for women who have had a hysterectomy. HRT has been used for short-term treatment of perimenopausal symptoms and long-term reduction of cardiovascular risk and as a major therapy for osteoporosis. Most of the literature on HRT is based on large population studies that include very few women with diabetes. Because of their increased risk for cardiovascular disease, dyslipidemias, and osteoporosis, the risks and benefits of HRT are particularly important for women with diabetes. New prospective data (covered below) have dramatically altered the prescription of HRT for cardiovascular protection, and more data are necessary to apply to decisions for women with diabetes.

Cardiovascular Disease

The cardiovascular benefits of HRT have been the major reason for its use in nondiabetic women. Premenopausal women have a lower risk of heart disease than do men of the same age, but that advantage disappears after menopause. Large-scale epidemiologic studies have shown that restoration of the premenopausal hormones with HRT is associated with a 30% to 50% reduction in death from cardiovascular disease (120–122). Unfortunately, most of the major studies (Rancho-Bernardo, Postmenopausal Estrogen/Progestin Interventions, Framingham, and Nurses' Health) include relatively few women with diabetes. On the basis of these studies, it used to be recommended that most postmenopausal women use HRT to reduce cardiovascular risk. Mortality due to cardiovascular disease is fourfold greater in postmenopausal women with diabetes than in postmenopausal women without diabetes (123). However, premenopausal women with diabetes do not share the lower premenopausal cardiovascular risk in comparison to men that is seen in women without diabetes (124). This suggests that premenopausal women with diabetes may derive less cardiovascular benefit from HRT. Two case-control studies in diabetic women have shown that current users of HRT have no increased risk or a reduced risk of myocardial infarction compared with never-users (96,125).

Several components of the cardiovascular system that may contribute to the estrogen-associated mortality benefits are adversely affected in diabetes, including lipids, carbohydrate metabolism, hemostasis, and vascular function. In addition, the effects of diabetes on the incidence of coronary heart disease are exacerbated by each of the standard risk factors: smoking, hypertension, lipid concentrations, and BMI (126). Short-term studies (6–12 weeks) of ERT and HRT in women with type 2 diabetes have shown improvement in lipid profiles and in glucose control (127,128). These metabolic effects are relevant when HRT is used for any indication.

Lipids

Women's total and LDL cholesterol levels increase after menopause. This change in the lipid profile is associated with an increased risk of cardiovascular disease and is improved with HRT (129). Up to 25% of the benefits of HRT have been attributed to the effects on lipids (122). Diabetes can further exacerbate the postmenopausal lipid profile, and treatment is

Triglycerides	cholesterol	LDL cholesterol
$\stackrel{\leftrightarrow}{\uparrow\uparrow}$	$\stackrel{\downarrow}{\stackrel{\downarrow}{}{}{}{}{}{}$	$\uparrow \\ \downarrow$
	$\stackrel{\uparrow\uparrow}{\uparrow}$	

essential because of the already heightened risk of cardiovascular disease in diabetes. In patients with type 1 diabetes, the most common abnormality is an elevation of very-low-density lipoprotein (VLDL) triglycerides, which is correlated with diabetic control (130). This elevation is due to the dependence of triglyceride clearance on the activity of lipoprotein lipase, which is insulin-dependent, as well as to the increase in production of VLDL from the mobilization of free fatty acids. In type 2 diabetes, insulin resistance and obesity combine to cause additional elevations in LDL cholesterol and/or to lower the HDL cholesterol (Table 44.4). Studies of HRT in type 2 diabetes show improvement in LDL cholesterol with little or no change in total cholesterol and a small increase or no change in triglycerides (even in a subset starting with elevated triglycerides) (127,131-134). Although two (127,132) of these studies found an improvement in HDL cholesterol, the others found no change or a small decline. Transdermal HRT regimens do not present the same high dose of estrogen to the liver and do not appear to raise the triglyceride level as much as do oral regimens in women without diabetes. In fact, the one study looking at transdermal estrogen use in type 2 diabetes found a decrease in total cholesterol and triglycerides (97). Because there is also a rare risk of severe hypertriglyceridemia with ERT (78), transdermal estrogens are a better choice for women with moderately elevated triglycerides, but any estrogen is contraindicated in women with markedly elevated triglycerides (>600 mg/dL). Poor glucose control without other metabolic problems typically increases triglyceride concentrations only by twofold to threefold, but in combination with many illnesses and medications that cause hypertriglyceridemia, or in the presence of familial hyperlipoproteinemia syndromes, severe hypertriglyceridemia is more likely to occur.

Glucose Tolerance

Although glucose intolerance was seen in early studies of OCPs and high-dose ERT (100 μ g of ethinyl estradiol) (135), current low-dose oral HRT, which has approximately 1/20 the dose of estrogen, has not been shown to adversely affect insulin sensitivity and may improve it. Data from large cohort studies show lower fasting glucose levels in nondiabetic and diabetic women taking estrogen (136,137). Also there is neither a deterioration in glucose tolerance after 12 months of estrogen use in normal women (138) nor an increase in the number of women who develop diabetes after using HRT for several years (139). Decreases in HbA_{1c} have been demonstrated in women with type 2 diabetes taking HRT (128,133,140,141). Brussaard et al. (127) have demonstrated decreases in HbA_{1c}, hepatic glucose production, and waist/hip ratio after 6 weeks use of HRT in type 2 diabetes.

Vascular Effects

A concern about HRT that has been carried over from the experience with OCPs is the risk of hypertension. Fortunately, HRT does not appear to increase the risk of hypertension and has even been shown (in nondiabetic women) to lower blood pressure by a few points (142). One small prospective study looking at HRT in type 2 diabetes saw no change in resting blood pressure (140). Szekacs et al. (143) observed a protective effect of decreased proteinuria without a change in blood pressure.

Vascular changes have also been proposed as a mechanism for decreased cardiovascular morbidity and mortality among women receiving HRT. In nondiabetic women, estrogen has been shown to have a myriad of effects on the vasculature, decreasing plasma fibrinogen and PAI-1 concentrations and stimulating nitric oxide release and vasodilation, as well as long-term genomic effects promoting vasodilation and repair of endothelial cell damage (91). Patients with diabetes have an increased risk of thrombosis, which could be due to vascular dysfunction or altered coagulability but is still poorly understood. Increased levels of fibrinogen, PAI-1, and some of the coagulation factors, as well as abnormalities of platelets and endothelial function, have been found (144). Although levels of some of these factors have been evaluated with HRT in women with diabetes, no correlation has yet been made with absolute risk of clotting. This represents an important area for further study.

Very recently, prospective data that are causing some concern regarding the use of HRT in nondiabetic women are becoming available. The Heart and Estrogen/Progestin Replacement Study (HERS) has shown no clear benefits from HRT for secondary prevention of cardiovascular disease in the first 4 years of treatment (145). The risk of a recurrent coronary heart disease was skewed to a marked increase in the first 4 months of therapy, which tapered down until a relative advantage showed in years 4 and 5. This has been further substantiated by Heckbert et al. (146), who found an increased risk of recurrent myocardial infarction within 60 days of the initiation of HRT, which declined thereafter. These studies highlight the importance of prospective data. Although the above studies of serum markers of cardiovascular risk factors show improvement with HRT in patients with diabetes, it will be several years before definitive evidence of potential mortality benefits of HRT in diabetes becomes available. In the meantime, most guidelines are discouraging the initiation of HRT solely for cardiovascular risk reduction.

OSTEOPOROSIS

The extension of the average life expectancy of people with diabetes that has accompanied improvements in medical care has increased the significance of osteoporosis. Although once controversial, the evidence that bone health is compromised in diabetes is now strong. Bone mineral density (BMD) is lower and the risk of fractures is increased. Several mechanisms have been proposed for diabetes-related osteoporosis and include both the comorbidities of diabetes and more direct pathophysiologic effects of the disease itself.

Fractures

Hip fractures, in particular, are now recognized not only as a major cause of morbidity and mortality but also for their significant impact on economic and social circumstances. Mortality is high in the general population with hip fractures, but the presence of diabetes in a patient with a hip fracture is a risk factor for increased mortality (147). Case-control studies of patients with hip fractures have found an excess of patients with diabetes, suggesting at least a twofold relative risk in all patients with diabetes (148). Women with type 1 diabetes had a 6.9- to 12-fold relative risk of hip fractures compared with women without diabetes (149,150). Data are controversial about the risk of hip and spine fractures in patients with type 2 diabetes. Most studies (148-151) in women with type 2 diabetes also have found an increased risk of hip fractures, with estimates of relative risk almost double the risk in other postmenopausal women. In the Study of Osteoporotic Fractures, women older than 65 years with type 2 diabetes (as defined by excluding those with a diagnosis before the age of 40 years or with a BMI <30), had an increased risk of hip and proximal humerus fractures despite having a higher BMD than women without diabetes (152). There was also a trend toward increased risk of vertebral, forearm, ankle, and foot fractures. In contrast, other investigators have found fewer fractures in women with type 2 diabetes, with a similarly increased BMD at the spine (153,154). The one site with an undisputed increased fracture risk is the foot, which may be related in part to obesity or neuropathy (152,155,156). Focal osteopenia and fractures associated with severe diabetic peripheral neuropathy (Charcot foot) are long recognized as a complication of any type of diabetes.

Bone Density

Although many factors influence the probability of fractures, including number and type of falls, padding of the bony prominences, and geometry of the bone, the most significant factor is the strength of the bone itself. Bone strength is proportional to BMD, which can be measured radiographically. An individual measurement is classified based on the degree of radiographic density in comparison to that in a normal population, with osteopenia defined as 1.0 to 2.5 standard deviations below normal and osteoporosis defined as 2.5 or more standard deviations below normal (157). Bone densitometry techniques have become much more sophisticated in the past two decades, allowing more precise and accurate measurement, as well as measurement at different sites. Based on these changes, more recent data are more sensitive to differences between groups.

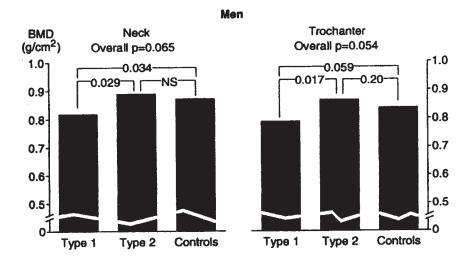

Osteopenia was initially described in adolescents with diabetes, 50% of whom were found to have decreased cortical and trabecular forearm BMD (158). Several subsequent studies found that the forearm BMD in children with only 4 to 6 years of type 1 diabetes was 20% to 50% lower than that in controls (159). One study examining vertebral BMD did not see a difference in children with diabetes (160). Most studies in adults confirm that BMD is lower in patients with type 1 diabetes than in subjects without diabetes (111,161). In contrast, studies in women with type 2 diabetes, controlling for age and obesity, show BMD that is either the same or greater than that in normal subjects (153,154), even in patients treated with insulin (111)

(Fig. 44.5). The Rancho Bernardo studies also looked at men with type 2 diabetes and found that their BMD was similar to that in men with normal glucose tolerance, despite the differences the studies found in women (162).

Mechanisms

Is osteoporosis another complication of poor glycemic control? Short-term measures of control such as glucose levels or HbA_{1c} levels would not be expected to reflect cumulative bone damage measured by BMD. Diabetic complications are the cumulative results of long-term poor control. Several investigators have demonstrated an association between BMD and microvascular complications, with the BMD inversely correlated with the presence and extent of microvascular complications in women with normal menstrual cycles (161,163). Mathiassen et al. (164) observed the BMDs of 19 patients with type 1 diabetes (8 women), initially free of complications and found that after 11 years only those who developed retinopathy or proteinuria had worsening of their BMD. The presence of severe peripheral neuropathy in patients with type 1 diabetes has also been found to correlate with decreased BMD at all sites, in comparison to patients with type 1 diabetes without neuropathy and in comparison to healthy subjects (165). Although these were small groups, they were matched for other complications and for activity levels. Using the same paradigm, Forst et al. (166) found a decreased BMD in the cortical bone at the hip and distal limb in association with peripheral neuropathy but normal BMD in the spine of patients with insulin-dependent diabetes. In the Blue Mountain Eye Study in Australia, an association between retinopathy and all fractures was seen in both men and women with all types of diabetes (167). Hypercalciuria has long been noted in patients with poorly controlled insulin-dependent diabetes (168,169) and non-insulin-dependent diabetes (170,171) and has been shown to improve with improved HbA_{1c} (172). Comparably, one study has shown attenuation of bone loss in patients with type 1 diabetes with good glucose control (173). Thus, metabolic control appears to be a major factor in the increased incidence of osteoporosis in patients with diabetes. Poor control, however, would not appear to be the only factor, unless there were also a concomitant compensatory factor to increase BMD in patients with type 2 diabetes.

If the relationship between osteoporosis and diabetes were related only to hyperglycemia, one would expect a similar incidence of osteoporosis in patients with type 1 and type 2 diabetes, but most studies show more osteoporosis in patients with type 1 diabetes (111,174). There may be differences between types of diabetes other than glucose control that impact BMD. Several factors have been investigated, including treatment with insulin, endogenous insulin levels, age of onset, and HbA_{1c}, but the actual mechanism for lower BMD in type 1 diabetes is not known. Osteoporosis is also not associated with exogenous insulin treatment per se. Krakauer et al. (173) and Tuominen et al. (111) separately compared patients with type 1 and type 2 diabetes treated with insulin, showing that insulin is not the cause of the bone loss. Krakauer et al. also found decreased BMD in men and women with type 1 diabetes as compared with those with type 2 diabetes or with controls. Epidemiologic studies at Rancho Bernardo, California, and in Rotterdam, The Netherlands, suggested a correlation between fasting insulin level and BMD in nondiabetic women (175,176). In patients with type 2 diabetes, no consistent association of BMD with endogenous insulin levels, using fasting and 2-hour postchallenge levels, has been found (162,177,178). An autoimmune- or inflammation-mediated process has also been considered because a decrease in BMD has been noted during the first

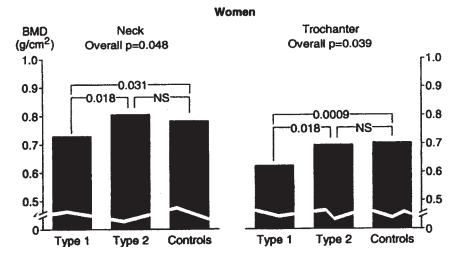

Figure 44.5. Bone density in diabetes. Mean bone mineral density (BMD) (adjusted for age and body mass index) at the proximal femur of subjects with type 1 diabetes (29 men, 27 women), type 2 diabetes (34 men, 34 women), and without diabetes (240 men, 258 women). (Copyright © 1999 American Diabetes Association. From Tuominen JT, Impivaara O, Puuka P, et al. Bone mineral density in patients with type 1 and type 2 diabetes. *Diabetes Care* 1999;22:1196–1200. Reprinted with permission from the American Diabetes Association.)

several years after diagnosis, with an attenuation thereafter (158,164). This suggests an initial insult not specifically related to control, but perhaps to the autoimmune process, similar to that seen in rheumatoid arthritis, in which bone loss is seen in the involved joints. Age of onset of diabetes might be expected to affect either the young adulthood accrual of bone or the agerelated loss. However, no correlation between BMD and duration or current glycemic control (by HbA_{1c}) was seen in diabetic children (5.2 years duration, excluded if complications) (160) or postmenopausal women (8.9 years duration, 14 years postmenopausal) (179). Because of the myriad of factors other than diabetes incorporated into BMD over time, as well as the gradual nature of diabetic complications, shorter-term measures of bone metabolism are needed.

Markers of Bone Turnover

Serum and urine markers of bone turnover have been developed to assess short-term changes leading to osteoporosis. Serum levels of alkaline phosphatase and osteocalcin reflect bone formation, while serum levels of collagen cross-links reflect bone resorption. Osteoblast secretion of osteocalcin is decreased by high glucose levels, so bone formation as assessed by osteocalcin is decreased in proportion to diabetic control (180). Thus, in patients with diabetes, this marker is applicable only in limited situations. Similar problems arise with urinary markers such as deoxypyridinoline, which are confounded by glucosuria and thus require very good glycemic control to be useful. Bone resorption measured by deoxypyridinoline after a 12-hour glucose clamp was greater in age- and height-forage-matched adolescents with diabetes than in controls, suggesting that bone loss in early-onset type 1 diabetes is related to increased turnover (181). This is important because instead of the presumed high turnover rate, as can occur with excess cortisol or with hyperparathyroidism, a low turnover resulting in adynamic bone, also seen in renal failure, is an alternate mechanism for osteoporosis. This possibility is suggested by the observation that fractures take a longer time to heal in persons with diabetes (182). Krakauer et al. (183) have proposed that a low turnover state due to functional hypoparathyroidism and hyperglycemia accounts for the differences between type 1 and type 2 diabetes, but this has yet to be investigated. The heterogeneity of types of diabetes, as well as variable contributions from associated conditions affecting BMD, make it difficult to designate one underlying mechanism for diabetic osteopenia.

Conditions Associated with Diabetes and Osteoporosis

Factors extrinsic to the metabolic changes of diabetes, such as age of onset of type 1 diabetes in relation to stage of bone growth and the lifestyle factors such as obesity and inactivity in

type 2 diabetes, have secondary consequences relative to BMD. One such age-related risk for osteoporosis is low peak bone mass. In American women, peak bone mass is achieved by the end of the third decade (184). Thus, to the extent that diabetes may cause osteopenia, women who are young at diabetes onset may never achieve a normal peak bone density and thus reach osteoporotic thresholds earlier in life (Fig. 44.6). Delayed puberty is associated with a lower peak BMD (185); therefore, women with diabetes and delayed menarche may also have a lower peak BMD. In a carefully controlled Finnish study (111), Tuominen et al. defined type 1 diabetes by C-peptide values and therefore were able to use only subjects who had been diagnosed after age 30. Even in these patients, BMD was lower in patients with type 1 diabetes compared with those with type 2 diabetes or with controls, suggesting a secondary loss of bone. Another age-related factor is estrogen status, the major cause of osteoporosis in the general population. Because of their increased risk for menstrual dysfunction, women with type 1 diabetes may also have osteopenia due to estrogen deficiency. Most studies have not assessed the menstrual histories in these women, but one study did find a positive correlation between oral contraceptive use and BMD in women with type 1 diabetes, supporting a component of estrogen deficiency (186). One of the strongest risk factors for osteoporosis is low body weight (187), which is more typical of patients with type 1 diabetes than of those with type 2 diabetes. The obesity commonly present in persons with type 2 diabetes (and often for years before) may have a cumulative protective effect on bone density.

Several other diseases that increase the risk of osteoporosis are particularly relevant in diabetes. Diseases associated with autoimmune diabetes, including Graves disease and celiac sprue, also carry an independent risk for osteoporosis. Treatments for hypertension and hyperlipidemia, which are associated with both types of diabetes, may also affect BMD. Use of loop diuretics to treat hypertension can increase urinary loss of calcium, while thiazides may decrease it. Interesting preliminary case-control studies have suggested that treatment of hyperlipidemia with HMG-CoA reductase inhibitors may increase BMD (188), but these results have not been supported by other studies (189,190) and may represent confounding due to higher BMD in patients with hyperlipidemia (191).

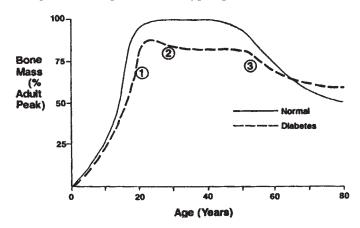

Figure 44.6. Diagram of bone loss. Model for the effects of diabetes on bone mineral density at different times of life. In diabetes, the initial accumulation of bone during adolescence is diminished (1), thus reaching a lower plateau with continued loss associated with hypercalciuria in early adult life (2), followed by later onset and retardation of age-related bone loss (3). Depending on the age of onset, stages 1 and 2 could overlap. (Copyright © 1995 American Diabetes Association. From Krakauer JC, McKenna MJ, Buderer F, et al. IABLE 44.5.	Risk Factors for Osteoporotic	
Fi	actures in Diabetes	

Risk for osteoporosis Directly due to diabetes
Type 1 diabetes
Hypoglycemia or hyperglycemia
Nephropathy
Due to complications of diabetes
Nephropathy
Diabetic diarrhea
Due to disease associated with diabetes
Graves disease
Celiac sprue
Risk for falls
Poor vision due to retinopathy or cataracts
Poor balance due to neuropathy
Orthostatic hypotension
Impaired joint motility due to neuroarthropathy

Among women with osteoporosis, almost all hip fractures are due to falls (192). The risk of falling is increased by diabetic complications, including impaired vision due to retinopathy or cataracts and poor balance and orthostatic hypotension due to peripheral and autonomic neuropathy. Acute hypoglycemia and hyperglycemia may also cause impaired vision, incoordination, and muscle weakness. Patients with amputations are at increased risk for falls and immobility-induced osteoporosis because of their limited mobility (Table 44.5).

Treatment

All patients with type 1 diabetes and those with type 2 diabetes and advanced complications should be evaluated for osteoporosis and counseled about modifiable risk factors (getting appropriate exercise, calcium, and vitamin D and avoiding smoking and excessive alcohol). No preventive strategies specific to diabetes are yet known, although as reviewed above, good glycemic control appears to be beneficial. Treatment of osteoporosis in women with diabetes also has not been specifically evaluated and therefore follows guidelines for patients without diabetes. Common comorbid conditions such as nephropathy or gastrointestinal complications require attention. Renal impairment necessitates evaluation of the parathyroid-vitamin D axis as well as dose adjustment of medications. None of the current therapies for osteoporosis have been clinically studied in renal failure. Gastroparesis, malabsorption or sprue, and diabetic diarrhea can all contribute to osteoporosis by interfering with calcium and vitamin D absorption and require separate evaluation and treatment. All patients with diabetes who have extensive neuropathy, amputations, orthostatic hypotension, or impaired vision are at increased risk for falls. In addition to treatments to strengthen bone, these patients need counseling on prevention of falls, including use of walkers, night-lights, muscle-strengthening exercises, and removal of hazards in the home.

ENDOMETRIAL CANCER

A final postmenopausal health issue for women with diabetes is the risk of endometrial cancer. Endometrial cancer is the fourth most common cancer in women, and diabetes has long been considered a risk factor for endometrial cancer. After controlling for body weight, most (193–196) but not all (197) studies

have shown that women with diabetes of all types have at least double the risk of endometrial cancer in comparison to the nondiabetic population. The risk directly related to diabetes is controversial because of frequent co-existence of other known risk factors, including obesity, hypertension, and sedentary lifestyle. The confounding of obesity in particular has been evaluated in case-control studies. Shoff and Newcomb (195), studying women in Wisconsin, and Salazar-Martinez et al. (198), studying women in Mexico, found that the additional risk due to diabetes over the risk of body size alone was mostly in obese (BMI >29) women with diabetes. Independent of weight, physical activity greatly decreases the risk of endometrial cancer. In the Swedish Twin Registry of nearly 12,000 women, even "light exercise" such as "walks or gardening" decreased the risk by half, and "hard physical training" reduced the relative risk to one tenth (199). Sturgeon et al. (200) found similar benefits from either recreational or nonrecreational activity and noted that the subjects who were less active also tended to be more obese. Similarly, patients with type 2 diabetes tend to be more obese and less active.

Several potential mechanisms for the risk of endometrial cancer have been postulated. One of the major recognized risk factors for endometrial cancer is unopposed estrogen exposure (201). Recognition of this in the 1970s changed the prescription of estrogen replacement therapy to include progesterone for women with a uterus, a regimen that has eliminated the increased incidence of endometrial cancer seen with estrogen alone. It has been postulated that additional estrogen exposure in obese women, from peripheral conversion in the increased body fat, induces the cancer. Estrogen levels correlate with percentage of ideal body weight in patients with endometrial cancer, and women with diabetes tend to be more obese and have higher levels of estrogens than women without diabetes (202). More directly, Nyholm et al. (203) found that, in comparison to weight-matched controls, women with diabetes had higher levels of total estrogens, although higher levels of sex hormonebinding globulin kept the levels of free estrogen comparable. Because obesity and physical inactivity, as well as type 2 diabetes, are associated with higher insulin levels, investigators have examined the influence of insulin levels in nondiabetic women. C-peptide levels correlated with BMI and estrogen levels, but after adjustment for these factors, no further relationship was seen between C-peptide levels and endometrial cancer (204). Another approach to this issue is to compare the risk in type 1 diabetes versus that in type 2 diabetes, but studies evaluating these variables have also yielded conflicting results (194, 196,205). The heterogeneity of patients with diabetes and of the insulin levels in diabetes has likely obscured these epidemiologic correlations. A long duration of diabetes also was not seen to correlate with the risk of endometrial cancer (195), but insulin levels usually decline with prolonged duration of diabetes. Hyperglycemia, which might be roughly estimated over the long term by incidence of diabetic complications, has not been assessed in relation to endometrial cancer.

SUMMARY

Diabetes has diverse effects on reproductive and postmenopausal health. As with other complications of diabetes, good glucose control may ameliorate some of the problems; others require approaches particular to diabetes. Many of the issues have not been specifically studied, and generalizations can only be made from studies of nondiabetic women. An appreciation of the unique reproductive consequences of diabetes will improve health care for these patients but also highlights the need for further research.

ADDENDUM 773

THE PROBLEM

The devastating complications associated with both type 1 and type 2 diabetes are now clearly linked to hyperglycemia (1-3). The implication of these findings is that normalization of glucose levels with proper treatment early in the course of the disease would prevent the development of the microvascular and neuropathic complications and probably much of the macrovascular disease. The cost of these complications, both in personal and financial terms, is enormous, and the incidence of both forms of diabetes is increasing. Impressive improvements in treatment have been made thanks to self-glucose monitoring, advances in insulin therapy, new oral medications, and higher standards of care, but most people with diabetes continue to develop disabling complications. Although progress is being made in the development of approaches that could prevent autoimmune diabetes, the prospects for preventing type 2 diabetes seems less promising. A mechanical β-cell equivalent consisting of a glucose sensor and an insulin pump could provide patients with normoglycemia, but efforts to develop a satisfactory glucose sensor have been frustrating in spite of many ingenious approaches (4,5). The most obvious solution is to provide patients with the β -cells they are missing, which can be done with pancreas, islet, or β -cell transplants. This appealing concept even was tested clinically as early as 1893 in Bristol, England, when a physician unsuccessfully transplanted pieces of sheep pancreas into the subcutaneous space of a 15-year-old boy with diabetes (6). This conceptually simple goal continues to look like an attractive solution to the problem of diabetes but has turned out to be extraordinarily difficult to accomplish.

β -CELL REPLACEMENT AS A TREATMENT FOR TYPE 1 AND TYPE 2 DIABETES

While it is generally assumed that β -cell–replacement therapy will be useful for people with type 1 diabetes, many fail to appreciate that it could be a very effective treatment for those with type 2 diabetes, thinking that the main problem in type 2 diabetes is insulin resistance, with a deficiency in insulin secretion making only a small contribution. This misses the point that type 2 diabetes develops only when β -cells fail to compensate for insulin resistance (7). The incidence of type 2 diabetes has skyrocketed, largely because of our sedentary Western lifestyle, with its plentiful food, which leads to central obesity with its concomitant insulin resistance. However, to understand the role of the β -cell, it must be appreciated that most people with insulin resistance never become hyperglycemic because their β -cells compensate with increased insulin secretion: hence the key role of β -cell failure in the development of diabetes.

People argue that a prohibitive number of islets would be required for people with type 2 diabetes and that the hyperinsulinemia would be atherogenic. In fact, many people with type 2 diabetes have insulin requirements that are not very different from those of people with type 1 diabetes, in part because of the residual insulin production in the latter. Moreover, the requirement for a large number of islets for so many patients may be solved once ways are found to make insulin-producing cells readily accessible. The health benefits of such transplants would be enormous. The microvascular and neuropathic complications of diabetes should be prevented, and there are reasons to think that the cardiovascular events would be less common. After such a transplant, an individual would still be left with obesity and insulin resistance, with their health consequences, but these would be associated with far less illness than when diabetes is superimposed. There are many approaches that could help with the problem of type 2 diabetes, such as improving insulin sensitivity with new drugs and reducing obesity, but β-cell replacement also could provide major benefits. If one follows the same arguments, β-cell replacement could prevent the hyperglycemiarelated complications for almost all forms of diabetes, such as various forms of maturity-onset diabetes of the young (MODY), mitochondrial diabetes, cystic fibrosis, and diabetes secondary to pancreatectomy. In fact, these non-type 1 forms of diabetes may actually be easier targets for β -cell replacement because the transplanted islets would be encountering only allograft rejection and not autoimmunity.

PANCREAS TRANSPLANTATION

Pancreas transplants were first performed on an experimental basis in the 1960s, but the procedure was not widely applied until the mid-1980s (8-11). By the year 2000, more than 1,200 transplants were being performed yearly, with many of these being made possible by an increase in access to insurance coverage. The vast majority of these transplants have been done in the United States and Europe. Improvements in outcome have been due to advances in organ preservation, surgical techniques, and immunosuppressive drugs. The most common transplants and the best results have been obtained with simultaneous kidney/pancreas (SKP) transplants given to patients with type 1 diabetes who have advanced nephropathy. Much less common are pancreas transplants done after a kidney allograft (PAK), which usually require more immunosuppression. Decisions about pancreas transplants often are driven by the availability of a kidney from a living related donor because of the superior outcomes of such transplants compared with dialysis and even transplantation with a cadaveric kidney. Few patients receive a pancreas transplant alone (PTA), although a single center recently reported 225 of these cases (12). Justification of PTA, with its risks of mortality, morbidity, and immunosuppression, requires that patients have serious problems with their diabetes, which might include life-threatening insulin reactions, instability of control, and various psychological problems. A final, even less common, approach is the use of the distal portion of the pancreas provided by a living related donor. There continues to be debate about the efficacy of using only

half of the pancreas and the risk of development of either glucose intolerance or frank diabetes in the donors (13).

The excellent results obtainable by simultaneous transplantation of a kidney and pancreas (SPK) are now being experienced by an increasing number of centers, with approximately 85% of the pancreases maintaining euglycemia in the recipient 1 year after transplantation and approximately 50% functioning well after 5 years. The euglycemia means that recipients have normal glucose levels around the clock, are without increased risk of reactive hypoglycemia (14), have normal glycohemoglobin levels, and have no dietary restrictions, even if they are taking medications such as cyclosporine or tacrolimus (FK-506) and glucocorticoids that can inhibit insulin secretion (15,16). Results reported for PAK and PTA have not been as good, but they have been improving steadily (10).

Strategies for drainage of transplanted pancreases have evolved, with most centers now using enteric drainage with a side-to-side anastomosis of the donor duodenum and the recipient ileum (17) (Fig. 45.1). Although this procedure is associated with some risk of infection, it avoids the problems that plagued the use of bladder drainage via the donor duodenum: acidosis, dehydration, infection, and a variety of other problems (18). Bladder drainage was widely used for about 10 years, but many patients who originally had bladder drainage were later converted to enteric drainage. The venous drainage from a transplanted pancreas usually goes directly into the systemic circulation, but some centers are now employing the superior mesenteric vein to allow drainage into the portal vein, which is more physiologically correct but a more technically demanding procedure (19,20).

The most commonly used immunosuppressive therapy in the past has been triple therapy with cyclosporine, azathioprine, and prednisone, but centers are now more likely to use tacrolimus (FK-506), mycophenolate mofetil, and prednisone (21). Antibodies to T cells or the interleukin-2 (IL-2) receptor are usually used during the induction phase. In general, higher doses of immunosuppressive drugs are required for patients who receive pancreas transplants than for those who receive kidney transplants alone, which is worrisome because of the increased risks of infection and malignancy (22). For SKP transplants, kidney rejection is used as a surrogate marker for rejection of the pancreas. Detection of problems with the pancreas is more difficult for PAK and PTA procedures. Some have considered amylase output a useful marker for patients with bladder drainage, but current approaches are more likely to use serum levels of amylase and lipase and pancreas biopsies (23). Immunosuppression is necessary to control not only allograft rejection but also the autoimmunity that originally caused type 1 diabetes in the recipients. The persistent autoimmunity may be especially aggressive, as indicated by SKP transplants performed between identical twins who were not given immunosuppressive medication (24). Neither the exocrine pancreas nor the kidney was rejected, but diabetes recurred, with immune destruction of the islets demonstrated by biopsy. Remarkably, this destruction occurred in only a matter of weeks, which is far more rapid than the normal progression of type 1 diabetes, which typically takes years to produce hyperglycemia (25).

Risk and Benefits of Pancreas Transplantation

Debate continues about how much patients benefit from pancreas transplants (26). This transplantation requires complex surgery and is accompanied by significant mortality and morbidity; patients frequently are hospitalized for extended periods and readmitted for problems such as intraabdominal infection and vascular thrombosis (27). Nonetheless, some studies sug-

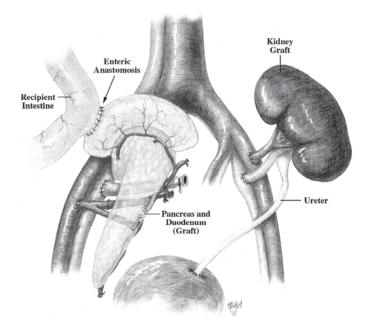

Figure 45.1. Combined pancreas and kidney transplant. The digestive juices of the pancreas are drained into the intestine via an enteric anastomosis between the donor duodenum and the recipient ileum. Venous outflow can be either into the peripheral circulation via the iliac vein as shown or into the portal vein. (Drawing courtesy of Dr. David Sutherland.)

gest that survival is better for patients with SKP transplants than for those with kidney transplants alone (28,29), although it is difficult to find studies with well-matched treatment groups. The impact of these transplants on the complications of diabetes seems to be modest, which is not surprising considering that so many recipients already have advanced abnormalities when they receive the transplant. Various studies have found some stabilization of retinopathy and improvement in nerve conduction velocity, but these changes seem to have little clinical impact (30–32). A recent study found that some histologic improvement of transplanted kidneys can take place after pancreas transplantation (33). Specifically, biopsies of kidneys of patients with PTA that were obtained 5 years after the pancreas transplant showed no benefit, but biopsies at 10 years showed impressive reversal of histologic abnormalities toward normal. A provocative study suggested that patients with autonomic neuropathy before a pancreas transplant have better survival after 7 years than those with failed grafts (34); although encouraging, this finding needs to be confirmed. The most obvious benefit of pancreas transplants is that patients consider their quality of life improved, particularly because of their freedom from insulin injections, hypoglycemic episodes, and food restrictions. It must be remembered that quality of life is a difficult parameter to evaluate (8,26). For example, it has been difficult to show, using standard parameters such as whether patients are more active or perform better at work, that their lives are improved. Nonetheless, the most striking finding, and of undeniable importance, is that patients are very happy to be free of their diabetes.

Debates continue about the risk-to-benefit ratio of pancreas transplantation, particularly with a cost of approximately \$100,000 per patient (26). Now that more insurance programs have agreed to cover the costs of this procedure, the demand has increased. There is no prospect for doing large controlled trials of pancreas transplantation, but new knowledge about its value will continue to emerge from smaller studies. Until a major advance occurs in islet transplantation or in the develop-

ment of some kind of improved insulin delivery system, it seems likely that pancreas transplantation will continue. The use of half of a pancreas might make this form of β -cell replacement therapy available to more patients. The possibility of doing more PTAs may receive more scrutiny, particularly as a procedure for patients with early proteinuria, with its poor prognosis. As renal failure worsens in these individuals, their risk of macrovascular disease and mortality is markedly increased. The Diabetes Control and Complications Trial (DCCT) has proven that improved glycemic control is strongly protective against the development of kidney disease (1); thus, pancreas transplantation could prove valuable for patients headed toward renal failure. This possibility becomes even more attractive because of recent evidence that the progression of diabetic nephropathy might be partially reversible in patients with pancreas transplants (33).

ISLET TRANSPLANTATION

The first successful islet transplants, performed in rodents in the early 1970s (35,36), were made possible by the development of a method of isolating islets from pancreases with collagenase (37), leading to the expectation that such transplants would soon be available to everyone with type 1 diabetes. At the beginning of the 21st century, the failure to meet these expectations has been heartbreaking for countless patients, their friends and families, and the investigators struggling to progress as rapidly as possible. Indeed, there has been much debate about how science should proceed when there are so many opinions about how to balance applied versus basic research (38). The simple explanation for why the problem of islet transplantation has not been solved is that, despite the conceptual simplicity of the task, it has turned out to be extraordinarily difficult. Nonetheless, despite the frustrations and missteps, substantial progress has been made that should provide a foundation for eventual success.

Two Major Barriers to Successful Islet Transplantation

For the sake of simplicity, one can consolidate the problem of islet transplantation into two major barriers: how to provide an adequate supply of insulin-producing cells and how to prevent the processes of transplant rejection and autoimmunity from destroying these cells once transplanted.

Human Islet Allografts

Much work with small and large animal models was necessary before the first serious human islet allografts could be provided in the late 1980s to immunosuppressed patients with kidney transplants (39-43). These early transplants initially used islets obtained from as many as five donor pancreases, with some of these islets being cryopreserved. The islets were injected into the portal vein, using a direct approach with dissection along the umbilical vein; more recently, however, a transhepatic angiographic procedure has gained favor (Fig. 45.2). These islets become wedged in the portal tributaries and engraft, presumably receiving most of their vascular supply from host vessels growing into the islets (44). Portal hypertension, hemorrhage, or thrombosis can occur, but such complications have been rare (45). There were a few early successes, with some recipients being insulin-free for more than 2 years, but then it became apparent that most of these transplants were failures. The initial results were disappointing. Data from the International Islet Transplantation Registry show that between 1990 and 1998, only 33 (12%) of the 267 recipients of islet allografts remained insulin-free for more than 1 week and only 8% maintained that status for over 1 year (45,46). The longest period of independence from insulin was 70 months. About 35% of these allografts had continuing graft function (C-peptide greater than 0.5 ng/mL) after 1 year. However, about 30% of the patients had a marked reduction in C-peptide levels within 1 month, a phenomenon called primary nonfunction. Because such a rapid loss is rarely seen with allografts in the absence of autoimmunity, autoimmune destruction is thought to be largely responsible.

The poor results obtained during the 1990s were very disheartening and discouraged the expansion of clinical trials. Fortunately, the few centers that persisted with transplants made advances that produced important insights (40,45–50). Although very few recipients were freed of their insulin requirements, it became apparent that the function of the grafted islets persisted in some of them, as evidenced by measurable C-peptide production. As is the case with the early stages of type 1 diabetes, residual insulin secretion greatly improved glycemic control even though insulin treatment was still required. Thus, in about 20% to 30% of carefully performed, well-documented islet transplants, C-peptide secretion did persist and appeared to lead to improved glycohemoglobin levels and fewer severe insulin reactions (47).

The Complexities of Islet Allografts

As investigators became more rigorous about details, results began to improve, although they continued to be disappointing. Better results could be obtained if the cold ischemia time of the cadaver pancreases was limited to less than 8 hours before islet isolation and if more than 6,000 islet equivalents per kilogram were transplanted (45,46). Better techniques for islet isolation have evolved. Some find that the new standardized collagenase preparation, Liberase, gives better and more consistent islet yields (51), and efforts have been made to minimize the amount of endotoxin in the reagents. The period immediately after the transplant may be critical. The phenomenon of primary nonfunction, with rapid disappearance of measurable C-peptide, is likely caused by autoimmunity, because such rapid failure vir-

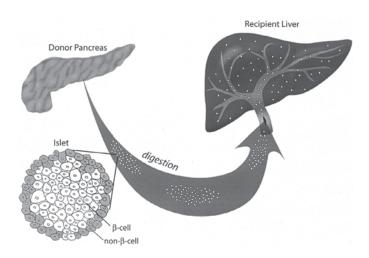

Figure 45.2. Islet transplantation in humans usually is done starting with a cadaver pancreas that is digested with a collagenase/protease mixture. The isolated islets are then introduced into the portal vein either by transhepatic angiography or via laparoscopy. The islets then are carried downstream and wedge in the portal tributaries, whereupon they are vascularized by vessels from the recipient.

tually never occurs with autotransplants. Other complex events during the early implantation phase must lead to considerable loss of islet mass. For example, there must be some obligatory loss of cells to local hypoxia in nonvascularized clumps of islet tissue (52,53). In addition, a nonspecific inflammatory response (54) and possibly localized clotting (55) may enhance the immune processes of rejection and autoimmunity and activate the innate immune system (56). Hyperglycemia may produce increased oxygen consumption by β -cells, which would further deprive them of oxygen in their local environment, so every effort should be made to maintain euglycemia with aggressive insulin therapy. A case may be made for using intravenous insulin during the first 10 days after the transplant while new vessels from the host enter the islet grafts (44). The hyperglycemic environment appears to have an adverse influence on the outcome of islet transplants (57). There was evidence that the use of anti-thymocyte globulin during the induction period was beneficial (45,50). Some thought the use of nicotinamide, verapamil, pentoxifylline, and vitamin E was valuable (45), but the efficacy of these agents remains to be established.

Despite these partial successes, the results were far inferior to those of pancreas transplantation, which results in the immediate achievement of normoglycemia in 85% of recipients and in the remaining 15% for at least a year. This indicates that the islets contained in one pancreas should be enough and that both transplant rejection and autoimmunity can be controlled by conventional immunosuppression. Somehow, the islets contained in their normal home in the pancreas must be less vulnerable to immune injury and/or the toxic effects of the immunosuppressive agents. It is also possible that the ability of the pancreas to generate new islets from ducts may be helpful (58). Moreover, the presence of draining lymph nodes contained in the whole pancreas seems to provide a protective effect against autoimmunity (59,60).

A puzzling finding is that the mean time required for the development of insulin independence in the 33 reported successful allograft recipients was 179 ± 24 days (45). One explanation is that insulin independence tended to coincide with the lowering of the doses of immunosuppressive medications such as prednisone, which are diabetogenic, but the actual reason may be much more complex. One might not expect β -cell mass to have increased during this time, but precursor duct cells carried along with the islets (61,62) might have been the source of some new islets. Although host vessels grow into transplanted islets in only 7 to 10 days (44), we have no idea how long it takes the vessels to be fully established. In their normal location in the pancreas, islets have a specialized vasculature; arterioles break into capillaries within the core of the β -cells and then exit through the islet mantle that contains glucagon-secreting α cells (63,64). When transplanted islets are revascularized, the normal relationship between β - and non- β -cells may not be reestablished, possibly leading to altered β -cell function (65). In addition, reinnervation (66) and topographic remodeling of the islet micro-organs may take a long time. There are other reasons for being concerned that transplanted islets may not function as efficiently as normal islets in the pancreas. It has been found that the oxygen tension of islet grafts situated under the kidney capsule of rodents is considerably lower than that for islets in the pancreas (67), a factor that could result in a reduction in glucose-induced insulin secretion.

Although we now realize that increasing the mass of islets transplanted is helpful, this was not clear in the 1990s. Islets from as many as five donors often failed, while islets from a single pancreas were sometimes sufficient. Another complex variable is islet purity; many of the successful transplants have used islet preparations that had a purity of more than 80%, and others had a purity of 50% or less, raising questions about the influ-

ence of non-islet elements such as duct cells. The benefits of immunologic matching of donor and recipient have not been carefully studied, but most successful transplants have been matched only for blood type and not for histocompatibility antigens (45). Measurement of islet autoantibodies prior to transplantation is usually of little help because the titers are typically low, but some have found that the presence of autoantibodies may be associated with a worse outcome (68,69). An approach that may be worth pursuing is the measurement of gene expression of various immune mediators in circulating lymphocytes during the course of transplantation, as this has been found to correlate with kidney allograft rejection (70).

The Edmonton Protocol

Frustrated by the mediocre results of earlier trials, a group of investigators in Edmonton, Alberta, Canada, tried a new approach in 1999 (71). They thought that rapamycin (sirolimus) might be beneficial and that glucocorticoids were toxic to islets. They also did everything possible to improve the quality of their islet preparations and reasoned that more islets would be required than was previously considered necessary. They recruited patients with type 1 diabetes who had serious problems with hypoglycemia, which justified the use of potentially dangerous immunosuppressive agents. In contrast to the procedure for earlier transplants, the islets were used immediately after their isolation rather than being maintained in tissue culture. The immunosuppression regimen included rapamycin (sirolimus) and tacrolimus (FK-506) but no prednisone. For induction, antibody to the IL-2 receptor (daclizumab) was used. Islets were introduced into the liver through the portal vein via transhepatic angiography. Islets from more than one cadaver donor were required, with two sufficing for most of the patients. Normoglycemia was never attained after the first transplant but did occur immediately after the second or third transplant. A total of about 11,000 islet equivalents (IE) per kilogram were used. At the time of this writing, 17 patients have been rendered insulin-free with glycohemoglobin levels in the normal or near normal range. Most of the patients have glucose intolerance, and their stimulated C-peptide release is approximately one third of normal, which suggests that their β -cell mass is marginal or that the grafted β -cells are less efficient than pancreatic β -cells. Some of the patients have maintained normal glycohemoglobin levels without insulin for almost 2 years.

The results of the Edmonton group are spectacularly better than any previous results, but this enthusiasm must be tempered by the reality that patients must receive dangerous immunosuppressive therapy and that two or more cadaver pancreases are required, which means that very few patients will be treated. Nonetheless, this is a true advance that should provide a foundation for future improvements with different protocols. To bring other groups up to the same level, the Immune Tolerance Network funded by the National Institutes of Health, with help from the Juvenile Diabetes Foundation, is funding 10 centers to perform 40 transplants to try to reproduce the Edmonton results. As with the Edmonton trial, the multicenter trial will enroll patients without kidney transplants who have threatening episodes of hypoglycemia; however, patients with severe instability of their control and advancing complications will also be considered.

Allografts in the Absence of Autoimmunity

Insight into the possible problems caused by autoimmunity have been provided by cluster operations for abdominal cancer in which the liver, pancreas, and other organs were removed from the patient, who then received a cadaver liver into which islets isolated from the same cadaver donor were placed, providing a pure allograft situation (46). These islet allografts more often produced normoglycemia than did islets given to patients with type 1 diabetes; patients became insulin-independent 60% of the time, and one patient was insulin-free for 5 years. Although transplantation of the liver may have had some beneficial influence on the immune system, the absence of autoimmunity is suspected to be a major reason for the success. In addition, these recipients are typically unhealthy, so they may require less β -cell mass to accommodate their reduced nutritional intake and weight.

Islet Autografts

Transplantation of islets that do not face immune attack provides important lessons about how well islets can perform in the liver. When pancreases are removed because of painful pancreatitis or some other reason, it is often possible to isolate the islets and transplant them into the liver via the portal vein. These digested pancreatic preparations have typically been relatively impure, containing non-islet pancreatic elements, including duct cells that have the capacity for neogenesis. These patients do remarkably well, with about 70% being insulin-independent at 1 year if they receive more than 300,000 IE (46). Sometimes success can be achieved with even fewer than 200,000 islets-considerably fewer than the usual requirement for successful allografts (72,73). The most obvious explanation for success is that there are no problems with either allorejection or autoimmunity; it must also be remembered, however, that the removal of glucagon by the pancreatectomy and the tendency of these patients to be thin could make them relatively insulin-sensitive.

EFFORTS TO CONTROL TRANSPLANT REJECTION AND AUTOIMMUNITY

Current organ transplants are successful because of immunosuppression, which although more effective than ever, continues to be associated with notable risk, the main threats being susceptibility to infection and the development of malignancy (22). There is great reluctance to use such dangerous drugs in people with type 1 diabetes whose prognosis might otherwise be good. Fortunately, considerable progress is being made in the quest for safer and more effective immunosuppressive drugs. As we learn more about the differences between rejection and autoimmunity, we can expect different approaches to be used for each process. Even different drugs are likely to be required for xenograft rejection.

Induction of Tolerance

A major goal for the transplantation field is to be able to induce tolerance, that is, treatment given only at the time of transplantation will somehow trick the recipient's immune system into accepting transplanted foreign tissue as his or her own. Many different approaches currently being studied could lead to full or operational tolerance (Table 45.1). Tolerance to transplanted tissue has been induced by a variety of techniques in a number of experimental models (74), but many scientific and safety hurdles must be overcome before such approaches can be used in humans. One hopeful example was the islet transplants between different species of nonhuman primates in which anti-CD3 immunotoxin, cyclosporine, and steroids were given only during the peritransplant period, with normoglycemia persisting for more than 100 days in the absence of further immunosuppression (75).

TABLE 45.1. Approaches to the Induction of Tolerance Induction

Graft-based tolerance induction

MHC knockouts (class I or II MHC antigens) Remove donor antigen-presenting cells (passenger lymphocytes) Masking of class I MHC antigens by antibodies Privileged sites (brain, testes, thymus, anterior chamber, other) Gene transfer to islets (eg, CTLA4Ig, IL-4, TGF-β)

Host response-based tolerance induction

Central tolerance Clonal deletion: thymic injection of antigen Clonal inactivation: thymic irradiation Peripheral tolerance Anergy Immune deviation: from Th1 to Th2 Inhibition of co-stimulation (CTLA4Ig, Anti-CD40 ligand) Peptide-based therapy (parenteral or oral for autoimmunity) Immunosuppression Donor-specific transfusion (DST) Peripheral cell suppression (CD4 subsets) Clonal deletion of peripheral T cells Chimerism Clonal T cells that home to islets and inhibit immune destruction

Immunosuppression and Immune Modulation

Impressive success with islet allografts in nonhuman primates has been found by blocking co-stimulation with antibodies to CD40 ligand (CD 154) on T cells, which results in inhibition of T-cell activation by antigen-presenting cells. This new agent has produced excellent results in experiments with monkeys and baboons, with normalization of glucose levels and seemingly minimal toxicity (76,77). Unfortunately, trials of this agent in persons with lupus nephritis had to be stopped because of thromboembolic phenomena. Although treatment with anti-CD40 ligand controlled allograft rejection, it is not clear if blockade of co-stimulation will protect against autoimmunity (78).

Another new agent used with some success in nonhuman primate islet allografts has been CTLA4Ig, which also blocks costimulation (79). T cells can be inhibited by antibodies in various other ways. An agent in clinical islet transplant trials is a nonmitogenic humanized, Fc receptor-nonbinding OKT3 antibody, which inhibits T-cell activation (80). A variety of other experimental agents could turn out to be useful. FTY720 is an agent that displaces lymphocytes from the peripheral circulation and is effective in various transplantation models (81). Monoclonal antibodies to the transmembrane protein tyrosine kinase phosphatase CD45 have been found to inhibit the rejection of islet allografts (82). The soluble complement receptor 1 (sCR1) TP10 may inhibit the inflammation around newly transplanted islets and may help control primary nonfunction (55). Blockade of the IL-15 receptor with mutated IL-15/Fc can inhibit T-cell expansion and protect islet transplants (83). In other experiments, IL-10/Fc prolonged islet xenografts, possibly by inhibiting macrophage function (84). These are just a few examples of agents that are being developed. Previous experience shows that combination therapy usually provides the best results, so it will be challenging to determine how these new drugs will interact.

Immunologists also are learning more about immunoprivileged sites such as the testes, brain, thymus, and the anterior chamber of the eye, knowledge that may provide insights into possible new strategies (85). Cotransplantation of islets with Sertoli cells has been found to provide some protection against rejection (86). This originally was assumed to be caused by the expression of Fas ligand on Sertoli cells, but recent experiments suggest that the protection is caused by secretion of transforming growth factor- β (TGF- β) (87).

THE SHORTAGE OF INSULIN-PRODUCING TISSUE

At present the only sources of islets for transplantation into humans are cadaver pancreases, which are in very short supply. It is currently not possible to use living donors because not enough islets can be reliably obtained from a donated portion of a pancreas. In the United States, it will be a major challenge to obtain 3,000 usable cadaver pancreases per year, yet the incidence of type 1 diabetes is about 30,000 cases per year (88), and type 2 diabetes develops in more than 10 times as many people. The success of the Edmonton protocol depended on the use of two or more cadaver pancreases. There have been some successes with islets isolated from only one pancreas, but it may be necessary for the donor pancreas to have a large islet mass and for the recipient to be small and insulin-sensitive. Another problem is competition for pancreases with those doing whole-pancreas transplants, particularly because whole-pancreas transplants are presently more often covered by health insurance. This competition is likely to cause problems until islet transplants have been proven to provide superior results. There has been much discussion about the possibility of using human fetal tissue, but despite some advances, this is proving to be a difficult route (89,90). Many transplants of human fetal pancreas have been performed around the world, but no clear benefit has been demonstrated (45). At present, no one has found a way to exploit the growth potential of fetal pancreases; moreover, many ethical and practical issues cloud the future of this approach.

Expansion of Human β -Cells from Stem Cells, Other Precursor Cells, and Cell Lines

It is now appreciated that new β -cells are generated throughout adult life, both from replication of preexisting β -cells and through the formation of new β -cells from precursor cells contained in pancreatic ducts (91). In the presence of hyperglycemia and insulin resistance, β -cell hypertrophy also can contribute to the increase in β -cell mass (92,93). To maintain β -cell mass, birth of new β -cells is balanced by death of β -cells, mainly through apoptosis. There is increasing excitement about the possibility of expanding β -cell number by exploiting the developmental capacity of precursor cells. This could be accomplished with stem cells or other precursor cells by finding new ways to stimulate the replication of existing β -cells or by creating a useful β -cell line.

Stem Cells

The definition of stem cells has become very complex. There are true stem cells, such as hematopoietic or intestinal cells, that have the capacity of unlimited expansion and are capable of generating various cell types. There are embryonic stem cells found in blastocysts that are capable of developing into any specialized cell type. Then there are facultative or functional stem cells that are differentiated cells capable of generating new cells. These can include differentiated pancreatic duct cells that, with the proper stimulus, can change their differentiation and become activated to form new islet and acinar cells (94). It has recently become apparent that stem cells have a much wider capacity for differentiation than has previously been appreciated, with there being examples of hematopoietic stem cells differentiating into liver, nerve, and muscle cells (95). It may also be possible for differentiated cells to turn into cells with characteristics of embryonic stem cells (96).

Recent advances have generated optimism that stem cells might be used to make new β -cells and thus solve the problem of limited β -cell supply. For example, it has recently been shown that duct cells obtained from adult human cadaver pancreases can be expanded in vitro and that when these precursor cells (functional stem cells) are stimulated with growth factors and matrix, they form duct cysts from which sprout islets that contain β -cells and the other islet cell types, these being called cultivated human islet buds (CHIBs) (58). At present, not enough CHIBs can be generated to be useful for clinical transplants, but there seems to be potential for further expansion. Although adult pancreatic duct cells have this capacity for islet regeneration, it seems that the process is normally suppressed in vivo to accommodate the need for a low rate of neogenesis. With the proper in vitro or in vivo stimulus, these restraints can be removed, as has been shown to occur after partial pancreatectomy in rats (97,98). These studies raise the hope that a single pancreas could provide enough islets to supply β -cells for more than one recipient. In addition, it might be possible to obtain pancreatic tissue from a person with diabetes and then cultivate new islets, which can be returned in the form of a transplant. For type 1 diabetes, this would mean that allorejection would not be a problem, but autoimmunity would still need to be controlled. For type 2 diabetes, the tantalizing possibility exists that CHIBs could be provided as an autotransplant with no immune rejection. Other workers have obtained considerable expansion of cells obtained from human islets, which unfortunately seem to contain little insulin (99,100). Efforts continue to make these cells differentiate into a β -cell phenotype useful for transplantation.

The possibility of using embryonic stem cells has become more attractive with the demonstration that mouse embryonic stem cells can be grown to form insulin-containing cells capable of curing diabetes in mice with chemically induced diabetes (101). This was accomplished by means of a selection process employing antibiotic resistance genes driven by the insulin promoter. Specialized tissue culture techniques then were applied that produced aggregates of cells containing near-normal amounts of insulin and having the capacity to secrete insulin in response to glucose levels in the physiologic range. This success raises the possibility that human embryonic stem cells might be developed in a similar manner to generate an unlimited supply of β -cells.

Production of Insulin-Producing Cell Lines

Advances in molecular and cell biology have made it theoretically possible to manipulate the differentiation of cells by genetic engineering so that they could be used for transplantation. It has been possible to transform murine insulin-producing cells with the SV40 T antigen, expand these cells, and then turn off the oncogene with a tetracycline response element, with resultant redifferentiation (102). Although such modified murine cells could conceivably be used for transplants into humans if the cells were somehow protected from immune destruction, human cells would be a preferable source. Unfortunately, it has proven difficult to create a β -cell equivalent by adding genes or inhibiting the expression of existing genes (103,104). For example, the proinsulin gene can be expressed in cells that normally do not make insulin, with the resulting cells capable not

only of making proinsulin and cleaving it to insulin but also of storing and secreting insulin in response to a variety of stimuli. By adding additional genes that influence glucose metabolism, it is even possible to manipulate these cells so that their insulin secretion is partially regulated by glucose. Another approach has been to engineer cells from the intermediate lobe of the pituitary to make insulin (105). These cells are of interest because despite their production of significant quantities of insulin, they are not subject to autoimmune attack. Although these preliminary results are encouraging, it is becoming clear that normal βcells are remarkably complicated, which means it may be difficult to create near-normal β -cells by altering a few genes. On the other hand, as more is learned about the master switches that control the differentiation of cells, more promising results may emerge. Human insulin-producing cell lines have been derived from β -cells from patients with persistent hyperinsulinemic hypoglycemia of infancy (106). Although these cells can be expanded in tissue culture, they do not contain much insulin and have not yet been engineered to secrete insulin properly in response to physiologic levels of glucose. In considering the potential use of insulin-secreting cells for transplantation, the question remains of whether the non- β -cells of the islet or some equivalent should be contained in the transplanted cell aggregates. It seems that non- β -cells are probably not required, as suggested by experiments in which relatively pure β -cell populations prepared by flow cytometry functioned reasonably well when transplanted into diabetic rodents (107).

Xenotransplantation

Despite increased optimism about the prospects for developing new sources of human β -cells, investigators are still exploring the possibility of using tissue from other species as xenotransplants (Table 45.2). The list of species that are potentially useful include pigs, cows, rabbits, rodents, and even fish. Pigs have had particular appeal because pig insulin has been used in the past for treating people with diabetes, pigs have glucose levels similar to those in humans, pigs are part of the food chain, and people seem to be comfortable about the prospect of using this source. Unfortunately, pig islet tissue is not easy to work with. It continues to be difficult to generate high-quality islets from adult pigs (108,109). Much work is now being done to develop ways of using either fetal or neonatal islet tissue, which are attractive sources because of their growth potential (110–114). One of the problems with this tissue is the immaturity of the cells, which means that it can take weeks or months to normal-

ize glucose levels in transplant recipients. Another potential problem is that porcine tissue contains porcine endogenous retroviruses, which can be transferred to human cells in tissue culture (115,116). There is considerable uncertainly about whether this represents a health threat, but in the United States, transplantation of porcine tissue for the treatment of neurologic disease has been allowed to proceed with caution. Thus far, no human recipients of porcine tissue have been reported to carry porcine retroviruses (117).

Immune Attack on Xenogeneic Islets

Rejection of xenografts is a complex and effective process (118-120). There is an early attack called hyperacute rejection mediated by antibodies and complement that can lead to destruction of transplanted organ within minutes. These preformed IgM antibodies recognize a glycoprotein called the Gal- $\alpha(1,3)$ Gal epitope (Gal epitope) that is strongly expressed on the surface of endothelial cells. This is a particular problem for organ transplants because the attack on endothelial cells produces ischemia that leads to rapid death of the organ. Cell transplants may not be as vulnerable to this process. For example, it seems that islet cells from adult pigs have little of this Gal epitope (121). However, even though islet cells might escape hyperacute rejection, they will be subjected to T cell-mediated damage, which seems to be similar to allorejection, and to other insults, such as infiltration with eosinophils and macrophages (118,122). Surprisingly, xenografted tissue may also be susceptible to autoimmune attack, which does not seem to be species-specific (123).

IMMUNOBARRIER TECHNOLOGY

Semipermeable membranes that create an immunobarrier can prevent destructive lymphocytes from killing transplanted islet tissue (124–126). These membranes have openings large enough for glucose, oxygen, and nutrients to reach the encapsulated islets and for insulin to be released to enter the bloodstream. Yet, the holes are small enough to keep white blood cells from penetrating the membrane and reaching the islet cells. Important questions remain about just how permeable the membranes need to be. Recently, it was found that merely maintaining a distance between lymphocytes and islet cells may be enough to prevent autoimmune destruction and allorejection (127,128). Protection of xenotransplants seems to be more difficult because smaller openings might be necessary to limit leakage of shed antigens and to prevent entry of potentially toxic cytokines. It is hoped that immunobarriers, if successful, will make the use of immunosuppressive medication completely unnecessary. Although safe drug treatments that will protect transplanted islet cells may be available in the future, there may be a period during which membrane protection could be clinically useful. The two major approaches are macroencapsulation and microencapsulation.

Macroencapsulation

Macroencapsulation uses devices such as hollow fibers or parallel flat sheets sealed at the edges in which many islets are contained within a single device (125,129–131). Large gel beads or even slabs made of either agarose or alginate can also be considered for macroencapsulation (132). One of the major advantages of such an approach is the possibility of implanting the devices in a variety of locations but of still being able to retrieve or reload them. The main problem with this approach has been the difficulty achieving a practical density, which means that too great a surface area would be required to support the encapsulated islet cells (130). Moreover, questions persist about whether the release of insulin will be rapid enough, particularly from large gel beads, to control blood glucose levels adequately. It is hoped that advances in tissue engineering will improve the potential of macrodevices.

Microencapsulation

Microencapsulation is an approach in which single islets, a small number of islets, or aggregates of cells are contained within a membrane The most commonly used method uses alginate obtained from seaweed, which can form a gel after exposure to calcium or barium in solution (133–137) (Fig. 45.3). Thus, islets can be captured in a small gel bead (less that a millimeter in diameter) that can be coated with a material such as poly-L-lysine that can provide permselectivity. Because poly-Llysine can generate an inflammatory tissue reaction, an outer layer of alginate usually is added to make the capsules more biocompatible. Recent studies indicate that simple barium alginate microcapsules without a poly-L-lysine coating can successfully protect against autoimmunity and allorejection in mice (128). Agarose has also been used for microcapsules (138), as has alginate mixed with other polymers, such as cellulose sulfate (139). Another approach is to use a polyethylene glycol with photopolymerization to form a coating (140). For a human transplant, probably more than 300,000 islets will need to be encapsulated and placed into the peritoneal cavity, but that can be accommodated, as suggested by a pilot study performed in humans (135).

Although some successes with immunobarrier approaches in both small and large animal models have been reported (126, 133,141), the feasibility and reproducibility of this methodology have still not been established. Many aspects of this technology could be explored to improve the prospects for success. Cooperation between scientists working with polymer chemistry, bioengineering, and islet cell biology needs to be promoted. The field now faces some fundamental questions: how can bio-

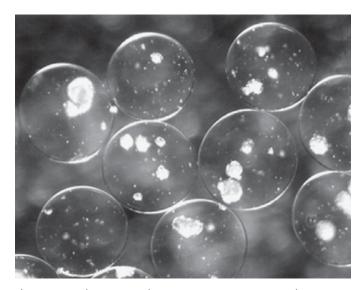

Figure 45.3. Alginate capsules containing porcine neonatal pancreatic cell clusters. Islet cells or aggregates of cells are protected from immune destruction by a semipermeable membrane. A common approach is to use small beads of alginate covered with poly-L-lysine. In some situations the poly-L-lysine is not used. The membrane will prevent penetration by cells and limit the entrance of antibodies. The membrane must be permeable enough to allow the passage of glucose, nutrients, and oxygen to the islets and of insulin out to diffuse into small vessels. GENE-TRANSFER TECHNOLOGY TO PROTECT ISLETS

Prospects are improving for finding clinically useful vectors that can efficiently transfer genes into cells (142–144), meaning that it will be possible to express genes in islet cells with resultant overproduction or underproduction of designated proteins. Potential vectors for gene transfer include viruses, lipid carriers, or electroporation. An important goal would be to transfer genes so that they would be permanently expressed in all of the insulin-producing cells of an islet. Adenoviral vectors that can transfer genes into islets on a temporary basis are now available; unfortunately, however, their expression cannot be expected to last longer than 80 days. Nonetheless, they can be used for short-term proof-of-principle experiments to learn which genes might be helpful for protecting transplanted islets. Another candidate is the "gutless" adenovirus, which has had so much of its adenovirus structure removed that it should not generate an immune response to the infected cells (145). Another vector that holds attractive promise for efficient gene transfer is the lentivirus, a retrovirus that can transduce genes into the genome of nondividing cells (143,146,147). Permanent transduction can also be obtained with adeno-associated virus vectors (148). It is possible that some way will be found to use synthetic lipid carriers effectively. Yet another possibility is to make transgenic pigs to introduce genes into porcine β-cells using an insulin-promoter construct.

There are many ways by which islets might be protected from either transplant rejection or autoimmune attack. For example, some of the proteins on the outside of a cell, such as class I major histocompatibility (MHC) antigens, might be deleted or changed so that the β -cells would escape recognition by the immune system (149). Another approach is to introduce proteins that might be secreted by transplanted islets and serve as missiles to disable invading lymphocytes. It has already been shown that islets engineered to secrete the small protein CTLA4Ig are more resistant to transplant rejection (150-152). Production of an antibody that would bind to CD40 ligand (CD154) might exert a similar effect. A number of cytokines, such as IL-4, vIL-10, or TGF-β, might exert different kinds of inhibitory influences on attacking lymphocytes. The combination of IL-4 and IL-10 has been able to prevent the development of diabetes in NOD mice, presumably by tilting the immunity away from the destructive Th1 pattern of immune attack (153). Unfortunately, adenoviral expression of IL-10 in transplanted islets has not slowed rejection of rat islets transplanted into mice (154). A recent report suggests islet production of IL-4 was not helpful in preventing allograft rejection (155) but that lentivirus-mediated transduction of islets with IL-4 could protect transplanted islets from insulitis (156). TGF- β can modulate lymphocyte reactions from a Th1 to a Th2 pattern (157,158), but high doses can cause fibrosis, which probably would lead to graft failure. Inhibition of IL-12 with a dominant-negative mutant may also have value for islet transplantation (159). Other potentially valuable peptides that might be secreted by transplanted islets are the IL-1 receptor antagonist protein (IRAP) and soluble type 1 TNF receptors (144). Work is also being carried out with indoleamine 2,3-dioxygenase (IDO), a

tryptophane-catabolizing enzyme expressed by the trophoblast that helps inhibit fetal rejection (160).

Another way to improve survival might be to bolster the internal defense mechanisms of β -cells. Various proteins can protect cells against oxidant injury and apoptosis. Thus, one could introduce a gene to make β -cells overexpress catalase or manganese superoxide dismutase, glutathione peroxidase, or heme-oxygenase, which are enzymes that protect against oxidant injury. Alternatively, genes for the anti-apoptotic proteins A20, Bcl2, Bcl-xL, FLIPs, or Myd88 could be used (161–163). Still other genes could provide protection against injury from a combined attack by antibody and complement, which occurs in the early stages of xenograft rejection of organs, but may not be a problem with islets.

It might even be possible to deliver genes to islets *in vivo*, which could be useful for preventing autoimmunity or transplant rejection. One approach is to develop genetically modified lymphocytes that could home to islets through the recognition of islet antigens. A T-cell clone that has been found in mice can home to the islets of NOD mice by recognizing insulin, subduing the autoimmune reaction in the islets, and thereby preventing diabetes (157). This modulation of autoimmunity seems to be exerted by secretion of TGF- β by the T cells. The development of T cells that produce other cytokines, such as IL-4, might also be an attractive strategy. With time, other approaches that could deliver genes to islets *in vivo* are likely to be developed.

PREDICTING THE FUTURE

Attempts to predict the future of islet transplantation have proved hazardous. Unexpected obstacles have plagued this difficult field for decades, and one is not safe predicting anything different for the future. However, with the extraordinary advances occurring in biomedical science, there might be a major breakthrough in the near future; on the other hand, progress might be made in small increments. The results obtained with human allografts should continue to improve as new methods for immunosuppression and immunomodulation are developed that make it possible for more people without kidney transplants to receive islets. There are reasons to be optimistic about the possibility of expansion of human β -cells so that cell supply will no longer be a limiting factor. New approaches to protection from immune destruction are being pursued on many fronts. Even though tolerance is the major goal, it will be necessary to keep working on other approaches, such as better immunosuppressive medications, immunobarrier technology, and gene transfer approaches. Recently, the field of islet transplantation has been infused with new energy and resources that should accelerate the journey to success.

ADDENDUM

Since the initial writing of this chapter, by mid-2004 the Edmonton group transplanted islets to more than 70 patients, using various protocols, and has continued to obtain insulin independence in the vast majority of subjects, although islets from two or more pancreases are still usually required. Other centers in the United States and Europe have been less active, but progress is being made. Two groups have now reported success in obtaining insulin independence from single-donor transplants (164,165). Although encouraging that single-donor islet transplants can succeed, this usually happens only when the recipient has very low insulin requirements and the islet preparation was of excellent quality. It seems likely that the β -cell

mass required to normalize glucose levels is proportional to the insulin requirements of the recipient. The Miami and Baylor groups have been successful in coordinating islet transplants between cities, with pancreases flown from Houston to Miami and isolated islets flown back to Houston for implantation (166). This work and that of others show that islets need not be transplanted immediately after isolation, but can be placed in culture and transplanted 1 to 2 days later. To answer the question of whether islets transplanted to individuals with kidney transplants could do as well as the islets-alone Edmonton approach, several groups have had success with a variety of regimens (167-169). A group in Zurich has had comparable success with simultaneous islet kidney transplants (170).

Notable progress has been made in developing immunologic strategies to create tolerance and block autoimmune destruction. This work has been carried out in mice, pigs, and nonhuman primates (171-174).

For further updates on pancreas and islet transplantation, readers are referred to several excellent recent reviews (175 - 178).

ROLE OF THE CARE PROVIDER 790

In the United States, the medical costs of diabetes are substantial. As the prototype of the chronic disease involving multiple organ systems, diabetes has presented a great challenge to the health-care system at a time of transition from traditional fee-for-service

reimbursement to managed care and capitation. In the United States, a significant proportion of the individuals with diabetes have undiagnosed disease (1). A review of all of the currently accepted performance measures and indicators of quality of care

778 JOSLIN'S DIABETES MELLITUS

for patients with diabetes shows that goals for care are not being met in the United States and in the world at large (2,3).

In reviewing the management of diabetes mellitus, one must be aware of certain general principles. First of all, diabetes is a complex, chronic disorder. Unlike some other chronic disorders, such as asthma and osteoarthritis, it involves multiple systems. Diabetes is not just an endocrine disease, and control of glycemia, although important, is not the only aim of therapy. Prevention and treatment of the long-term complications of the disease comprise a major part of the overall care of diabetes. Many of the efforts of treatment involve measures that have incremental effects and result in changes in patient behavior that have no perceivable benefit to the patient at the time of intervention but may have significant effects many years later. In accomplishing these goals, the primary caregiver must be able to work in a team with specialists and educators.

PREVALENCE OF DIABETES IN THE UNITED STATES AND IN THE WORLD

Diabetes is one of the most common chronic diseases affecting people in the United States. It is estimated that currently 18.2 million Americans have diabetes, representing 6.3% of the population. This figure includes 13 million individuals with diagnosed diabetes and an estimated 5.3 million people who are currently undiagnosed and untreated. It is estimated that approximately 798,000 new cases of diabetes are diagnosed each year (4). The prevalence of diabetes in the United States increased progressively during the second half of the 20th century, with an approximately 40% increase recorded since the late 1970s. It is clear that the overall burden of diabetes will increase substantially worldwide in the next 20 years.

Several factors have contributed to the increasing burden of diabetes in the United States and worldwide. These include a specific increase in the risk factors for type 2 diabetes, such as increasing obesity (5,6) and lack of adequate physical activity (7), both of which have been shown to increase the likelihood of developing diabetes (8,9). The increased aging of the population worldwide (10) is contributing to the prevalence of a disease associated with aging. In addition, the United States has seen a rapid and proportionately greater growth of those minority populations at the greatest risk for type 2 diabetes and its associated complications (11), as well as of populations throughout the world with increased risk (12). Another factor contributing to the apparent increase in the prevalence of diabetes has been the

improvement in surveillance systems for diabetes, which has allowed better assessment of the true burden of diabetes (13).

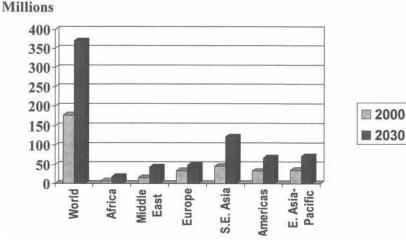

Many additional new cases probably still go undiagnosed. Data from the National Health Interview Survey indicate that approximately 93% of all people with diabetes have characteristics of type 2 diabetes (14). The prevalence of both diagnosed and undiagnosed diabetes increases progressively with age—from approximately 1.6% of individuals 20 to 39 years of age to approximately 20% of individuals 60 years of age and older. The great majority of individuals older than age 40 years have type 2 diabetes (even a majority of those younger than 40 have type 2 diabetes).

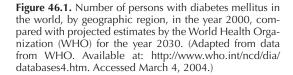

Both diagnosed and undiagnosed diabetes are especially prevalent in minority ethnic populations. When the prevalence is standardized for age and sex, diabetes is 1.6 times more prevalent among non-Hispanic African Americans and 1.9 times more prevalent among Hispanic Americans than among non-Hispanic whites (15). Impaired fasting glucose levels, a condition that is thought to be a precursor to, and to predispose individuals to, type 2 diabetes, is significantly more prevalent in Hispanic-Americans than among non-Hispanic whites and tends to occur at earlier ages in this ethnic population. The incidence and severity of the major secondary complications of diabetes are also greater in these populations than in the general population.

Although the incidence of diabetes will continue to increase substantially in the United States and other developed nations, the rate of increase will be much more rapid in developing countries, which are much less able to handle the financial burden imposed by either conventional or intensive treatment of diabetes. The World Health Organization estimates that the number of people in the world with diabetes may nearly double by the year 2030, approaching 360 million people (16). Enormous increases in diabetes are projected for Southeast Asia, the western Pacific, the eastern Mediterranean, and the Americas. The actual cause of this increasing worldwide epidemic is not entirely clear, but it is likely related to decreased physical activity and changes in diet related to the industrialization in these regions (Fig. 46.1).

IMPACT OF THE COMPLICATIONS OF DIABETES

Diabetes has a major impact on the health of the U.S. population. It is the leading cause of new blindness, end-stage renal disease (ESRD), and non-trauma-related amputations in adults. Care for diabetes and its complications consumes approximately 15% of

the total healthcare expenditures in the country. That figure is out of proportion to the 6% prevalence of diabetes, reflecting the excess morbidity of and medical care required by patients with diabetes.

Diabetes is associated with a substantially increased mortality risk in both men and women. Risk of death is increased threefold to fivefold for persons age 45 to 64 and twofold to threefold for those age 65 to 74. The relative risk declines with advanced age as mortality due to other disease increases. In each age group, women with diabetes have a greater relative mortality risk than do men with diabetes. In the United States, approximately 18% to 20% of those persons who die between the ages of 45 to 74 years have diabetes (17).

People with diabetes are two to four times more likely to experience heart attack or stroke than are people without diabetes (4). People with diabetes younger than age 45 years are 11.5 times more likely to have cardiovascular disease than are people without diabetes. The relative risk of having cardiovascular disease, as well as other comorbidities, which decreases with increasing age, still remains substantially elevated for people with diabetes older than age 65 years (4).

The most common cause of death in people with type 1 or type 2 diabetes is cardiovascular disease, which is the cause of more than 50% of deaths. The acute complications of diabetes, such as ketoacidosis, hyperosmolar coma, and hypoglycemia, are the next most common cause of death, representing about 13%. As individuals with diabetes age, the relative contribution of cardiovascular disease to mortality increases and the contribution of acute complications decreases (18). In the Multiple Risk Factor Intervention Trial, the absolute risk of death related to cardiovascular disease in men with diabetes was substantially increased compared with that in men without diabetes for every age group, ethnic background, and number of additional cardiovascular risk factors (19). The mortality rates for men with diabetes increased steeply as the number of risk factors increased. When patients with diabetes are followed up for 6 years after a myocardial infarction (MI), their mortality risk is increased by 40%, compared with the risk following MI in patients without diabetes (20). The increased risk of post-MI mortality is even more pronounced in women with diabetes than in men with diabetes. Although there has been a substantial decline in mortality due to coronary heart disease in the United States over the past 30 years, this has not been seen in patients with diabetes. In fact, age-adjusted mortality due to heart disease has increased 23% for women with diabetes (21). It is thought that the general decrease in cardiovascular mortality in the general U.S. population is due to a reduction in cardiovascular risk factors and improved methods of treatment of coronary artery disease. These measures have been less effective for patients with diabetes, especially women.

The morbidity associated with the chronic complications of diabetes also represents a significant public health problem. Diabetes is the leading cause of new blindness in adults aged 20 to 74 years (4), accounting for 20% of all new cases of blindness in persons aged 45 to 85 years caused in large part by diabetic retinopathy (22). It is estimated that approximately 90% of these cases can be prevented with improved glycemic control, annual ophthalmologic examinations, and the use of laser treatment if necessary. The prevalence of cataracts is twofold to fourfold higher in patients with type 2 diabetes than in the population without diabetes. Cataracts are a common cause of visual impairment, but not permanent blindness, in older individuals.

Diabetes is also the leading cause of ESRD (4), accounting for 43% of new cases—substantially more than either hypertension or glomerulonephritis. In the United States, the number of new

cases of ESRD due to diabetes increased fivefold to sixfold between 1984 and 2001 (23), and the percentage of all cases of ESRD due to diabetes has increased from 28% to 43% (24). A high percentage of these cases could be prevented or substantially delayed with measures aimed at improving glycemic control, more aggressive treatment of hypertension, and early treatment of microalbuminuria with angiotensin-converting enzyme inhibitors.

The risk for amputation in individuals with diabetes is substantially greater than that in people without diabetes; diabetes accounts for greater than 60% of nontraumatic lower-limb amputations in the United States (25). This is due in large part to either peripheral vascular disease or peripheral neuropathy, which occurs in approximately 50% of individuals who have had diabetes 20 years or longer (26). Many of these cases could be prevented by regular foot examinations and treatment, appropriate education in foot self-care, improved control of blood glucose and cholesterol, and smoking cessation.

In the United States, diabetes costs are more than \$132 billion annually, with \$92 billion related to direct medical costs. In 1992 the cost was \$85 billion, and the numbers are increasing each year (27). There is currently no healthcare policy agenda focused on arresting the increase of this chronic disease, which involves 18 million Americans and is the second most expensive disease in the United States. In this country, diabetes is the leading cause of blindness, amputations, ESRD, kidney dialysis, and kidney transplantation (18). The mortality due to type 1 diabetes is 30% higher in the United States than in Europe, and in the United States serious renal disease in all types of diabetes is more than quadruple the rate in Europe (28,29).

GLYCEMIC CONTROL AND MORBIDITY

Poor glycemic control is a major reason for the high incidence of microvascular complications involving the eyes, kidneys, and nerves of people with diabetes. The Diabetes Control and Complications Trial (DCCT) clearly demonstrated the benefits of improved glycemic control in reducing both the incidence and the progression of retinopathy and nephropathy in people with type 1 diabetes (30). Substantial clinical and epidemiologic evidence, especially from the United Kingdom Prospective Diabetes Study (31), the Kumamoto Study (32), and the Wisconsin Epidemiological Study (33), indicates that the same principle applies to patients with type 2 diabetes.

The diagnosis of diabetic ketoacidosis involved approximately 100,000 hospitalizations in the United States between 1989 and 1991 and represented almost 5% of all patients with diabetes admitted to hospitals. Most of these admissions are preventable. Severe hypoglycemia is also a major cause of increased emergency department visits and hospitalizations.

DISABILITY, ABSENTEEISM, AND EMPLOYMENT ISSUES ASSOCIATED WITH DIABETES

Disability affects many persons with diabetes in the United States, with estimates ranging from 20% to 50% of the diabetic population. Individuals with diabetes report rates of disability that are substantially higher than those reported by the general U.S. population. Reported activity limitations were two to three times higher among persons with diabetes than among those without diabetes (34). Patients with type 1 diabetes from the Children's Hospital of Pittsburgh IDDM (insulin-dependent diabetes mellitus) registry were seven times more likely to report work disability than were their nondiabetic siblings.

Impairments for persons with either type 1 or type 2 diabetes increase with age. Disability is more common in minority groups. Disability is proportionately more common in persons with type 2 diabetes than among those with type 1 diabetes (63.5% versus 42.9% report activity limitations), possibly because of the older average age of patients with type 2 diabetes. The major determinant for disability appears to be the presence of the late complications of diabetes.

The effects of disability on the population of persons with diabetes are very extensive. Patients with type 1 diabetes who are disabled have dramatically lower rates of employment than do individuals with diabetes who are not disabled (49% not working versus 12%) and higher rates of absenteeism (13.8 days per year versus 3.0 per year). Disabled individuals with diabetes use healthcare services more frequently, with greater than twice the hospitalization rates and average number of physician visits and a decreased quality of life.

Rates of absenteeism among employees with diabetes are reported as elevated in some studies but not others (35–37). Although there is controversy regarding the importance of absenteeism in persons with diabetes, it is clear that significant rates of absenteeism tend to be limited to a small subset of the population of individuals with diabetes—not more than 30%. Most employees with diabetes have normal work attendance records. There is a suggestion that many of the persons who have high rates of absenteeism may be disabled (34). Disabled people with diabetes tend to be absent more frequently and have longer absences than do people with diabetes who are not disabled.

If the impact of disability in persons with diabetes is similar to that in the general population, disability will have significant effects on their employability. A lower proportion of persons with diabetes than persons without diabetes are currently employed, even after adjustments are made for age (Fig. 46.2), but the proportion of those not employed who are disabled is similar to that in the general population (34).

With a higher degree of unemployment and absenteeism, there is concern that persons with diabetes may face discrimination in the workplace. This has been reported in several studies (38,39). The 1990 Americans with Disabilities Act, however, expanded the opportunities of disabled persons with diabetes. This legislation provides standards in employee hiring and allows for work-rule and work-environment changes to meet the needs of individuals with disabilities. It applies to all employers with at least 15 employees, and diabetes is specifically listed as a disability under the Act. The concept that diabetes is in and of itself a disability is a controversial one, but the legislation makes it illegal to discriminate against an individual just because he or she has diabetes.

Nevertheless, there are specific areas of employment where employment of persons with diabetes continues to be restricted. Persons with diabetes taking insulin have been restricted from being airline pilots, drivers in interstate commerce, drivers of local mass transit, and, until recently, air-traffic controllers. The major concern has been the risk of developing hypoglycemia during situations in which alterations in judgment or consciousness could put the pilot or driver in danger or at risk to others. The availability of self-monitoring of blood glucose, along with a greater variety of insulin regimens in recent years, the ability to adjust doses, and count carbohydrates, has ameliorated this problem somewhat, but the DCCT established that intensified insulin treatment can be associated with an increased risk for severe hypoglycemia (30). Since 1984, the American Diabetes Association has taken the position that "Any person with diabetes, whether insulin dependent or non-insulin dependent, should be eligible for any employment for which he/she is otherwise qualified" (40). It is understood, however, that a small minority of patients with diabetes lack or are unable to recognize the warning signs of hypoglycemia and are at greater risk for alterations in mental function that might lead to confusion or alteration in consciousness. Those individuals who have recurrent episodes of severe hypoglycemia should be individually evaluated and, in some situations, be considered for modification of their employment responsibilities.

OTHER SOCIAL ISSUES IN DIABETES

Driving

It has long been claimed that diabetes is associated with an increased risk of automobile accidents and crashes. Three studies, of drivers in California, Oklahoma, and Washington state, identified increased rates of crashes in drivers with diabetes (41–43). However, it is possible that the drivers with diabetes in these studies were selected because they had more severe disease. In addition, selection bias may have played a role in some of these studies because the drivers with chronic disease were under review for driving offenses. Another study (44) linked the diagnosis of diabetes to an increased risk of hospitalization for driving-related road trauma, but only among younger drivers.

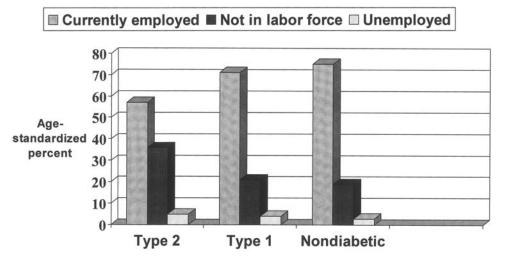

Figure 46.2. The employment status of individuals with type 2 diabetes, with type 1 diabetes, and without diabetes. (From Songer TJ. Disability in diabetes. In: Harris MI, Cowie CC, Stern MP, et al, eds. *Diabetes in America*, 2nd ed. Bethesda, MD: National Institute of Diabetes and Digestive and Kidney Diseases, 1995:259–278. NIDDKD publication no. 95-1468.)

A study of truck-permit holders and commercial drivers in Quebec found an increased relative risk of crashes for drivers with non–insulin-treated diabetes without complications but not for those treated with insulin or with complications (45). Other studies, however, have failed to find an association between driving accidents and diabetes (46–49).

Driving requires complex psychomotor skills, processing of information, and accurate judgment. It is impaired by acute hypoglycemia. Repeated episodes of mild hypoglycemia can be associated with a decreased ability to recognize its symptoms and an increased risk of cognitive impairment. A study of the performance of individuals with diabetes in a driving simulator during induced episodes of mild and moderate hypoglycemia showed that driving performance can be significantly disrupted during relatively mild hypoglycemia, and many individuals fail to take corrective action to treat the hypoglycemia (50). Another study, however, reported that most drivers with hypoglycemia who were cognitively impaired recognized this and reported the perception that they could not drive safely at hypoglycemic levels, but men and middle-aged patients were more likely than women and men under 25 years of age to judge that it was safe for them to drive during hypoglycemia (51). It is important for those with diabetes to have educational reinforcement of safe driving habits and to be encouraged to check glucose levels before driving. Persons whose glucose levels are below 70 mg/dL should be treated before driving. Blood glucose awareness training (BGAT), an 8-week training program that uses behavioral techniques to increase awareness of fluctuations in blood glucose levels, has been associated with fewer and less extreme hypoglycemic events (52) and in follow-up studies has been found to be associated with a reduction in motor vehicle crashes and violations (53).

Because hypoglycemia may be a factor in motor vehicle accidents, most regulatory authorities put restrictions on applicants who have insulin-treated diabetes, whether they have type 1 or type 2 diabetes. However, only individuals with type 1 diabetes appear to be at greater risk for driving mishaps (54). For many years, the U.S. Federal Highway Administration prohibited individuals using insulin from obtaining commercial vehicle driving licenses. However, it had temporarily permitted waivers for some insulin-using drivers (55) but is currently not giving them. Many states are allowing some individuals with insulin-treated diabetes to drive commercial vehicles within state boundaries. The American Diabetes Association has argued for repeal of federal restrictions on commercial drivers with insulin-treated diabetes because of the claim that it is discriminatory and contrary to the Americans with Disabilities Act (56). This remains a complex and contentious issue, in which the justified advocacy for the rights of people with diabetes must be balanced with careful analysis of the risks to public safety.

Travel

The successful management of diabetes requires careful attention to the synchronization of insulin or oral hypoglycemic agents to meals and physical activity. The changes in meals, activity, and time zones that occur with air flight can create unique problems for individuals with diabetes, especially those injecting insulin or using subcutaneous insulin infusion pumps. In addition, travelers to distant countries have to carry syringes and vials of insulin, and the increased security needs of air travel pose special problems. This has become acutely evident since the events of September 11, 2001. Many airlines and countries now require air-travel passengers to carry written documentation of their medical condition and the need to carry syringes, needles, and vials of insulin for injection. Despite these inconveniences, there is no reason why most individuals with diabetes, whether or not they require insulin, should not be able to travel extensively by air across long distances or time zones. Travelers with diabetes should observe the following guidelines, which are modified from the previous edition of this text (57).

- 1. The patient should review travel plans with his or her care provider and adjust the timing of meals and insulin dosages to the schedule of travel. How this is accomplished is highly individualized for each patient and travel plan. Good communication between patient and care provider is essential.
- 2. The patient should be supplied with a note from the physician outlining the diagnosis, listing the generic and proprietary names of medications, giving the physician's name and telephone number, and, if possible, listing physicians at the destination who can be consulted in an emergency. Most countries have diabetes associations that can assist international travelers. If the patient carries syringes, lancets, or needles for injection, the note should document the medical necessity for their use.
- 3. The patient should carry adequate supplies of medications and materials to treat hypoglycemia. He or she should not depend upon the local availability of these materials. These supplies should never be checked in baggage that is not accessible or that might reach a different destination. On some trips, it may be appropriate to carry extra prescriptions for insulin, syringes, and other essential supplies in case of loss or theft.
- 4. It is important for the insulin-requiring patient to have on his or her person easy identification of diabetes in case of emergency. These individuals should wear medical-alert bracelets or necklaces whether or not they are traveling, but it is especially important for them to wear them during travel to distant places or foreign countries.
- 5. The patient should conduct frequent glucose monitoring throughout the trip, especially when traveling across time zones and when meal schedules are altered.
- 6. The patient should take special precautions to avoid motion sickness or travelers' diarrhea, both of which may contribute to hypoglycemia, dehydration, or ketoacidosis, and must be especially careful to have the proper immunizations when traveling abroad.

COSTS OF MEDICAL CARE OF DIABETES

The economic costs of diabetes were reported as \$11.6 billion in direct medical costs in 1986 for people with type 2 diabetes (58) and \$45.2 billion in direct medical costs in 1992 for all people with a diagnosis of diabetes (59). A study comparing the costs of treatment of patients with and without diabetes in 1992 showed that, on average, the annual per capita health expenditures for patients with diabetes were approximately three and a half times the costs for patients without diabetes. From this it could be calculated that the costs of care of patients with diabetes represented almost 15% of total healthcare expenditures in the United States.

The American Diabetes Association published more extensive analyses of the economic costs of diabetes, calculating that direct medical and indirect expenditures attributable to diabetes totaled \$98 billion in 1997 (60) and \$132 billion in 2002 (61). Direct costs are those associated with hospitalization, ambulatory care, and medication. Indirect costs represent lost productivity due to morbidity and premature mortality. To this must

782 JOSLIN'S DIABETES MELLITUS

also be added intangible costs, such as reduced life expectancy and quality of life, for which the assignment of a monetary value is difficult (62,63). The per capita mean costs for persons with diabetes, \$13,243 per year, were found to be five times those for persons without diabetes, but this ratio overstates the impact of diabetes because these patients tend to be older, on average (61). The ratio of per capita expenditures between people with and without diabetes was substantially greater for nonwhite patients (4.5:1) than for white patients (3.6:1). Expenditures for outpatient medications were 3.2 times greater for patients with diabetes. The ratio of expenditures between persons with diabetes and persons without diabetes was nearly identical in patients who were younger than 45 years of age (3.2:1) and in those 45 to 64 years of age (3.3:1). This ratio dropped to 1.6:1 for patients 65 years of age and older, as the increased medical costs for nondiabetic elderly patients narrowed the gap.

Direct medical expenditures associated with diabetes totaled \$91.8 billion, of which \$23.2 billion was related to control of diabetes and blood glucose, \$24.6 billion to excess prevalence of the chronic complications of diabetes, and \$44.1 billion to excess prevalence of general medical conditions. As expected, the largest proportion of expenditures attributable to diabetes was for inpatient care (43.9%), then for nursing-home care (15.1%), and then for outpatient care (10.9%). Two thirds of the costs for medical care for diabetes are due to care of the elderly. Indirect costs related to diabetes were calculated to be \$39.8 billion, of which \$7.5 billion was attributed to disability.

The payment for medical services for diabetes is in significant flux. In 1987, 15% of patients were self-paying, whereas in 1991, the number increased to 20%. In 1991, health maintenance organizations (HMOs) became a significant payer group, accounting for 12% of payments for patients with diabetes nationally. This number is now increasing steadily. For some HMOs, diabetes accounts for 15% to 20% of the medical costs, although patients with diabetes are acutely aware that there is less support for this disease, with regard to education, supplies, and healthcare access.

In 1992, the direct costs of hospitalizations related to diabetes were \$37 billion. There has been a decrease in the absolute number of admissions of patients with diabetes-probably approximately 15% during the decade of 1980 to 1990-and a decrease in the primary diagnoses of diabetes by 38% between 1983 and 1990 (64). These data reflect more stringent criteria for hospital admissions. Although the absolute number of admissions of patients with diabetes has decreased, the percentage of diagnoses of diabetes among all discharged patients increased by 27% between 1983 and 1990. These data reflect a relative enrichment of inpatient cases of individuals with diabetes, explaining the increases in hospitalization costs. Diabetes accounted for 8.4% of all hospital admissions during 1989 through 1991, and female patients represented 57% of these admissions. Patients with diabetes are hospitalized 2.4 to 3 times more frequently than are individuals without diabetes. In addition, the duration of their hospital stay is 30% longer on average, exceeding that of patients without diabetes by 1.7 days (65,66). Diseases of the circulatory system were the most frequently listed primary diagnosis: 33% of cases. The proportion of cases in which diabetes was listed as the primary diagnosis declined significantly from 29% in 1980 to 15% in 1990, as treatment of hyperglycemia has shifted from the inpatient to the outpatient setting under managed care in the United States. That trend should be expected to continue. Although hospitalizations for control of glycemia have decreased, the age-adjusted number of hospitalizations per 100 people with diabetes increased 11.7% during 1980 through 1990 (64). It has been estimated that costs associated with the hospitalization of individuals with diabetes in the United States were \$37 billion in 1992 and that between 64% and 80% of direct expenditures for people with confirmed diabetes were incurred in the inpatient setting (34,67) (Fig. 46.3).

Diabetes is associated with increased medical care costs in the managed care setting. A comparison of 85,209 patients

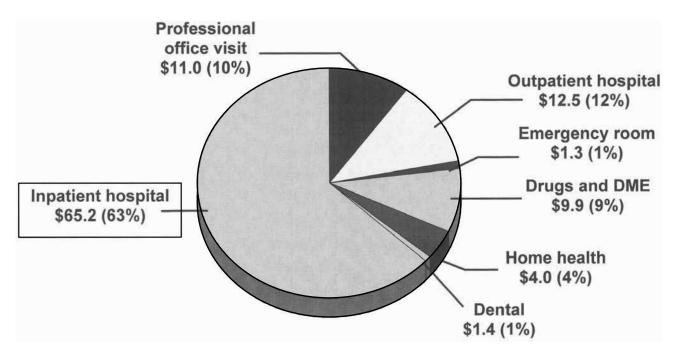

Figure 46.3. Annual healthcare expenditures for patients with diabetes in 1992. Amounts are in \$ billions. DME, durable medical equipment. (Data from Rubin RJ, Altman WM, Mendelson DN. Health care expenditures for people with diabetes mellitus, 1992. *J Clin Endocrinol Metab* 1994;78:809A–809F.)

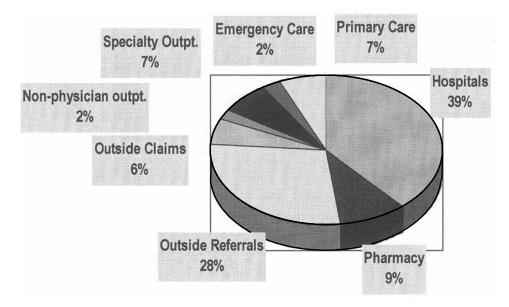

Figure 46.4. Calculation of distribution of excess medical care costs attributable to diabetes in the Kaiser Permanente Health Care System (Data from Selby JV, Zhang D, Ray GT, et al. Excess costs of medical care for patients with diabetes in managed care population. *Diabetes Care* 1997;20:1396–1402.)

with diabetes in the Kaiser Permanente System with age- and sex-matched nondiabetic control subjects showed excess expenditures of \$3,494 per person, with per-person expenditures for patients with diabetes 2.4 times those for control patients (68). The largest part of the total excess cost was for inpatient hospital care within the HMO, representing 38.5% of the total. Costs related to primary care in the outpatient setting represented only 6.8% of the total, with specialty outpatient care only 7.2%. (Fig. 46.4). As might be expected, the largest proportion of the total excess charges were related to the treatment of long-term complications of diabetes, principally atherosclerotic heart disease, stroke, and chronic renal failure.

The increased cost of medical care for patients with diabetes is evident from the time of diagnosis. In one study of patients with type 2 diabetes in an HMO setting, medical care costs for the first year after diagnosis were 2.1 times higher than for matched patients without diabetes (69). For the next 8 years after diagnosis, the diabetes-related incremental yearly inpatient, outpatient, and pharmacy medical costs remained relatively constant, averaging \$2,257. Although the incremental costs were relatively flat during the course of the study, they did appear to rise in the last 2 years, and it was assumed that they would increase greatly as persons with diabetes developed major chronic complications with longer duration of disease.

From the perspective of the employer, diabetes imposes a substantial economic burden, with respect to both medical care and productivity. In a recent study of the impact of diabetes on the workforce of a large corporation, the incremental costs were substantial (70). The incremental cost of diabetes among employees ranged from \$4,671 in the group 18 to 35 years of age to \$4,369 in individuals 56 to 64 years of age. Although the largest proportion of the incremental costs were related to medical inpatient care, a substantial amount was related to medically related work loss. It is interesting that the costs related to medically related work loss were higher in the younger group of employees, possibly because after a certain age, the sickest individuals with diabetes may be dropping out of the workforce.

Data have been accumulating that if managed care plans do not improve the overall glycemic control of their patients with diabetes, they, or the healthcare system in general, will be facing higher medical care costs in the long term as the excess costs of care due to complications and comorbidities become manifest. In one study of patients from HealthPartners in Minnesota, 3-year medical care costs were closely correlated with baseline hemoglobin A_{1c} (Hb A_{1c}) levels at the start of the measurement period (71). Increases in Hb A_{1c} of 1% were associated with a 7% increase in costs. The incremental increases in costs with rising Hb A_{1c} were even greater for those patients with hypertension, lipid disorders, and cardiovascular disease.

Recent studies have indicated that efforts to improve glycemic control, although costly in themselves (72), will have long-term benefits, not only in reducing complications but also in reducing costs. An analysis of the DCCT indicated that, if substantial additional resources were invested each year in patients with type 1 diabetes, the increased treatment would be highly cost effective, with an incremental cost of \$28,661 per year of life gained. If this is adjusted for improved quality of life, the incremental cost per quality-of-life year gained is \$19,998 (73). Marked reductions in cost would be achieved by decreasing ESRD and lower-extremity amputation. Further improvements in cost, life expectancy, and quality of life are achieved if the economics of intensive control are extrapolated over a patient's lifetime (73). Economic modeling of the costs and benefits of intensive control based on the DCCT has been performed and applied to the population of patients with type 2 diabetes in the United States (64). It calculated that the lifetime costs for general and diabetes-related care using intensified treatment for type 2 diabetes would be approximately twice that for standard care. The reduction in lifetime medical costs of complications, however, would largely offset the difference (Table 46.1, reference 74). Although intensive therapy for type 1 and type 2 diabetes is more expensive than conventional therapy in the short run, its long-term cost-effectiveness is comparable to that of pharmacologic treatment of hypertension and elevated cholesterol. This means that from the perspective of public health and the healthcare system, programs to help physicians achieve intensive management of their patients with diabetes would be a worthwhile long-term financial investment (75).

More modest interventions in improving diabetes care have also been shown to improve glycemic control and reduce longterm costs for medical care (76–78). Cost analysis of the care of patients with type 2 diabetes followed in the United Kingdom Prospective Diabetes Study has also shown substantial savings

784 **IOSLIN'S DIABETES MELLITUS**

in costs with interventions to control glucose (79,80) and blood pressure (81). Although intensive glucose control in the study increased trial treatment costs by £695 per patient, it reduced the cost of complications by £957 compared with conventional treatment. However, if standard-practice visit patterns were to be assumed rather than trial conditions, the per-patient yearly costs would be lower, at £478. The cost per event-free year of intensive blood glucose control was calculated to be about £1166, indicating that this form of therapy in persons with type 2 diabetes is highly cost effective and supportable economically. Similar economic advantages were found in modeling the results to costs in the Swiss healthcare system (82). In addition, improved glycemic control may also lead to a more productive workforce, reduce the economic burden due to medically related work loss, and improve quality of life (83).

DIABETES, MANAGED CARE, AND DISEASE MANAGEMENT

The burgeoning disease-management concept is rapidly establishing itself as a significant and powerful entity in the healthcare industry for managing chronic diseases. During the past few years, a growing number of disease management vendors have offered a wide variety of programs with multiple incentives for quality improvement and increased cost-effectiveness. The backgrounds and their motivation for providing disease management to healthcare providers can be highly variable. Programs have been developed and are being marketed and implemented by independent disease-management vendors, pharmaceutical corporations, managed care companies, specialized consultants, patient educational services companies, home healthcare companies, and high-technology data management and software companies in what is becoming an exceedingly competitive environment. Many of these companies are joining forces with clinical organizations or other businesses to combine products, skills, and strategies more effectively in the marketplace.

WHAT IS DISEASE MANAGEMENT?

Disease management is a complete and comprehensive method of providing healthcare that focuses on management of care

across the continuum for populations of patients with chronic diseases. Disease management is a comprehensive integrated approach to care and reimbursement based fundamentally on the natural course of the disease, with treatment designed to address the illness with maximum effectiveness and efficiency (84). Disease management can be thought of as an approach to care that identifies the optimal processes for care of a patient with a specific condition and implements those processes while measuring the outcome to demonstrate improvement economically, humanistically, and clinically (85). Disease management is oriented toward wellness and prevention. The goals of disease management are to extend the periods of wellness that patients experience, to improve the overall quality of their lives, to prevent occurrence or exacerbation of complications or acute episodes, to direct utilization of services and resources appropriately, and to measure outcomes consistently. In practice, disease management is being implemented as a way to contain costs while maximizing the overall quality of care across an insurance company or employer's population (86,87). Therefore, disease management is being implemented most widely in patients with conditions for which cost savings are most substantial.

WHY IS DISEASE MANAGEMENT NECESSARY?

At least 90 million Americans are diagnosed with one chronic illness; as many as 39 million are diagnosed with more than one chronic illness (88). Research demonstrates that approximately 20% of the population with diabetes incur 80% of healthcare costs (89). This disproportionate utilization is very significant and has the potential to worsen with the aging of the population (88). Traditional healthcare directs efforts at reacting to the acute episode. There is often a lack of continuity of care because of the existence of a healthcare system that provides fragmented and uncoordinated care. Clinical and budgetary priorities are concentrated in conflicting positions, with little common understanding or integration. Disease management provides a responsive, coordinated healthcare system that integrates the activities and priorities of all participants in the delivery of care.

Diabetes is one of the most complex and significant chronic diseases in healthcare. Its emergence as a major cause of clinical

TABLE 46.1. Cost of Treatment, Effectiveness, and Incremental Cost-effectiveness under Standard and Comprehensive Care for Type 2 Diabetes

	Standard care	Comprehensive care	Difference

LEA, lower-extremity amputation; QALY, quality-adjusted life-years. Data from Eastman RC, Javitt JC, Herman WH, et al. Model of complications of NIDDM: analysis of the health benefits and cost-effectiveness of treating NIDDM with the goal of normoglycemia. Diabetes Care 1997;20:735-744.

morbidity and increasing healthcare costs was amply discussed earlier in this chapter. The disease in many people is diagnosed only upon their developing serious and life-threatening complications related to the underlying diabetes. In evaluations of the impact of diabetes on the healthcare system and the effect it has on a population, the facts give a convincing picture of diabetes as an appropriate target for disease management. According to the results of the DCCT, maintaining blood glucose levels as close to normal as possible slows the onset and progression of eye, kidney, and nerve complications related to diabetes (31). The DCCT showed that sustained lowered blood glucose levels had positive effects, even in those patients who had prior histories of poor control. Tighter control also contributed to a lower number of glycemic events that led to hospitalizations. Achieving and maintaining such consistent blood glucose control is extremely challenging both for people with diabetes who are attempting to balance busy lives with management of this disease and for their care providers. Disease management offers an infrastructure for integrating all the key members of the healthcare team with the patients and their significant others, in combination with proactive and comprehensive services to improve the quality and cost-effectiveness of diabetes care.

Notable challenges in the healthcare system affect the ability of clinicians to manage diabetes successfully and support the necessity for disease management as a concept and as a practice. Those challenges include

- The lack of standardized care throughout the continuum of care that has contributed to high variability in physician practice and in resultant patient outcomes
- The lack of accessible and immediately available screening, treatment, prevention, and pharmacologic utilization guidelines and protocols for clinicians in active practice settings
- Lack of resources and systems that provide consistent education and reinforcement for professional care providers
- Inappropriate utilization of services and resources, including hospitalizations and emergency department visits secondary to often preventable glycemic occurrences and events related to acute and/or chronic complications of diabetes
- Lack of consistent systems that can assist clinicians to identify high-risk patients, to institute comprehensive preventive and education programs, and to coordinate appropriate utilization of services
- Absence of systems, formats, and resources for performance and outcome measurement; data collection and analysis; trend analysis; patient identification and risk stratification; tracking and monitoring of patients; and reporting and feedback mechanisms that have strong potential to influence effective healthcare delivery
- Inadequate resources and systems to provide comprehensive patient education and support in long-term self-management
- Inadequate systems for coordinating the care and priorities of multiple participants—the patient, primary care physician, specialists, case managers, nurses, and other care providers in a focused, concerted, integrated team approach

Diabetes is a disease with multiple stakeholders who have a vested interest in improved systems and outcomes, i.e., patients, providers, employers, community agencies, health plans, health facilities and agencies, and pharmaceutical and other vendors. As a disease state, diabetes presents a combination of high variability in practice and cost, high prevalence of work or school days lost, and significant difficulties in management. However, there is a realistic ability to alter the course of the disease across the continuum of care through implementation of a disease-management program that provides a focused and specific set of goals and interventions, as well as a consistent evaluative process.

ESTABLISHING A DIABETES DISEASE-MANAGEMENT PROGRAM

Several components are necessary for the development and implementation of a successful disease-management program. The purpose of the disease-management program is to provide tools and processes to patients and care providers that integrate the patient as a responsible and empowered partner of the healthcare team.

The objectives of the diabetes disease-management program should encompass clinical standards and expectations, utilization management, patient self-management issues, patient quality of life, staff satisfaction, and the establishment of evaluative processes and tools.

The first objective is to improve clinical outcomes by standardizing care and providing guidelines that have integrated best practice with accreditation criteria for quality and by providing systems that enable clinicians and patients to adhere to the expected standards. Evaluation of improvement is measured by the successful lowering of HbA_{1c} levels across the patient population. Process improvements also include the percentage of patients receiving foot examinations yearly, blood pressure measurements twice a year, comprehensive eye examinations annually, lipid profiles once a year, and urine protein/microalbuminuria screenings once a year.

The second objective is to improve resource utilization by promoting better control over diabetes management as evidenced by reduced number of hospitalizations or emergency department visits, reduced duration of stay related to hypoglycemic or hyperglycemic events, and reduced cardiovascular and lowerextremity complications.

The third objective is to improve patient self-management behaviors and skills by providing patients with accessible and consistent educational programs and behavioral support. Improvement is measured by the increase in the number of patients who self-monitor blood glucose levels daily, check their feet daily, understand how to manage hypoglycemia, and have a sick-day management plan.

A fourth objective is to contribute to a higher quality of life for people with diabetes by providing educational and psychological support during the process of their achieving mastery of self-management and throughout the ongoing experience of living with a chronic illness. Evaluating depression measures and surveying satisfaction levels regarding availability of educational and support mechanisms, access to care, and clinical outcomes are important components of understanding what learning and psychosocial supports are needed. Appropriate support mechanisms are designed to be effective and to have a positive impact on the quality of life. Referral guidelines are designed for individual intervention and follow-up with certified diabetes educators or mental health professionals as needed.

A fifth objective of the disease-management program is to provide evaluative processes and tools for measuring, documenting, analyzing, and reporting patients' compliance rates and responses to treatment, patient outcomes, trends, and overall program effectiveness. Included are the development of risk stratification; tracking and monitoring of clinical, economic, and quality-of-life outcomes; and measurement of key indicators.

A sixth objective is to improve clinician satisfaction by integrating patient and care provider priorities into the overall program structure and by providing ongoing support and feedback.

RECOMMENDED ELEMENTS FOR A DIABETES DISEASE-MANAGEMENT PROGRAM

A diabetes disease-management program should be designed to address the overall needs of the general patient population that has been identified, as well as to target specific activities for patients who have been identified as at high risk for complications. The elements that have been identified as core components for an effective diabetes disease-management program follow:

- Establishment of a collaborative work team
- Development of an assessment process
- Implementation of a risk-management process
- Physician education programs and processes
- Implementation of clinical guidelines
- Educational programs and support mechanisms for professional and office staff
- · Programs and tools for patient self-management
- Data management and technological support
- Integration into quality improvement
- Management of care coordination and utilization
- Ongoing support mechanisms

ESTABLISHMENT OF A COLLABORATIVE WORK TEAM

Establishment of a collaborative work team is a key component in the process of providing the foundation for diabetes disease management that promotes and supports the integration and coordination of interdisciplinary members as healthcare teams for management of patient care. The disease-management concept relies on a multidisciplinary methodology for preventing fragmentation and for building a care infrastructure that maximally supports the needs of the patient. The charge of the work team is to tailor the core disease-management program to meet the needs of the patient and care providers and to guide the development, implementation, and evaluation processes. The work team is accountable for developing and maintaining a collaborative process for completing all necessary steps toward achieving a successful program for diabetes disease management. The responsibilities of the work team include the following:

- Assessing the organizational practices and resources, including staffing patterns and skill mix; availability and accessibility of databases; data-management capacity; management systems; and pertinent relationships with patients, families, payers, and referral sources,
- Assessing the current baseline clinical practices and outcomes
- Clarifying the goals and objectives and identification of target areas for improvement
- Modifying the components of the disease-management program as required to address the specific needs of the organization
- Determining the forums, schedules, and materials required for adequate physician and staff educational processes
- Developing and implementing patient educational tools and processes that are appropriate for the general population and for those more intense measures that are specified for highrisk patients
- Planning and developing the steps, conditions, and tools for the implementation phase
- Acting as champions and advisors during the implementation phase
- Providing guidance in the evaluative phase; identifying the most effective and appropriate utilization of the outcomes

data and analysis; and directing the information to be used in quality-improvement activities

ASSESSMENT

The assessment process is conducted to determine current baseline clinical and organizational practices. Evaluation of the clinical practices includes determining how well the course of the disease is understood, what the best practice standards are, whether major obstacles to achieving best practice exist and what those barriers are, what the composition of the patient population with diabetes is, and what the specific influences upon compliance and prevention are. The assessment of organizational practice includes determination of the available workforce resources for implementation, as well as technological availability and requirements.

PATIENT IDENTIFICATION

A crucial element in the diabetes disease-management program is the ability to identify all patients within the practice or facility setting who meet criteria for enrollment into the program. Any patient with a diagnosis of diabetes should be considered as a participant in the overall program. The program should be designed to meet the needs and to provide services to all patients with diabetes. In addition to a basic program, other components are designed to target patients who require intensified services, education, and support. Patients can be identified through a variety of sources, i.e., claims data, emergency department data, inpatient admission data, home care admission data, pharmaceutical claims data, physician referrals, and other referrals (e.g., case-management referrals, self-referrals).

In the case that the enrollment is based on a referral system versus inclusion of all patients in a population, referrals can be retrieved from multiple avenues: primary care physicians; nurse practitioners; and staff nurses from a variety of acute inpatient, ambulatory, office, or home care settings.

The role of the primary care physician is very important to the disease-management process. Once the patient has been identified, the primary care physician is contacted to provide a review and approval and to initiate the invitation process to the patient. Whether the enrollment process is automatic inclusion, criteria based, or reliant on referral, once the patient has been identified, he or she becomes an active participant in the program.

RISK STRATIFICATION

A diabetes disease-management program is designed to improve the quality and cost-effectiveness for the entire patient population that has been identified. However, within that larger population there is a group of patients who are considered to be high risk for complications and who account for a significant proportion of resource utilization and medical costs. This subset of patients represents candidates for intensified therapy and intervention.

Risk stratification is a critical process in disease management because it provides a detailed patient profile and identifies those patients who are at risk for developing severe chronic complications (90,91). The risk-stratification information is used as a guide for care providers to enable them to achieve two objectives. The first objective is the development of programs, systems, processes, and tools targeted to the high-risk patient group. Patient educational tools and processes, care coordination, and case-management activities, referrals to certified diabetes educators or specialists, and follow-up regimens are directed by the information that is provided by risk stratification. The second objective is individualization of care based on scientific information that describes the patient's circumstances.

The goals for integrating a risk stratification component into the diabetes disease-management program include (a) prevention or delay of onset of chronic complications or acute events; (b) decrease in the severity of complications that do occur; (c) extension of the patient's life, (d) improvement in the patient's quality of life; (e) decrease in preventable hospitalizations, emergency department visits, or inappropriate utilization of resources; and (f) improvement in patient and care provider satisfaction.

PROFESSIONAL AND OFFICE-STAFF EDUCATIONAL COMPONENT

The complexities and complications inherent in the care and treatment of diabetes have increased the demands on care providers to remain current and competent in the management of this disease. The professional and office staff educational component is designed to maximize the knowledge base, to increase the levels of practical skills, and to expand the level of confidence of care providers in the management of diabetes care. The educational programs are prepared with flexible formats and curriculums to address the scheduling needs of care providers. Programs should be developed that can respond to multiple learning needs at various levels of intensity. The following are suggested types of programs for inclusion in the curriculum.

- Introductory Continuing Medical Education (CME) programs to review the diabetes disease-management program and introduce guidelines or protocols
- Professional staff (certified educational unit; CEU) educational programs for nurses and allied health professionals. These programs include the following:

Introduction to the disease-management program and clinical guidelines and protocols

Ongoing educational series about diabetes, including pathophysiology, screening and treatment methodologies, medication management, patient self-management and educational techniques, psychosocial issues, management of acute complications, and prevention and management of chronic complications

Educational sessions for office staff regarding the administrative components of the disease-management program: formal and informal

Sessions for training the trainer

The goal of the diabetes disease-management professional and staff educational component is to provide consistent and continuous learning opportunities that are accessible and meaningful.

PATIENT SELF-MANAGEMENT

Education in self-management of diabetes is a critical element in providing patients with the mechanisms necessary for managing the disease and its subsequent effects on their lives. Empowering patients and helping them acquire the skills for effective self-management are the foundation of the educational process for the patient with diabetes.

For people with diabetes, management of their disease relies on continual treatment and constant balancing of the integral parts of their lives every day. Effective management of diabetes requires vigilance and commitment on a 24-hour-a-day basis and significant lifestyle modifications. Education and selfmanagement play vital roles in guiding the patient toward independent and competent management of diabetes. The goal of the patient educational component of disease management is to facilitate the patient's and the family's ability to increase their diabetes knowledge base for self-management, to increase their confidence in applying the knowledge to practical situations, and to share experiences with other people with diabetes. The effective diabetes disease-management program incorporates multiple individual and group formats, with an emphasis on interactive participation. The healthcare team is provided with standardized patient educational materials so that the patient is receiving consistent information. Technology has enabled care providers to present educational material to patients in a wide range of creative ways, including and not limited to call centers, videos, e-mail, interactive Web sites, and interactive software (88). Curriculums can focus on meaningful topics ranging from survival skills, to meal planning, to intense monitoring of blood glucose, to more in-depth self-management techniques and information. Incentives for maintaining attendance and compliance with educational programs may be a helpful tool for supporting the patient. It is important for the educational programs to address and integrate psychosocial needs and the enormous emotional and psychological toll exacted by living with diabetes. Engaging the patient and family as active partners in the healthcare team and addressing educational needs across the continuum are important attributes for success.

CLINICAL GUIDELINES

Clinical guidelines provide a basis for screening, treatment, evaluation, and pharmacologic management processes in the delivery of care to patients with diabetes. They must be linked to commonly recognized measures of clinician performance (92). Part of every disease-management program entails the development, implementation, and evaluation of diseasespecific clinical pathways, which can also encompass care algorithms or protocols. The guidelines must incorporate current knowledge and reference reliable resources. HEDIS (Health Plan Employer Data and Information Set) (93) and American Diabetes Association Clinical Practice Recommendations (3) can be used as important reference elements for the development of guidelines. Consistent reviews for necessary updating and modifications contribute to the credibility of the guidelines. Clinical guidelines that are evidence based, with formal evidence reviews incorporated into their development process, and that have been stringently and authoritatively tested receive much stronger positive responses from physicians and integration into practice (88,94).

Easy accessibility and user-friendly formats for using the guidelines reasonably in a busy practice are often prerequisites to successful implementation (95). Tools that support the guidelines, including documentation forms, physician order sheets, patient surveys, and data collection forms, frequently are developed for use in conjunction with the guidelines. Increased efforts are being made to provide online and Web-based applications. Gaining access to the guidelines can also be combined with the data collection and variance-tracking mechanisms. The objectives of the clinical guidelines are (a) to support optimal

788 JOSLIN'S DIABETES MELLITUS

clinical practice, (b) to influence clinical behavior to produce improved patient outcomes, and (c) to ensure that patients' expectations are informed and reasonable (3).

If guidelines are developed and implemented by local organizations or care groups, they should be based on the collaboration of an interdisciplinary clinical team that has performed a careful review of current evidence, literature, and reliable clinical practice.

CARE COORDINATION, UTILIZATION MANAGEMENT, AND CASE MANAGEMENT

Care coordination, utilization management, and case management are critical to the implementation of a successful diabetes disease-management program. The population with patients with diabetes encompasses a significant number who are actively experiencing serious or life-threatening complications, have been identified as being in a high-risk category for development of complications, or demonstrate the potential for progression to a high-risk level. In addition, because of the complexity of managing this difficult chronic disease on a daily basis, patients require the intensive support and coordination offered by disease-management programs via care and case management. Patients with diabetes need to have a supportive service available that is geared to assist them toward better self-management and subsequently to an improved quality of life.

The processes of care coordination, utilization management, and case management are closely related in the management of the functions required for ensuring that the patient receives optimal levels of care and services at the right time and in the most appropriate settings. These processes are necessary throughout the continuum of care and have proven to be highly effective in increasing quality and cost-effectiveness of care.

The role of the case manager has expanded beyond the original context of acute, inpatient care and extends into continued management of the patient's care throughout the outpatient and community experience and the coordination with primary care. The case manager supports the disease-management process from the perspective of both the individual patient and the population as a whole. The case manager's responsibilities include the following:

- Coordinating the patient's care throughout the continuum, thereby facilitating the achievement of optimal quality outcomes in clinical care, cost-effectiveness, and patient satisfaction
- Assessing patients to identify specific case-management/ care-coordination needs
- Assessing and risk-stratifying patients to identify patients in the high-risk population
- Collaborating with a wide variety of members of a multidisciplinary healthcare team in multiple settings to plan, implement, and evaluate patient care and the related care-delivery systems
- Coordinating multiple services and resources required by the patient and family
- Monitoring and tracking patient response and outcomes to treatment and changes in risk level
- Identifying variances that affect the quality and cost of care and participating in the development and implementation of short- and long-term patient care strategies
- Performing utilization review and management to ensure that appropriate services and resources are provided in a reasonable, high-quality, and cost-effective manner

- Assisting and guiding patients and families in communicating with healthcare providers and in maneuvering through the healthcare system without difficulty
- Assessing and integrating the patient's physical, psychosocial, economic, and lifestyle circumstances into an effective case-management plan
- Analyzing, monitoring, and evaluating complex patient information over significant periods versus concentrating on specific episodes

Quality Improvement

A major purpose of disease-management programs is to support quality-improvement initiatives and to provide a system for outcomes analysis. Within the context of a diabetes disease-management program, the evaluative process that contributes to effective quality improvement is reorganized to encompass entire populations. In this population-based concept, the ability to stratify for risk and identify high-risk patients; to develop and implement "best-practice" protocols, guidelines, interventions, and processes; and to measure patient and system responses and outcomes is increasingly important to the many stakeholders in healthcare delivery.

Integration of valuable data on patient outcome into the quality-improvement program enables care providers to respond to the physical, psychological, functional, and environmental needs of patients in the population with diabetes. Consistent and reliable reporting structures provide a mechanism for utilizing the data in meaningful and productive ways. Including the perspectives of the patient and care provider in the evaluation of quality promotes a comprehensive viewpoint. Prompt response to the data through the development and implementation of plans for improvement or corrective action strengthens the program and increases its credibility.

Some of the indicators measured to evaluate quality and incorporated into the quality-improvement program are level of clinical quality; accessibility to care and services; the patient's quality of life and functional status; levels of satisfaction; and levels of utilization management.

Level of Clinical Quality

The level of clinical quality can be evaluated by assessing patient outcomes, as well as processes. For patients with diabetes, the primary clinical indicator that provides evidence of improvement is the HbA_{1c} level. Other outcomes to measure include physiologic parameters, rates of acute and chronic complications, and mortality rates. Processes to measure for compliance with expected standards of care include foot examinations, comprehensive eye examinations, blood pressure measurements, HbA_{1c} monitoring, lipid-profile monitoring, and urinary protein/microalbumin screening (96,97).

Accessibility to Care and Services

For both patients and care providers, accessibility to prompt, reliable, and comprehensive care and services is of paramount concern. Availability of clinical care and educational and support programs are important to patients with diabetes. Prompt response times and expeditious scheduling promote the sense of security and fortifies the perception of high-quality care.

Quality of Life and Functional Status

Evaluation of quality of life and functional status includes monitoring for improvements in self-care ability, achievements in individual- and population-based goals for self-management and behavior change, treatment and follow-up compliance rates, and patient and family comprehension of self-management.

Satisfaction Levels

To obtain a comprehensive view of how the quality and effectiveness of the diabetes disease management is perceived, assessments need to consider satisfaction levels from the perspectives of multiple stakeholders in the care-delivery process: patients, families, care providers, payers, employers, and others. The indicators for such assessment include levels of satisfaction with the care provided, the accessibility to care and services, and the resultant outcomes of the care provided.

Utilization Management

Utilization management and quality improvement are often very closely linked. Determining and monitoring the appropriateness of care and services and proactively directing care to the most suitable and pertinent settings affect the quality of care from all perspectives. Reductions in unnecessary or preventable hospitalizations and emergency department visits, as well as lost work and school days, decreases in acuity levels, and need for multiple, high-cost services certainly, contribute to a higher level of quality of care and to a lower level of financial risk for the care provider.

DATA MANAGEMENT AND TECHNOLOGY

Advanced technology is essential in the current complicated healthcare industry, with its need for managing enormous amounts of detailed and complex patient information. The establishment of disease management has promoted the need for increasingly powerful and sophisticated technology that can support multiple demands. Technology is an important tool in disease management and has actually become a critical element for achieving the following:

- Establishment of a data-management system with data collection/download capacity and data mining of a multitude of diverse and comprehensive patient databases that allow care providers to collate and analyze multiple types of data, including clinical, insurance claims, utilization, pharmacy, patient survey, referral, and marketing information (88).
- Implementation of a communication network that provides the means for care providers and patients to maintain strong interactive relationships. A communication network may include interactive e-mail, voice mail, Web-based applications, or Internet applications (98).
- Institution of tracking and monitoring systems that alert the care provider when individual patients require attention or intervention.
- Implementation of reliable reporting mechanisms to care providers regarding individual and collective patient information.

Technology can be used to enhance many elements of a diabetes disease-management program but should not be considered the entire program. Technology can accomplish many things:

- Contribute positively to providing a comprehensive network among care providers and patients
- Provide on-time capability for receiving information
- Provide a central database for patient data

• Systematize and automate the data collection, storage, analysis, and reporting functions (98)

Technology should not be used to substitute for the human interaction and personal relationships that exist between patients and care providers but should be integrated into the disease-management program to facilitate and strengthen those components (98).

PHYSICIAN SUPPORT FOR DISEASE MANAGEMENT

Disease-management programs have a significant potential to improve outcomes and reduce costs. However, many physicians remain wary about participating, and physician resistance is one of the top three reasons why disease-management programs are not implemented (94). Several factors influence the physician's perspective. Disease-management programs are built on sophisticated and complex infrastructures that support focused and comprehensive management of a chronic disease and yield positive outcomes. Physicians report that given that same infrastructure without a disease-management vendor they could produce even more impressive improvements in outcome (94). Positive outcomes are based on the physician's commitment to and belief in the disease-management program. If physicians perceive that the disease-management program reduces their control over the management of patient care or dilutes their relationships with their patients, they will not accept the program.

Several success factors that influence physician participation have been identified. First, structuring the program on evidence-based medicine establishes credibility and a more positive response by physicians. Educating the physician about the program, its value to the patient, its support of the physician's role in the coordination of care, and its value to the physician is an important element (94). Maximizing the opportunities for physicians to have input in the development, implementation, and evaluation of the program helps them become more comfortable with the concept of disease management. Modifying the program according to physician input or practices builds support. Demonstrated success of positive outcomes in previous activities encourages physicians to participate. Structuring the program so that the physician truly owns and champions the program is an element for success (98). The impetus of the program should be to support and strengthen the physician-patient relationship. The foundation of an effective disease-management program that will find greater support among physicians is built on a trusting relationship that

- Advocates for the welfare and care of the patient
- Recognizes and values the importance and commitment of the physician to the success of the program
- Upholds the autonomy of the physician and the physician's control over the care of the patient
- Values and incorporates the physician's perspective into the development and implementation of the program
- Provides outcomes that are value-added as identified as important by physicians and patients.

LIFESTYLE MODIFICATIONS AND PSYCHOSOCIAL ISSUES

Diabetes is a chronic disease that affects the patient physically, psychologically, socially, spiritually, cognitively, and economically. It requires a careful balance of activities, 24-hour-a-day

management, and significant lifestyle changes. Living well with diabetes means combining a lifelong commitment to maintaining a lifestyle that balances sound nutritional, activity, and overall health habits with adherence to a strict medical-management regimen. Patients with diabetes live with it all day, every day. The person's self-esteem, sense of independence, and self-image all experience enormous strain as his or her lifestyle undergoes significant modifications and alterations. Providing systems, processes, and supports that assist the patient to learn selfmanagement of diabetes is an important factor in the healthcare plan.

Education regarding self-management and lifestyle modification is a critical component in helping patients take control of diabetes and its impact on their lives. Education about managing diabetes is about mastering a wide range of new skills and activities, as well as about adapting to life with a chronic disease (99). Patients are faced with learning self-management skills, including monitoring blood glucose levels, planning meals, scheduling meals and medications, and maintaining exercise programs. They also are faced with the challenge of learning to prioritize commitment to a treatment plan over other activities, to manage unexpected events, to develop contingency plans, to know when to contact supportive resources, and to maintain eternal vigilance to stay well. Effective education in diabetes self-management is associated with many positive outcomes, including improvement in patients' physical and emotional health, improvement in ability to achieve glycemic and metabolic control, a reduction in hospitalizations, a reduction in diabetes-related healthcare costs, and fewer acute and chronic complications.

Patients view diabetes as an integral part in the totality of their lives and not as a separate entity (100). When developing an educational plan, it is important to consider several types of experience in the patients' lives: the emotional experience, the behavioral experience, the ability to make and maintain lifestyle change, and the stage of development.

The emotional experience of a patient is a strong influence on the patient's ability to cope and to learn. A patient's emotional experience encompasses the patient's emotions as related to life events and relationships, as well as the emotional response to having diabetes, and its subsequent effect on life and those events and relationships (101). The emotional response to diabetes encompasses many complex feelings: confusion, grief, anger, denial, ambivalence, and guilt. Patients often feel overwhelmed and out of control. The behavioral experience includes all the actions that the patient needs to employ to deal effectively with diabetes management and all the associated emotions and attitudes. Chronic disease requires a significant adaptation process, and strong coping skills are important tools for the patient (102). Understanding the developmental stage of the patient is critical in developing a plan that addresses the specific needs of the patient.

THE PATIENT'S ROLE IN DIABETES MANAGEMENT

The patient plays the most important role in diabetes management. Patients with diabetes must perceive themselves as active, empowered members of the healthcare team and be able to accept responsibility for self-management and for adhering to treatment plans (100). There must be a commitment to understanding the disease as well as possible and a willingness to continue to learn. The patient's active participation in decision making and planning treatment as a member of the healthcare team contributes substantially to successful self-management. The patient must be able to change behaviors and learn new skills to be able to feel better, to be healthier, and, in some cases, to survive. Working with the team to set goals for treatment and behavior allows the patient to have more immediate control over care that reflects his or her preferences and priorities. The patient needs to make appropriate decisions, multiple times, on a daily basis about self-management and to act on those decisions accordingly (100). The patient must have strong communication skills and a sense of assertiveness to be able to inform the healthcare team when difficulties arise, when circumstances change that impact the treatment plan, or when the goals for glycemic control have not been met.

ISSUES THAT AFFECT PROFICIENT SELF-MANAGEMENT

Changes in behavior and adjustments of lifelong habits and choices are difficult processes. The difficulties of learning new skills, understanding how and why to control a chronic disease, and managing all the associated feelings often lead to frustration and discouragement. Some issues that compound these feelings are stress, burnout, coexisting common psychiatric conditions [e.g., depression (103–105)], physical illness, negative feedback, lack of empowerment, and lack of self-efficacy.

Any of these factors can exert a forceful influence on successful self-care behavior. The more confident a person feels about performing self-care behaviors, the more likely he or she will perform those behaviors (102). Consistent ability to cope with emotional stresses in daily life can be a critical component in a person's success in achieving significant changes in lifestyle. The ability to change and overall behavior are reflections of the person's level of maturity and cognition. A person's capacity to maintain a complicated regimen has an effect on self-care behavior.

ROLE OF THE CARE PROVIDER

The care provider's role is to determine how to support the patient's ability to become a competent self-manager in diabetes care. Several important steps maximize the support a patient needs for learning self-management: (a) performing an accurate and comprehensive patient assessment, (b) developing a mutually trusting relationship, (c) setting reasonable and achievable goals, (d) facilitating an optimal learning experience, and (e) basing the learning experience on empowerment of the patient.

Understanding the impact of the many complex components of a person's life on the learning process is a fundamental element in developing and implementing effective teaching strategies that support each individual. Important information about a person's readiness and ability to learn about self-management can be obtained by a thorough assessment that includes (a) evaluating the patient's current health status; (b) evaluating the patient's psychological status, ability to cope, and emotional well-being; (c) assessing the patient's cognitive skills and literacy level; (d) exploring the patient's life experiences, particularly in managing diabetes; (e) determining the level of understanding the patient has about diabetes and self-care; (f) determining the patient's relationship with care providers; (g) assessing the patient's cultural, social, and economic background and environmental influences; and (h) assessing the patient's priorities and interests.

A relationship based on respect, trust, and understanding supports the learning process. It is the responsibility of the care provider to establish a nonjudgmental, supportive environment

that enables the patient to be a motivated, active participant in the learning experience (103). Communication and acceptance of the patient's choices are essential to a productive experience. Incorporating the expectations and values of the patient into the teaching plan provides a base from which the patient can become effective in self-management (106).

Goals provide a framework to guide the patient and the care provider in identifying the specific tasks and activities that need to be achieved. Goals are critical tools in the learning process and should encompass the commitment to behavior change necessary for successful self-management. Patients need to feel accountable for achievement of stated goals, and they respond to goals that are individualized and incorporate their priorities. Setting goals that are measurable, attainable, and action oriented helps the patient to have a clear understanding of what is expected.

An important role for the care provider is to facilitate an optimal learning experience for the patient. A current goal for diabetes education is to provide programs or teaching sessions that integrate the clinical, behavioral, and psychosocial elements of diabetes care and self-management (100). The purpose of diabetes education is not simply to deliver information about the importance of managing diabetes but also to provide information that supports the patient's ability to make informed decisions (99). The learning process is designed to address and incorporate the patient's lived experience with diabetes (100). Education is a continuous and interactive process that assesses and encourages patients to express their concerns and questions, presents information that addresses those issues, and reviews strategies to deal with the behavioral aspects of managing these issues and concerns. Patients are more likely to be engaged participants in a process that is based on their experiences and concerns and is personally relevant. Empowerment is an important concept that requires the redesign of traditional methods for providing patient education. The empowerment model postulates that the patient is responsible for providing and managing the majority of diabetes care and is thus not a passive participant but the center of decision making and control in daily management and treatment (102). As mentioned earlier, the healthcare team is responsible for providing the patient with information enabling the patient to make informed decisions. The patient has both the right and the responsibility to perform in the role of equal partner in the treatment program (101). It is the responsibility of the healthcare team to provide and foster an environment that supports the patient's development or discovery of the capacity to actively solve problems of diabetes care, thus reinforcing the sense of self-efficacy and accountability.

This chapter reviews the descriptive epidemiology of late complications of diabetes mellitus in the eyes, kidneys, and heart and examines their occurrence in relation to diabetes duration and other risk factors, particularly the level of hyperglycemia. Our intent is to emphasize the findings that are relevant to generating etiologic hypotheses or to developing interventions against these outcomes. To describe their occurrence, we use the indices that were defined in Chapter 20 of this volume: the incidence rate, cumulative risk, and prevalence. For illustrating the natural history of late diabetic complications, we frequently use data from cohort studies carried out in the patient population of the Joslin Clinic. A less selective review of the epidemiology of late diabetic complications can be found in Chapter 35 of the previous edition of Joslin's Diabetes Mellitus (1). We first review data for patients with type 1 diabetes and then discuss their similarities and differences to the data for type 2 diabetes.

MEASURE OF DIABETES EXPOSURE

Although conventional hypoglycemic therapies prevent acute metabolic complications in patients with diabetes, they do not restore metabolic homeostasis (2,3). The result of this imperfect treatment is a novel milieu that includes various combinations of metabolic, hormonal, and physiologic alterations. These include hyperinsulinemia, hyperglycemia, hyperlipidemia, abnormalities in blood flow, and the formation of glycation products (2–5), all of which constitute *diabetes exposure*. As a consequence of this exposure, diverse functional and morphologic alterations develop that lead to severe complications affecting the eyes, kidneys, and heart. Despite intensive research, it is not known which components of this collective exposure are responsible for particular complications. Various hypotheses have been proposed, ranging from global hypotheses that invoke a single mechanism and a single component of diabetes exposure as responsible for

all complications, to separate hypotheses for each complication that invoke interactions of diabetes exposures with genetic susceptibility and environmental factors (4–9).

For the purpose of epidemiologic studies, diabetes exposure can be characterized by the level of hyperglycemia or the level of glycosylated hemoglobin (HbA1c). The distribution of the intensity of diabetes exposure as estimated from glycosylated hemoglobin levels ranges widely. For example, in the population of patients who visited the Joslin Clinic in 1999/2000, the distribution of HbA_{1c} levels ranged from 5% to 16% (6% is the upper limit of normal values in the nondiabetic population). The distribution of values varied slightly according to age (Table 47.1). Patients age 20 years and older had slightly lower values than younger patients. The medians for measurements repeated approximately a year later in this same population remained unchanged, and patients tended to maintain their position within the distribution. The majority of those with a high HbA_{1c} level at the first visit in 1999/2000 had a similar value at the second visit 6 to 18 months later. This "tracking" of the level of diabetes control is a notable feature of patients with diabetes (10,11). During follow-up of participants in the Diabetes Control and Complications Trial (DCCT), patients formerly in the intensive treatment group worsened their glycemia within a year so that their distribution of glycosylated hemoglobin A_{1c} (HbA_{1c}) converged with that for the conventionally treated group (12). Interestingly, it became similar to the distribution for patients of the Joslin Clinic (Table 47.1).

EPIDEMIOLOGY OF DIABETIC RETINOPATHY

Cumulative Risk of Retinopathy According to Duration of Diabetes

The most frequent late complication of type 1 diabetes is retinopathy. Following the onset of type 1 diabetes, there is a lag period of about 3 to 4 years before the first cases of nonproliferative retinopathy appear (13–15). The risk then increases exponentially (13–15). For example, during the 5th year of diabetes, nonproliferative retinopathy develops in 1 of 100 patients, whereas in the 14th year, it develops in 11 of 100 patients who have escaped it up to that time (14). By the 15th year of type 1 diabetes, the cumulative risk of nonproliferative retinopathy approaches 100% (Fig. 47.1). Despite its apparent inevitability, the onset of nonproliferative retinopathy can be postponed significantly by improved glycemic control, as was demonstrated by the DCCT (15).

Once patients have developed nonproliferative retinal lesions, they are vulnerable to the development of proliferative retinopathy, the principal cause of blindness in diabetes. The first cases of this advanced stage of diabetic retinopathy appear after 10 years of diabetes and then continue to occur at a constant incidence rate of about 3 per 100 per year regardless of the duration of type 1 diabetes. This constant incidence rate of proliferative retinopathy yields, after 40 years of type 1 diabetes, a cumulative risk of 62% (16), a value supported by several studies (17–19). The absence of a decline in the incidence rate of proliferative retinopathy after most of the population has been affected suggests that almost all patients with type 1 diabetes are susceptible to this complication, just as they are to

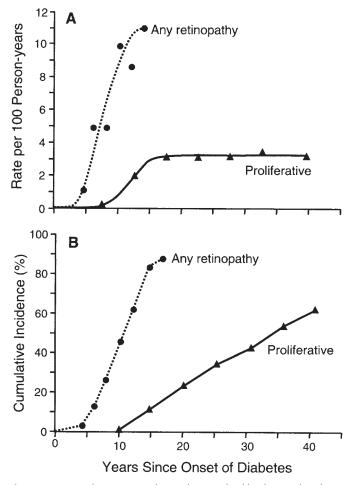

Figure 47.1. Incidence rate and cumulative risk of background and proliferative retinopathy, according to the duration of type 1 diabetes. **A:** The incidence rate of background retinopathy (estimated from Klein et al.) and proliferative retinopathy (adapted from Krolewski et al.), according to the duration of type 1 diabetes. **B:** The cumulative risk of background retinopathy measured by its prevalence (adapted from Klein et al.) and the risk of proliferative retinopathy measured as the cumulative incidence (adapted from Krolewski et al.), according to duration of type 1 diabetes. (Adapted from Klein R, Klein BEK, Moss SE, et al. The Wisconsin Epidemiologic Study of Diabetic Retinopathy. II. Prevalence and risk of diabetic retinopathy when age at diagnosis is less than 30 years. *Arch Ophthalmol* 1984;102:520–526; and copyright © 1986 American Diabetes Association. Krolewski AS, Warram JH, Rand LI, et al. Risk of proliferative diabetic retinopathy in juvenile-onset type I diabetes: a 40-yr follow-up study. *Diabetes Care* 1986;9:443–452. Adapted with permission from the American Diabetes Association.)

Diabetes Exposure and Risk of Retinopathy

Because nonproliferative retinopathy is extremely rare in persons without diabetes but is almost universal in patients with type 1 diabetes, one can infer that this complication is an outcome of diabetes exposure. Many observational studies (20–25) and clinical trials (15,26–28) have demonstrated a relationship between hyperglycemia and the development of various stages of diabetic retinopathy. However, only the results of the DCCT have provided enough data for the evaluation of the doseresponse relationship between hyperglycemia and the development of nonproliferative retinopathy and its progression to proliferative retinopathy (15,28).

It appears that high levels of hyperglycemia have an impact on both the onset and progression of retinopathy, whereas low levels have only a moderate impact (15,28). As shown in Figure 47.2, the incidence of retinopathy (development or progression) in the group assigned to intensive diabetes treatment fluctuated around 2.0 per 100 person-years in the nine deciles of the HbA_{1c} distribution below 8.5% and rose to 7.0 per 100 person-years in the highest decile. The results of other followup studies showed a similar threshold effect of hyperglycemia on the development and progression of diabetic retinopathy (29,30).

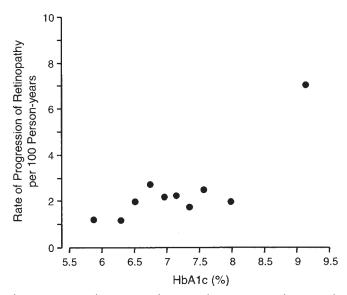

Figure 47.2. Incidence rate of sustained progression of retinopathy according to deciles of the distribution of mean glycosylated hemoglobin A_{1c} (Hb A_{1c}) values during the Diabetes Control and Complication Trial (DCCT). Figure was adapted from Figure 5 in DCCT study (15) by omitting the fitted dose-response curve (linear in the log-log scale) to emphasize the pattern of the data. For the first nine deciles, the incidence rate was well approximated by a straight line whose slope coefficient was not statistically significantly different from zero, whereas the incidence rate for the 10th decile lies significantly above the line. This pattern is consistent with a threshold value for HbA_{1c} between the 9th and 10th deciles. (Adapted in 2004 with permission from The Diabetes Control and Complications Trial Research Group. The effect of intensive treatment of diabetes on the development and progression of long-term complications in insulin-dependent diabetes mellitus. *N Engl J Med* 1993;329:977–986. Copyright © 1993 Massachusetts Medical Society. All rights reserved.)

Other Risk Factors for Retinopathy

Several other factors in addition to diabetes exposure are associated with the development of the several stages of diabetic retinopathy. This includes systemic variables such as hypertension, nephropathy, and cardiovascular autonomic neuropathy, as well as ocular variables such as elevated intraocular pressure and myopia.

We reported one of the first prospective observations of the relation between elevated blood pressure and risk of retinopathy (21,31). In that study, the risk of progression of nonproliferative retinopathy was particularly increased in patients with type 1 diabetes with diastolic blood pressure above 70 mm Hg. Subsequently, the Wisconsin Epidemiologic Study of Diabetic Retinopathy showed that systolic blood pressure was associated with the onset of nonproliferative retinopathy, whereas diastolic blood pressure was associated with its progression (32). Data from a clinical trial of sorbinil also demonstrated that elevated diastolic blood pressure was an important risk factor for progression but not for onset of nonproliferative retinopathy (25). Because there has been no clinical trial of blood pressure reduction in the prevention of diabetic retinopathy, the implication of these associations is not clear. Elevated systemic blood pressure may be a risk factor for diabetic retinopathy or just an indicator of microvascular dysfunction, which is also manifested as microalbuminuria and leads to complications in the kidneys as well as the eyes (33).

Previously, it had been supposed that the development of diabetic retinopathy and other late diabetic complications was due to one underlying pathologic process in small vessels (4-6,8,9). However, clinical and epidemiologic studies during the last two decades have provided evidence that the causes of these complications may be different (8,34,35). Still the occurrence of one complication may be a risk factor or indicator for the development of others. For example, the onset of diabetic nephropathy is almost always followed by the development of proliferative retinopathy (16,36,37). Certain aspects of overt proteinuria and declining renal function may accelerate progression of diabetic retinopathy to proliferative retinopathy (36,37). Also, a relation between the presence of autonomic cardiovascular neuropathy and the development of proliferative retinopathy was found. This association, which we demonstrated first in a case-control study (37) and subsequently in a follow-up study (38), was independent of the level of glycemic control, elevated blood pressure, or presence of diabetic nephropathy. However, it is still not clear whether cardiovascular autonomic neuropathy is a risk factor or risk indicator for the development of proliferative diabetic retinopathy.

In addition to these systemic factors, ocular factors seem to modulate the risk of onset and progression of diabetic retinopathy. Higher ocular perfusion pressure predicted the onset and progression of diabetic retinopathy in the Wisconsin Epidemiologic Study (39). This agrees with an earlier study of patients with asymmetric diabetic retinopathy in which lower retinal artery pressure due to carotid occlusion was found on the same side as the eve with less severe retinopathy (40). In a multivariate analysis of the Wisconsin data to adjust for other covariates, the effect of high ocular perfusion pressure remained significant only for the onset of retinopathy. Myopia is another ocular factor that modulates the development of proliferative retinopathy. We were the first to find its protective effect against severe retinopathy in a case-control study of determinants of proliferative diabetic retinopathy in type 1 diabetes (41). This finding has since been confirmed in a prospective study, and several explanations for it have been proposed (39); however, empiric data to distinguish among them are lacking.

Comparison of Risk of Retinopathy in Type 1 and Type 2 Diabetes

The Wisconsin Epidemiologic Study of Diabetic Retinopathy provides the best data to compare the natural history of diabetic retinopathy in whites with type 1 and type 2 diabetes. During a 10-year follow-up, the incidence of retinopathy, the progression of retinopathy, and the development of proliferative retinopathy were highest in patients with type 1 diabetes, intermediate in insulin-treated patients with type 2 diabetes, and lowest in patients with type 2 diabetes treated with oral agents or diet (42). Most of these differences could be accounted for by different levels of glycemic control in the three study groups (24). The contribution of other risk factors to different risk of diabetic retinopathy in type 1 and type 2 diabetes has been less well studied.

Can the Occurrence of Diabetic Retinopathy Be Changed?

As was demonstrated in several clinical trials conducted in highly selected populations of patients with diabetes, improved glycemic control can significantly delay the development of nonproliferative retinopathy and postpone its progression to proliferative retinopathy (15,28,43,44). However, there is less evidence that the natural history of diabetic retinopathy can be changed in the general population of patients with diabetes.

The cumulative risk of proliferative diabetic retinopathy in type 1 diabetes had not changed during the 30-year period between 1950 and 1980. In the cohort study that we conducted at the Joslin Clinic, the cumulative risk of proliferative diabetic retinopathy after 20 years of diabetes was identical in patients who had type 1 diabetes diagnosed in 1939, 1949, and 1959 despite significant differences in the care of these cohorts (16). Similar findings have been reported from Sweden; a secular decline in risk was found for nephropathy but not for proliferative retinopathy over the period from 1970 to 1990 (45,46). Furthermore, in the Wisconsin Epidemiologic Study of Diabetic Retinopathy, no significant change in the incidence of retinopathy was found during 10 years of follow-up despite significant improvement in glycemic control in the study group (24).

EPIDEMIOLOGY OF DIABETIC NEPHROPATHY

Cumulative Risk of Diabetic Nephropathy According to Duration of Diabetes

The natural history of diabetic nephropathy has generally been viewed as a progressive path from normoalbuminuria to endstage renal disease (ESRD) through intermediate stages marked by microalbuminuria and then overt proteinuria (47). The cumulative risk (estimated by prevalence data) of these stages in patients of the Joslin Clinic with type 1 diabetes according to duration of diabetes is summarized in Figure 47.3. Because several studies have demonstrated that the duration of diabetes before puberty does not contribute to the risk of diabetic nephropathy (48,49), the data in Figure 47.3 are presented according to postpubertal duration of type 1 diabetes. To develop more advanced nephropathy, patients must develop microalbuminuria first, so the top curve can be considered as the cumulative risk of microalbuminuria according to duration of diabetes. Similarly, the height of the intermediate curve indicates the cumulative risk of persistent proteinuria, and the height of the lowest curve traces the cumulative risk of ESRD according to duration of type 1 diabetes.

The cumulative risk of persistent microalbuminuria with duration of diabetes rises at a variable rate (Fig. 47.3). A particularly notable feature is the very early appearance of significant numbers of patients with microalbuminuria: 8% of patients with type 1 diabetes for only 1 to 3 years, a value ten times the 0.8% prevalence among persons without diabetes (50,51). A similarly high prevalence of microalbuminuria in patients with type 1 diabetes with a short duration of diabetes was found in another study (52). The prevalence of microalbuminuria leveled off after 10 years of diabetes (prevalence 20%) and then resumed its steep climb in the second decade, reaching a new

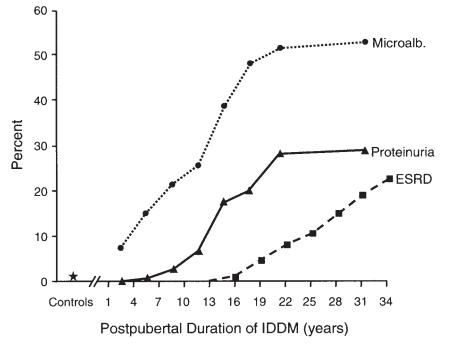

Figure 47.3. Prevalence of stages of diabetic nephropathy according to postpubertal duration of type 1 diabetes (IDDM). Data for microalbuminuria and proteinuria were adapted from Warram et al. Data on end-stage renal disease (ESRD) were adapted from Krolewski et al. For patients with type 1 diabetes diagnosed before age 10 years, postpubertal duration was counted from age 11 years. (Adapted from Warram JH, Gearin G, Laffel LMB, et al. Effect of duration of type 1 diabetes on prevalence of stages of diabetic nephropathy defined by urinary albumin/creatinine ratio. *J Am Soc Nephrol* 1996;7:930–937; and Krolewski M, Eggers PW, Warram JH. Magnitude of end-stage renal disease in type I diabetes: a 35-year follow-up study. *Kidney Int* 1996;50: 2041–2046 with permission from Blackwell Publishing.) plateau at around 58% prevalence after 30 years of postpubertal duration of diabetes.

The cumulative risks of overt proteinuria and microalbuminuria within the same population can be compared in Figure 47.3. The first cases of overt proteinuria occurred after 5 years' duration, after which the prevalence of overt proteinuria increased abruptly and then leveled off after 21 years, a feature similar to the pattern for microalbuminuria. Following another increase, the prevalence of overt proteinuria leveled off again at around 30% by 30 years of postpubertal duration of type 1 diabetes. This agrees with a 33% cumulative risk of persistent proteinuria after 30 years of diabetes in two previous cohort studies (48,53). The contrast between the 30% cumulative risk for persistent proteinuria and the 58% cumulative risk for microalbuminuria after 30 years of type 1 diabetes has important implications. It indicates that many patients with microalbuminuria, approximately half, may never progress to overt proteinuria (54).

Patients with overt proteinuria are at risk of renal function loss and the development of ESRD. Recently, we determined the cumulative risk of ESRD in a cohort of patients who had type 1 diabetes diagnosed at the Joslin Clinic in 1959 and were followed until 1994 (55). The first case of ESRD occurred after 15 years of postpubertal duration of type 1 diabetes, and the cumulative risk of ESRD reached 22% after 35 years (Fig. 47.3). Because most individuals with persistent proteinuria progress to ESRD (48), one would expect the cumulative risk of ESRD to reach about 30% if followed another 10 years.

Diabetes Exposure and Risk of Diabetic Nephropathy

The level of glycemia seems to be the strongest factor influencing the onset of microalbuminuria. This has been demonstrated in several observational studies (22,51,56-59) as well as in clinical trials (15,26,27,60). In our recent 4-year follow-up study involving 943 normoalbuminuric patients with type 1 diabetes, we determined the shape of the dose-response relationship between the intensity of hyperglycemia and the onset of microalbuminuria (59) and found a nonlinear effect of hyperglycemia on the development of microalbuminuria (Fig. 47.4A). Below HbA1c values of 8.0%, the incidence of microalbuminuria varied little. In contrast, above an HbA_{1c} value of 8.0%, the incidence of microalbuminuria rose steeply with increasing values of HbA1c. For comparison, the risk of microalbuminuria increased almost 20-fold faster between HbA_{1c} values of 8% and 10% than between values of 6% and 8%. This nonlinear pattern of the relationship between level of HbA1c and the risk of microalbuminuria was independent of other risk factors. This finding is consistent with our previous data from a case-control study (51). Evidence of a threshold effect in the relation between HbA_{1c} and microalbuminuria has been reported in DCCT publications, although it was not interpreted as such by the authors (60,61).

In our recent 4-year follow-up study involving 312 patients with microalbuminuria, we examined the relationship between hyperglycemia and progression of microalbuminuria to overt proteinuria (62). The incidence rate of progression increased rapidly between HbA_{1c} values of 6% and 8.5% and then leveled off at higher values, being similar for HbA_{1c} values of 8.5% and 12% (Fig. 47.4B). Since this pattern differs from the dose-response relationship between HbA_{1c} and the onset of microalbuminuria, one may hypothesize that different mechanisms are responsible for the onset of microalbuminuria and its progression to proteinuria.

Using incidence rates from Figure 47.4B, we estimated the cumulative risk of progression of microalbuminuria to overt proteinuria over a 10-year follow-up period according to quartiles of

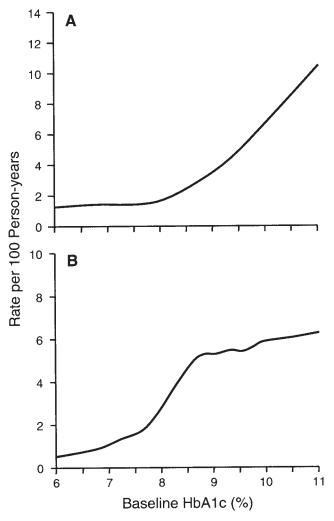

Figure 47.4. A: Dose-response relationship between level of glycosylated hemoglobin A_{1c} (HbA_{1c}) and incidence of microalbuminuria in patients with normoalbuminuria and type 1 diabetes (adapted from Scott et al.) **B:** Dose-response relationship between level of HbA_{1c} and progression to proteinuria in patients with microalbuminuria and type 1 diabetes (adapted from Warram et al.) (Adapted from Scott LJ, Warram JH, Hanna LS, et al. A nonlinear effect of hyperglycemia and current cigarette smoking are major determinants of the onset of microalbuminuria in type 1 diabetes. *Diabetes* 2001;50:2842–2849; and Warram JH, Scott LJ, Hanna LS, et al. Progression of microalbuminuria to proteinuria in type 1 diabetes 2000;49: 94–100. Copyright © 2001 and 2000, respectively, American Diabetes Association. Adapted with permission from the American Diabetes Association.)

 HbA_{1c} (<8.5%, 8.5% to 9.6%, 9.7% to 10.6%, and >10.7%). The risks were 12%, 46%, 42%, and 50%, respectively. These estimates are similar to data reported by several recent studies (63–66), but are only one half the values reported in the initial publications in the 1980s on the risk associated with microalbuminuria (67–69). This discrepancy is more likely due to an overestimation of the risk of progression in the early studies than to a decline in the risk during the last 15 years.

Confirmation in a clinical trial that good glycemic control reduces the risk of progression of microalbuminuria to overt proteinuria is lacking. Only one very small clinical trial found that improved glycemic control reduced the risk of progression of microalbuminuria to overt proteinuria (70), whereas a larger clinical trial found no relationship between improvement of diabetes control and slower progression of microalbuminuria to overt proteinuria (71).

800 JOSLIN'S DIABETES MELLITUS

Patients with diabetes start losing renal function when they have high levels of microalbuminuria or overt proteinuria (50). So far, only a few observational studies have examined the impact of glycemic control on the rate of decline in renal function in patients with type 1 diabetes and proteinuria. Two of them demonstrated a significant association between the HbA_{1c} value and the rate of decline of the glomerular filtration rate (72,73). Interestingly, one study found a dose-response relationship similar to that shown in Figure 47.4B for the association between HbA_{1c} value and progression of microalbuminuria to overt proteinuria (72).

Other Risk Factors for Diabetic Nephropathy

Epidemiologic studies have shown that several factors besides hyperglycemia influence the development of the several stages of diabetic nephropathy. These include predisposition to essential hypertension (74–77), elevated systolic blood pressure (58,76), cigarette smoking (59,78), elevated levels of serum cholesterol and triglycerides (57), and genetic susceptibility to diabetic nephropathy (7). The last seems to play a major role.

The leveling off of the cumulative risk of overt proteinuria after 30 years of diabetes (Fig. 47.3) has previously been reported (48,53) and is evidence that only a subset of individuals are susceptible to the development of this complication (7). The hypothesis about susceptibility to diabetic nephropathy has been strengthened by evidence gained from family studies.

Familial clustering of diabetic nephropathy has been demonstrated in four studies of families with two or more siblings with type 1 diabetes (79–82). In all these studies, if the index sibling had advanced diabetic nephropathy, the other diabetic siblings were more likely to develop nephropathy than if the index sibling did not have nephropathy. The best illustration of the familial clustering of diabetic nephropathy is provided by a

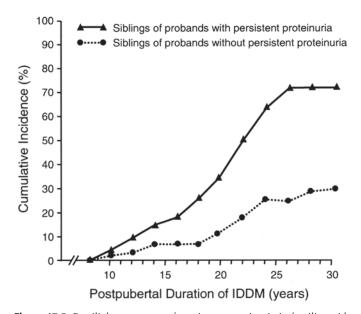

Figure 47.5. Familial occurrence of persistent proteinuria in families with two or more siblings with type 1 diabetes (IDDM): cumulative incidence of persistent proteinuria in the diabetic siblings of the first sibling with diabetes (index case) according to the proteinuria status of the index case. The higher curve is for the diabetic siblings of index cases with proteinuria. The lower curve is for diabetic siblings of index cases without proteinuria despite a long duration of diabetes.

study we conducted at the Joslin Diabetes Center in which we attempted to obtain unbiased estimates of familial clustering (81) (Fig. 47.5). The risk of overt proteinuria, expressed as the cumulative incidence after 30 years of type 1 diabetes, was 72% in siblings of affected index cases and 25% in the siblings of unaffected index cases. Adjustment for familial clustering of the level of glycemic control could reduce this difference only slightly. Overall, the conclusion from that study is that susceptibility to overt proteinuria is likely to involve a major gene effect (81). Currently, the search for such a gene is under way using linkage as well as association studies (83).

Comparison of Risk of Diabetic Nephropathy in Type 1 and Type 2 Diabetes

Although the risk of diabetic nephropathy in type 2 diabetes seems to be similar to that in type 1 diabetes, the occurrence of this complication in type 2 diabetes is a much larger burden to society because of the 10-times greater frequency of type 2 diabetes than type 1 diabetes. The following is a brief description of some salient features of the natural history of diabetic nephropathy in type 2 diabetes highlighted by pairing them with the features of diabetic nephropathy in type 1 diabetes that were described earlier.

There are no published follow-up studies on the onset and progression of microalbuminuria in patients with type 2 diabetes. However, in a recent cross-sectional study conducted in the population of patients (90% white) attending the Joslin Clinic, the prevalences of persistent microalbuminuria and overt proteinuria according to duration of type 2 diabetes were similar to those for type 1 diabetes (Fig. 47.3) (Krolewski et al., unpublished observation). A similar conclusion can be drawn from comparisons of the results of cohort studies of the natural history of overt proteinuria in type 2 diabetes (84,85) with the corresponding results of studies in type 1 diabetes (48,53). The cumulative risk of persistent proteinuria during long-term follow-up of a cohort of patients with newly diagnosed type 2 diabetes in the population of Rochester, Minnesota, was similar to the cumulative risk of persistent proteinuria in the cohorts of Joslin patients with type 1 diabetes (48,84,85). The first cases of persistent proteinuria occurred after a shorter duration of diabetes in patients with type 2 diabetes than in patients with type 1 diabetes, but the subsequent increases in cumulative risk with duration of diabetes were very similar for the two groups of patients, reaching almost the same cumulative risk after 25 years of diabetes. Similarly, the incidence rate of ESRD in the white U.S. population with diabetes is approximately the same in young patients (mainly type 1 diabetes) as in middle-aged and older patients (predominantly type 2 diabetes) (Fig. 47.6).

Various risk factors were found to have an impact on the occurrence of persistent proteinuria in type 2 diabetes, including the level of glycemic control (84,86). So far, no study has determined the dose-response relationship between the level of hyperglycemia and the risk of diabetic nephropathy in patients with type 2 diabetes that can be compared with that shown for patients with type 1 diabetes in Figure 47.4.

Several studies have demonstrated that the level of systemic blood pressure and predisposition to hypertension are related to the subsequent development of microalbuminuria and overt proteinuria (87,88). Particularly elegant studies of this issue were conducted in Pima Indians with type 2 diabetes (88). Some other reports, however, failed to demonstrate this relationship (84,86). As in type 1 diabetes, many studies demonstrated familial clustering of diabetic nephropathy in patients with type 2 diabetes, in both white (89–92) and minority (93–95) populations.

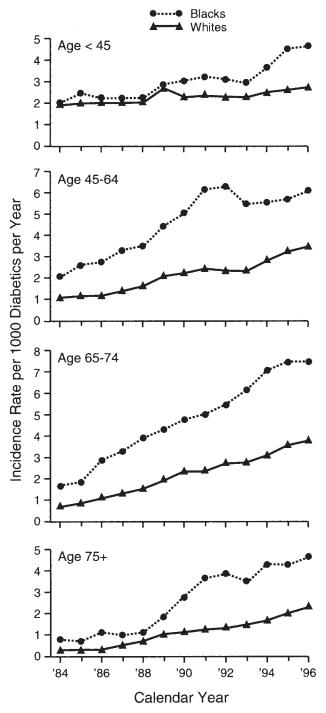

Figure 47.6. Incidence rate of end-stage renal disease in the United States in patients with diabetes according to race, age, and calendar time. (Adapted from Centers for Disease Control and Prevention. Diabetes surveillance 1999. Atlanta, U.S. Department of Health and Human Services, 1999.)

During the past decade, much has been learned about the development and clinical course of diabetic nephropathy in type 2 diabetes in populations such as Asians, blacks, Hispanics, and Native Americans (96–100). In all of these populations, type 1 diabetes is very rare, but type 2 diabetes occurs at a much earlier age than it does in whites. Furthermore, diabetes in these populations is accompanied by a much higher risk of the development of ESRD than it is in white patients (101–105; see also

Fig. 47.6). The extent to which this higher risk might be attributable solely to poorer glycemic control is unknown. Higher prevalences of other environmental factors or genetic susceptibilities that interact with hyperglycemia may play important roles.

Can the Occurrence of Diabetic Nephropathy Be Changed?

The natural history of diabetic nephropathy in type 1 diabetes has been changing over the last half-century. We reported the first study documenting this phenomenon and showed that the cumulative incidence of overt proteinuria was significantly lower in patients with type 1 diabetes diagnosed in the late 1940s and 1950s than in those with diabetes diagnosed in the late 1930s (48). As discussed earlier, the cumulative risk of proliferative diabetic retinopathy remained constant in these three cohorts (16). A similar decline in the risk of persistent proteinuria according to calendar time was observed in Denmark (106), and although the mechanisms responsible for the decreased risk are not clear, improved glycemic control during that time interval might have been a factor in both populations. Investigators from Sweden have demonstrated a significant decline in the risk of overt proteinuria in patients with type 1 diabetes followed 10 to 15 years after the implementation of intensified diabetes treatment at the community level (45). Several studies have demonstrated that vigorous antihypertensive treatment might also slow the rate of declining renal function in patients with proteinuria (107,108).

These observations would suggest that a decline in the occurrence of ESRD in patients with diabetes would be evident in recent decades. However, the incidence rates of ESRD in patients with diabetes in the U.S. population showed the opposite trend (109). The incidence rate of ESRD in the U.S. diabetic population during the period from 1984 to 1996 according to age and race is shown in Figure 47.6. Among whites under the age of 45 years with diabetes (mainly type 1 diabetes), the incidence rate increased slightly from 1.9 per 1,000 a year in 1984 to 2.5 per 1,000 a year in 1996. The incidence rates of ESRD increased in an even more dramatic way in the middle-aged and older diabetic population, predominantly with type 2 diabetes. In those aged 45 to 74 years, the incidence rate of ESRD was 0.9 per 1,000 a year in 1984 and has increased steadily every year, reaching 3.5 per 1,000 a year in 1996. Increases also were seen among whites with diabetes in the oldest age group, although the rates were lower than in the three other age categories. In blacks with diabetes, the incidence rate of ESRD was two to three times that in whites with diabetes and the secular trend paralleling that seen in whites (Fig. 47.6).

The secular increase in the incidence of ESRD in the U.S. diabetic population occurred despite the increasing prevalence of antihypertensive treatment in the 1980s and 1990s (110) and the wide use of angiotensin-converting enzyme inhibitors beginning in the early 1990s (111–113). The effect of the latter may not have been evident by 1996, but unpublished data for the years 1997 to 1999 suggest that the incidence rate of ESRD has continued to increase at the same rate as before. At present there is no explanation for the "epidemic" of ESRD among patients with diabetes in the United States and in other countries as well (114).

DIABETES AND CORONARY ARTERY DISEASE

In contrast to eye and kidney complications, which affect patients with diabetes in all populations, coronary artery disease (CAD) is a frequent complication in diabetic patients only in populations in which there is a high risk of CAD in individuals without

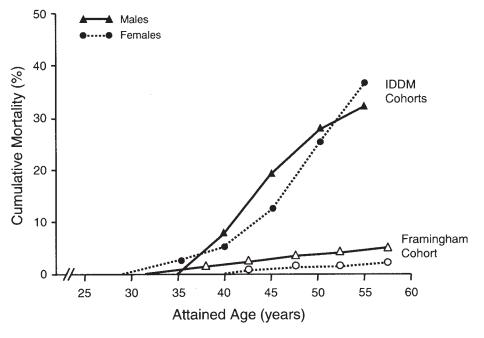

Figure 47.7. Cumulative mortality due to coronary artery disease up to age 55 years in patients with type 1 diabetes (IDDM) and in the nondiabetic participants of the Framingham Heart Study. (Adapted from Krolewski AS, Kosinski EJ, Warram JH, et al. Magnitude and determinants of coronary artery disease in juvenile-onset, insulin-dependent diabetes mellitus. *Am J Cardiol* 1987;59:750–755, copyright 1987, with permission from Excerpta Medica.)

diabetes. The excess of CAD in persons with diabetes in these populations is influenced by the conventional CAD risk factors as well as diabetes-specific exposures (115,116). The following review emphasizes data on the role of diabetes-specific exposures on the development of CAD, namely duration of diabetes, level of hyperglycemia, treatment with insulin, insulin resistance, and the presence of diabetic nephropathy.

Risk of Increases in Coronary Artery Disease with Duration of Diabetes and Attained Age

In white populations, the risk of CAD among individuals with diabetes generally increases with the duration of diabetes, but this effect depends on attained age. Figure 47.7 shows the cumulative mortality due to CAD according to attained age in patients who had type 1 diabetes diagnosed before age 21 years and were followed for 20 to 40 years. Also shown for comparison is the cumulative mortality due to CAD in the nondiabetic participants of the Framingham Heart Study. In both groups, the first deaths due to CAD occurred in the fourth decade of life. However, between ages 30 and 55 years, CAD mortality claimed 35% of the group with type 1 diabetes but only 8% of the men and 4% of the women in the nondiabetic group (117). In addition to this excess of CAD deaths, patients who were alive at the end of the 20- to 40-year followup had high prevalences of symptomatic and asymptomatic CAD. When all forms of CAD (including CAD deaths) were combined, the cumulative risk of this disease in juvenile-onset type 1 diabetes by age 55 years was about 50% (117). It is notable that the risk of CAD among patients with type 1 diabetes was similar in men and women and increased at the same rate after the age of 30 years, regardless of whether the onset of diabetes had been at age 0 to 9, 10 to 14, or 15 to 20 years (117). These findings suggest that exposure to diabetes before the age of 20 does not contribute to the enormous risk of CAD seen in these patients after age 30. One may postulate, however, that exposure to diabetes after age 20 accelerates the progression of the intermediate stages of coronary atherosclerosis that appear in the general population in the third and fourth decades of life (117–119).

Mortality due to CAD in a cohort of middle-aged white patients with type 2 diabetes is shown in Figure 47.8. Ageadjusted CAD mortality rates during the 24 years following diagnosis of type 2 diabetes are compared with the corresponding rates in nondiabetic individuals followed over the same interval in the Framingham Heart Study (119). From the time of diagnosis of diabetes, the mortality rate in diabetic patients was higher than in the Framingham population, and this excess risk grew larger with increasing duration of diabetes. Other investigators have obtained similar findings (120–123).

Interpretations of these findings vary, however, depending on whether the effect of diabetes is measured as the rate difference or the rate ratio. To illustrate, note that CAD mortality was quite high in diabetic patients in Figure 47.8 (and Figure 47.7 as well) and was the same in men and women. When these rates and the rates in the Framingham population are compared in terms of rate differences (additive scale), the impact of diabetes exposure on CAD mortality increases with diabetes duration in both men and women (Table 47.2). However, when the rates are compared in terms of rate ratios (multiplicative scale), the effect of diabetes exposure does not change with increasing duration in men and diminishes with increasing duration of diabetes in women. These data on mortality among patients with type 1 or type 2 diabetes and in the Framingham population were based on the period 1950 to 1980. Since that time, mortality due to CAD has declined significantly in the general population but not in the diabetic population (see later). As a result of these different trends, the rate differences and rate ratios shown in Table 47.2 may be considered as underestimates.

At present, there is no biologic justification for choosing one scale over the other to estimate the effect of duration of diabetes exposure on the risk of CAD. However, an increasing effect measured on the additive scale has a straightforward interpretation (124–126). It is a measure of CAD risk that is attributable to the cumulative effects of diabetes exposure, which includes both its independent effects and any synergistic effects due to interactions with age-related risk factors. For this reason, a public health perspective is better served by measuring effects on the additive scale (124). Interpretation of the constant or decreasing effects seen on the multiplicative scale, on the other hand, requires

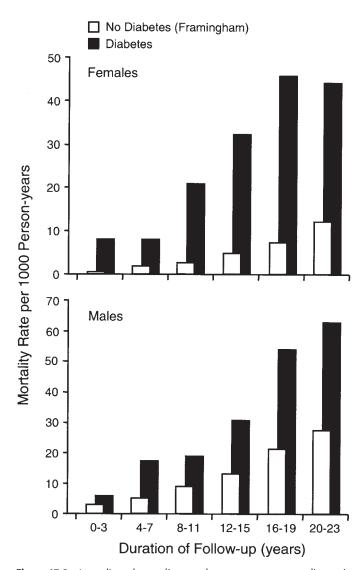

Figure 47.8. Age-adjusted mortality rate due to coronary artery disease in a cohort of patients of the Joslin Diabetes Center whose diabetes was diagnosed between ages 35 and 62 years and who came to the center soon after diagnosis and in the nondiabetic participants of the Framingham Heart Study, according to sex and duration of follow-up. (Adapted from Krolewski AS, Warram JH, Valsania P, et al. Evolving natural history of coronary artery disease in diabetes mellitus. *Am J Med* 1991;90[Suppl 2A]:56S–61S, copyright 1991, with permission from Elsevier Science.)

allowance for the age-related pattern of increasing risk of CAD that occurs independently of diabetes exposure. Uncritical interpretation of such results can be misleading (124–126). For example, some investigators have concluded that the effect of diabetes exposure (127) and other CAD risk factors (128) on the natural history of CAD diminishes with increasing age or duration of diabetes, although most observers would not draw this conclusion from the empiric data displayed in Figures 47.7 and 47.8.

Level of Glycemic Control and Risk of Coronary Artery Disease

At present, data are not adequate to evaluate the relationship between the level of hyperglycemia and risk of CAD in type 1 diabetes. Several observational studies found associations between level of glycemic control and total mortality, and some

47: EPIDEMIOLOGY OF LATE DIABETIC COMPLICATIONS 803

of the authors of these studies attempted to examine the effect of HbA_{1c} on the risk of CAD specifically (129,130). However, interpretations of negative or positive findings from these studies are confounded by two issues. First, it is not known whether exposure to hyperglycemia has an impact on the early or late stages of CAD. If the first is true one ought to measure HbA_{1c} decades before the CAD event, but if the second is true one ought to measure HbA_{1c} at a time closer to the event. Second, the level of glycemic control determines the risk of diabetic nephropathy, which in turn increases the risk of CAD. Therefore, one cannot dissect the roles of these two factors without a stratified analysis. In patients with type 1 diabetes in the DCCT, there was less CAD among those receiving intensive therapy (better glycemic control) than in those receiving conventional therapy (worse glycemic control), but the difference was not statistically significant (131). If the result had been significant, one would still have to qualify the interpretation in terms of the issues mentioned previously.

The results of observational studies in type 2 diabetes, although less frequently confounded by diabetic nephropathy, are also ambiguous. The results of two cohort studies showed a positive association between the level of hyperglycemia and mortality due to CAD (129,132). However, the findings were confounded by the association of other factors with severe hyperglycemia. The persistence of high levels of glycemia in patients with type 2 diabetes generally leads to the patient being treated with insulin. It was insulin treatment (rather than the severe hyperglycemia) that was associated with the high risk of CAD in several studies (1,120,133–137).

The interpretation of the high CAD risk among patients with type 2 diabetes who are treated with insulin is not clear. Hyperinsulinemia has been implicated in the acceleration of coronary atherosclerosis (138–141). Thus, one can hypothesize that treatment with insulin may contribute to the excess mortality due to CAD. One cannot, however, exclude the possibility that metabolic or cellular abnormalities that underlie insulin resistance and produce the hyperglycemia that requires insulin treatment are the true risk factors for acceleration of atherosclerosis (142–146).

The results of the University Group Diabetes Program (UGDP), conducted in patients with type 2 diabetes and published more than a decade ago, showed that fatal and nonfatal cardiovascular events occurred with equal frequency in patients who received intensive insulin treatment and had good glycemic control and in patients treated with diet and whose average fasting blood glucose level deteriorated from 120 mg/dL at baseline to 160 mg/dL after 3 years of the trial (147). In the recent United Kingdom Prospective Diabetes Study (UKPDS), individuals treated with insulin or a sulfonylurea had slightly less CAD than did individuals treated with diet, although the difference did not reach statistical significance (44).

Other Diabetes-Specific Risk Factors/Indicators of Risk of Coronary Artery Disease

Both type 1 and type 2 diabetes have long preclinical periods. Immunologic abnormalities, which precede by several years the clinical manifestation of type 1 diabetes, do not have an impact on the natural history of atherosclerosis. On the other hand, the metabolic abnormalities associated with low insulin sensitivity, which precede the onset of type 2 diabetes by decades, seem to have an impact on the natural history of coronary atherosclerosis (148,149). In a large cross-sectional study (Insulin Resistance and Atherosclerosis Study, or IRAS), low insulin sensitivity was associated with atherosclerosis in nondiabetic individuals, and this effect was independent of insulin level (150). Interestingly, TABLE 47.2. Excess Mortality due to Coronary Artery Disease in Patients with Type 2 Diabetes as Compared with That in Nondiabetics, According to Duration of Diabetes, Expressed as the Rate Difference and as the Rate Ratio (Results Adjusted for Age and Type of Diabetes Treatment)

Duration of follow-up	Rate difference ^a (rate/1,000 person-years)		Rate ratio ^b (relative risk)	
(duration of diabetes)	Males	Females	Males	Females
0–3	2.7	7.4	1.9	19.5
4–7	12.2	6.1	3.5	4.6
8–11	10.0	18.6	2.1	8.0
12–15	17.5	27.4	2.3	6.8
16–19	32.6	38.5	2.5	6.4
20–23	35.2	31.7	2.3	3.6

^aThe difference between the standardized mortality rate in the diabetic population and the nondiabetic population. Within each duration stratum, both sets of age-specific rates were standardized to the same age distribution. Within the diabetic population, the treatment-specific rates were standardized to the same distribution within each duration stratum.

^bThe ratio of the standardized mortality rate in the diabetic population to the corresponding rate in the nondiabetic population of Framingham.

Data from Krolewski AS, Warram JH, Valsania P, et al. Evolving natural history of coronary artery disease in diabetes mellitus. *Am J Med* 1991;90 [Suppl 2A]:56S–61S.

the effect appears to be peculiar to whites, being diminished in Hispanics and perhaps absent in blacks. Because low insulin sensitivity is also the strongest risk factor for the development of type 2 diabetes, the IRAS findings can account for the excess CAD in patients with newly diagnosed type 2 diabetes and the excess CAD mortality seen in patients with short-duration diabetes (see Fig. 47.8 and Table 47.2).

Diabetic nephropathy is the most potent risk factor/indicator for CAD in white patients with diabetes. In a large study of patients with type 1 diabetes conducted in Denmark, cardiovascular mortality rates (per 1,000 person-years) in those with proteinuria, in those without proteinuria, and in nondiabetic individuals were 22.1, 2.5, and 0.6, respectively (151). We obtained similar findings in our cohort study conducted in patients of the Joslin Clinic (117). Moreover, in a large multinational study of older diabetic patients, proteinuria was a major predictor of cardiovascular deaths (152). Patients with significant (heavy) proteinuria and type 1 or type 2 diabetes had mortality rates of 42.2 and 27.9 per 1,000 person-years, respectively. The rate in those without proteinuria was 9.4 and 9.2 per 1,000 person-years, respectively. Finally, recent studies in patients with type 2 diabetes found similarly elevated cardiovascular mortality rates in those with overt proteinuria and those with microalbuminuria or normoalbuminuria (153,154).

Several mechanisms can account for the excess of CAD in diabetic patients with proteinuria. First, patients who develop diabetic nephropathy come from families with essential hypertension (74–77) and an excess of CAD (155). Second, the majority of patients with diabetic nephropathy are hypertensive and have lipid abnormalities (56–58,76,156). These abnormalities appear long before the clinical manifestation of diabetic nephropathy. Furthermore, the effect of hypercholesterolemia on CAD mortality is much more potent in patients with diabetic nephropathy than in patients without proteinuria (157,158). Third, patients with diabetic nephropathy and declining renal function have very high plasma levels of advanced glycation end products (159). According to some theories, this could account for accelerating atherosclerosis in these patients (160).

Different Risk of Coronary Artery Disease in Different Diabetic Populations

In some populations of patients with diabetes, CAD is an infrequent complication. The World Health Organization Multinational Study of Vascular Disease in Diabetics documented marked variation in the occurrence of CAD among 14 samples of middle-aged diabetic patients throughout the world. In the cross-sectional part of this study conducted in the 1970s, a high prevalence of indicators of cardiovascular disease, such as electrocardiographic abnormalities and chest-pain symptoms, were found in patients with diabetes from Switzerland, Berlin, and London. A low prevalence of these indices was found in patients with diabetes from Tokyo, Hong Kong, and Native Americans (Pima) in Arizona (161). Similar findings were obtained during the 7-year follow-up study. The CAD mortality rate was highest in the samples of patients with diabetes from Berlin, Switzerland, and London, whereas it was lowest in the patients from Tokyo and Hong Kong and in Pima Indians (162).

The low risk of CAD in the Pima with type 2 diabetes is particularly curious (163). More than half of this population develop type 2 diabetes and most of these patients have poor glycemic control and are insulin-resistant and hyperinsulinemic for most of their lives. Furthermore, renal complications develop as frequently in the Pima with diabetes as in the white population with type 1 diabetes (100). At present there is no explanation for these observations. A similar lack of effect of diabetes exposure on the development of CAD was found among patients with type 2 diabetes in Japan. Figure 47.9 contrasts the mortality rate due to CAD in a cohort of patients with type 2 diabetes patients in Tokyo who were followed for almost 30 years with the mortality rate in a similar cohort of white patients with diabetes followed at the Joslin Clinic (164). Whereas the mortality rates increased steeply with the duration of diabetes in the Joslin cohort, there was minimal CAD mortality in the Tokyo cohort regardless of duration.

In summary, wide variation in the occurrence of CAD among different diabetic populations is consistent with the hypothesis that certain components of prediabetic exposure

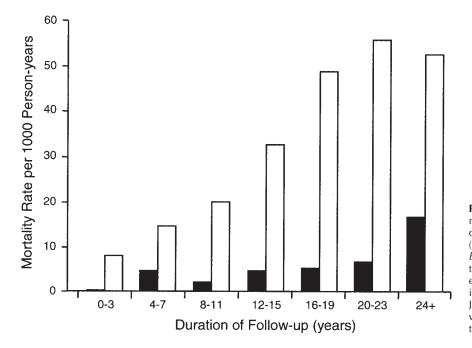

Figure 47.9. Age-adjusted mortality rate due to coronary artery disease in cohorts of patients with type 2 diabetes followed at the Tokyo University in Japan (*shaded bars*) and at the Joslin Clinic in Boston (*open bars*). Adapted from Matsumoto T, Ohashi Y, Yamada N, et al: Coronary heart disease mortality is actually low in diabetic Japanese by direct comparison with the Joslin cohort. *Diabetes Care* 1994;17:1062–1063, with permission from the American Diabetes Association.)

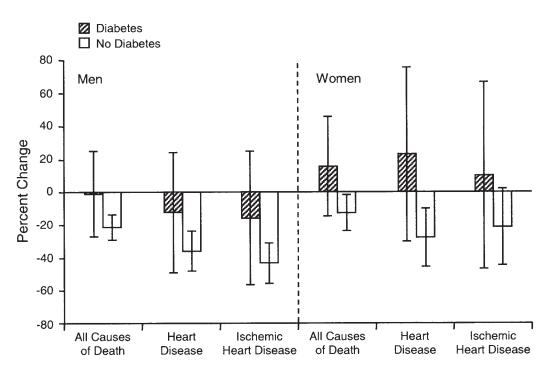

Figure 47.10. Percentage change in age-adjusted mortality rates due to all causes, heart disease, and ischemic heart disease in the general population of the United States between the 1980s and 1990s. Mortality rates were determined during 9 years of follow-up of two representative samples of the U.S. population: the participants of the first National Health and Nutrition Examination Survey (NHANES I) examined between 1971 and 1974 and the participants of the second survey (NHANES II) examined between 1982 and 1984. The former is designated the first cohort and the latter, the second cohort. The change in age-adjusted rates is expressed as a percentage of the rate in the first cohort together with its 95% confidence interval. (Adapted from Gu K, Cowie CC, Harris MI. Diabetes and decline in heart disease mortality in U.S. adults. *JAMA* 1999;281:1291–1297.)

(e.g., insulin resistance and/or hyperinsulinemia), as well as exposures during diabetes, have an impact only on progression of atherosclerotic lesions (117,119). These exposures have no impact on the frequency of atherosclerosis in patients with diabetes from populations in which the initiation of atherosclerosis is infrequent, such as the Pima, Japanese in Tokyo, and Chinese in Hong Kong.

Can the Natural History of Coronary Artery Disease in Patients with Diabetes Be Changed?

Over the past 30 years, there has been a constant decline, about 1% to 2% a year, in mortality due to CAD in the general U.S. population (165,166). This extraordinary phenomenon results from the declining incidence of CAD events as well as improved survival among those who developed CAD. Declining incidence reflects a modification of CAD risk factors, and improving survival reflects improved effectiveness of the treatment of patients with CAD (167–169).

Figure 47.10 shows data from a study that compared mortality in patients with and without diabetes in two cohorts that are representative of the U.S. population-the subjects of the First and Second National Health and Nutrition Examination Surveys (170). One was examined between 1971 and 1974 and the other between 1982 and 1984. The majority of individuals with diabetes in these cohorts had type 2 diabetes. Each cohort was followed for 9 years. Between the two periods, nondiabetic men experienced a 43.8% decline in age-adjusted mortality due to ischemic heart disease, whereas diabetic men experienced only a 16.6% decline. Age-adjusted mortality due to ischemic heart disease declined 20.4% in nondiabetic women but increased 10.7% in diabetic women. Whereas the declines in nondiabetic men and women were highly significant statistically, the changes in individuals with diabetes were not significantly different from 0. The patterns of changes for heart disease mortality as well as all-cause mortality were similar. No other study of the natural history of CAD in individuals with type 2 diabetes has evaluated the change or lack of it over time.

-Roger Bacon, 1450

The relationship between metabolic control and development of long-term complications of diabetes mellitus was one of the most contentious issues in medicine (1–5). Whether intensive forms of diabetes therapy, which have as their goal the achievement of near-normal glycemia, would prevent the development and/or ameliorate the progression of diabetes-associated complications (the only testable question in humans) was answered only in the previous decade. This chapter reviews the history of the debate and the human studies that shed light on this relationship. The important clinical trials that finally resolved the debate, including the Diabetes Control and Complications Trial and the United Kingdom Prospective Diabetes Study, are reviewed in detail (6,7).

HISTORY

Although the recognition of diabetes mellitus itself has a venerable history (8), the recognition and description of diabetic complications is relatively new. The first description of retinopathy in diabetes was recorded only 100 years ago (9), and both the occurrence and character of retinal lesions in relation to diabetes were the subject of active debate as recently as 60 years ago (10). The classic lesions of diabetic glomerulosclerosis were described less than 70 years ago (11).

The major reason for the previous lack of clinical appreciation of diabetic complications is related to their dependence on duration of diabetes, the most potent known risk factor for

complications (12-18). In the preinsulin era, the limited life span of patients after they developed type 1 diabetes precluded the development of long-term complications. Eight years after the introduction of insulin, diabetic children were described as having "invulnerable" eyes and a future of "limitless hope" (19). Twenty years after insulin became available, however, the results of long-term survival with insulin therapy were noted to include retinopathy, nephropathy, and peripheral and cardiovascular disease (20-22). In a prescient set of observations made more than 50 years ago, Dolger noted that duration of diabetes appeared to be more important than age at onset or type of therapy; that all patients whose diabetes was of sufficient duration developed retinal lesions; that approximately 50% developed proteinuria; and that complications developed in patients whose long-term metabolic control was judged to be good as well as in those whose metabolic control was poor (22). On the other hand, retrospective studies suggested that children with "adequately" controlled diabetes were not vulnerable to growth retardation, cataracts, or retinal hemorrhages (23). Thus, the debate regarding the effects of metabolic control on long-term complications was born.

The history of type 2 diabetes and long-term complications is even murkier. Until the recent extension of the human life span and accompanying increase in the prevalence of obesity led to a dramatic increase in the prevalence of type 2 diabetes (24), type 2 diabetes was a relatively rare disease. Moreover, elderly patients with type 2 diabetes rarely survived the 10 to 20 years after onset of diabetes that are necessary for the development of clinically significant complications. Major advances in general medical care, and especially in cardiac care, now have allowed older patients with type 2 diabetes to live longer. This

810 JOSLIN'S DIABETES MELLITUS

increased life expectancy has unmasked the risks of long-term complications in type 2 diabetes, much as insulin therapy did for type 1 diabetes. Type 2 diabetes is now widely recognized as a cause of duration-dependent complications similar to those in type 1 diabetes (14,16,25–27). Although the frequency of retinopathy and nephropathy is relatively lower in type 2 than in type 1 diabetes, the 10-fold-greater prevalence of type 2 diabetes makes it the major contributor to vision loss and renal failure secondary to diabetes in the United States (26,28). The association of type 2 diabetes and elevated levels of blood glucose with microvascular complications has been recognized implicitly in the definition of blood glucose criteria for the diagnosis of type 2 diabetes, which are predicated on those glucose levels that are accompanied by microvascular complications (29).

MAJOR ISSUES

Several major questions should be framed before a critical examination of the data are undertaken. The occurrence of retinopathy, nephropathy, and neuropathy as long-term, diabetes-specific complications of all types of diabetes is clear. As noted previously, the diagnostic criteria for type 2 diabetes include glucose levels selected specifically because of the risk they impart for development of long-term complications, specifically retinopathy. (The profound hyperglycemia and absolute requirement for insulin in type 1 diabetes make diagnostic glucose criteria generally unnecessary.) Persons whose glucose levels are elevated but who are not vulnerable to diabetes-specific complications are not considered diabetic but are described nosologically as having impaired glucose tolerance or impaired fasting glucose ("pre-diabetes") (29). Thus, the association of hyperglycemia with certain long-term complications is incorporated into the clinical definition of diabetes, and a glucose threshold for the development of specific complications is implicit in the accepted definition of type 2 diabetes.

The glucose hypothesis, that is, that the long-term complications of diabetes are a consequence of hyperglycemia, is a natural, albeit potentially fallacious, outgrowth of these observations. Although diabetes of diverse etiologies is defined as being related to both hyperglycemia and long-term complications, the conclusion that one leads to the other, although attractive, is not necessarily true. A primary question, therefore, is what relationship exists between the level of hyperglycemia and the occurrence or development of complications.

Even if the relationship between different levels of hyperglycemia and complications is established and delineated, association does not necessarily impute causation. More important, even if hyperglycemia results in the development or progression of complications, the practical questions of whether control of glucose levels will prevent or reverse complications, the extent and duration of the effect, and the costs of such control must be answered.

Important subsidiary questions include the following: (a) Will all diabetes-specific complications respond similarly to changes in glucose level? (b) Is the timing of intervention important, that is, is treatment effective only if instituted before the development of any complications (primary prevention) or is it also effective after the development of complications (secondary intervention)? (c) Does maintenance of a specific glucose level prevent or ameliorate any or all complications? (d) Will different methods (e.g., exogenous administration of insulin vs. pancreatic transplantation) of achieving more normal glycemia have similar effects on complications? (e) Will long-term complications in type 1 and type 2 diabetes respond similarly to therapy? (f) Will nonspecific macrovascular complications, the severity and frequency of which are increased in diabetes, be affected by therapies directed at achieving glucose levels closer to physiologic values?

STUDIES IN ANIMAL MODELS AND OBSERVATIONAL STUDIES IN HUMAN DIABETES

Retinopathy

ANIMAL STUDIES

Although none of the animal models of diabetes and its complications are sufficiently similar to human diabetes to provide more than suggestive evidence, they overwhelmingly support the premise that therapies that normalize blood glucose levels can prevent and/or ameliorate retinopathy, nephropathy, and neuropathy. The animal models fall into three different groups. In one model, animals with chemically induced (with alloxan or streptozotocin) diabetes are treated with insulin with the goal of achieving either tight or loose control of blood glucose levels (30,31). In another model, animals are pancreatectomized and treated with pancreatic or isolated islet cell transplantation (32,33). Finally, animals with genetic diabetes and various degrees of glycemia have been studied (34). Most studies have demonstrated efficacy of intensive therapy aimed at maintaining glucose levels close to the physiologic range in preventing complications. The ability of intensive diabetes therapy to affect complications once they have been initiated is arguable.

Studies by Engerman et al. of dogs with alloxan-induced diabetes are the most compelling of the animal studies (30,31). The diabetic dogs developed microaneurysms and pericyte loss similar to those seen in diabetic humans, changes not generally found in nondiabetic dogs. In an early study, therapy with two daily injections of isophane insulin (NPH insulin) with the goal of aglycosuria ("good control") was initiated soon after the dogs were made diabetic (30). Good control was shown to be associated with fewer microaneurysms than was therapy with one daily injection of isophane insulin ("poor control") over a 5-year period. A later study demonstrated that if dogs with alloxaninduced diabetes were treated with the poor-control regimen for 2.5 years followed by the good-control regimen for 2.5 years, they developed an intermediate number of microaneurysms, suggesting that secondary intervention was not as effective as primary prevention (31). Of note, severe hypoglycemia resulted in the deaths of several dogs in "good control."

HUMAN STUDIES

Type 1 Diabetes. Early studies that examined the relationship of retinopathy to glucose control used relatively insensitive measures of retinopathy and nonquantitative, imprecise measures of chronic glycemia. Knowles reviewed 47 studies of glucose control and development of complications conducted before 1964 and concluded that the studies were hampered by the absence of quantitative methods of evaluating long-term glucose control and complications and by a poor appreciation of clinical-trial methodology (35). In the modern era, nondilated ophthalmoscopy has given way to seven-field stereoscopic fundus photography and fluorescein angiography, and sporadic blood glucose measurements and semiquantitative measures of glycosuria have been supplanted by assays of glycosylated hemoglobin (HbA_{1c}).

Although lacking in these modern innovations, the noninterventional, longitudinal study of Pirart deserves mention, if only for its magnitude (36). Pirart followed a large (4,400) cohort of patients with early- and late-onset diabetes for as long as 25 years. He noted that retinopathy, nephropathy, and neuropathy were more common in patients with a higher glycemic index, a value derived from intermittent measurements of blood and urine glucose levels and other factors. The high attrition rate over time, the lack of objective measures of complications and glycemia, and the possibility that complications led to worsened glucose control—rather than vice versa—detract from this study.

In the modern era, the population-based, observational Wisconsin Epidemiologic Study of Diabetic Retinopathy (WESDR) examined diabetic residents of Wisconsin over time using measurements of HbA1c and seven-field stereoscopic fundus photography. Follow-up over 4 years included more than 90% of the original subjects and revealed a striking association between the incidence of any retinopathy, progression of retinopathy, progression to proliferative retinopathy (37), macular edema (38), and vision loss (39) and the level of HbA_{1c} at baseline. The relationship between levels of HbA_{1c} and retinopathy was continuous; no threshold within the diabetic range for HbA_{1c} with regard to risk of retinopathy was noted. The observed associations remained after the comparisons were controlled for duration of diabetes, age, and baseline retinopathy. Although WESDR subjects were not strictly categorized as having type 1 or type 2 diabetes, the separation by age at onset (<30 years vs. ≥30 years) effectively provided populations of subjects with predominantly type 1 or type 2 diabetes. Other observational studies have confirmed these findings in moreselected type 1 populations (40-43) and have suggested that higher glycemic levels are a risk factor for the development of proliferative retinopathy (18,41,43).

Type 2 Diabetes. An association between retinopathy and glycemia similar to that for type 1 diabetes has been demonstrated for type 2 diabetes. Both the WESDR (14) and a study of type 2 diabetes in an aging population (55–75 years old) (16) showed that the relative risk of developing retinopathy increases as the level of HbA_{1c} increases (Fig. 48.1). Putative risk factors for diabetic retinopathy, other than the level of glycemia, include hypertension (44), pregnancy (45), a family history of diabetic retinopathy (46), and possibly hypercholesterolemia (47), but probably not smoking (48).

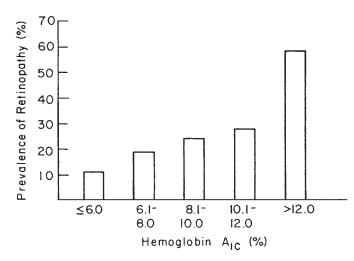

Figure 48.1. Association between mean glucose level as measured by level of glycosylated hemoglobin (HbA_{1c}) and presence of retinopathy in older patients (55 to 75 years) with type 2 diabetes. (Copyright © 1986 American Diabetes Association. From Nathan DM, Singer DE, Godine JE, et al. Retinopathy in older type II diabetics: association with glucose control. *Diabetes* 1986;35:797–801. Reprinted with permission from the American Diabetes Association.)

Nephropathy

ANIMAL STUDIES

Although glomerular lesions in several animal models of diabetes are similar to those seen in diabetic nephropathy in humans, the time course of the development of the lesions is difficult to compare with that in human diabetes. In addition, the contribution of other factors that play important roles in the genesis of human diabetic nephropathy cannot be evaluated in these models. As with retinopathy, studies of nephropathy in animal models can lend support to, but cannot prove, the glucose hypothesis.

Studies in animal models appear to demonstrate that nephropathy can be prevented or even reversed when diabetic animals are treated with pancreatic transplantation or with intensive insulin therapy. Rats with streptozotocin-induced diabetes develop mesangial thickening with immunoglobulin deposition within 6 to 9 months of diabetes onset (32). Successful islet transplantation can prevent the development of such lesions or lead to stabilization and some improvement in established lesions concurrent with normalization of glucose levels (32). Several fundamental problems apply to this model. First, diabetic rats develop a renal lesion (mesangial expansion) that differs from the early lesion of human nephropathy (glomerular basement membrane expansion) and do not develop end-stage renal failure. Second, other potentially important variables that might predict or influence development of nephropathy in humans (e.g., hypertension) cannot be studied in animal models. Third, rats in which transplants of pancreatic islet cells do not succeed in correcting glucose levels also show improvements in renal results (32). Despite these objections, studies in other animal models such as the BB/W (spontaneously diabetic) rat (49) and uninephrectomized, alloxan-treated dog (50) tend to support the role of glucose control in the genesis of nephropathy.

HUMAN STUDIES

Diabetic nephropathy poses several different problems, when compared with retinopathy, regarding the analysis of its association with glucose levels and of the effects of intensive therapy on its development and course. The natural history of diabetic nephropathy, although duration-dependent, extends over many more years than retinopathy before clinical expression becomes evident (51,52). Generally, a minimum of 12 years but usually 15 to 18 years of type 1 diabetes is required before the development of clinical-grade (dipstick-positive, i.e., ≥500 mg per 24 hours) proteinuria, the first incontrovertible sign of developing end-stage renal disease. After the development of clinical-grade proteinuria, a mean of 5 years is required for the decline in creatinine clearance, that terminates in end-stage renal disease, to begin (53). Thus, compared with the time course of diabetic retinopathy, for which signs will appear in 50% of individuals within 5 to 7 years of diabetes onset, the time course for the development of clinical nephropathy (dipstickpositive proteinuria), when it occurs, is much prolonged, requiring a duration of diabetes of approximately 15 years.

With the reluctance to perform kidney biopsies early in the course of diabetes for documentation of microscopic changes in the glomerulus and the less-than-perfect correlation between microscopic changes and clinical course, surrogate markers of evolving nephropathy have tentatively been identified. "Incipient" nephropathy, as demonstrated by microalbuminuria (generally >20–30 mg and <300 mg of urinary albumin per 24 hours), has been identified in retrospective studies of type 1 (54–57) and type 2 (58) diabetes as a predictor or marker for the development of end-stage renal disease. Unfortunately, microalbuminuria can vary considerably in individuals over time, with levels fluctuating from abnormal to normal values. Therefore, a urinary

812 JOSLIN'S DIABETES MELLITUS

albumin excretion rate of greater than 20 µg per minute (>28 mg per 24 hours) but less than 200 µg per minute (<288 mg per 24 hours) in at least two of three urine collections within a 6-month period has been suggested as a definition of "persistent" microalbuminuria (59). In addition, microalbuminuria may not be a predictor of nephropathy unless hypertension and a decreasing glomerular filtration rate also are present (60). Microalbuminuria can reverse in as many as 58% of affected persons, with lower levels of glycosylated hemoglobin, lower systolic pressure, and lower levels of cholesterol and triglycerides independently associated with regression (61). Finally, most of the data indicating an association between microalbuminuria and nephropathy are retrospective in nature. Whether any intervention that affects this presumed marker for nephropathy also will affect the long-term course of nephropathy has yet to be demonstrated conclusively. Despite these limitations, changes in microalbuminuria have been used as renal endpoints in many controlled trials.

There are several reasons to suspect that the association between glucose control and nephropathy may be more complex than that with retinopathy. The occurrence of nephropathy in no more than 40% of patients with type 1 diabetes and 25% of patients with type 2 diabetes suggests that variables other than glycemia are operant. Hypertension and family history of hypertension (62), smoking (63), and hyperlipidemia (64) have been suggested as possible mediators of nephropathy.

Type 1 Diabetes. The association between levels of glycemia and nephropathy has not been as clearly delineated as that for retinopathy. Although the Pirart study (36) demonstrated an association between the derived glycemic index and an increase in creatinine level over time, cross-sectional or longitudinal studies using objective measurements of glycemia and proteinuria are rare and have not consistently revealed such an association. Only one longitudinal study has demonstrated an association between mean levels of glycosylated hemoglobin, measured over 7 years, and risk of microalbuminuria in type 1 diabetes (65). Although this association persisted when age and duration of diabetes were taken into account, measurements of microalbuminuria at baseline, blood pressure, and other possible confounders were not considered in the analysis.

Potential reasons for the difficulty in establishing a relationship between glycemia and nephropathy, if such a relationship exists, are numerous. First, the development of renal failure may influence glycemic control in a number of ways (e.g., alterations in sensitivity to insulin and development of hypertension and effects of antihypertensive medications on glycemia). Second, uremia, anemia, and transfusions may interfere with or influence the accuracy of measurements of glycosylated hemoglobin. Finally, and most importantly, given the long duration of diabetes necessary before the development of renal failure, it is possible that infrequent measurements of glycosylated hemoglobin, representing a relatively brief period of exposure, may not be predictive of the development of nephropathy. The most convincing data come from the follow-up of long-term clinical trials, such as the DCCT.

Neuropathy

Diabetic neuropathy is protean in nature, with distal, symmetrical, somatosensory neuropathy, autonomic neuropathy, and mononeuropathies. Although electrophysiologic measures of nerve conduction have been available for more than 40 years, their questionable relevance to symptomatic clinical diabetic neuropathy has made the study of glucose control and neuropathy problematic. For example, the early observation that insulin treatment of new-onset type 1 diabetes reversed the slowed motor nerve conduction within 6 weeks in asymptomatic patients supported an acute effect of hyperglycemia on nerve conduction and cast doubt on the role of electrophysiologic testing (66). The absence of histologic data (e.g., sural nerve biopsy) in the vast majority of studies has been a major impediment to our understanding of diabetic neuropathy. A weak association between glycemia and motor and sensory nerve conduction has been documented in type 1 (67) and type 2 (68) diabetes.

CLINICAL TRIALS

Type 1 Diabetes

Although of interest, cross-sectional and longitudinal observational studies can at best only indicate associations between glycemic control (and other confounders) and complications. Randomized, controlled clinical trials examine the effects of treatments designed to achieve near-normal glucose control on the development and progression of complications and can establish causality. The introduction and refinement of methods for self-monitoring of blood glucose levels and of intensive therapies, such as continuous subcutaneous insulin infusion (CSII) with pumps and multiple daily injection (MDI) regimens (69), provided the opportunity to test whether such therapies would have salutary effects. Four well-designed randomized studies (70–73) set the stage for the larger and comprehensive Diabetes Control and Complications Trial (DCCT) (6,74). The first four clinical trials included the multicenter study by the Kroc Collaborative Study Group (70) and studies by the Steno Study Group (71), the Oslo group (72), and the Stockholm Diabetes Intervention Study group (73). All of these trials were secondary intervention studies, including only subjects with retinal lesions at baseline. In addition, the mean duration of diabetes was relatively long. The duration of the trials ranged from 8 to 60 months and included 30 to 100 subjects. (By contrast, the DCCT studied 1,441 subjects with a mean follow-up of 6.5 years.) The total number of patient-years of study was less than 800 in the four previous secondary intervention trials combined. The total number of patient-years for the secondaryintervention component of the DCCT was almost 5,000 at study end in 1993. Except for the Oslo study, which included two intensive-treatment groups, the studies compared subjects with type 1 diabetes randomly assigned to conventional treatment with subjects randomly assigned to CSII (Kroc and Steno) or

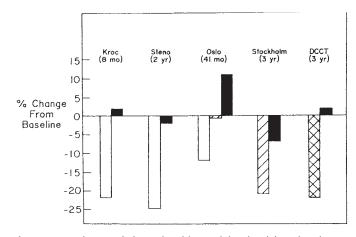

Figure 48.2. Change of glycosylated hemoglobin level from baseline in five controlled clinical trials. *Solid box:* Conventional treatment. *Open box:* Continuous subcutaneous insulin infusion (CSII). *Diagonal:* Multiple daily injections of insulin (MDI). *Hatched:* CSII or MDI. (From Nathan DM. Relationship between metabolic control and long-term complications. In: Kahn DR, Weir GC, eds. *Joslin's diabetes mellitus,* 13th ed. Philadelphia: Lea & Febiger, 1994:620–630. Copyright © 1994 Joslin Diabetes Center.)

MDI (Stockholm). In all the studies the groups receiving intensive treatment maintained significantly lower levels of glycosylated hemoglobin than did those receiving standard treatment (Fig. 48.2). The results of the Kroc (70), Steno (71,75), and Oslo (72,76) studies were similar with regard to retinopathy. In the first 6 to 12 months, a transient worsening of retinopathy occurred in the patients receiving intensive treatment. Only the Stockholm Diabetes Study demonstrated a beneficial effect of intensive therapy over time (73).

DIABETES CONTROL AND COMPLICATIONS TRIAL

In 1993, the DCCT reported the unequivocal salutary effects of intensive diabetes management on the development and progression of the microvascular and neurologic complications of type 1 (insulin-dependent) diabetes (6), ending the 60-year debate regarding the relationship between metabolic control and long-term complications.

Design. The DCCT, initiated in 1983, was designed to answer definitively whether intensive diabetes management would affect the development and/or progression of long-term complications in type 1 diabetes, and at what cost (74). The

DCCT provided remarkably clear answers to the following questions: (a) Will intensive therapy aimed at achieving glycemic levels as close to the nondiabetic range as possible prevent the development or slow the progression of complications in patients with type 1 diabetes with no complications at base-line (primary prevention)? (b) Will intensive therapy prevent the progression of complications in patients with type 1 diabetes who already have some evidence of complications at base-line (secondary intervention)? (c) What are the adverse events associated with intensive compared with conventional therapy?

To answer these questions, the DCCT selected two separate cohorts of patients. The primary prevention cohort was 13 to 39 years of age with a duration of diabetes of 1 to 5 years and no evidence of retinopathy or nephropathy. The secondary intervention cohort was of similar age but could have had diabetes for as long as 15 years. They had to have at least one microaneurysm but no more than moderate nonproliferative retinopathy, and they could excrete as much as 200 mg of albumin per 24 hours. The baseline characteristics of the two study cohorts are shown in Table 48.1. Study patients were selected on the basis not only of demographic, clinical, and biochemical cri-

teria but also of an assessment that they would accept random assignment of therapy and of the likelihood that they would continue to participate in a long-term study. On average, these patients were probably more motivated than the usual patient with type 1 diabetes.

DCCT Intensive Treatment and Metabolic Goals. The primary prevention and secondary intervention cohorts were randomly assigned either to conventional therapy (designed to mimic the usual diabetes therapy with one or two daily injections of insulin and daily glucose monitoring) or to intensive therapy (designed to normalize blood glucose control). Conventional therapy had the clinical goals of avoiding any symptoms of hyper- or hypoglycemia but had no specific numeric blood glucose targets. Intensive therapy had the goal of achieving blood glucose control as close to the nondiabetic range as possible, including premeal blood glucose levels between 70 and 120 mg/dL (3.9 to 6.7 mmol/L), peak postprandial levels under 180 mg/dL (10 mmol/L), and HbA_{1c} levels in the nondiabetic range (<6.05%). To reach these goals, patients assigned to intensive therapy used three or more insulin injections per day or insulin pump therapy, guided by frequent self-monitoring of blood glucose levels (Table 48.2). Insulin therapy was adjusted frequently in response to ambient blood glucose levels, diet, and exercise.

DCCT Results. The detailed results of intensive compared with conventional therapy in the DCCT have been reported (6,77-94). The initial report (6) summarized the major results, whereas subsequent reports presented expanded analyses of the effects of intensive therapy on long-term complications, including retinopathy (77-79), nephropathy (80), neuropathy (81-83), and macrovascular disease and its risk factors (84); the effect of intensive therapy on quality of life (85), neurobehavioral outcome (86), and residual insulin secretion (87); the implementation (88) and adverse effects of intensive therapy (89,90); the cost-benefit analysis of intensive therapy compared with conventional therapy (91); the results of intensive therapy in pregnancy (92); and the association among glycemia, longterm complications, and other risk factors (93,94). A long-term follow-up study of the DCCT cohort, the Epidemiology of Diabetes Interventions and Complications (EDIC) study, is under way and is providing further insight into the long-term consequences of intensive therapy (95-99)

Adherence and Metabolic Results. Over the 6.5-year mean follow-up time of the study (range, 3 to 9 years), compliance was excellent, with 99% of the cohort completing the trial (6). In

addition, there was virtually no crossover between assigned treatments. Subjects adhered to their assigned treatment more than 97% of the study time. Intensive therapy decreased HbA_{1c} to a nadir of approximately 6.9% by 6 months and maintained a mean HbA_{1c} level during the remainder of the trial that was approximately 2% lower than with conventional treatment (7.2% vs. 9.1%) (Fig. 48.3). Of note, intensive therapy did not lower mean HbA_{1c} to the nondiabetic range.

Retinopathy. Retinopathy was evaluated every 6 months by seven-field stereoscopic fundus photography. The photographs were graded in a central facility, with the graders masked to patient identity. Although many analytic levels of retinopathy were assessed, the principal outcome in the primary prevention study was the development of a sustained (seen on two consecutive exams) three-step or greater progression on a retinopathy severity scale adopted from the Early Treatment of Diabetic Retinopathy Study (ETDRS) (100). Similarly, the principal outcome in the secondary intervention study was a sustained progression of three or more steps from the baseline level. Intensive therapy reduced the development of these end points by 76% in the primary prevention study and by 54% in the secondary intervention study compared with conventional therapy (Fig. 48.4). Other retinopathy outcomes and the effects of intensive therapy are shown in Table 48.3.

The overall effect of intensive therapy was to decrease all stages of retinopathy included in the DCCT. However, intensive therapy was relatively more effective when initiated early in the course of diabetes (shorter vs. longer duration) and when retinopathy was less severe at baseline (77,78). Although intensive therapy reduced the risk for more advanced stages of retinopathy somewhat less than for earlier stages, patients with more advanced retinopathy still benefited from intensive therapy. The beneficial effects of intensive therapy were not seen for the first 3 years of therapy, presumably because of the natural "momentum" of diabetic complications. In addition, intensive therapy was associated with a transient worsening of retinopathy during the first year of therapy. Both of these factors conspired to delay the beneficial effects of intensive therapy, which were similar in almost all subgroups of patients defined by age, gender, and other baseline characteristics.

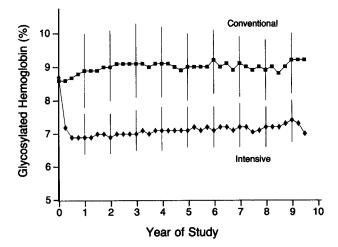

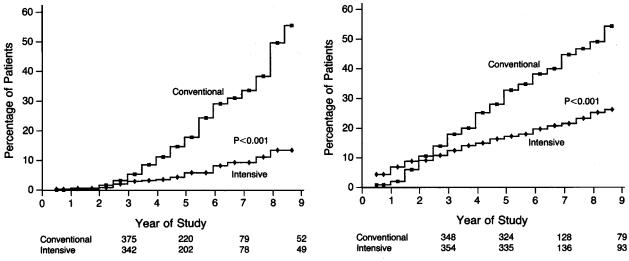

Figure 48.3. Median levels of glycosylated hemoglobin A_{1c} during the Diabetes Control and Complications Trial. (From DCCT Research Group. The EDIC follow-up has shown further improvement in retinal status in the previous intensive treatment group compared with the previous conventional treatment group (Table 48.3). The difference between the two treatment groups persists, and even expands, 7 years after the end of the DCCT, even though the majority of the previous conventional treatment cohort has changed to intensive therapy and the mean HbA_{1c} levels have drifted closer between the two treatment groups (96,97). The persistent benefit of 6.5 years of intensive therapy during the DCCT further supports the concept of "momentum" with regard to diabetic complications. In addition, the beneficial effects of lower glycemia appear to persist beyond the period of lower glycemia that has been called "imprinting" or "metabolic memory."

The study of families of DCCT volunteers in which there is more than one person with diabetes has revealed clustering of retinopathy within families (101). The tendency for some families

with diabetes to develop retinopathy whereas other families do not may be mediated by genetic factors or by some as yet to be identified shared environmental factor. It is interesting that regardless of the cause of clustering, intensive therapy decreased the development and progression of retinopathy in DCCT volunteers who were members of "high-risk" families as well as in DCCT volunteers in low-risk families.

Nephropathy. Nephropathy was assessed by measurements of albumin excretion and standard creatinine clearance, based on an annual standardized 4-hour collection and by periodic measurement of iothalamate clearance. The primary analytic end points for nephropathy are shown in Table 48.3 and Figure 48.5. As with retinopathy, the risk for progression of nephropathy was reduced by intensive therapy. This included reduction in the development of microalbuminuria (≥40 mg per 24 hours) and clinical-grade albuminuria (>300 mg per 24 hours). The small number of patients developing clinical nephropathy, defined as a creatinine clearance of less than 70 mL per minute per 1.73 m² with albumin excretion greater than 300 mg every 24 hours, precluded a statistically valid analysis of any difference between treatment groups. However, the number of conventionally treated patients who developed this level of renal dysfunction (n = 5) was more than twice the number of intensively treated patients (n = 2). The relatively small number of patients with secondary intervention who had microalbuminuria at baseline (n = 70) made it difficult to demonstrate a benefit of intensive therapy with regard to slowing progression to clinical-grade albuminuria once microalbuminuria had occurred (80). The Steno study had demonstrated such a benefit previously with only 36 patients (71). Their success may have been rooted in the very frequent measurement of repeated 24-hour albumin excretion rates, which decreased the variance of the measurements. The long-term follow-up of the DCCT cohort has reinforced the role of intensive therapy in delaying and perhaps preventing diabetic nephropathy (Table 48.3). During approximately 8 years of post-DCCT follow-up, when HbA1c levels were almost identical, the former intensive therapy group continued to have a markedly reduced risk of microalbuminuria, albuminuria, and more advanced stages of nephropathy (Table 48.3), and had less frequent development of hypertension, compared with the former conventional treatment group (99).

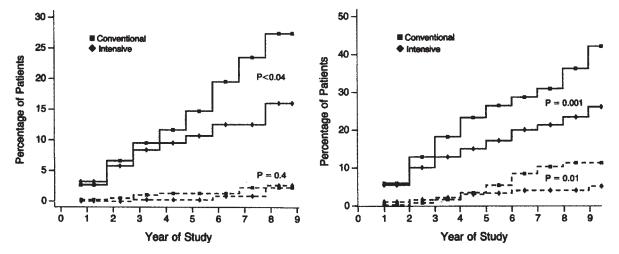

Figure 48.5. Effects of intensive therapy on development of microalbuminuria (\geq 40 mg/24 h; *solid line*) and clinical albuminuria (\geq 300 mg/24 h; *dashed line*) in the primary **(A)** and secondary **(B)** Diabetes Control and Complications Trial cohorts. Copyright © 1993 Massachusetts Medical Society. All rights reserved.)

Neuropathy. Confirmed clinical neuropathy was defined as the presence of signs or symptoms of peripheral neuropathy plus either abnormal nerve conduction in at least two peripheral nerves or unequivocally abnormal autonomic nerve testing. Intensive therapy reduced the risk of developing clinical neuropathy 60% in the combined cohorts (Table 48.3) (6,81-83). In addition to the decreased development of confirmed clinical neuropathy, the most stringent of the neurologic outcomes, intensive therapy reduced the risk of deterioration of nerve function, as measured with electrophysiologic methods, that occurred with conventional therapy (81). The decline in autonomic nerve function, assessed with measures of cardiovascular autonomic function, that occurred with conventional therapy was significantly reduced with intensive therapy in the primary prevention, but not in the secondary intervention, cohort (82). There were no significant differences between treatment groups in clinical events secondary to autonomic neuropathy, but the frequency of events was very low in both groups.

Association of Glycemia and Microvascular Complications. The frequent measurements of HbA_{1c} and detection and measurement

of microvascular complications using uniform, standardized methods during the mean 6.5 years of the DCCT provided the opportunity to examine the relationship between glycemia and the diabetes-specific complications (93,94). The mathematical modeling of long-term glycemia and complications revealed a continuous relationship between glycemia and retinopathy and nephropathy, with no apparent threshold or breakpoint in the range of diabetic glycemia (Fig. 48.6). The analyses support a continuous benefit of lowering HbA_{1c}, even into the near nondiabetic range. Every 10% decrease in HbA_{1c}, for example, from 10% to 9% or 9% to 8.1%, is associated with a 43% reduction in risk for developing retinopathy. Although the absolute rate of retinopathy decreases in the lower HbA_{1c} persists.

Macrovascular Outcomes. The DCCT did not demonstrate a significant difference in major macrovascular outcomes (death from cardiovascular disease, myocardial infarction, and major peripheral vascular events) between treatment groups (84). Although the risk for these combined events was reduced by 41% with intensive therapy, the difference between groups failed

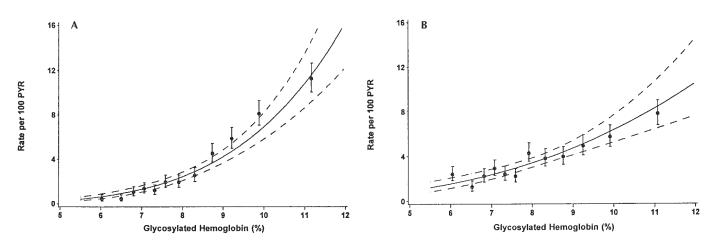

Figure 48.6. Association of mean percentage of glycosylated hemoglobin A_{1c} and sustained retinopathy (A) and microalbuminuria (B). (Copyright © 1996 the American Diabetes Association. to achieve conventional levels of statistical significance (p = 0.06). However, several risk factors for cardiovascular disease were improved with intensive therapy, including a 34% reduction in low-density lipoprotein cholesterol (p = 0.02). Further study is required to ascertain whether intensive therapy improves the risk of macrovascular disease that accompanies type 1 diabetes. It was reassuring to note that intensive therapy, which included modestly higher insulin doses (0.01 to 0.05 \dot{U}/kg per day more insulin with intensive than with conventional therapy), did not increase cardiovascular disease. Although the DCCT population being followed long term in the EDIC study remains relatively young and without a large number of cardiovascular events, carotid ultrasound measurements of atherosclerosis (intimalmedial thickness, or IMT) have revealed significant differences between the original intensive and conventional treatment groups, suggesting a beneficial effect of intensive therapy on atherosclerosis (98).

Other Outcomes and Adverse Events. Accompanying the salutary effects of intensive therapy on long-term complications was an approximately threefold increase in severe hypoglycemia, defined as an episode that required assistance to treat (6,89,90). Although the majority of these episodes were clinically benign, the incidence of hypoglycemia resulting in coma and seizures or requiring emergency department treatment was also increased approximately two- to threefold. The more severe hypoglycemic reactions, such as those resulting in seizure or coma, were relatively rare (16 vs. 5 episodes per 100 patient-years in the intensive and conventional treatment groups, respectively). Other adverse events that accompanied intensive therapy included an increased risk for weight gain, secondary in part to the decrease in caloric wasting with decreased glycosuria, and catheter-related infections in patients using insulin pumps. Taken together, none of these adverse events caused significant morbidity or mortality. There were no patient deaths or macrovascular events ascribed to hypoglycemia. Moreover, the increased frequency of hypoglycemia had no adverse effects on neurocognitive function as judged by repeated testing in both treatment groups (86). Finally, despite the demands of intensive therapy, quality of life, measured yearly by self-report (85), did not differ between the two treatment groups.

Imprinting and Metabolic Memory. The long-term follow-up of the DCCT cohort has revealed a persistent effect of the original DCCT intervention even after the differences in HbA_{1c} levels between the two treatment groups have dissipated (96,97). At the end of the DCCT, the subjects in the conventional treatment group were offered instructions in intensive therapy, and all subjects were returned to their own care providers for therapy. HbA_{1c} levels in the original conventional treatment group decreased by approximately 1%, and HbA_{1c} in the original intensive treatment group drifted up so that over the next 5 to 7 years the HbA_{1c} levels were nearly identical. Despite the similar HbA_{1c} levels, the differences in rates of retinopathy and nephropathy continued to expand between the two treatment groups when analyzed on the basis of the original intention-to-treat assignments. This phenomenon has been called "imprinting" and reflects a metabolic memory effect with regard to complications. Whether the apparent long-lasting effects of glycemia are mediated by glycation of proteins that turn over very slowly, or by some other mechanism, is unknown.

Type 2 Diabetes

Until recently, the only clinical trial that examined the impact of glycemic control on long-term complications in type 2 diabetes was the University Group Diabetes Program (UGDP)(102). This

multicenter trial compared the effects of five different treatment modalities (diet, diet plus tolbutamide, diet plus phenformin, diet plus standard insulin dose, and diet plus variable-dose insulin) on long-term outcome in patients with newly diagnosed type 2 diabetes. Although the variable-dose insulin regimen maintained mean fasting levels of blood glucose approximately 20% lower than baseline levels, compared with no significant changes from baseline glucose values over time with the other treatment regimens, no significant differences between any of the groups were noted in the degree of retinopathy as measured by fundus photography. The Kumamoto study in Japanese patients with type 2 diabetes, a controlled clinical trial patterned after the DCCT, was the first study to demonstrate convincingly a salutary effect of intensive therapy in type 2 diabetes (103). Although the intensively treated patients had a decrease in retinopathy and nephropathy that paralleled the DCCT results, the Kumamoto study was not considered to be a definitive proof of the glucose hypothesis in type 2 diabetes, in part owing to the clear differences between the Japanese patients with type 2 diabetes and patients with type 2 diabetes in non-Asian societies. The Japanese patients were all relatively thin with small insulin requirements (~0.2 U/kg compared with >0.75 U/kg in the United States).

UNITED KINGDOM PROSPECTIVE DIABETES STUDY

Rationale, Aims, and Design. The United Kingdom Prospective Diabetes Study (UKPDS), which ended in 1997, provided more definitive answers. Originally planned and initiated in 1977 to address the confusion left by the UGDP results, the UKPDS was designed to answer two questions. First, is an "intensive strategy" aimed at achieving fasting glucose levels less than 6 mmol (108 mg/dL) superior to conventional therapy with diet in preventing the complications of diabetes in patients with relatively recent-onset type 2 diabetes (Table 48.4)? Second, are any therapies particularly advantageous with regard to preventing or delaying diabetic complications? The outcomes were aggregated into diabetes-specific complications (combining retinopathy, nephropathy, cataracts, and cardiovascular outcomes), all-cause mortality, and diabetes-related mortality. The study design included stepwise addition of therapies in the conventional and intensive treatment groups if glucose goals were not met. In addition, the intensive therapies were numerous, including three types of sulfonylureas and insulin. The obese subset of patients were also randomly assigned to metformin (104). The results of the UKPDS revealed that metabolic control in type 2 diabetes worsened over time, probably owing to waning β -cell function (105) and requiring the addition of alternative therapies to the originally assigned therapy (Fig. 48.7) (106). Thus, over the course of the study, the majority of subjects

(From Turner RC, Cull CA, Frighi V, et al. Glycemic control with diet, sulfonylurea, metformin, or insulin I patients with type 2 diabetes mellitus: progressive requirement for multiple therapies (UKPDS). *JAMA* 1999;281:2005–2112, with permission. Copyrighted 1999, American Medical Association.)

receiving conventional treatment had one or more of the intensive therapies added and a substantial fraction (often $\geq 20\%$) of the subjects receiving intensive treatment had the alternative intensive therapies added to or substituted for their originally assigned intensive therapy. This design feature, intended to keep glycemia as low as possible in the intensive treatment group, severely undercut the ability to compare the specific intensive therapy modalities (107). Finally, other randomized interventions (early addition of metformin to sulfonylurea therapy, use of acarbose, and intensive vs. conventional hypertension treatment) made the UKPDS protocol byzantine in its complexity.

UKPDS Results. The UKPDS results, analyzed by intention to treat, revealed a benefit of intensive therapy, which resulted in a 1% absolute reduction of HbA_{1c} (11% relative reduction), on the aggregate diabetes outcomes, decreasing the risk by 12% (Table 48.5). This benefit was predicated to a great extent on a beneficial effect on retinopathy and cataracts. There was no significant benefit with regard to cardiovascular disease. The results with metformin were analyzed separately. [The validity of this analysis strategy has been called into question (107)]. Metformin

therapy resulted in less weight gain and less hypoglycemia than other intensive therapies. In addition, aggregate diabetes mortality, but not diabetes-related outcomes, were significantly reduced by metformin (104). Early addition of metformin to sulfonylurea, however, resulted in a large and statistically significant increase in cardiovascular mortality. The UKPDS complex design, numerous crossovers, and controversial analytic strategy left many questions. However, the fundamental observation, when combined with the results of the Kumamoto study, that intensive diabetes management improves outcome, specifically microvascular outcomes, is unquestionable.

MACROVASCULAR DISEASE

The multifactorial etiology of cardiovascular disease (CVD) makes it unlikely that the association established between levels of glycemia and complications specific to diabetes, such as retinopathy, will also pertain to CVD. Almost all studies have been in populations with type 2 diabetes or impaired glucose

TABLE 48.5. Major Findings of the United Kingdom Prospective Diabetes Study (UKPDS) Number of the United Kingdom Prospective Diabetes Study (UKPDS)			
Nonobese + obese	Obese only		
Intensive therapy reduced ^a	Metformin reduced ^a		
Aggregate diabetes outcomes by 12% ($p = 0.029$)	Aggregate diabetes outcomes by 32% ($p = 0.003$)		
Laser therapy by 29% ($p = 0.003$)	Diabetes-related death by 42% (p = 0.02)		
Cataract extraction by 24% ($p = 0.046$)	All-cause death by $36\% (p = 0.011)$		
Sudden death by 46% (p = 0.047)

Fatal myocardial infarction—6% ($p = 0.63$)			
Nonfatal myocardial infarction—21% ($p = 0.057$)			

tolerance (IGT). Although the presence of diabetes (or IGT) increases the prevalence of CVD (108-111), an association between the level of glycemia and the occurrence of CVD had not been easy to demonstrate (112). Recently, however, studies using more accurate measures of long-term glycemia have found a correlation between glycemic levels and prevalence of CVD (11,114). In the Framingham study, level of HbA_{1c} correlated with prevalence of CVD, but only in women (113). Whether diabetes affects CVD directly or through the established risk factors that accompany it, such as hypertension, dyslipidemia, and obesity (in type 2 diabetes), or through other potential risk factors, such as hyperinsulinemia, inflammation, or hemorheologic abnormalities, is not known. The UGDP trial did not demonstrate any impact of glucose control on CVD outcome (108). The UKPDS showed a beneficial impact of metformin therapy, but only when the obese metformin group was compared with the obese controls. The long-term follow-up of the DCCT has demonstrated a beneficial long-term effect of intensive therapy on atherosclerosis, as measured by carotid ultrasonography (98). Studies such as the Diabetes Prevention Program are examining the effects of glycemic control on macrovascular disease and atherosclerosis in the prediabetic population with IGT (115).

CONCLUSIONS: TREATMENT RECOMMENDATIONS

The DCCT Research Group, the UKPDS Research Group, the American Diabetes Association, and other groups have concluded that the significant and consistent effects of intensive therapy in reducing the risk of development and progression of long-term complications of diabetes outweigh its costs, the considerable effort to implement it, and the increased risk for hypoglycemia. Intensive therapy has been endorsed as the treatment of choice for most patients with type 1 or type 2 diabetes. This conclusion is further supported on the basis of the projected economic impact of intensive therapy. Although the annual cost of intensive therapy exceeds the cost of conventional therapy and must be incurred for at least 3 years in type 1 diabetes before a benefit is seen, the long-term benefits of intensive therapy (reducing loss of vision and the need for laser therapy, reducing the incidence of end-stage renal disease and the need for dialysis and transplantation, reducing the number of amputations, and reducing the costs associated with all these problems) make intensive therapy an economically viable therapy (91). The long-term follow-up in EDIC, demonstrating further benefits of intensive therapy even 8 years after the end of the DCCT, supports this conclusion.

Realistically, not all patients with diabetes are able to implement intensive therapy; however, the goal for all patients should be to lower blood glucose levels to as close to the normal range as safety and lifestyle allow. Lower HbA_{1c} levels should translate into an appreciably lower risk for complications (Fig. 48.6).

CHAPTER 49 Mechanisms of Diabetic Microvascular Complications

Christian Rask-Madsen, Zhiheng He, and George L. King

CHANGES IN VASCULAR MORPHOLOGY AND FUNCTION 824

General Vascular Changes 824 Tissue-Specific Vascular Changes 824

MECHANISMS FOR MICROVASCULAR PATHOLOGY IN DIABETES 825

Local Changes Caused by Systemic Factors 826

Intracellular Consequences of Altered Metabolism 827

Alterations in Intracellular Signal Transduction 828

Abnormal Regulation of Extracellular Signaling Molecules 829

CONCLUSION 832

Patients receiving modern care for diabetes have a dramatically lower risk for developing microvascular complications than they did a few decades ago. In particular, the risk for developing renal disease necessitating dialysis has decreased severalfold. However, diabetes is still the most common cause of blindness and end-stage renal disease and a major reason for peripheral neuropathy. Therefore, there is compelling reason to increase our knowledge about the cellular and molecular mechanisms of these complications so that rational strategies for prevention and treatment can be designed.

Microvascular complications in diabetes have traditionally included retinopathy, nephropathy, and neuropathy. In each of these complications, pathologic changes and cellular dysfunction are seen in nonvascular tissues at early stages and cannot be explained by circulatory changes alone. Thus, in retinopathy and neuropathy, dysfunction of neurons develops in parallel with microvascular pathology. Therefore, these complications cannot be explained entirely as being secondary to microvascular pathology. Nevertheless, this chapter will focus on vascular mechanisms for the development of these complications.

Cardiovascular disease is the major reason for morbidity and mortality among patients with diabetes. Many aspects of heart disease in patients with diabetes are secondary to atherosclerosis, i.e., macrovascular disease. But the mechanisms of some of the myocardial pathologies in diabetes have obvious similarities to mechanisms of complications in other organs, e.g, in the kidney. Therefore, in this chapter we have chosen to describe changes in regulation of vascularization and extracellular matrix in the heart.

Many of the disease mechanisms described below have been demonstrated in several tissues and cell types in diabetes; e.g., oxidative stress, glycation, and activation of protein kinase C

(PKC) have been described in all tissues affected by microvascular complications. Therefore, the later sections of this chapter discuss such mechanisms without systematically referring to where they operate. However, one of the biggest challenges in studying these mechanisms is to understand why certain tissues or cell types are preferentially affected by diabetes. For example, even though oxidative stress or activation of PKC occurs in both capillary endothelial cells and pericytes in the retina, there is a pronounced loss of pericytes rather than endothelial cells. Treatment with new drugs, especially those administered systemically, will also have to consider such tissue differences. For example, inhibitors of vascular endothelial growth factor (VEGF) have been proposed as therapy for proliferative retinopathy, but even though increased retinal expression of VEGF may be partly responsible for this complication, decreased expression of VEGF in the heart may be responsible for decreased vascularization of the ischemic myocardium in diabetes (1). Likewise, speculations that inhibition of renal expression of transforming growth factor- β (TGF- β) may prevent renal disease (2,3) should consider the possible importance of TGF- β for the development of collateral vessels to ischemic tissue (4).

The studies discussed below have used many methodologies. When interpreting results from studies in animals or *in vitro*, one should keep certain issues in mind. Animal models of nondiabetic insulin resistance, type 1 diabetes, and type 2 diabetes exist. They may be different from human diabetes for a variety of reasons: species differences; the introduction of hyperglycemia by a diet that is not typical for either the animal or humans (i.e., rich in galactose); induction of diabetes with a toxin given systemically (i.e., streptozotocin); the existence of a monogenic defect (mutations in the gene for leptin or the leptin receptor).

824 JOSLIN'S DIABETES MELLITUS

Cell-culture studies have limitations for explaining human disease. However, major advances in the understanding of diabetic complications have derived from the study of differentiated cells that preserve many of their characteristics *in vitro*.

CHANGES IN VASCULAR MORPHOLOGY AND FUNCTION

General Vascular Changes

GROWTH AND APOPTOSIS OF VASCULAR CELLS

In proliferative retinopathy, growth of endothelial cells is evident, whereas in diabetic nephropathy or in the microvessels of the diabetic heart, loss of endothelial cells is observed. On the other hand, the contractile cells of the retinal microvasculature, the retinal capillary pericytes, are lost in diabetic retinopathy, but proliferation of vascular smooth muscle cells (VSMCs) is increased in atherosclerotic lesions.

In retinal capillaries from patients with diabetes, apoptotic pathways are preferentially activated in pericytes rather than in endothelial cells (5,6). Apoptosis in pericytes can be induced by feeding with galactose (7) and by both high glucose concentrations (6) and advanced glycation end-products (AGEs) (8).

In heart biopsy specimens from patients with diabetes, apoptosis of endothelial cells and cardiomyocytes is increased severalfold (9). In endothelial cells cultured in high glucose concentrations, the signaling pathways mediating apoptosis involve hydrogen peroxide (10), nuclear factor- κ B (NF- κ B) (6), and c-jun N-terminal kinase 1 (JNK1) (10).

BASEMENT MEMBRANE AND EXTRACELLULAR MATRIX

A classic morphologic finding in diabetic microangiopathy is the thickening of basement membranes (11). This phenomenon is generalized and affects both vascular and nonvascular tissues. Basement membranes maintain tissue architecture, modify cellular functions such as proliferation, and provide a filtration barrier. Basement membranes separate cells from the interstitial space or from cells of a different type. In the glomerulus of the kidney, the basement membrane is situated between endothelial cells of the capillaries and epithelial cells of the Bowman capsule; in the retina, the basement membrane separates capillary endothelial cells and pericytes. Basement-membrane proteins are synthesized by several cell types. Thus, renal mesangial matrix proteins are synthesized both by mesangial cells and by endothelial cells. The morphology of the capillary basement membrane varies in different tissues, and its thickness often correlates with the intracapillary pressure. The chemical components of the basement membrane include collagens (mainly type IV), chondroitin, heparan sulfate proteoglycans, and various glycoproteins such as laminin (12-14).

The capillary basement membrane in the retina thickens with age (15) but at an accelerated rate in patients with diabetes and in animal models of diabetes (16). In the retinas of diabetic rats, capillary thickening is more prominent in the inner capillary bed (nerve and ganglion layer) than in the inner and outer plexiform layers (17). In the kidney, increased extracellular matrix manifests as thickening of the glomerular basement membrane, expansion of the mesangium, and tubolointerstitial fibrosis (14). The glomerular basement membrane and the mesangium have been studied most thoroughly. In these tissue compartments, both increased synthesis of extracellular matrix proteins and decreased degradation of matrix protein have been demonstrated. Some extracellular matrix are expressed in diabetes. However, most extracellular proteins overexpressed in diabetes are components of the normal mesangium and basement membrane. Collagen type IV and fibronectin are among the proteins most consistently demonstrated to be overexpressed in diabetes (14).

Heparan sulfate proteoglycans constitute a charge barrier to protein diffusion across the glomerular basement membrane. The majority of heparan sulfate anionic sites are in the lamina rara externa of the basement membrane (18). There is a decrease in the heparan sulfate content of the glomerular basement membrane relative to the collagen content (19). Furthermore, the number of anionic sites is decreased (18).

Expression of extracellular matrix protein is increased in diabetes. In the glomeruli, important mediators of this increased production include, among others, angiotensin II (ATII), TGF-β, and connective tissue growth factor (CTGF) (14). The roles of these mediators are discussed below. In addition, degradation of extracellular matrix protein, catalyzed by matrix metalloproteinase (MMP), is decreased. The expression of mRNA of several MMPs is reduced in patients with diabetes and in animal models of diabetes (14). Furthermore, this effect is recapitulated in cell-culture models of a diabetic milieu. For example, expression of MMP2 is decreased in mesangial cells stimulated with ATII (20). The activity of MMP is reduced by several mechanisms. MMP proenzymes are cleaved by plasmin-or in the case of MMP2, by membrane-type MMP1—to yield the active form of the enzyme. The activity of both plasmin and membrane-type MMP1 is reduced in diabetes (21). Furthermore, tissue inhibitor of MMP1 is increased in diabetes (22).

ENDOTHELIAL FUNCTION

Apart from being regulated by the autonomic nervous system and circulating hormones, blood flow is controlled by substances released from the endothelium, acting in a paracrine manner. In both types of diabetes, endothelium-dependent vasodilation is decreased. Endothelial dysfunction can be seen after relatively short periods of elevated concentrations of glucose. Thus, after 6 hours of a high glucose concentration, endothelium-dependent vasorelaxation is decreased in rabbit aorta *ex vivo* (23) or in the forearm of healthy humans (24).

Nitric oxide (NO) is an important mediator of endotheliumdependent vasodilation, but relatively few studies have quantified how much NO contributes to blood flow during basal or stimulated conditions in tissues prone to microvascular complications. When choroidal blood flow in the cat is stimulated by facial nerve stimulation, the increase in blood flow is completely dependent on NO (25). In humans, retinal blood flow at basal conditions and stimulated by flicker is dependent in part on NO (26). Loss of NO-mediated blood flow may underlie the decrease in retinal blood flow observed in diabetes (27). Nerve blood flow in experimental diabetes is associated with a decreased contribution of NO to basal vascular tone (28).

On the other hand, vascular leakage in early streptozotocininduced diabetes appears dependent on increased production of NO (29). This may be caused by increased expression of endothelial nitric oxide synthase (eNOS) (30–32) or induction of inducible NOS (iNOS) (33). Paradoxically, increased expression of eNOS or iNOS could be associated with decreased bioavailability of NO through the reaction of NO with superoxide, resulting in retinal damage through protein nitration (29,33).

Tissue-Specific Vascular Changes

VASCULAR CHANGES IN THE RETINA

Diabetic retinopathy is the leading cause of blindness in industrialized nations (34). Pathologic changes in retinal microvessel structure and function have been considered the major cause of diabetic retinopathy (35,36). Structural changes include thickening of the capillary basement membrane, increased vessel permeability, loss of retinal pericytes, and formation of capillary microaneurysms. These structural changes are accompanied by decreased retinal blood flow, capillary occlusion, angiogenesis, hemorrhage, fibrotic tissue formation, and tractional retinal detachment. Some of these events, or all of them in combination, can ultimately result in impairment or complete loss of vision (35).

In physiologic states, retinal capillaries consist of contractile pericytes and endothelial cells at an approximate ratio of 1:1, which is lower than the ratio of contractile cells relative to endothelial cells in other vascular beds in the systemic circulation (37,38). This ratio drops to 1:10 in moderate-to-severe stages of nonproliferative retinopathy (39,40). Areas of pericyte loss are generally associated with microaneurysms, where endothelial cells are not supported by pericytes. It has been proposed that there are extensive interactions between pericytes and capillary endothelial cells and that the presence of pericytes is necessary for stabilization of endothelial cells and the maintenance of integrity of the vasculature (41-43). Loss of pericytes causes the formation of microaneurysms and acellular capillaries, further contributing to increased permeability, decreased retinal blood flow, and leukostasis (41-43). The role of pericytes in the integrity of retinal capillaries has been confirmed by studies of mice null for the platelet-derived growth factor- β (PDGF- β) receptor. These animals show loss of pericytes, the formation of microaneurysms, and retinal hemorrhage similar to the changes seen in diabetic retinopathy (44).

Retinal hypoxia increases the expression of a host of angiogenic factors, including, among others, VEGF and placenta growth factor (PIGF), that in turn promote neovascularization. The mechanisms for the altered expression of these growth factors and their molecular effects are discussed in later sections of this chapter.

THE RENAL VASCULATURE IN DIABETES

Acute glomerular hypertrophy occurs early in the course of diabetes (45,46), but with the progressive increase in the mesangial matrix, there is a loss in capillary surface area and thus a decrease in filtration area. Changes in the composition of the basement membrane result in altered permeability and accumulation of glomerular extracellular matrix, eventually leading to glomerular occlusion, fibrosis, and deceased filtering capacity.

The glomerular basement membrane is continuous with the tubular basement membrane via the Bowman capsule. Thickening of basement membrane and expansion of the mesangium are the dominant morphologic features in early diabetic renal disease. Thickening of the glomerular basement membrane was first described by Kimmelstiel and Wilson (47). The hemodynamic factors implicated in the pathogenesis of diabetic nephropathy include increased systemic and intraglomerular pressure. Permeability of the capillaries is altered such that the excretion of proteins with molecular masses of 44 to 150 kDa is increased. Thus, albumin excretion is increased early in diabetes and, like an elevated glomerular filtration rate, can be normalized by intensive insulin treatment (48) or islet cell transplantation (49). This initial alteration in permeability seems to be due primarily to increased filtration pressures across the glomerulus, but altered electricalcharge selectivity of the permeability barrier-changes that permit an increase in the leakage of plasma proteins-may also be involved (50).

Changes in glomerular hemodynamics are mediated in part by circulating or paracrine factors such as ATII and endothelin-1 (ET-1) (51). Similarly, several mediators lead to increased production of extracellular matrix, most notably TGF- β and CTGF. As in changes observed in diabetic retinopathy, increased vascular permeability is also an early manifestation of diabetic nephropathy, with VEGF playing an important role. Signaling pathways operating in diabetic nephropathy are discussed further in subsequent sections.

VASCULAR CHANGES IN NERVES

Diabetic neuropathy is common in diabetic patients, with a prevalence of more than 50% (52). The pathogenesis is multifactorial and considered to be both hyperglycemia-induced pathologic changes intrinsic to neurons (53) and ischemia-induced neuronal damage by decreased neurovascular blood flow (54). Because of the vascular elements, diabetic neuropathy is considered a microvascular complication. Histologically, increases in endothelial cell area and luminar narrowing of capillaries are present in the endoneurium of patients with diabetes (55). Supporting a role for decreased neural blood flow was the finding that, in rats with streptozotocin-induced diabetes, in vivo gene transfer of VEGF restored blood flow in the neurotrophic blood vessels and improved nerve function (56). A role for PKC activation in the microvascular changes in diabetic nerve was demonstrated in the same animal model, in which an inhibitor of PKCB prevented diabetes-induced impairment of nerve blood flow (57,58).

MICROVASCULAR CHANGES IN THE HEART

Patients with diabetes have a high prevalence of chronic heart failure (59) and a high incidence of heart failure and re-infarction after acute myocardial infarction (60); these cannot be explained by more extensive coronary atherosclerosis, a higher prevalence of hypertension, or larger infarcts in this population than in people without diabetes. The causes are likely diastolic dysfunction (61) and insufficient neovascularization during myocardial ischemia (62). Myocardial disease is not a microvascular disease in the traditional sense, yet there are conspicuous similarities in the diabetic heart and traditional microvascular complications, on both pathoanatomic and molecular levels, especially with regard to the production of extracellular matrix as in the diabetic kidney.

An autopsy study showed that the capillary density in nondiabetic patients with a previous myocardial infarction was higher than in normal hearts, but capillary density in diabetic patients with a previous myocardial infarction was lower than in normal hearts (63). Similar observations have been made in animal models of diabetes (64,65), and increased capillary permeability has been reported (66). Cardiac angiogenesis and collateral formation are governed by the balanced action of a wide spectrum of proangiogenic and anti-angiogenic factors, including VEGF, fibroblast growth factor (FGF), PDGF, and angiopoietins (67). The altered expression and action of these growth factors is discussed in sections below. Regardless of the individual contribution of these factors to insufficient circulation in diabetic heart disease, clinical trials aimed at treating myocardial ischemia with transfer of certain of these growth factor genes show promise, albeit they have not yet yielded definite results (67).

Diffuse cardiac fibrosis is observed in diabetes (68) and may contribute to diastolic dysfunction. Similar to the pathology of the diabetic kidney, the amount of extracellular matrix is increased in the diabetic heart (69,70).

MECHANISMS FOR MICROVASCULAR PATHOLOGY IN DIABETES

The partial loss of insulin effects—due to dysfunction or destruction of β -cells or to peripheral insulin resistance—and the

826 JOSLIN'S DIABETES MELLITUS

ensuing hyperglycemia and other disturbances of metabolism have profound consequences on cellular function, extracellular matrix, organ function, and whole-body physiology. The discussion below starts with a description of systemic factors affecting the tissues prone to microvascular complications. On a cellular level, striking similarities exist between many mechanisms thought to be responsible for microvascular complications. Therefore, most of the discussion will be organized according to metabolic pathways or intracellular or extracellular signaling pathways altered by diabetes rather than being divided into sections concerned with the changes characteristic for tissues afflicted by microvascular complications.

Local Changes Caused by Systemic Factors

HYPERTENSION

Microvascular dysfunction and pathology may be initiated by hypertension. For example, the glomerular hyperfiltration observed in diabetes may be caused in part by systemic hypertension. Mechanisms have been described that link mechanical forces to vascular dysfunction, including pressure (71), stretch (72), and shear stress (73). Indirect proof that hypertension in itself may be a cause of microvascular complications is given by clinical trials of antihypertensive drugs that prevent diabetic nephropathy regardless of whether they are diuretics, calciumchannel blockers, or angiotensin-converting enzyme (ACE) inhibitors.

However, hypertension per se is not likely sufficient for the development of microvascular complications. In rats with streptozotocin-induced diabetes or in rats heterozygous for a renin transgene, endothelin receptor and angiotensin receptor 1 (AT1) antagonists both normalized hypertension and partly attenuated declining glomerular filtration rate, but only the AT1 antagonist affected renal pathology as well as expression of TGF- β and type IV collagen messenger RNA (mRNA) (74).

SYMPATHETIC NERVOUS SYSTEM

Overactivity of the sympathetic nervous system can be a participating factor in the development of hypertension in both types of diabetes (75). Furthermore, insulin is thought to have vasoconstrictor effects through activation of the sympathetic nervous system, but insulin-stimulated sympathetic activation is altered in states of insulin resistance (76). During late stages of diabetes, sympathetic denervation may alter vascular responses (76). How sympathetic overactivity, insulin resistance, and autonomic dysfunction quantitatively contribute to integrated vascular function in diabetes is unknown.

ADVANCED GLYCATION END-PRODUCTS

Modification of extracellular and intracellular proteins by sugars can result in the formation of AGEs, which is virtually irreversible (77). This reaction can take place nonenzymatically between glucose and protein through the Amadori product (1-amino-1-deoxyfructose adducts to lysine). However, much faster reactions occur between proteins and intracellularly formed dicarbonyls, including 3-deoxyglucosone, glyoxal, and methylglyoxal. These processes are accelerated by reactive oxygen species (78), perhaps by inhibition of glyceraldehydephosphate dehydrogenase (GAPDH), leading to an increase in the formation of triose phosphate, in turn increasing the production of methylglyoxal (79). The most prevalent AGE is carboxymethyl-lysine (80,81). Further nonenzymatic modification results in cross-linking of proteins. Because of their long turnover rate, structural extracellular proteins such as collagen are particularly susceptible to AGE modification. AGEs have

been demonstrated in numerous tissues in both types of diabetes, such as the retina (82) and the glomeruli (83).

AGEs may interfere with vascular signaling by facilitating breakdown of NO (84). Furthermore, AGEs may impair the function of intracellular proteins, as in the case of reduced activity of basic fibroblastic growth factor in endothelial cells (85). AGEs also alter the properties of the extracellular matrix. Thus, glycosylation of collagen type IV renders it resistant to degradation by MMP (86). AGE cross-linking of type I collagen expands the packing of collagen molecules (87). Glycosylation of a carboxy-terminal domain of type IV collagen interferes with the normal assembly of collagen networks (88). AGE formation in laminin inhibits assembly of laminin polymers (89) and decreases binding to type IV collagen and heparan sulfate (79). Furthermore, AGE modification alters matrix-cell interactions. For example, modification of type IV collagen decreases endothelial cell adhesion (90). Last, AGE also may act through binding to receptors, the most well characterized being the receptor of AGE (RAGE) (81). It is interesting that stimulation of RAGE can lead to transdifferentiation of renal tubular epithelial cells to myofibroblasts (91), which may be responsible for accumulation of extracellular matrix.

The ability of RAGE signaling to cause diabetic complications was demonstrated directly in a study in which transgenic mice overexpressing iNOS targeted to insulin-producing cells, providing a model for type 1 diabetes, were cross-bred with transgenic mice overexpressing RAGE. Development of glomerular lesions was accelerated in these double-transgenic mice (92) and could be prevented by an AGE inhibitor (92).

AGE formation has effects on numerous vascular signaling molecules. Thus, they reduce the expression of eNOS (93) and increase the expression of ET-1 (94) in endothelial-cell culture. AGEs, through increased production of reactive oxygen species (ROS), activate NF- κ B (95), which is responsible for induction of several growth factors. AGEs also increase expression of TGF- β in mesenteric vessels (96) and increase retinal VEGF expression (97). In endothelial-cell culture, AGEs, via RAGE, decrease production of prostacyclin, induce expression of plasminogen activator inhibitor-1 (PAI-1) (98), and induce expression of adhesion molecules in endothelium (99). A soluble receptor for RAGE inhibits barrier function in endothelial cells and vascular permeability in diabetic rats (100).

Many approaches to the pharmacologic inhibition of AGE formation are being attempted. Aminoguanidine, an inhibitor of AGE formation, has shown an effect on preventing nephropathy (101) and retinopathy (102) in animal models of diabetes. Newer agents are being developed, including 2,3-diaminophenazine, an inhibitor of AGE formation (103); ALT-711, which breaks AGE cross-links (104); pyridoxamine; and OBP-9195 (105). It is interesting that treatment with the ACE inhibitor ramipril decreased renal AGE accumulation to the same extent as did an inhibitor of AGE formation, aminoguanidine, perhaps by preventing activation of NAD(P)H oxidase [reduced form of nicotinamide adenine dinucleotide (phosphate)] (106). Results are not yet available from clinical trials with AGE inhibitors for the treatment of diabetic microvascular complications.

VASCULAR INFLAMMATION

Typical elements of inflammatory processes are evident in the vasculature in diabetes (107). Increased expression of vascular adhesion molecules leading to recruitment of leukocytes to the vascular wall is regarded as a pivotal event in early inflammation. Blocking intracellular adhesion molecule-1 (ICAM-1) prevents leukostasis and retinal vascular leakage. The proinflammatory cytokine tumor necrosis factor- α (TNF- α) is induced in rats with streptozotocin-induced diabetes (31). Treatment of such animals with high-dose aspirin; the cyclooxygenase-2 inhibitor meloxicam; or eternacept, which blocks TNF- α actions by competing with its tissue receptors, prevents increased ICAM-1 expression, leukostasis, capillary leakage, and upregulation of eNOS (31). Inflammation may therefore play a role in the development of microvascular complications of diabetes, but current information on this subject is sparse.

Intracellular Consequences of Altered Metabolism

INCREASED INTRACELLULAR GLUCOSE CONCENTRATIONS Interventional trials of hypoglycemic drug therapy have unequivocally linked hyperglycemia with the development and progression of microvascular complications (108–110). Lowering blood glucose levels has been less successful in preventing atherothrombotic complications, suggesting that factors other than hyperglycemia may be more important for the development of macrovascular complications. The perception of hyperglycemia as the primary cause for microvascular complications explains why the vast majority of studies of the mechanisms responsible have focused on the effects of increased glucose concentrations, even though multiple other metabolic alterations exist in diabetes.

Many of the mechanisms on the cellular level described below involve alteration of cellular homeostasis caused by increased cellular glucose uptake and increased intracellular glucose concentration. This is prevented in part in tissues where insulin resistance decreases cellular glucose uptake. Insulin resistance can thus be viewed as a compensatory mechanism to avoid excessive intracellular glucose concentrations; this has prompted the speculation that tissues that do not have this capability are those prone to diabetic complications (111). Aortic endothelial and smooth muscle cells express GLUT1 (a glucose transport protein not responsive to insulin) but do not express GLUT2 to GLUT5 (112). VSMC can downregulate GLUT1 in response to increasing extracellular glucose concentrations, but endothelial cells cannot (112), thus making endothelial cells more susceptible to the effects of hyperglycemia. Similarly, overexpression of GLUT1, which is not regulated by insulin, in mesangial cells cultured in normal glucose concentrations increased collagen metabolism and accumulation (113).

Characterization of the regulation of glucose transporters in different tissues prone to microvascular complications is not complete, and the dogma given above may not be valid in all tissues. For example, GLUT1, the primary glucose transporter in the retina, is downregulated in diabetes (114). Likewise, insulin stimulates glucose uptake and glycogen synthesis in retinal capillary endothelial cells, but—as expected from the expression of GLUT isoforms—not in aortic endothelial cells (115).

INTRACELLULAR REDOX STATUS AND OXIDATIVE STRESS

Oxidative stress, i.e., an imbalance between ROS and cellular antioxidant defense systems (116,117), may result from alterations of glucose metabolism or be secondary to activation or dysregulation of several enzymes not directly involved in glucose metabolism. In population-based cohorts, vascular oxidative stress, measured by plasma markers, is associated with diabetes, even after adjustments are made for several covariables (118). Furthermore, patients with diabetes have a depletion of the reduced form of intracellular glutathione (119), but an increase in plasma extracellular superoxide dismutase, which is associated with severity of retinopathy and nephropathy (120). Oxidative stress has been demonstrated in organs affected by complications of diabetes; thus, in the vitreous body of the eye of patients with diabetes, lower levels of oxidative metabolites are associated with better blood glucose control (121). On the other hand, intervention against oxidative stress has been shown to prevent organ damage in animal models. For example, transgenic mice overexpressing superoxide dismutase are protected from renal complications of streptozotocin-induced diabetes (122), and long-term treatment of diabetic rodents with antioxidants has had beneficial effects on the development of complications in the retina (123), the kidney (124), and the peripheral nerve (125,126).

In patients with diabetes, smaller trials have shown that dietary supplementation with vitamin E lowers the albumin excretion rate (127,128) and creatinine clearance (128), increases retinal blood flow (128), and improves nerve conduction (129). However, in a substudy of HOPE (Heart Outcomes Prevention Evaluation), currently the largest completed clinical trial of antioxidant therapy, vitamin E supplementation did not decrease the need for retinal laser therapy or improve the urine albumin-creatinine ratio (130).

Oxidative stress may cause cellular dysfunction by promoting formation of AGEs, by inducing DNA strand breaks and activating poly(ADP-ribose) polymerase (PARP) (131,132), by causing dysfunction of eNOS, and by activating p38 and other stress-activated pathways leading to apoptosis. These and other mechanisms are discussed below.

Polyol Pathway. Increased cellular glucose uptake increases the flux of glucose through the polyol pathway (also known as the sorbitol pathway), which consumes NADPH by the aldose reductase reaction and reduces NAD+ (the oxidized form of nicotinamide adenine dinucleotide) by the sorbitol reductase reaction (133). Activation of the polyol pathway not only may result from increased availability of glucose, the upstream substrate for the pathway, but also may be secondary to inactivation of GAPDH, thus diverting glucose from glycolysis to other pathways of glucose metabolism (132). An overactive polyol pathway will therefore deplete cytosolic NADPH, which is necessary to maintain the primary intracellular antioxidant, glutathione, in its reduced state. Aldose reductase inhibition reduces neuropathy in diabetic dogs (134) and patients with diabetes (135), but although early studies in animal models of diabetes showed promise with regard to an effect on retinopathy or nephropathy, such effects have not been demonstrated in patients with diabetes (134,136).

Pentose Phosphate Pathway. By a different mechanism, increased glucose concentrations may inhibit glucose-6-phosphate dehydrogenase, which catalyzes the first intermediary reaction in the pentose phosphate pathway, the primary source of intracellular NADPH (137–139).

Superoxide Production from Mitochondria. In mitochondria, the citric acid cycle provides NADH and FADH₂ (reduced form of flavin adenine dinucleotide), which can act as electron donors for the electron transport chain, creating a proton gradient over the inner mitochondrial membrane. If intracellular glucose concentrations are increased, yielding excessive reducing equivalents for this process, the proton gradient will be high and inhibit the transfer of electrons from reduced coenzyme Q (ubiquinone) to complex III of the electron transport chain (140). Instead, electrons will be transferred to molecular oxygen, producing superoxide.

Vascular NAD(P)H Oxidase. The most important source of superoxide quantitatively in the vascular wall is thought to be an NAD(P)H oxidase that resembles the phagocytic NADPH oxidase but favors NADH as a substrate (141). This oxidase is expressed in endothelial cells (142) and VSMCs (141). Expression and activity of vascular NAD(P)H oxidase is increased in rat models of type 1 (143) and type 2 (144) diabetes. This enzyme may be activated by an increase in the NADH/NAD⁺ ratio, which in diabetes may be caused by an increased flux through the polyol pathway (see above) or activation of PARP (131). The lactate/pyruvate concentration ratio is an index of cytosolic

NADH/NAD⁺ ratio, as pyruvate reduces NAD⁺ in the lactate dehydrogenase reaction. In endothelial-cell cultures, superoxide production is increased by the addition of lactate and decreased by the addition of pyruvate (145). Apart from regulation by cofactor requirements, vascular NAD(P)H oxidase may be regulated by alterations in signaling pathways. Thus, NAD(P)H oxidase activity may be increased by elevated concentrations of glucose and free fatty acids through PKC activation (146), and its expression may be increased by ET-1 (147).

eNOS Dysfunction. Oxidative stress may inhibit NOmediated endothelial function by degrading NO (148). Alternatively, it may lead to decreased intracellular concentrations of the reduced, active form of BH4, a cofactor for eNOS. The reason for this may be that BH4 either cannot be kept in the reduced form because of decreased NAPDH concentrations (139) or because BH4 is oxidized, preferentially by reaction with peroxynitrite (149). Suboptimal BH4 concentrations lead to "uncoupling" of the oxidase and reductase domain of NO synthase (150), which results in the oxidation of molecular oxygen instead of L-arginine and the synthesis of superoxide instead of NO. Thus, BH4 deficiency may be both cause and effect of vascular oxidative stress (151). Uncoupling of eNOS by peroxynitrate may also be caused by disruption of a zinc-thiolate cluster that stabilizes eNOS as a dimer (152).

In studies of fructose-fed rats, a model of insulin resistance, endothelial BH4 concentrations were reduced and concentrations of oxidized BH4 were increased (153,154). Furthermore, superoxide generation was increased, NO production was decreased, and endothelium-dependent vasorelaxation was impaired. The functional abnormalities were improved by *ex vivo* exposure of vascular tissue to BH4 (153). Oral administration of BH4 increased endothelial BH4 concentrations and improved the functional abnormalities (154). In patients with type 2 diabetes, intrabrachial infusion of BH4 increased forearm endothelium-dependent vasodilation (155).

Tyrosine Nitration. Superoxide reacts with NO with a very high rate constant. The product is the highly reactive intermediate peroxynitrate, which may react with a host of intracellular molecules. One such target is the tyrosine residues of proteins, a reaction that may result in tyrosine nitration (29). Mg-superoxide dismutase (SOD) seems to be a particularly susceptible target for such modification, which decreases its catalytic activity, thus potentially further aggravating oxidative stress (156). Examples of other enzymes modified in this manner include certain metabolic enzymes (157) and prostacyclin synthase (158).

Other Sources of Oxidative Stress. High glucose concentrations may also lead to oxidative stress through activation of xanthine oxidase (159), through glucose autoxidation (160), after formation of ketone bodies (161), or through lipid peroxidation (116).

Antioxidant Defense. Antioxidant defense may be increased in diabetes as a compensatory mechanism to counter the production of ROS, but this mobilization of defense may be inadequate. Thus, in endothelial-cell cultures, high glucose concentrations induce the expression of CuZn-SOD, catalase, and glutathione peroxidase (162), and in patients with diabetes, the plasma concentration of extracellular SOD is increased (120). Accordingly, transgenic mice overexpressing CuZn-SOD are protected from glomerular injury of CuZn-SOD after induction of diabetes (122). However, glutathione synthesis in endothelial cells may be inhibited by high glucose concentrations (163).

HEXOSAMINE PATHWAY AND O-LINKED GLYCOSYLATION

Posttranslational modification of nuclear and cytosolic proteins may occur as *O*-linked glycosylation on serine or threonine residues. As with phosphorylation, this may take place as a

dynamic modification that modifies protein function (164). O-linked glycosylation of certain proteins is increased in diabetes because increased cellular uptake of glucose activates the hexosamine pathway, which results in production of uridinediphospho-N-acetyl-glucosamine, a substrate in the glycosylation reaction (111,165). Activation of the hexosamine pathway is not only a result of increased substrate availability; in patients with diabetes, the expression of glutamine:fructose-6-phosphate amidotransferase (GFAT), the rate-limiting enzyme for the hexosamine pathway, is increased in several tissues prone to complications (166). Little is known about the signaling pathways responsible for GFAT induction, but an example is the activation by ATII of the promoter for GFAT via the AT1 receptor (167). Through activation of the hexosamine pathway, diabetes and high glucose concentrations may lead to O-linked glycosylation of eNOS on serine 1177, prohibiting activation of the enzyme by phosphorylation on this residue (168,169). When mesangial cells are grown at high glucose concentrations or with glucosamine or when the cells are transfected with GFAT, O-linked glycosylation of p65 NF-kB is increased; this nuclear factor in turn can activate several gene programs, among them pro-inflammatory genes (170). Activation of the hexosamine pathway in mesangial cells also increases the activity of PAI-1 gene transcription (171); this can be mediated through another nuclear factor, Sp1, which may also be glycosylated by high glucose concentrations, leading to increased expression of PAI-1 (172). In glomerular mesangial cells, this is dependent on activation of PKC β 1 and δ (173). Certain growth factors, including TGF- α , are other gene targets for Sp1 activation (174).

Alterations in Intracellular Signal Transduction

ACTIVATION OF PROTEIN KINASE C

In diabetes, PKC is activated in vascular tissue. At least 12 isoforms of PKC exist, and 9 of them are activated by the phospholipid diacylglycerol (DAG). The first described mechanism of PKC activation involves transient receptor-mediated stimulation of phospholipase C, which hydrolyzes inositol phospholipids of the plasma membrane to yield DAG, which again activates PKC after binding to an amino-terminal domain of the enzyme. In diabetes, however, intracellular DAG can also be increased in vascular tissue through de novo synthesis from glucose (175) via glyceraldehyde 3-phosphate and phosphatidic acid or from nonesterified fatty acids (176,177). In particular, the β 2 isoform of PKC is activated in the retina and renal glomeruli, and treatment with an inhibitor specific for the PKC β 2 isoform partly normalizes retinal blood flow and albuminuria in rats with streptozotocin-induced diabetes (27). Likewise, the same inhibitor decreases mesangial expansion and albuminuria in diabetic db/db mice (178).

Theoretically, PKC may be activated in diabetes independently of DAG synthesis. Thus, *cis*-unsaturated fatty acids may synergistically increase the effect of DAG at basal levels of Ca²⁺ (179,180). Furthermore, superoxide may directly activate PKC by releasing zinc from the zinc finger of the enzyme (181). Whether PKC is activated by such mechanisms in diabetes is unknown. It is interesting that treatment with vitamin E inhibits PKC by lowering vascular DAG concentrations (182), perhaps by increasing the enzymatic breakdown of DAG to phosphatidic acid (183) or by activating protein phosphatase 2A, which will dephosphorylate PKC (184). This may be independent of the antioxidant effects of the vitamin (185).

Vascular PKC activation causes endothelial dysfunction (186). Impaired endothelium-dependent relaxation during high glucose concentrations is prevented by a PKC inhibitor (186). Oral administration of a selective inhibitor of the PKC β isoform

prevents endothelial dysfunction in rats with streptozotocininduced diabetes (187) or in healthy humans after 6 hours of hyperglycemic clamp (188).

Activation of PKC in the vasculature by high glucose concentrations elicits a host of signaling responses in different vascular cell types. For example, increased concentrations of DAG and PKC activation result in increased expression of ATII in proximal tubular cells (189). Induction of TGF- β in the kidney in diabetic rodents is dependent on PKC. Furthermore, increased permeability of endothelial cells cultured at high glucose concentrations is mediated by PKC (190).

The complexity of the role of PKC in signal transduction pathways important for pathogenesis of microvascular complications is illustrated by the fact that PKC activity may be both upstream and downstream of other mediators such as VEGF and ET-1. Thus, activation of PKC by high glucose may induce VEGF (191) and ET-1 (192), but VEGF-induced proliferation of endothelial cells (193) and retinal neovascularization (194) are dependent on PKC. Furthermore, the induction of ET-1 by PDGF in retinal pericytes (195) and stimulation of mitogen-activated protein kinase (MAPK) by ET-1 in mesangial cells cultured in high concentrations of glucose (196) are dependent on PKC. Other roles for PKC in several signal transduction mechanisms are discussed elsewhere in this chapter.

SELECTIVE VASCULAR INSULIN RESISTANCE

Insulin stimulates skeletal muscle blood flow in healthy, lean individuals (197), but this effect is blunted in people who are obese (197) or who have type 2 diabetes (198). Whether insulinstimulated blood flow is limiting for insulin-stimulated glucose uptake in skeletal muscle is controversial (199), and vascular effects participating in insulin-stimulated glucose uptake may be represented by insulin-stimulated capillary recruitment rather than by insulin-stimulated blood flow (200,201). Retinal and kidney blood flow also is stimulated during systemic hyperinsulinemia (202,203).

Insulin-stimulated vasorelaxation is a direct effect on blood vessels mediated by endothelium-derived NO and is independent of hormones or activation of the autonomic nervous system (204–206). Regardless of the contribution of vasodilation to glucose uptake during insulin stimulation, insulin-stimulated endothelial NO production may be an important mechanism for vascular homeostasis that is absent in insulin resistance.

Insulin increases endothelial NO production by rapid posttranslational mechanisms (207), as well as by induction of eNOS gene expression (208). Both effects are mediated by the 1-phosphatidylinositol 3-kinase (PI3K)–Akt signaling pathway (207,208). However, the MAPK pathway, which mediates the effects of insulin on vascular growth, is intact (209). Thus, a selective insulin resistance to the vascular PI3K-Akt-eNOS signaling pathway exists. Insulin-stimulated insulin receptor substrate (IRS) tyrosine phosphorylation and activation of PI3K and Akt are decreased in the vasculature of Zucker rats (209). But several of these signaling molecules may be affected individually. As an example, O-linked glycosylation affects IRS and p85 (169), as well as eNOS itself (168,169). Inhibition of the PI3K pathway may have significance for a variety of stimuli for endothelial NO production, as shear stress, VEGF, and estrogen are also mediated by the PI3K-Akt pathway (210). The cause of vascular insulin resistance has not been described sufficiently but may involve inhibitory effects of ATII on IRS-1 and PI3K (211) or activation of PKC (208).

The physiologic importance of vascular insulin signaling has been demonstrated in knockout animal models. Mice with deletion of the insulin receptor gene in endothelial cells have decreased expression of eNOS in the aorta and in cultured lung endothelial cells (212). Insulin also induces ET-1, and mice with endothelial insulin receptor knockout have decreased vascular expression of ET-1 (212). Moreover, insulin induces VEGF (213), and mice with knockout of the insulin receptor in endothelial cells have decreased retinal neovascularization in the relative hypoxia model as compared with control mice, paralleled with a decreased induction of eNOS, VEGF, and ET-1 (214).

Insulin increases TGF- β secretion by renal proximal tubular cells (215). The effect of insulin on production of growth factors and profibrotic factors may be mediated by MAPK pathways, and to the extent that this insulin-signaling pathway is normal in diabetes (209), hyperinsulinemia may be a cause of microvas-cular complications.

MITOGEN-ACTIVATED PROTEIN KINASE

Many effects of the diabetic milieu are transduced through the MAPK Erk1/2, p38, and JNK. Inhibition of MAPK, and JNK in particular, is being tested as a treatment for diabetes (216). At high glucose concentrations, JNK is activated in VSMCs (217) and endothelial cells (10), which may lead to apoptosis (10). Under such conditions, activation of p38 MAPK [in VSMCs (217,218)] and Erk1/2 (in mesangial cells [219]) has also been reported.

CELL-CYCLE REGULATION

During cell proliferation, cells have to pass through the G1 phase of the cell cycle and enter the S phase and subsequent phases. The exit from the G1 phase is regulated by heterodimers of cyclins and cyclin-dependent kinases (CDKs), e.g., by phosphorylation of the Rb gene product. This can be modified by CDK inhibitors, among them p21^{Cip1} and p27^{Kip1}. There is evidence that the renal pathology in diabetes includes cellular hypertrophy in the glomerulus because cells are arrested in G1 phase, in which synthesis of structural proteins occurs without subsequent DNA synthesis or cell division (220).

Proof of the relevance of such mechanisms for diabetic complications is given in studies of streptozotocin-induced diabetes that caused glomerular expansion because of cellular hypertrophy in wild-type mice but not in mice with knockout of $p21^{Cip1}$ (221). Increased expression of glomerular fibronectin, as well as glomerular and renal hypertrophy, mesangial expansion, and albuminuria during streptozotocin-induced diabetes, is partly prevented in mice with knockout of $p27^{Kip1}$ (222,223).

Such maintenance of glomerular cells in G1 phase may be caused by sustained partial phosphorylation of Rb protein (224). In contrast, proliferating cells in the retina depend on hyperphosphorylation of Rb protein and exit from the G1 phase. Thus, in retinal endothelial cells, the mitogenic action of VEGF is mediated through phosphorylation of Rb by PKCβ2 (194).

Abnormal Regulation of Extracellular Signaling Molecules

GROWTH FACTORS, CYTOKINES, AND OTHER REGULATORS OF CELL GROWTH

The sections below describe selected growth factors separately, although growth factors often act in concert. Description of the cooperative actions of growth factors has begun only recently. A few examples are summarized in the following. Hypoxia and TGF- β , through the transcription factors hypoxia-inducible factor and Smad3, act synergistically to increase VEGF transcription (225). VEGF and PDGF act synergistically to stimulate angiogenesis when VEGFR-1, activated by PDGF, cross-activates VEGFR-2, in turn activated by VEGF (226). Insulin-like growth factor-1 (IGF-1) signaling through its receptor is necessary for the full effects of VEGF on neovascularization (227), and fibroblast

growth factor (FGF) and PDGF have superadditive effects on neovascularization (228).

Some growth factors not described below appear to lack major individual effects even though their expression may be altered in diabetes. As an example, fibroblast growth factor-2 (FGF2) concentrations are elevated in patients with diabetic proliferative retinopathy (229,230). Even though FGF can act synergistically with or lead to induction of other growth factors (228,231), transgenic mice overexpressing FGF2 or mice with knockout of the FGF2 gene show no difference in ischemia-associated neovascularization (232), thus arguing against an independent role for FGF in retinopathy.

Vascular Endothelial Growth Factor. VEGF initially was described as a factor mediating vascular permeability. It has since been found to be a potent mediator of angiogenesis (233). In diabetic retinopathy, VEGF is a key regulator of neovascularization and increased vascular permeability, which are key factors for loss of vision. In patients with diabetes, the concentration of VEGF is increased in ocular fluids (234), and its expression, which is rarely detected in normal retinas, is increased in retinas of patients with diabetes, particularly in endothelial cells and perivascular regions (235). Furthermore, retinal VEGF receptors are not detected in nondiabetic animals but are strongly expressed in rats with streptozotocin-induced diabetes (236). VEGF receptors are tyrosine kinase receptors and exist as two types, VEGFR-1 and -2 (previously named Flt-1 and KDR [or Flk-1], respectively) (233). Intravitreous injection of chimeric proteins constructed from the extracellular domain of either receptor joined to IgG showed very high efficiency in preventing ischemia-induced retinal neovascularization (237).

Increased expression of VEGF and its receptors also is found in the kidneys of rats with streptozotocin-induced diabetes (238) and patients with diabetes (239). Renal pathoanatomic changes and function in rats with streptozotocin-induced diabetes (240) or in db/db mice (241) are prevented by treatment with antibodies to VEGF.

Other diabetic complications, however, may result from a decreased angiogenic response and may be responsive to therapy with VEGF. This paradox is well recognized (242). In the heart, local actions of VEGF are needed for normal structure and function, as demonstrated by findings in mice with targeted knockout of VEGF in cardiomyocytes. This genetic manipulation results in several cardiac abnormalities, including fewer cardiac microvessels (243). In diabetes, expression of VEGF and its receptors is decreased in the myocardium even though expression is increased in the retina and glomeruli (1). Several clinical trials have shown an effect of intracoronary VEGF gene transfer to patients with ischemic heart disease (244,245). Similarly, gene VEGF transfer by intramuscular injection of plasmids normalizes the decreased number of blood vessels and reduces nerve blood flow and peripheral neuropathy resulting from streptozotocin- and alloxan-induced diabetes (56). Thus, increased VEGF expression mediates some of the pathology in retinopathy and nephropathy, and treatment strategies aimed at antagonizing VEGF in retinopathy are being evaluated. At the same time, a deficient VEGF response may be present in ischemic heart disease and peripheral ischemia of diabetes and in diabetic neuropathy. Therefore, caution must be taken to ensure the overall success of these therapeutic approaches.

Platelet-Derived Growth Factor. The concentration of PDGF in the vitreous is increased in patients with proliferative retinopathy (246). PDGF acts as a growth factor for retinal endothelial cells through a paracrine/autocrine mechanism (247). PDGF expression is increased in pericytes cultured in high glucose concentrations and in the retina of rats with streptozotocin-induced diabetes (195), and high glucose con-

centrations increase the expression of PDGF receptor- β in a variety of vascular cells (248). PDGF may upregulate expression of TGF- β protein synergistically with high glucose concentrations through stabilization of TGF- β mRNA (249).

Even though PDGF is upregulated in diabetes, deletion of the PDGF gene paradoxically leads to a phenotype resembling diabetic retinopathy. Thus, PDGF knockout mouse embryos show pericyte loss and endothelial cell proliferation (44), and mice with a heterozygous deletion of the PDGF gene (250) or deletion of PDGF gene targeted to endothelium (251) show pericyte loss and endothelial cell proliferation. It is therefore possible that PDGF upregulation in the diabetic retina is compensating for a postreceptor defect in PDGF signaling, although this remains to be investigated.

Transforming Growth Factor- β **.** TGF- β , as measured by the Fick principle, is excreted in the kidneys of patients with type 2 diabetes, whereas a net renal extraction is present in the kidneys of healthy people without diabetes (252). Also, among patients with type 2 diabetes, expression of TGF- β mRNA is higher in those with nephropathy (253). In db/db mice, TGF- β shows increased expression in both glomerular and tubular compartments (254).

In mice with streptozotocin-induced diabetes (2) or in db/db mice (3), treatment with neutralizing antibodies to TGF- β prevents glomerular hypertrophy; attenuates increased kidney size (2), mesangial matrix expansion, and increases in plasma creatinine (3); and attenuates induction of TGF- β , type IV collagen, and fibronectin (2,3). In mice with streptozotocin-induced diabetes, treatment with TGF- β antisense oligodeoxynucleotides has the same effects on kidney weight and expression of TGF- β on cellular hypertrophy may be caused in part by upregulation of its receptor (256).

Induction of TGF- β may be caused by accumulation of AGE (96). Downstream TGF- β signaling has been described to some extent; e.g., TGF- β mediates expression of type I collagen through Sp1 and Smad3 (257).

In cell cultures, TGF- β is produced by and is acting in a paracrine/autocrine manner on mesangial cells (258), cortical fibroblasts (259), tubular cells (91), and glomerular endothelial cells (260). But TGF- β can be induced by stimuli produced outside the kidney. For example, leptin induces TGF- β 1 in glomerular endothelial cells (261) and expression of type II TGF- β receptor (262). Therefore, the quantitatively most important stimulus for TGF- β secretion remains ill-defined, and so do the cell types that represent the source of TGF- β and the target of its actions.

Connective Tissue Growth Factor. As a downstream mediator of some of the effects of TGF- β , CTGF has attracted much attention (263). CTGF has been detected in glomeruli from patients with diabetic nephropathy but not in glomeruli from healthy subjects (264). In mesangial cells, high glucose concentrations induce CTGF expression, and this can be prevented by an antibody to TGF- β (265,266). TGF- β induces CTGF through binding of Smad to the CTGF promotor (267). Apart from TGF- β , CTGF appears to be regulated by PKC (266). TGF- β induction of extracellular matrix proteins, among them fibronectin and collagen isoforms, is dependent on CTGF (14).

It is interesting that the mechanisms described for glomerulosclerosis have a parallel in the mechanisms by which myocardial fibrosis in diabetes is mediated by CTGF. In mice with streptozotocin-induced diabetes or in transgenic mice with overexpression of PKC β 2 targeted to myocardium, TGF- β , CTGF, fibronectin, and type VI collagen are induced as compared with the expression in nondiabetic or wild-type mice (268).

Growth Hormone/Insulin-like Growth Factor. Hypersecretion of growth hormone (GH) occurs in type 1 diabetes (269) and may

be a cause of diabetic nephropathy. Thus, transgenic mice overexpressing GH and GH-releasing factor develop glomerular fibrosis (270), and this is accelerated in GH-transgenic mice with streptozotocin-induced diabetes as compared with wild-type diabetic mice (271). Furthermore, transgenic mice overexpressing a dominant-negative GH (271) or mice with knockout of the gene for GH receptor/binding protein (272) are protected from diabetic nephropathy.

Hypersecretion of GH may be a result of decreased plasma concentrations of IGF-1 (269). However, IGF-1 may be overexpressed locally in tissues. Thus, IGF-1 production in the kidney is increased in diabetic animals, and IGF-1 stimulates the production of extracellular matrix proteins from mesangial cells (14).

GH or IGF may also play a role in diabetic retinopathy. In transgenic mice overexpressing a dominant-negative GH mutant gene, or in wild-type mice treated with an inhibitor of GH secretion, ischemia-associated retinal neovascularization was inhibited despite unchanged retinal VEGF expression (273).

THE RENIN-ANGIOTENSIN SYSTEM

A large number of clinical trials have shown that treatment with ACE inhibitors, AT1 receptor blockers, or their combination can prevent the occurrence of renal disease or delay its progression to renal failure (274). Many studies also support the ability of treatment with ACE inhibitors to prevent diabetic retinopathy (274), and one trial showed that nerve electrophysiology parameters, although not clinical parameters, improved after treatment with an ACE inhibitor (275).

Hypertension is an independent risk factor for the presence of nephropathy in patients with type 2 diabetes (276). But the effect of ACE inhibitors on preventing diabetic nephropathy cannot be explained by their antihypertensive effect alone (277). Theoretically, the mechanism for the effect of ACE inhibitors on the prevention of diabetic nephropathy could be as an inhibitor of bradykinin proteolysis. However, a bradykinin B1 receptor antagonist, although efficient at blocking renal bradykinin receptors, did not prevent diabetic nephropathy by itself or affect the beneficial influence of an ACE inhibitor (278).

The demonstration that an ACE inhibitor could prevent increased glomerular capillary pressure (279) was the first indication that ACE inhibition could have renoprotective effects that were not dependent on lowering systemic blood pressure. ATI and ATII are produced locally in the kidney (280). Accordingly, in immortalized proximal tubular cells (189) and mesangial cells (20) grown in high glucose concentrations, ATII secretion is increased. It has been shown that ATII actions may lead to kidney damage through induction of local factors, including extracellular matrix protein synthesis via TGF- β (281). The same mechanism may contribute to cardiac fibrosis (282,283). Apart from promoting extracellular matrix protein synthesis in cardiac fibroblasts (282), ATII also induced myocardial PAI-1 expression, which—by inhibiting metalloproteinases—can inhibit extracellular matrix breakdown (282,284).

Intrarenal production of ATII may explain the low systemic plasma concentrations of renin in diabetes (285), as ATII suppresses renin production as a negative feedback mechanism (286).

ENDOTHELIUM-DERIVED VASODILATING AND VASOCONSTRICTING FACTORS

The most well established endothelium-derived vasomotor substances are NO, prostacyclin, and ET-1. It is important to realize that these factors have effects on several functions other than vasomotion. Endothelium-dependent vasodilating factors may substitute for each other. Thus, prostacyclin (287) and endothelium-derived hyperpolarizing factor (EDHF) (288) may substitute for NO, and decreased vascular NO production in diabetes may be compensated for, in part, by increased production of prostacyclin (289).

Nitric Oxide. Glucose-induced endothelial vasodilator dysfunction seems to be caused to a large extent by ROS. They react directly with NO, causing its degradation, and can be prevented by treatment *in vivo* with probucol, a scavenger of reactive oxygen species, by *in vivo* transfection with the Mn-SOD gene (290), or by antioxidant enzymes *ex vivo* (23).

The mechanisms responsible for decreased NO production are unclear. There are reports of downregulation of eNOS protein (291). Contradicting this finding, other results have shown eNOS mRNA and protein upregulation, accompanied by increased superoxide production, which can degrade NO (143,292). The mechanism in vivo, however, seems to be a compensatory increase in eNOS expression secondary to increased breakdown of NO by ROS (293). Regardless of the mechanism, the presence of impaired NO availability is supported by studies showing that in vitro transfection of the eNOS gene to aorta (290) and carotid artery (294) of alloxan-treated rabbits prevents impaired endothelium-dependent vasorelaxation. Apart from its role in regulating blood flow, NO may be an intermediary signaling molecule in other pathways. For example, VEGF expression is dependent on NO production (295), and in mesangial cells, NO inhibits glucose-induced expression of fibronectin (296) and collagen (297).

Prostacyclin. In endothelial cells cultured in high glucose concentrations, tyrosine nitration has been shown to decrease the activity of prostacyclin synthase (158,298). This increases apoptosis and expression of adhesion molecules, perhaps by increasing the concentration of prostacyclin precursors such as prostaglandin H₂ (158). Thus, nitration of prostacyclin synthase is associated with upregulation of cyclooxygenase-2 and may be mediated by PKC through activation of NAD(P)H oxidase (299). Prostanoid vasoconstrictors have been shown to be responsible for decreased endothelium-dependent vasodilation in blood vessels from diabetic rabbits (300).

Endothelin-1. Another important aspect of endothelial dysfunction in type 2 diabetes is increased expression of endothelium-derived ET-1, the most potent vasoconstrictor known (301). In obese individuals and in patients with type 2 diabetes, infusion of an ET_A blocker caused a vasoconstriction not seen in healthy, lean individuals, indicating that in insulin-resistant states, ET-1 contributes to basal vasoconstrictor tone (302).

High glucose concentrations activate PKC β and δ isoforms in endothelial-cell cultures and lead to increased ET-1 expression, which is also dependent on MAPK activity in this situation (192). The downstream mediators of MAPK-regulated ET-1 induction may be the Jun/Fos proteins (303). In diabetes, ET-1 is partly responsible for abnormal retinal hemodynamics (304), and its induction may be mediated through upregulation of PDGF expression (195). Myocardial vascular tone is regulated by ET-1, but more so during rest than during exercise (305).

In endothelial cells, ET-1 expression is increased by insulin (306). The ability of insulin to increase vascular ET-1 production has also been demonstrated in humans (307). The hyperinsulinemia typical for type 2 diabetes in its earlier stages may thus be responsible for ET-1 upregulation, because the MAPK pathway of insulin signaling is not affected by diabetes (209). Apart from acting as a vasoconstrictor, ET-1 promotes fibrosis. ET-1 transgenic mice develop renal interstitial and glomerular fibrosis (308). This occurs in the absence of hypertension (308), which may be explained by a compensatory increase in vascular NO production (309). Renal fibrosis in this animal model may not be identical to that occurring in diabetes, as ET-1 transgenic mice show increased expression of laminin, but not of col-

lagen or fibronectin (310). However, streptozotocin-treated rats show increased expression of fibronectin in retina, renal cortex, and myocardium, and this can be prevented by treatment with an ET-1 receptor antagonist (311). Upregulation of ET-1 expression may be regulated by TGF- β (312).

CONCLUSION

The evolution of our knowledge about altered hormone and cytokine action and of intercellular and intracellular signaling in diabetes has been dramatic. A major limitation of our understanding of the mechanisms leading to microvascular complications is that the sequence of events in altered signaling is often unknown and the overall significance of alteration of an individual signaling parameter often is unclear.

Good glycemic control is difficult to achieve in many patients with diabetes, and diabetic microvascular complications occur even with intensive insulin treatment regimens. In fact, even though good control can be achieved much of the time, intermittent hyperglycemia may be more damaging than constant hyperglycemia to vascular cell homeostasis (313). Although good glycemic control will remain the primary focus of diabetes care, the development of therapy that targets signaling pathways that cause vascular dysfunction and, ultimately, diabetic complications is likely to be important. Further understanding of the mechanisms responsible for the pathogenesis of these complications will ensure a rational approach to their prevention and treatment.

CHAPTER 50 **Pathogenesis of Diabetic Neuropathy**

Phillip A. Low

UNIQUE CHARACTERISTICS OF THE PERIPHERAL NERVE 839

Resistance to Ischemic Fiber Degeneration 839 Lack of Autoregulation 839 Nerve Is a Nutritive-Capacitance Vascular Bed 840 Nerve Can Be Sustained on Aerobic Metabolism 840

UNIQUE CHARACTERISTICS OF HUMAN DIABETIC NEUROPATHY 840

Resistance to Ischemic Conduction Failure 840 Susceptibility to Entrapment/Compression Neuropathies 840

Excessive Susceptibility to Ischemic Fiber Degeneration of Diabetic Nerves 841 Insulin-Induced Neuropathy 841

PATHOGENESIS OF DIABETIC NEUROPATHY 841

Genetic Predisposition 841 Nerve Ischemia/Hypoxia 841 Oxidative Stress 842 Polyol Pathway Overactivity 845 Advanced Glycosylation End Products (AGE)–AGE Receptor–Nuclear Factor-κB 846 Excessive Lipolysis and γ-Linolenic Acid Deficiency 846 Induction of Protein Kinase C 847 Synthesis of Pathogenetic Hypothesis 847

CONCLUDING THOUGHTS 848

The diabetic neuropathies are those associated with the diabetic state. Although the neuropathies are clearly related to the presence, duration, and severity of hyperglycemia, controversies exist on the types of diabetic neuropathies and their pathogenesis. Diabetic neuropathies have many phenotypes (Table 50.1). Distal sensory neuropathy is the most common variety of neuropathy, with mild distal sensory impairment and minimal motor deficits. This category comprises greater than 50% of all diabetic neuropathies. Distal small fiber neuropathy is also common; it is characterized paradoxically by a combination of distal positive symptoms, including painfulness and impairment in both pain and temperature perception. Painfulness occurs in many types of diabetic neuropathies. The asymmetric neuropathies are distinctive and are likely due to a combination of microvascular disease, compression injury, and immune-mediated mechanisms. Despite the profusion of manifestations and types of neuropathy, the common garden-variety distal sensory neuropathy is present in essentially all varieties of diabetic neuropathies and comprises the major focus of this chapter.

UNIQUE CHARACTERISTICS OF THE PERIPHERAL NERVE

Because the peripheral nerve axons are extremely long relative to their diameters and are a great distance from their parent cell bodies (in dorsal root ganglion, autonomic ganglion, and motor neurons), their component motor, sensory, and autonomic axons, especially distally, are exquisitely dependent on endoneurial microenvironment for their blood supply, oxygenation, nutrition, and the removal of toxic metabolic products. The peripheral nerve is physiologically unique in several ways, information that has an important bearing on its response as a target to chronic hyperglycemia.

Resistance to Ischemic Fiber Degeneration

The nerve is supplied by a dual system of microvessels. It has an *intrinsic* interconnecting system, connected via arterioles and venules to an epineurial system, the *extrinsic* system (1). The dual system, low energy requirements, and relatively large energy stores together confer on the nerve a large safety factor in its resistance to ischemic fiber degeneration. Earlier experimental data in which peripheral nerve was undercut or the regional supply was ligated demonstrated that nerve fiber degeneration did not occur even when long stretches of nerve were deprived of their intrinsic supply either by arterial ligation (2) or by extensive nerve trunk mobilization with undercutting of connecting blood supply (3).

Lack of Autoregulation

Autoregulation refers to the maintenance of constant blood flow, in spite of changes in blood pressure [within a blood pressure

TABLE 50.1. Types of Diabetic Neuropathies

Symmetric neuropathies

- 6. CIDP

range (the autoregulated range)]. In most tissues, autoregulation is achieved by dynamically varying arteriolar tone and by myogenic rather than neurogenic mechanisms. There is a characteristic blood flow:blood pressure curve, which is flat within the autoregulated range and sloping at either end. We demonstrated a curvilinear relationship of nerve blood flow to blood pressure, a relationship that is explainable on the basis of a passive nonautoregulating system (4). This finding has subsequently been confirmed in anesthetized (5,6) and nonanesthetized rats (7).

Nerve Is a Nutritive-Capacitance Vascular Bed

Another unique characteristic of nerve microvasculature is its nutritive capacitance system (5). This is a disadvantaged system where a small change in blood volume results in a disproportionate change in nerve blood flow. The morphologic basis of this system appears to be the large-diameter capillary whose diameter exceeds that of the erythrocyte. The median diameter of the endoneurial capillary is 8 to 9 µm (8), considerably larger than that of erythrocytes (about 7 µm). In other tissues the capillary is smaller than the erythrocytes, resulting in a squeezing action that enhances oxygen release. The large diameter with poorly developed arteriolar smooth muscle (9) results in inefficient oxygen release.

Nerve Can Be Sustained on Anaerobic Metabolism

The peripheral nerve is metabolically unique, being able to function relatively well on anaerobic metabolism and having powerful adaptive mechanisms. Compared with rat brain, the nerve has about 10% of the brain's oxygen requirements but similar energy stores (10,11). When maximally active, the nerve increases its energy demands less than 100%, whereas the brain increases its demands severalfold (11). The relatively large energy stores and the low resting and maximal energy expenditure enable the nerve to function quite well on anaerobically generated highenergy phosphate. It is likely that the low-density capacitance system developed because of the low metabolism of the nerve. We have demonstrated that the nerve will conduct impulses for many additional minutes when energy substrates are increased, as in diabetes (11).

Another strategy of resistance to ischemic conduction failure is a further downregulation of energy-requiring enzymes, a situation that occurs in aging (12) and in chronic hypoxia (13).

UNIOUE CHARACTERISTICS OF HUMAN **DIABETIC NEUROPATHY**

There are a number of unique characteristics of human and experimental diabetic neuropathy. Four of these are relevant to the pathogenesis of diabetic neuropathy:

- Susceptibility to entrapment/compression neuropathies
- Susceptibility to ischemic fiber degeneration
- Insulin-induced neuritis

Resistance to Ischemic Conduction Failure

When the limb is rendered ischemic, paresthesias develop followed by the loss of sensory then motor functions. The electrophysiologic correlate is a failure of nerve conduction. Both diabetic humans and animals manifest resistance to ischemic conduction failure (RICF) (11,14). Nerve impulses continue to conduct for minutes in diabetic individuals after those in normal individuals have failed to do so. The clinical correlate is that patients are more resistant to paresthesias and retain nerve function for minutes beyond normal subjects.

MECHANISM

The mechanism of RICF likely relates to the unique metabolic characteristics described previously. Diabetic nerves have a severalfold increase in nerve energy substrates (glucose, fructose, glycogen) (11). Their energy requirements are sufficiently low to permit them to continue to conduct impulses on adenosine triphosphate (ATP) derived from anaerobic metabolism (1). Their energy requirements may also be downregulated. The relatively large endoneurial space (relative to brain) results in less susceptibility to lactate- and potassium-induced conduction failure (11).

Susceptibility to Entrapment/ **Compression Neuropathies**

Diabetic nerve trunks are unduly susceptible to focal neuropathies that occur in a limited number of circumstances (15). Focal neuropathies occur due to repetitive compression, as occurs with leaning on the ulnar nerve at its groove and pressure of the peroneal nerve against the fibular neck (15). Entrapment can occur within the carpal tunnel as with the median nerve, causing carpal tunnel syndrome (15). A third category is the acute onset of focal noncompressive neuropathy, e.g., third cranial nerve.

MECHANISM

The precise pathophysiology is not known. Circumstantial evidence suggests that the combination of ischemia and mechanical susceptibility might be responsible. Evidence for microvascular ischemia clinically includes the acute or subacute onset of, for example, third-nerve palsy in vasculopathic older patients. Pathologic evidence is limited but includes the presence of microinfarcts, multifocal pathology, and fibrinoid change (16). Such changes have been described in two diabetic patients; one died shortly after the onset of oculomotor palsy (17); in the second, a 73-year-old man with diabetes who died shortly after the onset of a focal limb neuropathy, the obturator, femoral, sciatic, and posterior tibial nerves were examined (18). Combined changes of florid round cell infiltration and microvascular changes have been interpreted as being due to a combination of microvascular ischemia and immune-mediated mechanisms. Three sets of findings are consistently found in chronic diabetic neuropathy: first, a thickening of basal lamina (19); second, endothelial-cell and smooth-muscle proliferation (20,21) with increased variance of capillary caliber and the closing of some capillaries (20); third, the tendency of fiber loss to be multifocal rather than diffuse (22,23). The combination of microvascular ischemia, connective tissue changes (24), and myelin alterations could presumably render the nerve trunk susceptible to compression injury.

Excessive Susceptibility to Ischemic Fiber Degeneration of Diabetic Nerves

Ischemia of mild-to-moderate severity is associated with excessive susceptibility to ischemic fiber degeneration. The latter is reported to occur in animals with chronic hyperglycemia in excess of 16 weeks but not with hyperglycemia of shorter duration (25,26). Other studies report excessive susceptibility much earlier in the course of diabetes. Reports include excessive susceptibility to ischemic fiber degeneration in response to epineurial application of endothelin in rats with a duration of hyperglycemia of only 6 to 8 weeks (27), and with the *in vitro* study showing that a medium with increased glucose causes intracellular acidosis with delayed recovery (28).

The human equivalent of susceptibility to ischemic fiber degeneration is not well documented.

Insulin-Induced Neuropathy

Infrequently, an acute painful neuropathy develops within 1 month of the institution of tight glycemic control with insulin therapy in a diabetic patient who previously did not have a neuropathy (29–31). The neuropathy is usually that of a painful distal sensory polyneuropathy, although it also can be a severe generalized neuropathy.

Recent experimental studies provide some insight into the mechanism of insulin neuritis. Insulin administration reproducibly causes acute endoneurial hypoxia by increasing nerve arteriovenous flow and reducing nutritive flow of normal nerves (32). The diabetic state confers resistance to this effect. Within 1 month of commencement of insulin treatment, this susceptibility to the endoneurial hypoxic effect of insulin recurs (32). Endoneurial hypoxia has been demonstrated in experimental and human diabetic neuropathy (33,34). We had suggested that diabetic nerve fibers survive under these hypoxic conditions because of the greatly increased energy substrate stores in experimental and human diabetes (11,35), coupled with the low energy requirements of peripheral nerve (1). Anaerobic metabolism suffices under these circumstances. Insulin treatment causes transient hypoxia in normal but not diabetic nerves (32). With continued insulin treatment, energy substrates are normalized and the susceptibility to insulin-induced endoneurial hypoxia returns in diabetic nerves. The hypoxic tissues with normal energy substrates fare poorly because anaerobic metabolism is inefficient (1), and there may be sufficient hypoxia to result in fiber degeneration.

PATHOGENESIS OF DIABETIC NEUROPATHY

The pathogenesis of the common, garden-variety distal sensory diabetic neuropathy is likely multifactorial. Hyperglycemia is central to any pathogenetic scheme. There are sufficient experimental and observational data to warrant consideration of the following mechanisms in mediating the effects of chronic hyperglycemia:

- Genetic predisposition
- Nerve hypoxia/ischemia

- Oxidative stress
- Overactivity of polyol pathway
- Increased advanced glycation end products
- Deficiency of γ-linolenic acid
- Protein kinase C, especially increase in β -isoform
- Growth factor(s) deficiency
- Dysimmune mechanisms

Genetic Predisposition

One patient with lifelong severe hyperglycemia is free of neuropathy; another has florid neuropathy within a few years of onset of hyperglycemia; another patient with a strong family history of diabetes may actually develop neuropathy before diabetes is diagnosable. Although these types of observations suggest a genetic predisposition to the development of neuropathy, the available data are very limited. Most of the studies to date have focused on the genetics of inheritance of type 1 and type 2 diabetes.

Nerve Ischemia/Hypoxia

EXPERIMENTAL DIABETIC NEUROPATHY

Vasoregulation of nerve microvessels is regulated at the arteriolar, venular, and endothelial cell levels. In the diabetic state, endothelial changes include those of AGE-RAGE-NF- κ B [advanced glycosylation end products (AGE)–AGE receptornuclear factor κ B (NF- κ B)], cell adhesion molecules, nitric oxide, and eicosanoids. Experimental diabetic neuropathy results in a reduction in nerve blood flow of about 50% (33,36), which begins by the first week of diabetes (36) and affects the cell body of sensory and sympathetic neurons as well as the axon (37). In diabetes, the combination of increased whole-blood or plasma viscosity, increased aggregability, and reduced red blood cell deformability results in a reduction of blood flow and stagnation hypoxia (1).

Regional nerve blood flow is regulated by systemic blood pressure (4) and the balance between neural vasoconstrictors and vasodilators. Vasoconstriction is known to be mediated by epineurial α -adrenergic (38,39), vasopressin (40), and endothelin receptors (41). The 50% effective concentration (EC₅₀) of endothelin, using identical methodology, is about three orders of magnitude lower, indicating greater potency, than that of adrenoreceptors (41). The EC₅₀ of vasopressin is of an order similar to that of endothelin. These potent vasoconstrictor actions are balanced by vasodilatation and are mediated by calcitonin gene–related peptide (42), substance P (42), nitric oxide (NO) (43), and the prostaglandins (44).

Alterations in microvessels in experimental diabetic neuropathy have been reported. These are reported to be excessively sensitive to α -adrenergic agonists (45) and endothelin (46,47). The nerve conduction and blood-flow deficits are prevented by specific antagonists to endothelin (48) and adrenoreceptors (49). Deficits in vasodilators are supported by restoration of blood flow and nerve conduction by an NO donor (50) and vasodilator prostaglandins (51). The reduction of NO is likely the most important in its magnitude and implications (43). The polyol pathway is overactive and competes with nitric oxide synthase for NADPH (reduced form of nicotinamide adenine dinucleotide phosphate). By siphoning off NADPH, chronic hyperglycemia results in a deficiency of NO in nerve endothelium (43,50). Endoneurial NO deficiency has a number of important consequences in the microvasculature. It normally inhibits the expression of P-selectin, intercellular adhesion molecule-1 (ICAM-1), vascular cell adhesion molecule-1 (VCAM-1), and other adhesion molecules (52), a mechanism that is mediated

842 JOSLIN'S DIABETES MELLITUS

through inhibition of protein kinase C and by preventing the activation of NF- κ B (53). NO also inhibits the cytoassembly of NADPH oxidase (54), thereby attenuating the release of superoxide by leukocytes (55). Inhibition of NO, therefore, explains a number of changes seen in experimental diabetic neuropathy (expression of adhesion molecules, activation of NF- κ B, expression of cytokines, and generation of superoxide anions).

HUMAN DIABETIC NEUROPATHY

Three main pathologic alterations affect human diabetic peripheral nerve. First, thickening of endoneurial capillary wall and thickening and reduplication of basal lamina have consistently been found (56,57), especially in more recent studies (16,58). Basal lamina thickening, although characteristic, is not specific to the diabetic state, occurring especially with aging and a number of other neuropathies. Second, alterations in capillaries are consistently present. These changes include a reduction in capillary density, reduced capillary area, and capillary closure (16,20,58). Third, the pattern of fiber loss is multifocal, suggestive of ischemic fiber loss (22,23). In a three-dimensional reconstruction of the distribution of fiber loss using autopsy specimens from lumbosacral trunk to sural nerve biopsy specimens, the changes seen in sural nerve manifest the cumulative loss of fibers, whereas multifocal fiber loss is better appreciated in more proximal nerve trunks (59). Although these alterations have been well defined, their specificity has been questioned (60). These studies are all important in attempting to define morphometric abnormalities of endoneurial vessels and fibers. They suffer from their ability to define the results but inability to define the pathogenetic process.

The most concerted and coherent studies of perfusion and oxygenation of human diabetic nerves have been undertaken by the Sheffield group. They were the first to demonstrate reduced oxygen tension in human diabetic neuropathy. They measured endoneurial oxygen tension in exposed sural nerve of 11 patients with diabetic neuropathy (34). Correlative pathologic studies in a separate study were supportive, showing reduced endoneurial capillary density and changes in capillary basement membrane and endothelial cells and in the derived total diffusion barrier that was significantly impaired in the nerves of patients with severe diabetic neuropathy as compared with control subjects (58). Blood flow and oxygen tension recordings in the operating room are not trivial. Recordings using laser Doppler methodology have been reported to show no change or even a slight increase in blood flow and oxygen tension (61). These results are un-interpretable in diabetic neuropathy, because it measures total and not nutritive flow, where shunt flow may actually be increased (62).

A number of innovative approaches have been developed to measure flow and oxygenation. Nerve photography and fluorescein angiography demonstrate delayed fluorescein appearance time and intensity of fluorescence in human diabetic neuropathy (62). These investigators observed direct epineurial arteriovenous shunting in the majority of diabetic neuropathic patients. A novel approach using microlightguide spectrophotometry to measure intravascular oxygen saturation and blood flow in human sural nerve after an intravenous injection of sodium fluorescein has confirmed impaired nerve blood flow and tissue deoxygenation. There was a correlation between rise time, nerve oxygen saturation, glycemic control, and sural nerve sensory conduction velocity (63).

THERAPEUTIC APPLICATIONS

Angiotensin-converting enzyme (ACE) inhibition with lisinopril administered to 13 hypertensive patients with diabetic neuropathy was reported to improve nerve conduction indices and sensory perception thresholds (64). A small, randomized, doubleblind, placebo-controlled trial on the effect of the ACE inhibitor trandolapril on 41 normotensive patients with type 1 or type 2 diabetes and mild neuropathy has appeared (65). Changes in the neuropathy symptom and deficit scores, vibration-perception threshold, peripheral-nerve electrophysiology, and cardiovascular autonomic function were assessed at 6 and 12 months. The primary end point was the change in peroneal nerve motor conduction velocity. Peroneal motor nerve conduction velocity (p = 0.03) and M-wave amplitude (p = 0.03) increased, the F-wave latency (p = 0.03) decreased, and sural nerve action potential amplitude increased (p = 0.04) significantly after 12 months of treatment with trandolapril as compared with response to placebo.

The study is interesting and has potentially important implications. There is controversy over whether ischemia is a central mechanism or is one of many mechanisms in the production of diabetic neuropathy. In view of the strength of the evidence of the benefits of ACE inhibition on renal function, it might be difficult to set up a specific study on neuropathy, in contrast to a neuropathy piggyback study similar to the Diabetes Control and Complications Trial.

Oxidative Stress

There is considerable evidence of oxidative stress in both experimental and human diabetic neuropathy. We will summarize the evidence in non-neural tissues followed by data on neural tissue. The data on non-neural tissues come from studies of plasma; erythrocytes; and primarily heart, liver, kidney, and pancreas. These studies have focused on evidence of increased lipid peroxidation and alteration in the patterns of glutathione and antioxidant enzymes. Evidence of oxidative stress may be manifested as a reduction or an increase in antioxidant enzymes (66). Not all experts espouse the role of oxidative stress. One view is that the predominant stress is reductive, characterized by an increase in the NADH/NAD⁺ (reduced form of nicotinamide adenine dinucleotide oxidized form of nicotinamide adenine dinucleotide) ratio (67). Another view, proposed by John Baynes (68), is thoughtful and complicated. He recognizes that increases in glycoxidation and lipoxidation products suggest that oxidative stress is increased in diabetes but that the data are best explained as an increase in carbonyl stress.

OXIDANT STRESS IN HUMAN DIABETES

Oxidative stress refers to a shift in the pro-oxidant:antioxidant status toward the former. Plasma levels of lipid peroxide are increased in human diabetes (69–74) and occur early, even in young persons with diabetes (75). The highest levels were reported in patients with microvascular angiopathy, as manifested as retinopathy or microalbuminuria; lowest in those patients with diabetes without angiopathy (69,76); and normal in patients with well-controlled diabetes (69). The relationship may relate to the observation that low-density lipoproteins of patients with diabetes are significantly more oxidizable than are those of controls, an abnormality that is correctable by 6 weeks of treatment with the antioxidant probucol (77). Presumably, patients with diabetes with angiopathy who have higher levels of low-density lipoproteins will have the greatest lipid peroxidation.

More recent data are more consistent with increased oxidant stress being secondary to metabolic status rather than to complications (78), including a positive correlation with glycosylated hemoglobin and a negative correlation of malondialdehyde with glutathione peroxidase (79). Recent work has focused on combining measurements of lipid peroxidation (increased) with indices of total antioxidant defense (reduced) in diabetes (80,81). Additional emphasis has been placed on evaluation of indices that reflect specific mechanisms and tissues affected by oxidant stress. Measurements include those of increased activation of the oxidative stress–sensitive transcription factor NF- κ B (82). Greater importance also is placed on products that specifically reflect neural or DNA damage, such as 4-hydroxynonenal and 8-oxo, 2'-deoxyguanosine in relevant tissue (83). Urinary 8-oxo, 2'-deoxyguanosine excretion and the 8-oxo, 2'-deoxyguanosine content in the mononuclear cells from diabetic patients with complications were higher than those from diabetic patients without complications (84,85).

Glutathione (GSH) is reduced in erythrocytes from patients with type 2 diabetes, with a corresponding increase in oxidized glutathione (GSSG) (86,87). In subsequent studies, this same group additionally demonstrated reductions in the glutathione synthesizing enzyme, γ -glutamylcysteine synthetase, and the transport of thiol [S-(s,4-dintrophenyl)glutathione] in erythrocytes of these patients. These abnormalities were reversible with improved glycemic control. They also demonstrated that a medium high in glucose augments the toxicity of xenobiotics on K562 cells, associated with reduction in both the enzyme and its mRNA (88). Lipid peroxidation is increased and antioxidant enzymes are reduced in the erythrocytes of persons with type 2 diabetes. Changes in GSH and antioxidant enzymes occur early, even at onset of type 1 diabetes (75).

Erythrocyte cuprozinc superoxide dismutase (SOD) is reduced in patients with type 2 diabetes (70,89), and catalase is variably reduced (89). It is suggested that this reduction is mediated by the accumulation of intracellular H_2O_2 (90). Changes in SOD occur early (75).

Levels of α -tocopherol are reported to be reduced in the platelets (90,91) and erythrocytes (92) but not in the plasma of patients with type 1 diabetes. Leukocytes from patients with diabetes were shown to have increased lipid peroxidation, reduced vitamin C levels in 53 patients with type 2 diabetes (93), and reduced cuprozinc SOD (94).

Wolff (95) has emphasized the role of decompartmentalized transitional metals in patients with diabetes, in addition to the effects of hyperglycemia, in producing auto-oxidative lipid peroxidation. Particular emphasis has been placed on copper and iron. Copper levels have been reported to be higher in persons with diabetes than in those without diabetes and are highest in patients with angiopathy (96,97).

OXIDANT STRESS IN EXPERIMENTAL DIABETES

Studies on non-neural tissues have examined plasma, erythrocytes, and tissues such as heart, liver, kidney, and pancreas. These studies have focused on evidence of increased lipid peroxidation, reduction of GSH, and alteration in the patterns of antioxidant enzymes. Evidence of oxidative stress may be associated with a reduction (presumably aggravating stress) or an increase (presumably a compensatory response) in antioxidant enzymes (66). The remainder of this section will focus on changes in nerves, particularly on (a) evidence for reduced freeradical defenses; (b) change in pro-oxidant status; (c) evidence for increased reduced oxygen species; and (d) neural targets.

FREE-RADICAL DEFENSES ARE REDUCED IN PERIPHERAL NERVE

Peripheral nerve has a number of cytosolic and lipophilic antioxidant defenses with closely integrated actions (Table 50.2). These comprise a number of low-molecular-weight and enzymic antioxidant molecules. The key enzymatic scavengers are SOD, catalase, glutathione peroxidase, and glutathione reductase. Glutathione is particularly important in that it is the main scav-

TABLE 50.2.	Some Free-Radical	Defenses

enger in the blocking of chain propagation (98). The cytosolic and membrane antioxidants work in concert in a well-organized interacting chain. Ample activity of all components is needed to maintain these antioxidants in their reduced state. The literature on free-radical biology is extensive, but information on peripheral nerve, and particularly on the diabetic peripheral nerve, is quite limited.

Free-radical defenses of peripheral nerve are reduced relative to those of brain and liver (99,100). Of great interest is the marked and selective reduction in antioxidant defenses in rodent sciatic nerve (Table 50.3). The activities of GSH and GSH-containing enzyme scavengers (glutathione peroxidase and reductase) are only about 10% that of brain, whereas the activities of other enzymes, such as SOD, are near normal (99). Corresponding enzyme activities of these enzymes in the brain are in turn about half that in the liver (100).

The diabetic state results in additional alterations in these defenses (Table 50.4). Cuprozinc SOD is reduced in sciatic nerve of experimental diabetic neuropathy, and this reduction is improved by insulin treatment (101). Glutathione peroxidase is further reduced in experimental diabetic neuropathy (102), and glutathione peroxidase activity regresses with blood glucose concentration. Plasma and leukocyte ascorbic acid are reduced, and oxidation of this antioxidant is increased (103,104). GSH is reduced in diabetic nerves (105,106).

REDUCED OXYGEN SPECIES ARE INCREASED IN EXPERIMENTAL DIABETIC NEUROPATHY

The potential sources of free-radical generation in diabetes will be briefly considered. Of note is that these mechanisms do not occur in isolation and are best considered as interacting mechanisms that converge to cause lipid peroxidation.

Ischemia/Hypoxia in Experimental Diabetic Neuropathy. A deficit in nerve blood flow of 50% in experimental diabetic neuropathy (107-109) results in the generation of hypoxanthine from ATP, NADPH (the cofactor) and conversion of the inactive enzyme to xanthine oxidase (110,111). The diabetic state and endoneurial ischemia increase lipolysis, resulting in an increase in ω -6 fatty acids such as linoleic acid and arachidonic acid (112), whose peroxidation results in 4-hydroxynonenal (HNE), an aldehydic product of membrane lipid peroxidation, and causes prominent cytotoxic effects in cultured endothelial cells, manifested by morphologic changes, diminished cellular viability, and impaired endothelial barrier function (113). HNE has a relatively long half-life within cells (minutes to hours), allowing for multiple interactions with cellular components (114). It impairs glutamate transport and mitochondrial function in neurons (115) and mediates oxidative stress-induced neuronal apoptosis (116).

Autoxidative Lipid Peroxidation. Hyperglycemia, by a process of autoxidation in the presence of decompartmentalized redoxactive trace transitional metals, can generate highly reactive oxidants and result in lipid peroxidation (117). We have demonstrated, using an *in vitro* lipid peroxidation model (ascorbate-iron-EDTA preparation), that a high-glucose medium will result in

Modified from Romero FJ, Monsalve E, Hermenegildo C, et al. Oxygen toxicity in the nervous tissue: comparison of the antioxidant defense of rat brain and sciatic nerve. *Neurochem Res* 1991;16:157–161; and Romero FJ, Segura–Aguilar J, Monsalve E, et al. Antioxidant and glutathione-related enzymatic activities in rat sciatic nerve. *Neurotoxicol Teratol* 1990;12:603–605.

lipid peroxidation, *in vitro*, of brain and sciatic nerve. The addition of 20 mM glucose to the incubation medium increased lipid peroxidation fourfold, confirming rapid and marked glucosemediated auto-oxidative lipid peroxidation (118). These studies confirm the observation of autoxidative glycation/oxidation in plasma (38,119). Glucose autoxidation results in the production of protein-reactive ketoaldehydes, hydrogen peroxide, and other highly reactive oxidants and in the fragmentation of proteins (indicative of free-radical mechanisms).

TABLE 50.3.

Advanced Glycosylation End Products (AGE)–AGE Receptor– Nuclear Factor κB (AGE-RAGE-NF- κB). Glycation and the formation of AGE is followed by binding with its receptor (RAGE), the activation of NF- κB (120), and the generation of reactive oxygen species (ROS) and an inflammatory response (121). There is induction of specific DNA binding activity for NF- κB in the VCAM-1 promoter region. The necessity for RAGE and the role of ROS was demonstrated by a block of this induction by anti-RAGE IgG or *N*-acetylcysteine (GSH donor). The application of this finding to humans is supported by the finding that peripheral blood mononuclear cells isolated from patients with diabetic nephropathy show increased activation of NF- κB (82). There is a vicious cycle, with AGE-producing superoxide, superoxideaccelerating AGE generation, and AGE-quenching NO (122).

Overactivity of the Polyol Pathway Generates Reactive Oxygen Species. The overactivity of the polyol pathway generates ROS in a number of ways. Depletion in NADPH results in NO deficiency and an increase in the generation of superoxide anion by leukocytes (see earlier). Because NADPH also is required for the regeneration of GSH, its depletion results in a reduction of GSH (123). Sorbitol dehydrogenase, the second

TABLE 50.4.	Changes in Antioxidant Defenses in
	Experimental Diabetes

Antioxidant	Change	Reference(s)
Superoxide dismutase (cuprozinc)	Reduced	101

Ascorbic oxidation	Reduced	103,104
Reduced glutathione (GSH)	Reduced	105,106

enzyme in the polyol pathway that converts sorbitol to fructose, also contributes to oxidative stress, most likely because depletion of its cofactor NAD⁺ leads to the channeling of more glucose through the polyol pathway (123). Overactivity of the polyol pathway results in reductions in myoinositol and taurine. The latter is a potent antioxidant, and its depletion (124) further contributes to oxidative stress.

Protein Kinase C. Although the activity of protein kinase C (PKC) in nerve is uncertain, it is known that inhibition of PKC- β will reduce oxidative stress (125) and will normalize the deficits in blood flow and nerve conduction (126). In endothelial cells, high glucose causes activation of NF-κB. Co-incubation with a selective PKC inhibitor, calphostin C, produced a concentration-dependent inhibition of glucose-induced activation of NF-κB, suggesting that PKC is important at the endothelial cell level in the activation of adhesion molecules and the generation of ROS.

Excessive Lipolysis. The diabetic state and endoneurial ischemia increase lipolysis, resulting in an increase in ω -6 fatty acids, such as linoleic acid and arachidonic acid (112), whose peroxidation results in 4-hydroxynonenal (113) (and discussed earlier). Malondialdehyde also is generated in the cyclooxygenase pathway.

Growth-Factor Deficit. Lipid peroxidation is aggravated by a reduction in nerve growth factor (127). Reduction in nerve growth factor will reduce, and its administration will restore, glutathione peroxidase and catalase (128,129).

Inflammatory Response. The main sources of ROS in mammals are leukocytes and mitochondria. The quantitative roles of the leukocytes, cytokines, and catecholamine oxidation in diabetic nerve are uncertain. Leukocytic infiltration is not a feature in most cases of experimental diabetic neuropathy. In human diabetic neuropathy, there are some suggestions of an immunemediated process, as suggested by the presence of iritis and inflammatory infiltrates in sympathetic ganglia (130). Some forms of diabetic neuropathy, such as acute autonomic neuropathy and the subacute proximal neuropathies, might be associated with prominent round-cell infiltration. A role of associated ROS and oxidative stress should be considered.

CHANGE IN PRO-OXIDANT STATUS

Altered pro-oxidant status occurs in the diabetic state, with an increase in polyunsaturated fatty acids increasing arachidonic acid (112). With ischemia, superoxide anion is converted to H_2O_2 ,

but its further decomposition, which is mediated by glutathione peroxidase (131), may be compromised if the low content of this enzyme is further reduced. HNE, an aldehydic product of membrane lipid peroxidation, is especially pertinent, in that ischemia, by increasing arachidonic acid, provides a substrate for HNE (114), which mediates neuronal apoptosis (116). Other alterations, especially increases in free iron and copper, have been proposed, but definitive evidence has not yet appeared.

TARGETS OF OXIDANT STRESS

The focus of investigations has been the nerve trunk. Recent emphasis has been based on the realization that human diabetic neuropathy is primarily a distal and sensory neuropathy, and emphasis has shifted to the sensory neuron and nerve terminals. Studies of human skin biopsy specimens of epidermal axons comprising unmyelinated sensory fibers have indeed demonstrated that these alterations precede and are more pronounced than changes seen in nerve trunk. Functional deficits of unmyelinated fibers also occur before deficits are demonstrable in the nerve trunk. Indeed, pathologic alterations of digital nerves have been described, although these changes have been ascribed to local trauma.

Recent studies on spinal roots (132) and dorsal root ganglion (DRG) have demonstrated the presence of prominent myelin alterations of dorsal and ventral roots after 6 months of diabetes. Changes in dorsal root ganglion are prominent (37), consisting of vacuolar degeneration; pigmentary changes are present and are associated with both distal sensory loss (106) and slowing of conduction of proximal nerves (including nerve roots) (133). There is oxidative injury of DRG neurons, with immunolabeling with 8-hydroxydeoxyguanosine, caspase-3, and terminal deoxynucleotidyl transferase-mediated deoxyuridine triphosphate (dUTP) nick and labeling (TUNEL) positivity (133a). A selective loss of the largest neurons is found (133b). Another recent focus is the Schwann cell as a target in hyperglycemic ischemic nerves. The Schwann cell is suggested to be a target of oxidative stress and its apoptosis responsible for delayed ischemic demyelination (134,135).

The specificity of targets needs to be coupled with specificity of mechanisms. HNE is a potent inhibitor of mitochondrial respiration (136). HNE mediates oxidative stress-induced apoptosis of neurons and terminals (116). HNE disrupts neuronal calcium homeostasis and perturbs mitochondrial function, resulting in caspase activation. Activated caspases, in turn, induce activation of c-Jun N-terminal kinase (JNK), resulting in stimulation of the production of transcription factor activator protein-1 (AP-1) DNA-binding protein (137). This action of HNE can be blocked by GSH, which is reduced in diabetes (106). More recently, apoptosis of DRG neurons, neurites, and Schwann cells *in vitro* and *in vivo* in experimental diabetic neuropathy has been reported (138).

THERAPEUTIC APPLICATIONS

Clinical trials with α -lipoic acid are under way. Studies to date have been summarized by Ziegler and Gries (139). The effects of the antioxidant α -lipoic acid have been studied in two multicenter, randomized, double-blind, placebo-controlled trials. In the Alpha-Lipoic Acid in Diabetic Neuropathy Study (ALADIN Study) (140), 328 patients with type 2 diabetes and symptomatic peripheral neuropathy were randomly assigned to treatment with intravenous infusion of α -lipoic acid (ALA) using three doses (ALA 1,200 mg, 600 mg, 100 mg) or placebo over 3 weeks. The total symptom score (TSS) (pain, burning, paresthesia, and numbness) in the feet decreased significantly from baseline to day 19 in the ALA 1,200 and ALA 600 groups compared with the placebo group. Each of the four individual symptom scores

was significantly lower in the ALA 600 group than in the placebo group after 19 days (all p < 0.05). The total scale of the Hamburg Pain Adjective List (HPAL) was significantly reduced in the ALA 1,200 and ALA 600 groups compared with the placebo group after 19 days (both p < 0.05). In the Deutsche Kardiale Autonome Neuropathie Studie (DEKAN Study) (141), patients with type 2 diabetes and cardiac autonomic neuropathy diagnosed by reduced heart-rate variability were randomly assigned to treatment with a daily oral dose of 800 mg of ALA (n = 39) or placebo (n = 34) for 4 months. Two of four parameters of heart-rate variability at rest were significantly improved in the ALA group compared with the placebo group. A trend toward a favorable effect of ALA was noted for the remaining two indexes. In both studies, no significant adverse events were observed. In conclusion, intravenous treatment with ALA (600 mg/day) over 3 weeks is safe and effective in reducing symptoms of diabetic peripheral neuropathy, and oral treatment with 800 mg/day for 4 months may improve cardiac autonomic dysfunction in type 2 diabetes.

Polyol Pathway Overactivity

Chronic hyperglycemia results in overactivity of the polyol pathway. Aldose reductase converts glucose to sorbitol, and the second enzyme, sorbitol dehydrogenase, converts sorbitol to fructose (141). Endoneurial sugar alcohols (especially sorbitol) are increased in human and experimental diabetes but not to osmotically relevant concentrations (141). Originally, electrophysiologic neuropathy was postulated as being due to the induction of polyol overactivity (142) by myoinositol deficiency (143). Subsequently, acutely reversible slowing of nerve conduction in diabetes has been linked to a myoinositol-related defect in the nerve Na⁺,K⁺-ATPase (144). This myoinositol-related abnormality in Na⁺,K⁺-ATPase function is viewed as a cyclic, metabolic defect involving sequential alteration of Na+-dependent myoinositol uptake, myoinositol content, myoinositol incorporation into membrane phospholipids, and phospholipid-dependent Na⁺,K⁺-ATPase function in peripheral nerve. Aldose reductase inhibitors have been shown to normalize both nerve myoinositol content and nerve Na⁺,K⁺-ATPase activity (144). Subsequently, as complexities of the polyol pathway were appreciated, the "sorbitolmyoinositol hypothesis" has been extended to incorporate the complex interactions between hyperglycemia and the vascular, genetic, and environmental variables in the pathogenesis of diabetic complications (145,146). Specifically, competition of aldose reductase with nitric oxide synthase for NADPH results in a deficit of this important endoneurial endothelial vasodilator (43). Abnormalities of this pathway also contribute to oxidant stress (see earlier). The effect of neural polyol pathway activity in diabetes and PKC activity is uncertain. Cytosolic PKC activity was reported to be reduced (147), unchanged (148), or possibly increased (149) in experimental diabetic neuropathy. The improvement in nerve perfusion and conduction with a PKC inhibitor suggests that an increase in PKC is relevant to neuropathy (126,150).

EXPERIMENTAL DIABETIC NEUROPATHY

Studies on experimental diabetic neuropathy have consistently demonstrated efficacy of aldose reductase inhibitors (ARIs) in preventing or ameliorating the conduction deficit. Sorbitol is increased (5- to 10-fold), myoinositol is reduced, and motor conduction is reduced. These biochemical abnormalities are prevented by various ARIs. Sorbinil was reported to partially prevent (151,152) or completely prevent the conduction deficit (153). Sorbinol also was reported to prevent and reverse deficits of the axonal transport of choline acetyltransferase in the

cholinergic neurons of the sciatic nerve (154). Similar findings were reported for other ARIs.

The careful electrophysiologic study of Cameron et al. (155) is instructive. They evaluated nerve conduction deficits caused by 2 to 4 months of diabetes in one sensory and six motor nerve branches of mature rats and the effect of the ARI ponalrestat. Diabetes suppressed a maturation-related increase in conduction velocity in the interosseous nerve supplying foot muscles. This was unaffected by any treatment. Large reductions in conduction velocity (22% to 29%) seen for fast nerves supplying four calf muscles and sensory saphenous nerves were prevented by treatment with ponalrestat. In a reversal group, which had 2 months of diabetes followed by 2 months of treatment, restoration of conduction varied among nerves, ranging from 100% in sensory saphenous to 25% in soleus motor branches.

More recent ARIs are more potent. For instance, Cameron et al. (156) reported a potent novel sulfonylnitromethane ARI, Zeneca ZD5522, in experimental diabetic neuropathy, with conduction velocity deficits after 4 months of untreated diabetes rapidly returned to normal within 12 days by treatment with ZD5522. There was a strong correlation between ZD5522-mediated increases in blood flow and conduction velocity. A 37% reduction in endoneurial oxygen tension after 2 months of diabetes was completely prevented by treatment with ZD5522. Similar effects have been reported for other novel ARIs, such as 8'-chloro-2',3'-dihydrospiro [pyrrolidine-3,6'(5'H)-pyrrolo[1,2, 3-de] [1,4]benzoxazine]-2,5,5'-trione (ADN-138) (157), [5-(3-thienyltetrazol-1-yl)acetic acid (TAT)] (158), and WAY-121,509 (159).

THERAPEUTIC APPLICATIONS

The effect of ARIs has now been studied in large numbers of patients with type 1 and type 2 diabetes. Electrophysiologic improvement occurs relatively early (160), but treatment beyond 3 months has not been shown to confer any additional benefits (161–163). Some improvement of symptoms, especially pain, has been reported (160). Improvement in autonomic indices has been reported (164). Overall, the larger studies have demonstrated only modest or no improvement in clinical neuropathic deficits. The majority of the more positive reports have been published only in abstract form or within supplements. There are encouraging data indicating that chronic users of the drug tolerestat who discontinued treatment demonstrated some worsening of nerve conduction and symptoms and improvement over placebo when they continued the drug for an additional 12 months.

Some caution is necessary in interpreting these negative results. It is my opinion that, while efficacy has not been demonstrated, neither has nonefficacy. For humans, the drug has to be well tolerated yet potent enough to normalize polyol pathway activity. The study needs to be done for a sufficiently long time period. On the basis of what is known about the natural history of progression of diabetic neuropathy, studies will need to be a minimum of 2 years. The severity of neuropathy should not be excessive, so that improvement is possible. These conditions have not been satisfied in the studies to date.

Advanced Glycosylation End Products (AGE)–AGE Receptor–Nuclear Factor-кВ

Chronic hyperglycemia has been suggested to cause macro- and microvascular atherogenesis by the generation of AGEs (165). The latter, by increasing macrophage recognition and uptake, stimulates macrophage-derived growth factor, comprising one mechanism suggested to result in the proliferation of smooth muscle and atherogenesis. There is also an AGE-induced increase in low-density lipoproteins in vessel walls and the involvement of other growth factors. Considerable experimental evidence supports this hypothesis (165). These findings also have important implications for treatment. Administration of aminoguanidine hydrochloride results in the formation of unreactive early glycosylation products rather than AGE. These workers have reported that rats treated with aminoguanidine for 10 months did not develop the thickening of renal glomerular basement membrane seen in untreated diabetic animals (165).

As described earlier, AGE binding to its receptor initiates the activation of NF-KB (120), the generation of ROS, and an inflammatory response (121). The quenching action of AGE binding on NO is relevant to nerve ischemia (122). Since AGEs have been suggested to mediate hyperglycemia-induced microvascular atherogenesis and because aminoguanidine prevents their generation, we examined whether aminoguanidine could prevent or ameliorate the physiologic and biochemical indices of experimental diabetic neuropathy. We examined the effects of dose and duration (up to 6 months) of treatment. Experimental diabetic neuropathy caused a 57% reduction in nerve blood flow, abnormal nerve conduction and amplitudes, and a 60% increase in conjugated dienes. Treatment with aminoguanidine normalized nerve blood flow by 8 weeks and significantly improved conduction, in a dose-dependent manner, by 16 and 24 weeks in sciatic-tibial and caudal nerves, respectively (166). Cameron et al. (167) demonstrated that aminoguanidine improved nerve conduction without an effect on polyol pathway metabolites and surmised that the effect was a vascular one.

THERAPEUTIC APPLICATIONS

To my knowledge, no placebo-controlled clinical trials have been published.

Excessive Lipolysis and y-Linolenic Acid Deficiency

Linoleic acid undergoes desaturation (by δ -6-desaturase) to γ -linolenic acid. In turn, it is elongated to dihomo- γ -linolenic acid, which in turn undergoes desaturation (by δ -5-desaturase enzyme) to arachidonic acid to polyunsaturated fatty acid. A defect at the desaturation step present in diabetic neuropathy can be overcome by the administration of γ -linolenic acid. Efficacy of γ -linolenic acid has been demonstrated in experimental diabetic neuropathy. Two multicenter studies of human diabetic neuropathy are unfortunately inconclusive.

EXPERIMENTAL DIABETIC NEUROPATHY

Dietary supplementation with evening primrose oil, which is rich in γ -linolenic acid, completely prevented the development of the deficit in motor-nerve conduction velocity without affecting levels of sorbitol, fructose, or myoinositol or the deficit in axonal transport of substance P (168,169). In a second experiment, treatment of diabetic rats with evening primrose oil was associated with significant attenuation of the conduction-velocity deficit but not in complete prevention (168). Improvement in conduction occurred *pari passu* with correction of deficits in blood flow and oxygen tension (170). Cameron et al. (171) demonstrated synergism between threshold doses of γ -linoleic acid and ARI and between γ -linoleic acid and antioxidant in reversing the neurovascular and conduction deficits in experimental diabetic neuropathy. They also reported synergism between γ -linoleic acid and ascorbate (172).

THERAPEUTIC APPLICATIONS

Treatment with oral γ -linoleic acid has been reported. A small open study reported improvement in nerve conduction and quantitative sensory indices (173), and improvement also was reported in a small placebo-controlled study involving 12 patients receiving 360 mg and 10 controls receiving placebo (174).

Recently, Keen et al. (175) reported the results of a sevencenter double-blind, placebo-controlled study involving 111 patients with mild diabetic neuropathy who were treated with γ -linoleic acid, 480 mg/day, or placebo for 1 year. Indices included motor and sensory conduction, quantitative sensory tests, clinical deficit scores, and a global score. A total of 16 parameters were evaluated and, for all 16 parameters, changes were favorable and reached statistical significance for 13.

A third blinded study has been completed. The study enrolled 291 patients, who were given a dose of γ -linoleic acid of 480 mg/kg. The study was placebo-controlled for the first 12 months. In the subsequent 12 months, both active and placebo groups received γ -linoleic acid. The study largely confirms the findings of the study by Keen et al. (175).

These results are most interesting and await confirmation with a larger study. A major limitations of these studies are the single-center effect and the apparently great deterioration in the placebo group. If the single center were excluded, the studies are clearly negative.

Induction of Protein Kinase C

The effect of hyperglycemia on endothelial cell, retinal, cardiac, and aortic tissue includes the increase of diacylglycerol (176) followed by the sequential activation of PKC and cytosolic phospholipase A_2 (cPLA2), resulting in the liberation of arachidonic acid and increased production of prostaglandin E_2 , which are known inhibitors of Na⁺,K⁺-ATPase (177). The reduction in Na⁺,K⁺-ATPase activity results in conduction slowing. The relevant PKC is the β -isoform in membrane (178).

Evidence for PKC induction in nerve is indirect. In nerve, inhibition of PKC results in a correction of the deficits in perfusion and nerve conduction (126). The benefits of the inhibitor were blocked by cotreatment with nitric oxide synthase inhibitor (126).

THERAPEUTIC APPLICATIONS

A phase II multicenter clinical trial on the effect of LY333531 on type 1 and type 2 diabetic neuropathy is under way. This is a double-blind, placebo-controlled study of three doses of the drug over 12 months. LY333531 is a specific inhibitor of the β -isoform of PKC; it was synthesized and shown to be a competitive reversible inhibitor of PKC- β_1 and PKC- β_2 , with a halfmaximal inhibitory constant of approximately 5 nM (179).

Synthesis of Pathogenetic Hypothesis

The above information has been synthesized into a pathogenetic model of diabetic neuropathy (Fig. 50.1). Hyperglycemia results in a reduction in nerve blood flow by altering vasoregulation (at the levels of the endothelial cell and arteriolar smooth muscle) of nerve microvessels and increasing blood viscosity. Microvascular vasocontrictor tone is increased (increased α -adrenergic and endothelin tone), and vasodilator tone is reduced (reduced endothelial activities of NO, calcitonin gene–related peptide, and substance P. NO deficiency, in addition to reducing microvascular flow, could enhance expression of adhesion molecules, impair the blood–nerve barrier, generate superoxide radicals, and activate PKC and NF-kB. Insulin administration could aggravate hypoxia (by increasing arteriovenous shunt flow and reducing nutritive flow). The ensuing endoneurial ischemia and

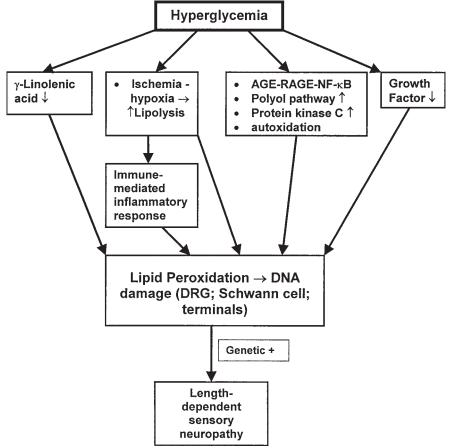

Figure 50.1. Suggested pathogenesis of diabetic neuropathy.

hypoxia, with resultant increased lipolysis, hyperglycemiainduced deficiency in γ -linolenic acid, generation of AGE (with binding to RAGE and activation of NF-kB), overactivity of the polyol pathway and PKC, autoxidation, and deficiency in growth factor result in a lipid peroxidation. The diabetic state exacerbates the inflammatory response to ischemia (180). HNE is particularly important in its ability to cause the apoptosis of neurons, their appendages, and support cells. The pathways in Figure. 50.1 are simplified. The figure depicts all mechanisms as going through oxidative stress and lipid peroxidation. In fact, it is likely that a number of the mechanisms could cause neuropathy by other mechanisms. For instance, PKC increase and polyol pathway overactivity/myoinositol deficiency could work in a significant degree via Na⁺,K⁺-ATPase deficiency. Growth-factor deficiency could work independently of oxidative stress. The synergism of antioxidants with ARI and with γ -linoleic acid suggests that there are significant interactions and synergism among mechanisms.

The targets of lipid peroxidation are likely multiple. Diabetic neuropathy is primarily a distal sensory neuropathy, so it is not surprising that the dorsal root ganglion appears to be a key target. Dendrites, nerve terminals, Schwann cells, and microvessels could also be important. The DRG has an especially high concentration of mitochondria because of its high energy metabolism. As in all tissues with vigorous oxidative metabolism, there is free-radical generation and a susceptibility to oxidative damage. The mitochondrion is an important microtarget. Impairment in mitochondrial function is manifested as a reduction in membrane potential, opening of the mitochondrial permeability transition pore, and vacuolar and pigmentary degeneration. Mitochondrial DNA is unusually susceptible to oxidative damage. There is normally about 1% leakage of free radicals. Increased free-radical leakage over time leads to increased mutations, as occurs with aging. These dysfunctional mitochondria have increased leakage of reduced oxygen species. A vicious cycle of oxidative damage to inner membrane proteins (of mitochondria) leading to imbalances in the electron transport chain, resulting in increased production of superoxide and hydrogen peroxide, which in turn further damages membrane proteins, is suggested. Leakage of cytochrome *c* leads to activation of the apoptotic cascade, and cells stain positively for activated caspase 3 and TUNEL. The process is slow, with only modest cell loss of large neurons (apoptosis lente). The physiologic alterations (distal sensory neuropathy, reduced sensory threshold, spontaneous firing) in experimental diabetic neuropathy could be due to the sensory neuropathy and radiculopathy described previously.

CONCLUDING THOUGHTS

A number of pathogenetic advances have been made during the past decade and a half. First is the validation that glucose is indeed a neurotoxin and that tight glycemic control will prevent target complications. Second is the appreciation that pathogenetic mechanisms are likely interactive and linked. There is no longer the simplistic view of the metabolic-versus-vascular hypothesis. The major candidate mechanisms are interlaced and may converge. Conversely, synergism appears to exist in methods to treat diabetic neuropathy, for example, antioxidant with ARI and γ -linolenic acid with antioxidant. Third is the evolving improvements in understanding of the targets of glucotoxicity. Evidence is still patchy, but a major target may be the DRG neurons, in addition to the Schwann cell and terminals. Fourth is a better understanding of molecular pathophysiologic mechanisms, especially in apoptosis.

CHAPTER 51 **Pathogenesis of Diabetic Nephropathy**

Gabriella Gruden and GianCarlo Viberti

THE INSULTS: HYPERGLYCEMIA, HYPERTENSION, AND PROTEINURIA 854

Hyperglycemia 854 Hypertension 856 Proteinuria 857

MOLECULAR MEDIATORS 857

Transforming Growth Factor-β1 857 Connective Tissue Growth Factor 858 Growth Hormone and Insulin-like Growth Factor 859 Vascular Endothelial Growth Factor 859 Angiotensin II 859

TRANSCRIPTION FACTORS AND INTRACELLULAR SIGNALING PATHWAYS 860

Nuclear Factor-κB 860 Fos, Jun, and the AP-1 Transcription Factor 860 Intracellular Signaling Pathways 860

TARGETS FOR PATHOGENESIS-SPECIFIC THERAPY 861

The abnormal glycemic milieu of diabetes is closely related to the development of microvascular complications. However, the evidence of a straightforward causal relationship between hyperglycemia and renal disease is less compelling in humans than in animal models. Only about 30% of patients develop clinically overt nephropathy. The majority of subjects with diabetes escape renal failure, and although some histologic damage occurs in their kidneys, their renal function remains essentially normal until they die. It therefore appears that in humans hyperglycemia is necessary, but not sufficient, to cause the renal damage that leads to kidney failure. The risk of developing kidney disease is not linearly correlated to the duration of diabetes; indeed, the incidence peaks after 17 years of type 1 diabetes and then sharply declines, a phenomenon likely due to exhaustion of the subgroup of susceptible subjects (1).

The central question is thus why some diabetic patients are susceptible to and others are protected from renal disease. A diabetic sibling of a person with type 1 diabetes and nephropathy has approximately a 72% cumulative risk of developing renal disease, whereas a diabetic sibling of a person with type 1 diabetes but without nephropathy has only a 25% risk (2). This indicates that inherited factors play an important role in determining susceptibility to diabetic nephropathy but does not provide insight into the nature of these factors.

Family studies have shown that a familial predisposition to raised arterial pressure is an important determinant of susceptibility to renal disease in persons with diabetes. Blood pressure levels are significantly higher in the parents of diabetic subjects with proteinuria than in the parents of diabetic subjects without proteinuria (3). Among Pima Indians with type 2 diabetes, the prevalence of proteinuria is higher in those with hypertensive parents than in those with normotensive parents (4). It has been calculated that the risk of nephropathy among patients with type 1 diabetes is three times higher in those who have at least one parent with a history of hypertension (5). Furthermore, prospective studies have demonstrated that mean blood pressure levels are significantly higher in those patients who progress to microalbuminuria than in those who do not, indicating that high blood pressure plays an important role in the pathogenesis of diabetic kidney disease (6).

Diabetic nephropathy and hypertension are multifactorial disorders that result from interaction between both environmental and genetic factors, making the identification of what confers susceptibility to diabetic kidney disease at the genetic level both difficult and complex. Polymorphisms of genes potentially involved in the genetic predisposition to hypertension, vascular reactivity, and insulin resistance, such as those of the renin-angiotensin system, nitric oxide, aldose reductase, GLUT I, and lipoproteins, have all been investigated in relation to diabetic nephropathy, but studies of candidate genes have, by and large, been inconclusive or, at best, have shown weak associations (7). However, a strong association between a polymorphism in the 5' end of the aldose reductase gene and the development of diabetic nephropathy in type 1 diabetes has been reported (8) and recently confirmed (9).

Studies of intermediate phenotypic markers of hypertension have provided some insight into the predisposition to diabetic renal disease. The red blood cell sodium-lithium countertransport system is a cell-membrane cation transport system whose activity is both genetically determined and increased in essential hypertension. Sodium-lithium countertransport activity is abnormally high in diabetic patients with proteinuria or microalbuminuria (10,11). High countertransport activity may thus constitute a suitable cell marker for identifying patients at risk of kidney disease. However, sodium-lithium countertransport is not operating *in vivo*; therefore, the pathophysiologic relevance of its abnormalities remains uncertain. The sodiumhydrogen antiport, a ubiquitous transmembrane protein that

catalyzes the electroneutral exchange of extracellular sodium for intracellular hydrogen, operates in vivo and regulates important cellular events, such as intracellular pH, cell volume, and cell proliferation. Furthermore, at the kidney level, the sodiumhydrogen antiport plays an important role in sodium reabsorption and may thus be involved in the pathogenesis of hypertension. Sodium-hydrogen antiport activity is increased in a number of cell types from patients with type 1 diabetes with microalbuminuria and proteinuria, as well as in subjects with hypertension (12,13). The activity of the sodium-hydrogen antiport is increased by high glucose concentrations in cells from patients with diabetic nephropathy but not in cells from diabetic patients without nephropathy or in cells from healthy controls (13). Furthermore, in prospective studies, the sodiumhydrogen activity of red blood cells predicts the development of proteinuria (14). Cultured skin fibroblasts from siblings of patients with type 1 diabetes show a very close concordance for the sodium-hydrogen antiport activity, indicating that antiport activity is by and large genetically determined (15). However, in both hypertension and diabetic nephropathy, the increased sodium-hydrogen antiport activity is not due to increased expression of the gene encoding for this protein. Alterations in the regulatory pathways of the sodium-hydrogen exchange are more likely to be implicated in its overactivity. Although the pathogenic role of the sodium-hydrogen antiport in diabetic nephropathy remains to be proven, together these studies of intermediate phenotype show that the increased susceptibility to diabetic nephropathy most likely resides in a genetically determined host-cell response to the diabetes environment (16).

In patients with type 2 diabetes, the evidence of a genetically determined susceptibility to the development of diabetic nephropathy is less compelling than in patients with type 1 diabetes. However, there is evidence of a familial clustering of diabetic nephropathy in type 2 diabetes (17–19), and affected sibpair linkage analyses have identified loci associated with diabetic nephropathy in type 2 diabetes (20–22). Moreover, in patients with type 2 diabetes, nephropathy is associated with cellular markers for hypertension (23), and in families with type 2 diabetes, albumin excretion rate is a heritable trait, with a heritability similar to that for blood pressure (24). Finally, in Pima Indians, blood pressure levels before the onset of diabetes predict the future risk of developing the complication (4).

THE INSULTS: HYPERGLYCEMIA, HYPERTENSION, AND PROTEINURIA

Diabetic nephropathy is characterized histologically by thickening of the glomerular basement membrane, increased fractional mesangial volume, and podocyte abnormalities. Expansion of the glomerular mesangium, which occurs at the expense of the glomerular capillary lumen and filtration surface area, correlates most closely with the decline in renal function and the development of proteinuria (25,26). *Ex vivo* studies have shown that the mesangial expansion is due to both increased production and reduced degradation of extracellular matrix proteins such as type IV and I collagen, laminin, and fibronectin (27).

Although the glomerulus, particularly the mesangium, has been the major focus of interest, tubulointerstitial injury is also a feature of diabetic nephropathy and a predictor of renal dysfunction. Pathologic changes that have been described in association with diabetic nephropathy include thickening of the tubular basement membrane, tubular atrophy, interstitial fibrosis, and arteriosclerosis. Interstitial expansion correlates closely with renal dysfunction, albuminuria, and mesangial expansion. Moreover, the impact of interstitial expansion on renal dysfunction is additive to that of mesangial expansion, suggesting an independent effect (28).

If diabetes-induced abnormalities were sufficient to cause renal disease, all diabetic patients, given time, would develop overt renal disease, and the study of hyperglycemia-induced abnormalities would be sufficient to explain the pathogenesis of these functional or structural abnormalities. But this is not the case. To gain insights into the pathogenic mechanisms of diabetic kidney disease, it is therefore necessary to take into account other insults that either influence the host response to diabetes-induced environmental disturbances, thus conferring susceptibility, or accelerate the progression of kidney damage.

Hyperglycemia

There is no doubt that poor glycemic control is associated with diabetic nephropathy. Levels of hemoglobin A_{1c} (Hb A_{1c}) are higher in patients with microalbuminuria and macroalbuminuria than in those with normoalbuminuria (29), and in two longitudinal studies, the glycemic control predicted the future development of microalbuminuria in normotensive type 1 diabetic patients with normoalbuminuria (6,30).

Intervention studies have demonstrated the renoprotective effect of optimal glycemic control in both human and experimental diabetes. In animals, structural glomerular changes and albuminuria can be prevented by the maintenance of normoglycemia by either islet cell transplantation or intensive insulin therapy or can be reversed by transplantation of an affected kidney into a nondiabetic animal (31-33). In humans, the Diabetes Control and Complications Trial (DCCT), a prospective multicenter randomized clinical trial comparing the effect of intensive and conventional insulin therapy on the risk of development and progression of diabetic chronic complications in 1,441 patients with type 1 diabetes, has demonstrated that a sustained improvement in HbA_{1c} reduces the risk of development of diabetic nephropathy (34). Similarly, the United Kingdom Prospective Diabetes Study (UKPDS) has shown that improved glycemic control is effective in the prevention of microalbuminuria in patients with newly diagnosed type 2 diabetes (35). Finally, in a small study of eight patients with type 1 diabetes, pancreatic transplantation and near normoglycemia for 10 years reversed structural abnormalities in the kidney (36).

There is strong evidence that hyperglycemia is necessary in the pathogenesis of diabetic nephropathy, and some of the mechanisms that link hyperglycemia to the functional and structural abnormalities of diabetic kidney disease have been elucidated.

Extracellularly, glucose reacts nonenzymatically with primary amines of proteins, forming glycated compounds. Glucose can also be transported into cells mainly by glucose transporters and can be metabolized to sorbitol via the polyol pathway and to glucosamine in the hexosamine biosynthetic pathway. These biochemical pathways have been implicated in hyperglycemia-induced kidney damage. Furthermore, it has become increasingly clear that excess glucose can exert toxic effects directly by altering intracellular signaling pathways; currently, this is believed to be a major mechanism by which hyperglycemia results in kidney damage.

NONENZYMATIC GLYCOSYLATION

Sustained hyperglycemia leads to nonenzymatic protein glycation, a posttranslation modification that occurs physiologically but is greatly enhanced in hyperglycemic conditions. Glycation results from condensation of reducing sugars with ε -amino groups of lysine residue of proteins. The resulting Schiff base undergoes rearrangement to form relatively stable ketoamines, the Amadori products. These glycated proteins undergo progressive dehydration, cyclization, oxidation, and rearrangement to form advanced glycation end-products (AGEs). Once these AGEs are formed, the reaction is not reversible, and they gradually accumulate over the lifetime of the protein (37).

The hypothesis that AGEs are involved in diabetic kidney disease is based on several observations. In both human and experimental diabetes, AGEs accumulate in renal glomeruli and tubules. This phenomenon is specific, as it does not occur in normal kidneys or in kidneys from patients with glomerulonephritis and without diabetes (38). In normal animals, injection of AGE-modified albumin results in overexpression of matrix molecules, albuminuria, and glomerulosclerosis (39). In diabetic animals, accumulation of AGEs in the kidney is paralleled by the development of albuminuria, mesangial expansion, and thickening of the glomerular basement membrane. Furthermore, administration of aminoguanidine (AGN), an inhibitor of AGE formation, attenuates renal accumulation of AGEs and reduces both albuminuria and mesangial expansion (40).

Ultrastructural and *in vitro* studies have cast light on the mechanisms whereby AGEs can lead to kidney damage. AGEs directly alter the structural and functional properties of extracellular matrix proteins. AGE-mediated protein cross-linking increases matrix rigidity and reduces the susceptibility of protein to enzymatic digestion, thus inducing accumulation and thickening, and favors trapping of plasma proteins, such as low-density lipoprotein (LDL) and immunoglobulin G (IgG). AGN normalizes the defect in matrix degradation that occurs when matrix is incubated in a medium high in glucose, suggesting that the AGN effect in preventing mesangial expansion is in part due to its capacity to normalize mesangial matrix digestion (41). In addition, AGEs can elicit a variety of cellular responses by binding to AGE-specific receptors present on many cell types, including mesangial cells and tubular epithelial cells (42). Interaction of AGE-modified proteins with the AGE receptors serves to degrade AGE proteins but also induces the synthesis and release of cytokines, such as transforming growth factor (TGF-β1), platelet-derived growth factor (PDGF), and insulin-like growth factor (IGF), and results in enhanced production of collagen, laminin, and fibronectin (43,44).

The importance of AGE receptors has recently been given further support by the observation that diabetic animals overexpressing the AGE receptor (RAGE) rapidly develop glomerular lesions similar to those seen in advanced diabetic nephropathy (45). RAGEs are also expressed on tubular epithelial cells, and it has recently been reported that RAGE activation can induce tubular epithelial cell transdifferentiation to myofibroblasts, a key event in the development of tubulointerstitial fibrosis (46).

THE POLYOL PATHWAY

In the polyol pathway, glucose is reduced to sorbitol by the enzyme aldose reductase. In many tissues, the physiologic significance of aldose reductase is difficult to define, but in the renal medullary cells, the primary role of aldose reductase seems to be the formation of sorbitol, an organic osmolyte, in response to the high salinity in the medullary interstitium. It has been argued that, in tissues in which glucose entry into cells is insulin independent, more glucose becomes available for reduction by aldose reductase, resulting in an increased concentration of sorbitol and/or a reduced intracellular concentration of myoinositol. These changes might contribute to diabetic complications via an upset of cellular osmoregulation (47,48). Enhanced activity of the polyol pathway has been demonstrated in diabetic glomeruli in humans (49). However, the initial hypothesis that accumulation

of sorbitol and reduction of myoinositol cause tissue damage is unlikely to operate in the kidney because compensatory mechanisms prevent the depletion of inositol in kidney cells (50).

More recently, enhanced AGE production and oxidative stress have been proposed as alternative mechanisms linking the polyol pathway to kidney injury in diabetes. In the polyol pathway, excess sorbitol is oxidized to fructose by the enzyme fructose dehydrogenase. The increased ratio of NADH/NAD (reduced form of nicotinamide adenine dinucleotide/oxidized form of nicotinamide adenine dinucleotide) coupled to the oxidation of sorbitol to fructose can result in cellular oxidative stress. Furthermore, fructose is a reactive sugar that can lead to AGE production (51,52). Recent experiments in cultured bovine aortic endothelial cells have demonstrated that high glucose concentrations increase the production of reactive oxygen species. Further, blockade of the electron transport chain complex II normalizes mitochondrial reactive oxygen species and prevents glucose-induced activation of protein kinase C (PKC), formation of AGEs, accumulation of sorbitol, and activation of the transcription factor nuclear factor- κ B (NF- κ B) (53).

Various pathophysiologic mechanisms linking activation of the polyol pathway to kidney damage can be postulated. However, to prove that activation of the polyol pathway is not merely an epiphenomenon but a mechanism of renal injury, it is important to have in vivo evidence that inhibition of the polyol pathway is beneficial in diabetic nephropathy. To gain this evidence, a series of studies of aldose reductase inhibitors (ARIs) have been carried out in both experimental and human diabetes. Early studies using the ARIs were inconclusive because of dubious compound specificity and drug toxicity. More recently, treatment of diabetic rats for 6 months with the ARI tolrestat resulted in a slight reduction in albumin excretion rate (54), but to date no convincing effect of aldose reductase inhibitors has been reported in controlled studies in humans. This indicates that activation of the polyol pathway is more likely to be an epiphenomenon and that other, more central mechanisms are operating in the pathogenesis of diabetic nephropathy.

HEXOSAMINE BIOSYNTHETIC PATHWAY

Approximately 5% of the glucose entering the cell is metabolized via the hexosamine biosynthetic pathway (HBSP), which converts glucose-6-phosphate into hexosamine-6-phosphate. Glutamine:fructose-6-phosphate aminotransferase (GFAT) is the first and the rate-limiting enzyme of this pathway. In both mesangial cells and NIH-3T3 fibroblasts, GFAT overexpression, which increases the flux through the HBSP, leads to enhanced expression of TGF- β and fibronectin (55,56). Furthermore, high glucose-induced production of TGF-β1 and matrix appears, at least in part, to be mediated by the HBSP because such production is significantly reduced by the GFAT inhibitor azaserine (57). A very low level of expression of GFAT usually is found in glomerular cells, but such expression is significantly enhanced in the glomerular cells of patients with diabetic nephropathy (58), suggesting a potential in vivo relevance of the in vitro findings. Both high glucose and angiotensin II activate the GFAT promoter in mesangial cells (59), and this provides a potential molecular mechanism of GFAT overexpression in the diabetic glomeruli.

GLUCOTOXICITY

Consistent with the finding in clinical studies that hyperglycemia per se plays a key role in the development of diabetic kidney disease, studies on both kidney cells and isolated glomeruli have confirmed that high glucose concentrations directly alter extracellular matrix deposition. In mesangial cells, high glucose concentrations induce cell hypertrophy and increase gene expression and protein secretion of extracellular matrix components, such as collagen, laminin, and fibronectin (60). Similarly, levels of type IV and I collagen messenger RNA (mRNA) are enhanced in tubular epithelial cells exposed to high glucose concentrations (28). An additional mechanism whereby high glucose leads to exaggerated matrix deposition is by reducing the activity of metalloproteases, enzymes responsible for extracellular-matrix degradation (61).

Renal cells, similar to cells at other sites of diabetic complications, do not have an absolute requirement of insulin for glucose uptake, so that the intracellular levels of glucose more directly reflect its plasma concentration. The importance of excess glucose entry into mesangial cells is underscored by the observation that glucose-induced effects can be mimicked in normal glucose concentrations by overexpression of the cellular glucose transporter GLUT 1, thus increasing basal glucose uptake (62). This finding also indicates that factors regulating expression of glucose transporter and/or activity can influence glucose uptake and thus glucotoxicity. High glucose concentrations would be expected to reduce glucose transporter expression/activity in order to protect cells from excess glucose entry. However, in vitro studies of cultured mesangial cells suggest that exposure to elevated glucose concentrations actually enhances GLUT 1 expression by mesangial cells, triggering a positive feedback mechanism that may result in progressive damage (63). Inhibition of GLUT 1 overexpression prevents overproduction of extracellular matrix molecules in mesangial cells exposed to high glucose (64), providing evidence of a key role of GLUT1 in glucotoxicity (64)

The cellular and intracellular mechanisms whereby high glucose can lead to matrix deposition have been extensively studied since the 1980s, and will be reviewed in depth below.

Hypertension

There is evidence that hypertension plays a critical role in the progression of diabetic nephropathy. Indeed the development of proteinuria is paralleled in most cases by a gradual rise in systemic blood pressure, and there is a significant correlation between the blood pressure levels and the rate of decline in glomerular filtration rate (65). Furthermore, intervention studies in both animals and humans have demonstrated significant renoprotective and antiproteinuric effects of antihypertensive therapy (66–68).

In diabetic nephropathy, hypertension is not merely the result of relentless kidney damage; there is considerable clinical evidence that the elevated arterial pressure is also important in the genesis of the glomerular lesion. In Pima Indians, higher mean blood pressure prior to the onset of diabetes actually predicts an abnormal albumin excretion rate after the diagnosis of diabetes (4). Further, prospective studies in both patients with type 1 and type 2 diabetes and normal albumin excretion have demonstrated that mean arterial pressure levels are significantly higher in those patients who progress to microalbumin-uria than in those who do not progress (6,69).

The difference in arterial pressure levels of diabetic patients who develop renal complications and those who do not is numerically small, and the levels in those who develop complications are often in the "normotensive range." However, this difference becomes biologically relevant in the presence of diabetes, which induces loss of autoregulation of glomerular capillary pressure. Under normal conditions, intraglomerular capillary pressure is tightly regulated by precise adjustments in afferent and efferent arteriolar resistance. Hyperglycemia induces vasodilatation, and in diabetes there is a marked reduction in afferent and a lesser reduction in efferent arteriolar resistance. This leads to an increase in levels of glomerular capillary pressure and moreover allows ready transmission of any increase in systemic blood pressure to the glomerular capillary network (70). The metabolic and the hemodynamic insults are thus intimately intertwined in determining altered glomerular hemodynamics.

The notion that enhanced glomerular capillary pressure is involved in diabetic glomerulosclerosis is based on several observations. Conditions known to increase glomerular capillary pressures, such as unilateral nephrectomy, Goldblatt hypertension, and high-protein diet, significantly enhance the extent of glomerular injury in rats with streptozotocin-induced diabetes. Conversely, amelioration of glomerular hypertension slows the rate of progression of the glomerular injury (71,72). Consistent with these animal studies, autopsy studies of diabetic patients with unilateral renal artery stenosis show nodular glomerulosclerosis lesions to be confined to the kidney with the patent renal artery (73). Finally, the greater efficacy of angiotensin-converting enzyme (ACE) inhibitors in their antiproteinuric and renoprotective action as compared with other blood pressure-lowering agents has been in part ascribed to the capacity of ACE inhibitors to reduce glomerular capillary pressure by removing the tonic constrictor effect of angiotensin II on the efferent arteriole (74).

Although increased glomerular capillary pressure has long been associated with the deposition of extracellular matrix, the mechanisms by which the mechanical insult of altered hemodynamics translates into kidney damage have only recently been elucidated. This has followed the demonstration of the unique elastic properties of the glomerular structure and the response of mesangial cells to mechanical stretch in culture.

Glomeruli are highly compliant structures, and when the intraglomerular pressure rises to levels approximating those observed in the diabetic and remnant kidney, glomerular volume increases by about 30%. Volume changes reach their maximum within 3 to 4 seconds following alteration in intraglomerular pressure, thus responding to the most transient variations in intraglomerular pressure. Glomerular expansion is associated with the stretching of its structural components, including the extracellular matrix and the cellular components. Because of the central location of the mesangial regions within the glomerular lobule, mesangial cells experience substantial mechanical stretching. Detailed morphologic studies have demonstrated how numerous cytoplasmic projections emerging from the mesangial cell body extend between adjacent capillaries and firmly attach to the perimesangial regions of the glomerular basement membrane. Therefore, the centrifugal displacement of these regions during glomerular expansion results in marked tridimensional stretching of mesangial cells (75).

Mesangial cells exposed to mechanical stretch in culture undergo alterations in morphology and synthetic activity. Cyclical stretch stimulates the synthesis and deposition of matrix components, such as collagen (I, III, and IV), fibronectin, and laminin, in a manner proportional to the intensity of cellular stretch (76-78). Interestingly, although cyclical stretch stimulates collagen synthesis at all glucose concentrations, net collagen accumulation in the medium can be demonstrated only at high glucose levels (79), the result of catabolic rates that are insufficient to match the increased synthesis in a high-glucose environment. Therefore, the cellular response to a hemodynamic insult can be influenced and exaggerated by high glucose concentration in the milieu. In addition, GLUT1 is overexpressed in an animal model of glomerular hypertension in vivo, and stretch enhances glucose uptake by inducing GLUT1 expression in human mesangial cells in vitro (80). This suggests that glomerular hypertension may enhance glucotoxicity.

Proteinuria

In diabetic nephropathy and other progressive glomerulopathies, proteinuria is a strong and independent predictor of decline in renal function (81). Excessive protein overload appears to induce tubulointerstitial damage and hence to contribute to the disease progression (82). Specifically, the excessive tubular reabsorption of proteins and the consequent accumulation of proteins in tubular epithelial cells induce the release of vasoactive and inflammatory cytokines, such as endothelin-1, osteopontin, and monocyte chemoattractant protein-1 (MCP-1). These factors in turn lead to overexpression of proinflammatory and fibrotic cytokines and infiltration of mononuclear cells, causing injury of the tubulointerstitium and, ultimately, renal scarring and insufficiency (28,81,83). A vicious cycle is then established in which changes in renal hemodynamics, either primary or in response to nephron loss, induce further proteinuria, perpetuating a mechanism of interstitial scarring and loss of more nephrons. The tubular toxicity of protein raises the possibility that the beneficial effects of ACE inhibitors in diabetic renal disease may reflect their potent antiproteinuric action in addition to the reduction of angiotensin II-mediated effects on growth-factor activation and glomerular hemodynamics (28,81). Limiting protein excretion and the consequent activation of tubular epithelial cell prosclerotic signals thus appears instrumental in protecting the kidney from further damage (Fig. 51.1).

MOLECULAR MEDIATORS

To enhance understanding of the pathogenesis of diabetic nephropathy, a number of studies have examined the cellular and molecular mechanisms of kidney damage. These studies have established the critical concept that the insults of hyperglycemia, high blood pressure, and protein overload converge at the cellular level by using similar molecular signaling pathways and influencing the expression of common cytokines (Fig. 51.2).

Transforming Growth Factor-β1

TGF- β is a ubiquitous cytokine that regulates a variety of cellular processes. It exists in three isoforms—TGF- β 1, TGF- β 2, and TGF- β 3—of which TGF- β 1 is the best characterized and most highly expressed in the kidney. Glomerular and proximal tubule cells produce TGF- β 1 and express both type I and type II TGF- β receptors, which bind to all TGF- β isoforms (84,85).

TGF- β 1 has important prosclerotic properties and is a potent inducer of cell hypertrophy and apoptosis. *In vitro*, both glomerular mesangial cells and tubular epithelial cells increase their synthesis of collagen, fibronectin, and laminin in response to TGF- β 1. Furthermore, TGF- β 1 inhibits the synthesis of collagenases and stimulates production of metalloprotease inhibitors. This results in reduced degradation of extracellular matrix and further contributes to accumulation of matrix (85). Finally, *in vivo*, TGF- β 1 induces glomerulosclerosis and proteinuria in healthy animals (86–88).

Numerous studies have explored the role of TGF- β 1 in diabetic glomerulosclerosis, and at present there is overwhelming evidence implicating overexpression of TGF- β 1 in the pathogenesis of diabetic nephropathy. In both human and experimental diabetes, TGF- β 1 gene expression and protein secretion are increased in the glomeruli and tubules (89,90). This effect is sustained in time and closely correlates with the degree of mesangial matrix expansion and with HbA_{1c} levels. The TGF- β type II receptor is also overexpressed in diabetic animals (91), suggesting that the diabetic kidney is hyperresponsive to TGF- β . Finally,

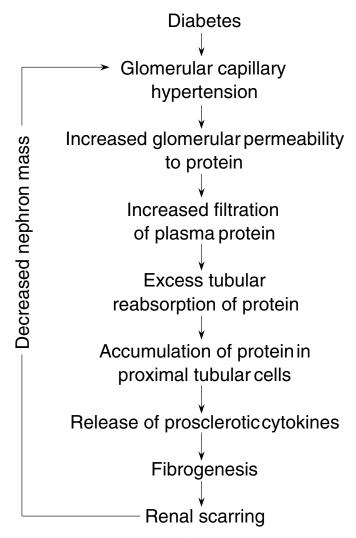

Figure 51.1. Potential mechanisms of proteinuria-induced renal damage. (Modified from Remuzzi G, Bertani T. Pathophysiology of progressive nephropathies. *N Engl J Med* 1998;12:1448–1456.)

and of the greatest importance, in diabetic mice TGF- β blockade significantly reduces overexpression of both type IV collagen and fibronectin and prevents glomerular hypertrophy, glomeruloscle-rosis, and renal insufficiency (92,93).

The importance of TGF- β 1 is further highlighted by *in vivo* and *in vitro* studies showing that the three key insults implicated in the pathogenesis of diabetic nephropathy promote the expression of this cytokine. These studies also suggest that TGF- β 1 may have a role in the interaction between metabolic and hemodynamic factors in mediating accumulation of extracellular matrix in the diabetic kidney.

High glucose concentrations induce the expression of TGF- β 1 in both mesangial and tubular epithelial cells. Further, inhibition of TGF- β 1 prevents glucose-induced hypertrophy of mesangial cells and production of extracellular matrix, indicating that these effects are mediated by TGF- β 1 via an autocrine mechanism (94). Exposure of mesangial cells to high glucose concentrations induces overexpression of TGF- β receptors, suggesting that high glucose concentrations may also enhance the response to TGF- β 1 (95). On the other hand, TGF- β 1 induces the GLUT1 transporter in mesangial cells and can thereby enhance glucotoxicity (96). *In vitro*, AGEs induce TGF- β 1 gene expression and protein secretion by mesangial cells (44), and *in vivo* administration of AGEs upregulates TGF- β 1 in the kidney (97).

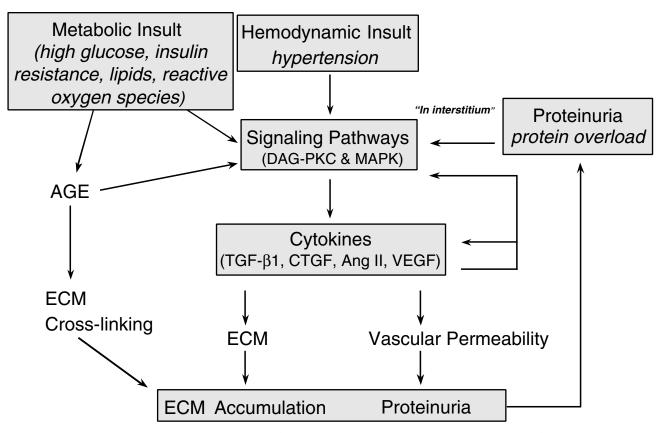

Figure 51.2. Schematic representation of the interaction, at the cellular and intracellular levels, of three insults operating in diabetic nephropathy. AGE, advanced glycation end-product; ECM, extracellular matrix; TGF- β 1, transforming growth factor-1 β ; Ang II, angiotensin II; CTGF, connective tissue growth factor; VEGF, vascular endothelial growth factor; MAPK, mitogen-activated protein kinases; PKC, protein kinase C; DAG, diacylglycerol.

The link between hyperglycemia, TGF- β 1, and kidney sclerosis is thus well established.

Recent studies in glomerular epithelial cells have shown that high glucose induces the TGF- β type II receptor without affecting TGF- β 1 production. TGF- β mediates high glucose–induced production of fibronectin and collagen type IV (α 3 chain) by glomerular epithelial cells, suggesting a role of TGF- β 1 in the thickening of the glomerular basement membrane (98,99).

In vivo in the remnant kidney, an animal model of progressive renal injury with many hemodynamic and structural similarities to diabetes, treatment with ACE inhibitors, which normalized glomerular capillary pressure, is associated with reduced expression of TGF-β1 (100). This provides indirect evidence that the hemodynamic insult may affect TGF-\u00b31. This hypothesis has been confirmed in vitro by studies showing that cyclic stretch of mesangial cells stimulates TGF-β1 gene expression and protein secretion in an intensity-dependent manner (101) and enhances the expression of the type II TGF- β receptor (102) Further, TGF-β1 mediates, at least in part, stretch-induced overproduction of mesangial matrix (103). Finally, stretchinduced glucose uptake is also mediated by TGF-β1 (80). This suggests a key role of TGF-β1 as final common mediator of sclerosis and glucotoxicity in mesangial cells exposed to metabolic and mechanical perturbations.

In rats with protein-overload nephropathy, inflammatory cells are recruited into the interstitium via a complement-mediated mechanism. These cells are then activated to secrete TGF- β 1, which in turn binds to specific receptors on interstitial fibroblasts

and induces them to proliferate and secrete matrix components. Thus, TGF- β 1 is also crucial in proteinuria-induced interstitial remodeling and scarring (83).

On the basis of this evidence, it is now generally believed that TGF- β 1 is the mediator of a final common pathway leading to sclerosis in diabetic nephropathy.

Connective Tissue Growth Factor

Connective tissue growth factor (CTGF) is a novel cytokine that is overexpressed in various sclerotic conditions (104). The importance of CTGF in diabetic nephropathy followed its identification by differential cloning as a gene overexpressed in mesangial cells cultured in high glucose concentrations (105). CTGF is only minimally expressed in the normal kidney, but it is strongly induced in the mesangium in both human and experimental diabetic nephropathy (106,107). AGN diminishes overexpression of both CTGF and intracellular matrix in diabetic mice (108). In vitro studies have provided potential mechanisms of CTGF involvement in the pathogenesis of diabetic nephropathy. In vivo studies then showed that CTGF is overexpressed in the glomeruli from proteinuric diabetic rats (106) and in the tubulointerstitium in the rat remnant kidney model (109). In vitro studies have provided potential mechanisms of CTGF induction in diabetic nephropathy. In mesangial cells, CTGF expression is induced by high glucose concentrations, mechanical stretch, and TGF-β1 (106). Furthermore, CTGF is a crucial downstream mediator of TGF-B1 signaling, but it appears to

mediate selectively the TGF-B1 profibrotic effect of increased production of extracellular matrix, whereas it does not have antiproliferative and immunosuppressive activity (110). CTGF also stimulates its own expression, and this capacity of autoinduction has been implicated in the perpetuation of the fibrotic process (106). Recent studies have shown that CTGF binds to IGF-1, TGF- β 1, and vascular endothelial growth factor (VEGF) in the extracellular space, whereby modifying their bioactivity. Specifically, CTGF appears to enhance IGF-1 prosclerotic effects, increasing the binding of TGF- β 1 to its receptors, and to prevent VEGF binding to the KDR receptor (111). This suggests that CTGF may play a role in the pathogenesis of diabetic nephropathy not only by acting directly on mesangial cells but also by modulating the activity of other cytokines implicated in the pathogenesis of the glomerular damage. In tubular epithelial cells, CTGF is a weak inducer of fibronectin production; however, CTGF may contribute to tubulointerstitial fibrosis by stimulating transdifferentiation of epithelial cells to myofibroblasts (112,113).

Growth Hormone and Insulin-like Growth Factor

IGF-1 is a potent mitogenic polypeptide, under growth hormone (GH) regulation, that binds to a specific receptor (IGF-R1) and to six binding proteins (IGFBPs) that modulate its bioavailability (114). Although circulating IGF-1 levels are normal or reduced in patients with diabetes (115), the local IGF-1 system appears to be upregulated. IGF-1 content of the kidney is increased in experimental diabetes. Furthermore, increases in IGF-R1 and changes in IGFBP expression, leading to enhanced IGF-1 trapping and possibly bioreactivity, have been reported in kidneys from diabetic animals (114). Transgenic animals overexpressing IGF-1 and GH develop glomerular hypertrophy (116). Furthermore, IGF-1 infused in pharmacologic concentrations in humans increases renal plasma flow and the glomerular filtration rate (117). Finally, suppression of the GH/IGF-1 axis prevents the onset of glomerular hyperfiltration and renal hypertrophy in diabetic animals (114,118). IGF is thus believed to play a role in the pathogenesis of early glomerular abnormalities in the diabetic kidney.

IGF-1 stimulates endothelial nitric oxide synthase (eNOS) activity *in vitro* in endothelial cells and induces vasodilation *in vivo*, and this provides a potential link between IGF-1 and glomerular hyperfiltration and hypertrophy (119). In a high-glucose milieu, IGF-1 induces the proliferation of mesangial cells, which also may contribute to the glomerular hypertrophy of early diabetes. In mesangial cells, IGF-1 increases both matrix production and GLUT1 activity (120), suggesting a role of IGF-1 in glomerulosclerotic processes; however, the demonstration that mice transgenic for IGF-1 do not develop glomerulosclerosis has weakened this hypothesis (116).

Vascular Endothelial Growth Factor

VEGF, also known as vascular permeability factor, is a potent inducer of angiogenesis and vascular permeability and dilatation (121). In the adult kidney, VEGF is expressed by both glomerular and tubular epithelial cells, and VEGF receptors are located on the vascular endothelium. However, other glomerular cell types, including mesangial cells, can produce VEGF and express VEGF receptors *in vitro* and in pathologic conditions (122,123). Insults relevant to diabetes, such as high glucose, AGEs, mechanical stretch, angiotensin II, IGF-1, and TGF-β1, have been shown to induce VEGF production *in vitro* in mesangial cells (124–128). Moreover, in glomerular epithelial cells, high glucose induces VEGF in a TGF-β-1–dependent manner, and stretch stimulates both production of VEGF and expression of VEGF receptor (129,130).

Both VEGF and VEGF receptors are overexpressed in the glomeruli *in vivo* in experimental diabetes (131) and in patients with type 2 diabetes (132), and plasma VEGF levels are raised in patients with type 1 diabetes with nephropathy (133). Recent studies in both type 1 and type 2 experimental diabetes have shown that VEGF blockade prevents glomerular hypertrophy and glomerular hyperfiltration and ameliorates proteinuria (134,135), suggesting a role for VEGF in the early glomerular abnormalities of diabetes.

VEGF potently stimulates eNOS expression and activity in cultured endothelial cells (136), and VEGF blockade normalizes eNOS expression by glomerular capillaries (134), providing a potential link between VEGF and both glomerular hyperfiltration and hypertrophy in diabetes. Although VEGF is a potent inducer of permeability of endothelial cells (137), the mechanism linking VEGF to proteinuria remains elusive, as VEGF receptors are expressed primarily on the glomerular endothelium, which plays a minor role in the filtration barrier.

Angiotensin II

Circulating angiotensin II is formed in the blood by the reninangiotensin system. In addition, there is an intact, independent renin-angiotensin system in the kidney (138) that is abnormally activated in diabetes. Indeed, in diabetic rats, both renin and angiotensinogen gene expression is increased in the kidney. Further, the intensity of ACE immunostaining is enhanced in both glomeruli and renal vessels (139).

ACE inhibitors appear to have a greater efficacy than other blood pressure–lowering agents in their antiproteinuric and renoprotective action. This has been classically ascribed to their effect on glomerular hemodynamics, as suggested by treatments that, by interfering with angiotensin II action, normalize glomerular capillary pressure in diabetic rats (74).

Moreover, in the kidney, angiotensin II can bind to receptors expressed on various renal cell types (140) and exerts important effects, independent of its systemic hemodynamic activity, that may contribute to the progression of renal disease (141). In particular, angiotensin II can directly induce matrix deposition via a TGF-B1-dependent mechanism in both mesangial and tubular cells (142). High glucose induces production of angiotensin II in mesangial cells (143), and stretch magnifies the response of mesangial cells to angiotensin II by upregulating the angiotensin II receptor AT1 (127). Therefore, in mesangial cells the deleterious effects of hyperglycemia and high intraglomerular pressure may result from an enhanced production of and responsiveness to angiotensin II. In glomerular epithelial cells, angiotensin II induces apoptosis via a TGF-β1-dependent mechanism (144), and ACE inhibitors prevent both proteinuria-induced glomerular epithelial-cell damage and overexpression of TGF-β1 (145). This suggests that angiotensin II may be causally implicated in the podocyte abnormalities seen in diabetic nephropathy (146).

In isolated glomeruli, angiotensin II increases glomerular permeability to protein and impairs the size-selective function of the glomerular filter (147,148). The underlying mechanism is still unclear; however, recent studies of human epithelial cells have shown that angiotensin II induces a rapid reduction in the expression of nephrin, a protein of the slit diaphragm implicated in the pathogenesis of proteinuric conditions (149). *In vivo* both angiotensin II receptor antagonists and ACE inhibitors normalize the reduced expression of nephrin that occurs in diabetes (150). Although further studies are required to establish whether reduction in nephrin is a marker of podocyte damage or a mechanism of proteinuria, these recent findings have opened an exciting new

area of research. It thus appears that the efficacy of ACE inhibitors and angiotensin II receptor antagonists is due not simply to inhibition of the hemodynamic effects of angiotensin II but also to direct blockade of the cytokine and growth factor action of angiotensin II. On the other hand, exposure of mesangial cells to hemodynamic stretch magnifies their response to angiotensin II via an upregulation of the angiotensin II receptor AT1, making it possible for the deleterious effect of high intraglomerular pressure to result not only from a direct mechanical insult but also from an enhanced angiotensin II effect (127).

TRANSCRIPTION FACTORS AND INTRACELLULAR SIGNALING PATHWAYS

It is important to understand which intracellular mechanisms affect the transcription of the genes coding for extracellular matrix proteins in diabetic nephropathy. Gene transcription is regulated by transcription factors that bind to specific binding sites in the gene promoter region. Cellular responses often result from coordinated activation of sets of genes with binding sites for common transcription factors. Sclerosis is a cellular response to insult, and it is likely to follow this pattern. It is thus critical to identify the transcription factor or factors implicated in matrix overexpression in diabetic nephropathy and to establish which intracellular signaling pathways are involved in induction or activation of these transcription factors.

Nuclear Factor-кВ

The transcription factor NF-kB plays a pivotal role in early gene responses by promoting the synthesis of mRNA for various celladhesion molecules and cytokines. NF- κ B is important in cell survival, and its inhibition has been causally related to apoptosis. Monocytes of patients with diabetic nephropathy have higher NF-KB activity than do monocytes of patients without renal complications (151), and in experimental diabetes, AGEs induce NF-κB activation in the tubuli (152). In vitro studies have demonstrated that high glucose, AGEs, angiotensin II, and stretch potently induce NF-kB activation mainly via formation of reactive oxygen species and activation of PKC (153,154), providing potential cellular mechanisms of NF-kB activation in the diabetic kidney. Inhibition of NF-kB reduces interstitial monocyte infiltration in rats with proteinuria, and NF-κB is believed to play a key role in proteinuria-induced tubulointerstitial damage in diabetes (83). Recent studies have shown than NF-KB mediates both stretch and high glucose-induced production of MCP-1 in mesangial cells (155,156), plays a role in apoptosis of glomerular epithelial cells (157), and modulates the TGF-B1 intracellular signaling pathway (158). There is thus preliminary evidence for a role of NF-KB in the pathogenesis of both glomerular and tubular damage in diabetes. Both ACE inhibitors and statins are potent NF-KB inhibitors, and their renoprotective action may be related, at least in part, to the suppression of NF-KB activity.

Fos, Jun, and the AP-1 Transcription Factor

c-*fos* and c-*jun* are two highly conserved proto-oncogenes. c-Fos and c-Jun proteins combine in homo/heterodimers (c-Fos/c-Jun, c-Jun/c-Jun) to form the AP-1 transcription complex, which binds to and induces genes with AP-1–binding consensus sequences in their promoter regions (159). Genes encoding for TGF- β 1, fibronectin, and laminin contain AP-1–binding sites in their promoters; thus, AP-1 may stimulate their transcription and induce expression of extracellular matrix protein genes via direct and indirect mechanisms (160,161).

Increased expression of *c-fos* and *c-jun* mRNA has been demonstrated *in vivo* in rat glomeruli 24 hours after the induction of diabetes (162). In rat mesangial cells *in vitro*, high glucose concentrations induce expression of *c-fos* and *c-jun*; furthermore, *c-fos* is induced after 20 minutes of exposure to mechanical stretch (163,164). There is also evidence *in vitro* that expression of *c-fos* and *c-jun* in mesangial cells induced by high glucose concentrations is associated with increased transcription of target extracellular matrix protein genes via formation of the AP-1 transcription factor (165).

Therefore, the AP-1 transcription factor plays an important role in the cascade leading to excess deposition of matrix deposition. However, which are the signal transduction pathways that cause increased AP-1 expression?

Intracellular Signaling Pathways

PROTEIN KINASE C

PKC, a family of ubiquitous serine-threonine kinases, is important in the transduction of many extracellular signals. There are at least 11 isoforms of PKC; these can be categorized into classical (α , β 1, β 2, γ), novel (δ , ε , η , θ), and atypical (ζ , λ , μ) on the basis of their common structural features. Both classical and novel PKC isoforms are activated by diacylglycerol (DAG) (166). PKC activation regulates a number of vascular functions, such as vascular permeability, contractility, cellular proliferation, basement membrane synthesis, and signal transduction mechanisms for hormones and cytokines (167). Furthermore, PKC induces expression of *c*-*fos* and *c*-*jun* (168,169); thus, PKC can be proposed as a potential candidate responsible for the increased AP-1 expression seen in diabetic nephropathy. This hypothesis is supported by both *in vitro* and *in vivo* data.

In diabetes, DAG levels are increased and PKC is activated in a variety of tissues, including kidney glomeruli (170). The direct role of hyperglycemia in causing these alterations was confirmed by exposing isolated glomeruli and cultured mesangial cells to high glucose concentrations. High glucose concentrations lead to de novo DAG synthesis, which is then responsible for PKC activation (171-173). It is interesting that activation of the DAG-PKC pathway in diabetic animals is maintained chronically, and this supports the hypothesis of a role of this system in the pathogenesis of chronic diabetic complications. Furthermore, glycated products and activation of the polyol pathway can also activate the DAG-PKC cascade, suggesting that the activation of DAG-PKC may be a common downstream mechanism by which multiple by-products of glucose exert their adverse effects (174). Recent evidence from studies of cultured bovine endothelial cells suggests that hyperglycemia induces superoxide production by the mitochondrial electron transport chain and that this is the causal link between PKC activation, AGE formation, and sorbitol accumulation (53)

PKC is also a crucial downstream mediator of TGF-β1, angiotensin II, VEGF, and cyclic stretch signaling, indicating that PKC activation is a key intracellular target of both metabolic and hemodynamic insults (175–177).

Multiple cellular and functional abnormalities in the diabetic kidney have been attributed to the activation of the PKC pathway. In mesangial cells *in vitro*, PKC agonists increase production of extracellular matrix components, whereas PKC inhibitors prevent glucose-induced expression of collagen type IV and fibronectin (178); further, many stretch-induced effects have been shown to occur, at least in part, via a PKC-dependent mechanism (78,175). *In vivo*, a specific PKC- β inhibitor prevents

the increase in type IV collagen and fibronectin expression in diabetic rat glomeruli and ameliorates albuminuria after 8 weeks of treatment (179–181). In addition, prevention of albuminuria by ramipril in rats with streptozotocin-induced diabetes is associated with the normalization of glomerular PKC (182).

As outlined previously, TGF- β 1 is a key mediator of sclerosis in the diabetic kidney, and PKC inhibitors prevent TGF- β 1 overexpression in diabetic glomeruli (179). Thus, PKC activation may be responsible for the increased expression of matrix molecules both directly and through TGF- β 1 overexpression. The capacity of active PKC to induce *c*-*fos* and *c*-*jun* transcription (168,170) and thus to stimulate the formation of the AP-1 transcription factor is believed to be the major underlying mechanism of this combined induction of TGF- β 1 and matrix protein genes.

MITOGEN-ACTIVATED PROTEIN KINASES

Extracellular signal–related kinases (ERK), stress-activated protein kinases (JNK), and p38 kinases (p38) are members of the mitogen-activated protein kinase (MAPK) superfamily. These kinases constitute functionally distinct, but structurally related, transduction pathways by which extracellular signals are transmitted to the nucleus to regulate gene expression. Specifically, MAPKs are activated by phosphorylation at specific threonine and tyrosine residues in response to various cytokines and extracellular stresses. Activated MAPKs translocate to the nucleus, where they phosphorylate and transactivate specific transcription factors, which regulate the expression of *c-fos* and *c-jun* genes. Thus, MAPKs may influence extracellular matrix protein genes and TGF- β 1 expression via an AP-1–dependent mechanism (183).

Recent *in vitro* and *in vivo* data demonstrate that both ERK and p38 are activated *in vivo* in glomeruli from diabetic rats and *in vitro* in mesangial cells exposed to either high glucose concentrations or mechanical stretch (78,184–188). Furthermore, specific p38 and ERK inhibitors prevent stretch-induced overproduction of matrix (78,188), and PKC inhibition abrogates p38 activation (78,189). This suggests that MAPKs are intracellular mediators leading to matrix overproduction and that they operate downstream of PKC.

In mesangial cells, p38 also is activated by TGF- β 1 and mediates TGF- β 1-induced fibronectin production; thus, p38 seems to be a key mediator of sclerosis (78). Accordingly, it was recently found that human mesangial cells exposed to stretch show rapid activation of p38, resulting in a direct and independent production of fibronectin and TGF- β 1; the latter in turn contributed to the maintenance of long-term p38 activation in a vicious cycle, resulting in the perpetuation of fibronectin accumulation (78) (Fig. 51.3).

TARGETS FOR PATHOGENESIS-SPECIFIC THERAPY

The combined action of various insults is required to explain the pathogenesis of diabetic nephropathy. Glucose-dependent pathways are clearly relevant, and therefore any therapeutic approach that involves intensification of glycemic control should be considered as part of treatment regimens for diabetic nephropathy. Indeed, in both type 1 and type 2 diabetes, intensified insulin therapy has been shown to retard the development of diabetic kidney disease (34,35). The importance of hemodynamic factors, including systemic and glomerular hypertension, in the pathogenesis of diabetic nephropathy has been underscored by clinical trials of ACE inhibitors and other antihypertensive agents, which have conclusively demonstrated their renoprotective and antiproteinuric effect (66–68).

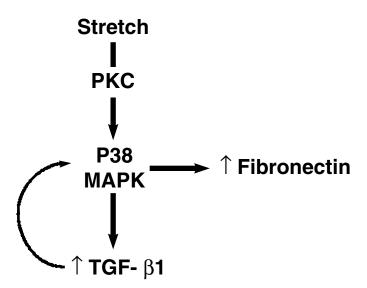

Figure 51.3. Central role of p38 in stretch-induced matrix production in human mesangial cells. Stretch induces p38 mitogen-activated protein kinase (MAPK) activation via a protein kinase C (PKC)–dependent mechanism. p38 mediates stretch-induced transforming growth factor-1 β (TGF- β 1) and fibronectin production. TGF- β 1 in turn maintains activation of p38 and leads to further accumulation of fibronectin. (Modified from Gruden G, Zonca S, Hayward A, et al. Mechanical stretch-induced fibronectin and TGF- β 1 production in human mesangial cells is p38 mitogen-activated protein kinase-dependent. *Diabetes* 2000;9:655–661.)

Furthermore, in diabetic nephropathy, proteinuria is a strong and independent predictor of decline in renal function (81). Therefore, the treatment of the diabetic patient at risk of or with established nephropathy requires a concerted approach that aims at optimization of glycemic control, lowering of blood pressure, and reduction of protein excretion either by using antiproteinuric agents or by lowering protein intake.

Formation of AGEs and activation of the polyol pathway have long been proposed as potential mechanisms linking hyperglycemia to kidney damage. However, clinical trials using agents that inhibit these biochemical pathways have so far been either disappointing or inconclusive. In humans, aldose reductase inhibitors have failed to shown any renoprotective effect in controlled studies, and no clinical trial is currently in progress to further test the effect of aldose reductase inhibitors in the prevention and treatment of diabetic nephropathy. AGN, an inhibitor of AGE formation, has been shown to reduce albuminuria and mesangial expansion in animals (40), but preliminary data from the recently completed clinical studies in both type 1 (ACTION 1) and type 2 (ACTION 2) diabetic patients failed to convincingly show a renoprotective effect of AGN and have raised some concern about the safety of this compound. Recently, a new class of compounds that cleave AGE-derived protein cross-links have been synthesized (190). Phenacylthiazolium bromide and other members of this family revert AGE-mediated tissue damage and are effective in the treatment of diabetic subjects with established renal disease (191); however, the role of these compounds in human disease is yet to be explored.

Recently, studies on the cellular and molecular mechanisms involved in the pathogenesis of diabetic nephropathy have provided new targets for therapeutic intervention. TGF- β 1 plays a pivotal role in the sclerotic process of the diabetic kidney; therefore, it is an important target for pathogenesis-specific therapy (192,193). However, TGF- β 1 has other functions besides promoting fibrosis; most important, TGF- β 1 modulates the immune and

inflammatory response. Therefore, any attempt at blocking TGF- β 1 may lead in the long term to inflammatory, autoimmune, and malignant responses, and this may prevent its use in humans. CTGF, a cytokine recently implicated in the pathogenesis of diabetic nephropathy, is induced by TGF- β 1 and seems to mediate TGF- β 1 prosclerotic effects exclusively. CTGF is thus a promising therapeutic target, and studies are ongoing to assess the effect of CTGF blockade in experimental diabetes (104).

Activation of PKC is believed to play a key role in diabetic complications. PKC exists in various isoforms (194), and analyses of retina, kidney, and cardiovascular tissues have shown a predominant activation of PKC-β isoforms in the diabetic state with minor increases of other isoforms, suggesting that a specific inhibitor for PKC- β isoforms could be used to circumvent the nonspecificity and in vivo toxicity of general PKC inhibition (173). Recent reports demonstrate that a number of in vivo abnormalities in diabetic rats can be prevented or normalized with an orally available specific inhibitor of PKC-β isoforms, LY333531. Oral administration of LY333531 to streptozotocin-diabetic rats for 2 weeks prevents changes in the retinal blood flow and glomerular filtration rate and improves the renal albumin excretion rate after 8 weeks of treatment. LY333531 also can prevent the diabetes-induced abnormalities in mRNA expression of TGF- β 1, type IV collagen, and fibronectin in the glomeruli and of caldesmon in the aorta (179-182). These findings provide strong evidence that PKC-B blockade can be beneficial in diabetic vascular complications in animals, and clinical trials are currently ongoing to test its safety and efficacy in humans. These studies also suggest that PKC inhibition is a promising therapeutic approach not only for diabetic nephropathy but also for chronic diabetic complications in general. Recent findings indicate that other intracellular signaling molecules, such as ERK and p38, play an important role in the pathogenesis of diabetic vascular complications. Specific p38 inhibitors can be orally administered and have disease-modifying activity in animal

models of chronic inflammatory diseases; however, their effect in diabetic complications is yet to be explored. Table 51.1 presents some of the therapeutic targets, either current or potential, along the pathogenic path leading to diabetic kidney disease.

The improvement of gene-transfer techniques, especially vectors for delivering genes, raises the exciting possibility that gene therapy may become a novel therapeutic approach to renal disease. Correction of cellular dysfunction by expressing a deficient gene, addition of a new function by transferring an exogenous gene, and inhibition of unfavorable action by introducing a counteracting gene are potential applications of gene-transfer technology to therapy. It is possible to selectively transfer somatic genes to the kidney using both in vivo and ex vivo approaches, and it has recently been demonstrated with the HVJ-liposome-mediated gene-transfer method that mesangial matrix expansion of experimental glomerulonephritis can be prevented by antisense oligonucleotides or soluble receptor chimera for TGF- β (195). The potential applications of gene transfer in diabetic nephropathy are enormous, but research in this field has just begun. The advances made in understanding the cellular and intracellular basis of diabetic nephropathy during the past decade can provide specific targets for future gene-transfer therapy.

CONCLUSION 879

Diabetes mellitus is a major independent risk factor for cardiovascular disease (CVD) (1). The increased prevalence of CVD in diabetes has been attributed in large part to the acceleration of coronary atherosclerosis, which occurs at an earlier age and advances more rapidly to clinical cardiovascular events in individuals with diabetes than in those without diabetes (2,3). Patients with diabetes are also prone to arterial thrombosis due to persistently activated thrombogenic pathways and impaired fibrinolysis (4–7). This combination of increased arterial disease and prothrombotic milieu in diabetes is a major underlying cause of acute ischemic coronary heart disease (CHD). Moreover, CHD in diabetes is often diffuse, with an increase in the pumber of affected vessels and in the incidence of moderate stenosis (3,8). Detection of narrowing of the coronary lumen in patients with diabetes is often impaired by autonomic neuropathy (9,10), which can reduce the symptoms of ischemic CHD, delay its detection, and worsen the prognosis. In addition, diabetic individuals are faced with increased restenosis and mortality rates following revascularization procedures, especially for percutaneous transluminal coronary angioplasty (PTCA) (11). The impact of CHD on myocardial function in diabetes is exacerbated by diabetic cardiomyopathies (12,13), which can impair cardiac contractile function and may accelerate heart failure. Multivariate analyses of a number of large prospective studies with follow-up of 12 to 20 years, including the Framingham Study, the Multiple Risk Factor Intervention Trial,

and the Nurses' Health Study, have demonstrated that diabetes is associated with two- to fivefold increases in CHD- and cardiovascular-related death (14–16). This CVD accounts for the majority of premature mortality associated with both type 1 and type 2 diabetes worldwide (17). A combination of factors related to hyperglycemia, hypertension, insulin resistance, dyslipidemia, hypercoagulability, and inflammation contributes to the etiology of CVD associated with diabetes.

HISTOLOGIC CLASSIFICATION OF ATHEROSCLEROSIS

Atherosclerosis is a progressive disease of the arterial wall involving components of inflammation, vascular lipid deposition and remodeling, fibrosis, and thrombosis. The American Heart Association has outlined a histologic classification of atherosclerotic lesions (Table 52.1) (18,19). Initial atherosclerotic lesions and fatty streaks represent the appearance of scattered lipid deposits in the intima associated with increases in macrophages and macrophage foam cells. Although these early lesions are not clinically significant and may regress (20), they also can provide precursors for the formation of advanced complex plaques. Intermediate lesions and atheroma involve increased focal accumulation of lipid within the neointima due to increased levels of foam cells, of both macrophage and vascular smooth muscle cell (VSMC) origin, and the appearance of extracellular lipid droplets, leading to the formation of a lipid-

rich plaque core. These intermediate lesions appear to arise from either fatty streaks or preexisting intimal cell masses (21). Fibrous plaques are formed as a cap of connective tissue, mainly involving VSMC in a collagen and proteoglycan matrix, and accumulate between the lipid core and vessel lumen. Thickness of the fibrous cap and its infiltration with macrophages affect the stability of these lesions, such that plaques with thin fibrous caps and those with increased levels of macrophages appear prone to rupture (3,22). Fibrotic lesions also can develop in plaques that do not display a well-defined lipid core. Complicated lesions occur when the plaque becomes disrupted owing to fissure, hemorrhage, or thrombus formation. Recent proposed modifications of this classification have emphasized that fibrous plaques or pathologic intimal thickenings can lead to significant stenosis without thrombi and that luminal thrombosis often occurs in vessels with a less than 50% reduction in diameter (23). Moreover, atherogenesis does not necessarily progress in a uniform manner, but lesion histology instead involves a mosaic of accumulations of lipid, fibrous material, and cellular mass.

Recent analyses of coronary tissue from autopsy studies have indicated that the main causes of coronary sudden death are plaque rupture or erosion, followed by thrombosis and stenosis (23). Plaque rupture is evidenced by contact between the thrombus and the necrotic atheromatous core. Plaque erosion is indicated when the thrombus occurs on a fibrous cap that has lost its luminal endothelium but retains a continuous connective tissue covering the necrotic core. Disruption of the endothelium and fibrous cap can expose the blood to the plaque

Lesion classification		Characteristics	Effects of diabetes
Туре І	Initial lesions	Atherogenic lipoprotein Increased macrophages Scattered macrophage foam cells	Impaired endothelial- dependent vasorelaxation
Туре II	Fatty streaks	Layers of macrophage foam cells Lipid-laden smooth muscle cells	 Increased monocyte- endothelial cell adherence and infiltration
Туре III	Intermediate stage	Scattered extracellular lipid droplets	 Increased production of reactive oxygen species
Туре IV	Atheroma	Dense lipid core	 Increased LDL oxidation and glycation
Туре V	Fibrous plaque	Fibrous connective tissue Type Va: Fibroatheroma Type Vb: Calcified Type Vc: Lipid core absent or minimal	 Increased LDL uptake by macrophages and SMC foam cells
Type VI	Complicated lesion	Type VIa: Surface disruption (fissure) Type VIb: Hematoma or hemorrhage Type VIc: Thrombosis	 Increased triglycerides Decreased HDL Increased small dense LDL Increased VSMC proliferation Increased ECM production, glycation, and turnover Increased calcification Increased macrophages and alterations in ECM protease and protease inhibitors Increased levels of acute- phase proteins (CRP and fibrinogen) Activated thrombogenic pathways and impaired fibrinolysis

core rich in tissue factor (24,25), which can trigger the extrinsic coagulation pathway. Moreover, fibrin-rich thrombi may be stabilized by plasminogen activator inhibitor-1 (PAI-1), either circulating or locally released from neointimal smooth muscle cells (SMC) (26,27). Although thrombosis is observed in the majority of cases of coronary sudden death, approximately 20% of these coronary events occur by luminal narrowing without intramural thrombosis (23). Multiple mechanisms lead to narrowing of the coronary lumen, including the progressive expansion of the lesion mass due to lipid accumulation, fibrosis, and neointimal SMC growth; intraplaque hemorrhage; healed plaque erosions and thrombi; and contracture caused by SMC constriction and vascular wound healing (28,29).

CHARACTERISTICS OF CORONARY ATHEROSCLEROTIC LESIONS IN DIABETES

Histopathologic comparison of coronary atherectomy specimens from nondiabetic and diabetic subjects has revealed an increase in the percentage of the total area occupied by lipidrich atheromatous tissue from $2\% \pm 1\%$ to $7\% \pm 2\%$ (*p* = 0.01) and an increase in the incidence of coronary thrombus from 40% to 62% (p = 0.04) for nondiabetics and diabetics, respectively (3). Coronary artery atherectomy specimens from subjects with type 2 diabetes have a twofold increase in PAI-1 antigen and a decrease in the level of immunoreactive urokinase plasminogen activator, compared with specimens from age- and gender-matched controls without diabetes (30). Macrophage infiltration was also elevated by nearly twofold (p = 0.003) in atherectomy specimens from diabetic subjects (3). In contrast, morphometric analysis of coronary atherectomy specimens from primary lesions has indicated that the relative amounts of collagen-rich and hypercellular plaque components, which comprised approximately 90% of the total lesion area, were similar in diabetic and nondiabetic subjects (3,30). However, given the nature of tissue isolation by directional coronary atherectomy, the cellularity of these specimens in these studies may not

52: PATHOGENESIS OF CARDIOVASCULAR DISEASE IN DIABETES 869

represent possible effects of diabetes on SMC hyperplasia at the base or peripheral areas of the stenotic lesions.

Coronary artery calcification in diabetic subjects appears either similar (31) or increased (32,33), compared with that in nondiabetic control subjects. Although plaque calcification can provide a marker of plaque burden and is predictive of future coronary events (34,35), the effects of calcification on the pathophysiology of atherosclerotic lesions are not fully understood. Calcium deposition does not appear to adversely affect plaque mechanical stability (36); however, arterial calcification can increase stiffening, resulting in reduced vascular compliance.

EFFECTS OF DIABETES ON THE PATHOGENESIS OF ATHEROSCLEROSIS

Combinations of pathophysiologic processes contribute to the development of atherosclerosis and its sequel of stenosis and coronary sudden death. As described above, atherosclerotic lesions can arise from fatty streaks or neointimal thickenings. These lesions can expand progressively to reduce luminal diameter and can undergo rupture or erosion, which can trigger thrombosis (23). The atherogenic effects of diabetes and insulin resistance appear to be initiated by a combination of metabolic abnormalities related to hyperglycemia, impaired insulin action or insulin deficiency, a proatherogenic dyslipidemia, and confounding factors such as hypertension and obesity (Fig. 52.1). In addition, vasoactive hormones, cytokines, and growth factors, including angiotensin II (ATII), tumor necrosis factor-a (TNF- α), and vascular endothelial growth factor (VEGF) amplify and in part mediate the adverse vascular effects of these metabolic abnormalities. These metabolic and hormonal imbalances can induce endothelium dysfunction, vascular inflammation, SMC growth, intimal lipid accumulation, fibrosis, and hypercoagulability, leading to atherosclerosis and thrombosis (Fig. 52.1). The effects of diabetes and insulin resistance on a number of these proatherogenic pathways are described further on.

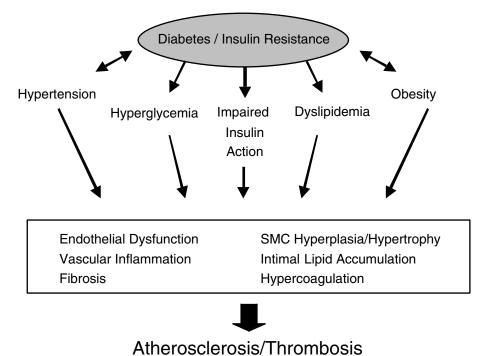

Figure 52.1. Diabetes, insulin resistance, and cardiovascular disease. Diabetes and insulin resistance are associated with a combination of metabolic abnormalities such as hyperglycemia, insulin resistance, insulin deficiency, hyperinsulinemia, hypertriglyceridemia, and reduced high-density lipoprotein that contribute to vascular dysfunctions, atherosclerosis, and thrombosis. In addition, diabetes and insulin resistance often coexist with additional cardiovascular risk factors, including hypertension and obesity, as the insulin resistance syndrome. SMC, smooth muscle cells.

Endothelial-Leukocyte Adhesion

Initial lesions and fatty streaks, also described as intimal xanthoma (23), are characterized by the appearance of macrophage foam cells in the subendothelial area. These foam cells arise from circulating monocytes that have adhered and infiltrated into the vessel wall, differentiated into macrophages, and become lipid laden via the avid uptake of modified low-density lipoprotein (LDL). Diabetes and insulin resistance promote leukocyte infiltration into the arterial wall via several mechanisms. Diabetes and hyperglycemia increase expression of Eselectin, vascular cell adhesion molecule-1 (VCAM-1), and intercellular adhesion molecule-1 (ICAM-1) by endothelial cells (37–39), which bind to leukocyte glycoprotein counterreceptors and integrins, thereby mediating leukocyte tethering, rolling, and firm adhesion (Fig. 52.2). In addition, leukocytes isolated from diabetic subjects display increased adhesiveness to endothelial cells (40,41). Following endothelial-leukocyte adhesion, infiltration of leukocytes to the subendothelial interstitium is stimulated by monocyte chemoattractant protein-1 (MCP-1), which is upregulated in diabetes (42). The infiltrated monocytes differentiate into macrophages, which produce a number of proatherogenic effects by accumulating lipids (43,44) and releasing proinflammatory cytokines and matrix metalloproteinases (45–47). The elaboration of cytokines, growth factors, metalloproteases, and procoagulants from these macrophages likely promotes plaque expansion and generates plaques prone to rupture and thrombosis.

Formation of Lipid-Rich Lesions

Monocyte-derived macrophages endocytose modified LDL via multiple receptors, including both class A and class B scavenger

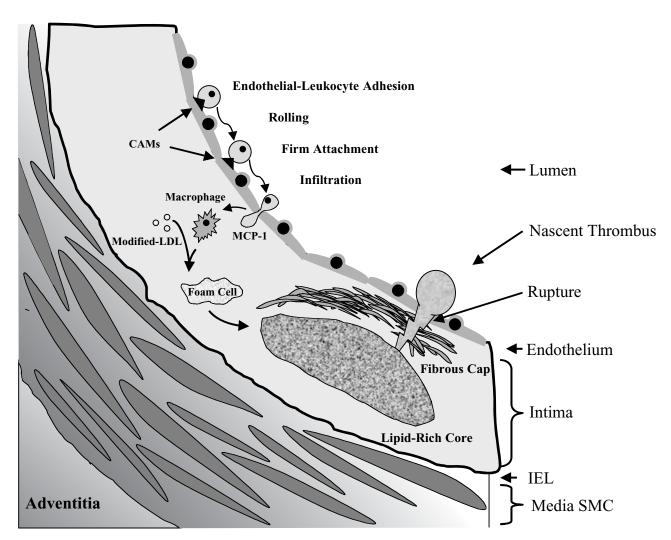

Figure 52.2. Components contributing to the development of fibrous-cap atheroma. Leukocyte binding to endothelial cell adhesion molecules (CAMs) and chemoattraction by monocyte chemoattractant protein-1 (MCP-1) increase the infiltration of monocytes into the subendothelial intima. These monocytes differentiate into macrophages, which release proinflammatory cytokines and endocytose modified low-density lipoprotein to generate foam cells. Focal accumulation of intimal lipid in the form of increased foam cells and extracellular lipid deposits results in the formation of a lipid-rich plaque core, which can become necrotic. Plaques also accumulate fibrotic material consisting of a collagen-proteoglycan matrix and smooth muscle cells (SMC) that have migrated across the internal elastic lamina (IEL). Rupture of this fibrous cap over the lipid core exposes this atheromatous material rich in tissue factor to circulating factors VII and VIIa, which initiates thrombogenic cascades and the formation of a thrombus.

receptors (43,44), lectin-like oxidized LDL receptor-1 (48), and lipoprotein lipase (49). Uptake of lipid in excess of its metabolism results in the formation of macrophage foam cells laden in cholesterol esters. In addition, foam cells can develop similarly from VSMC by the uptake of oxidized LDL via class A and class B scavenger receptors (50,51). Diabetes exacerbates the uptake of modified LDL by foam cells via several mechanisms. First, hyperglycemia increases glucoxidation, resulting in increased levels of oxidized and glycated LDL (52,53), which increase ligand availability for scavenger receptors and lipoprotein lipase. Second, diabetes increases the expression of macrophage class B scavenger receptor CD36 (54), which enhances oxidized LDL endocytosis. Third, diabetes causes a proatherogenic dyslipidemia resulting in reduced high-density lipoprotein (HDL) levels and increased triglycerides, which can reduce reverse cholesterol transport and contribute to increased levels of small dense LDL particles (55). In addition, macrophage foam cells release proinflammatory cytokines, such as TNF- α and interleukin-1, which can induce apoptosis of endothelial cells and VSMC (56). Focal accumulation of foam cells, formation of extracellular lipid droplets, apoptosis of VSMC, and disruption of vascular smooth muscle architecture can result in the formation of a necrotic lipid-rich core (Fig. 52.2).

Fibrous-Cap Formation

Atherosclerotic lesions accumulate fibrous material consisting mainly of VSMC in a collagen-proteoglycan matrix. The fibrous material that separates the plaque core from the luminal surface of the vessel is termed the fibrous cap (Fig. 52.2). Because the atheromatous material is thrombogenic in part attributable to high levels of tissue factor (24,25), the fibrous cap provides a barrier to thrombosis by separating this pool of tissue factor from the blood. The specific effects of diabetes on the composition and stability of the fibrous cap in primary lesions have not yet been described. Diabetes can increase SMC proliferation and extracellular matrix (ECM) production in a porcine atherosclerosis model (57) and increases neointimal hyperplasia and the accumulation of collagen-rich sclerotic tissue in restenotic lesions (58,59). Although these findings suggest that diabetes can promote the accumulation of fibrous material in restenotic lesions, it is unclear whether these findings can be extrapolated to characteristics of the fibrous cap. Several of the effects of diabetes on plaque composition may influence fibrous-cap formation and stability. Increased matrix metalloproteinase activity and macrophage levels in diabetic lesions (60) may shift the proteolytic balance within the cap, leading to the degradation of ECM and weakening of its structural integrity (61), thus increasing susceptibility to rupture or erosion. As described previously, PAI-1 levels are also increased in atherectomy specimens in diabetes. Elevated levels of PAI-1 can reduce SMC migration (62) and thereby might decrease incorporation of SMC into the fibrous cap. Alternatively, increased PAI-1 within lesions also may reduce plasmin-stimulated ECM turnover and thereby promote fibrosis (63). These effects of PAI-1 may lead to the generation of fibrous material with reduced cellularity and increased ECM.

Atherothrombosis

Thrombosis is the major cause of coronary stenosis and sudden death (23). Intramural arterial thrombosis can be triggered by the disruption of complex plaques, which expose the blood to thrombogenic factors that are enriched in the subendothelial area. Tissue factor, the major activator of the extrinsic coagula-

52: PATHOGENESIS OF CARDIOVASCULAR DISEASE IN DIABETES 871

tion pathway, is highly expressed in the plaque core (24,25). Disruption of the plaque surface allows this tissue factor to bind circulating factor VII in blood, resulting in the generation of active VIIa and the formation of tissue factor-VIIa complexes. This complex leads to a cascade involving activation of factor X, formation of prothrombinase complex, generation of thrombin, and cleavage of fibrinogen to fibrin. Elevated levels of tissue factor in vascular tissues in diabetic and obese/insulin-resistant murine models (64,65) may predispose diabetic arteries to the activation of this coagulation cascade. Moreover, increased arterial expression of PAI-1 in diabetes may impair the dissolution of nascent thrombi (30,66). Fibrin-rich thrombi that develop on ruptured plaques can expand to cause occlusion, can spontaneously undergo dissolution, or may become lined with endothelium and incorporated as an expansion of the neointima (28). Although atherosclerotic lesions in diabetes can have attributes (increased PAI-1 and macrophages) that would be expected to promote thrombosis, the direct effects of diabetes on atherothrombosis have not yet been established. A recent report, however, has provided evidence for an increase in healed ruptures in coronary sudden death in diabetes (glucose intolerance) (28), suggesting that diabetes is associated with an increased occurrence of ruptures that contribute to subclinical plaque burden.

Restenosis following Revascularization

The Bypass Angioplasty Revascularization Investigation (BARI) demonstrated that patients with treated diabetes who underwent PTCA or coronary artery bypass graft surgery (CABG) had cardiac-related mortality rates of 20.6% or 5.8%, respectively, after an average follow-up of 5.4 years (67). In contrast, the cardiac mortality rates for other BARI patients receiving PTCA and CABG were 4.8% and 4.7%, respectively. At 7 years of follow-up of BARI patients, the survival of the group with treated diabetes was 76.4% for CABG and 55.7% for PTCA (p = 0.0011) compared with survival rates of 86.4% (CABG) and 86.8% (PTCA) for patients without diabetes (11). The basis for the 3.5fold higher mortality rates for diabetic patients receiving PTCA compared with their nondiabetic counterparts is not fully understood. Serial intravascular ultrasound has indicated that increased restenosis following coronary interventions in diabetes is due to intimal expansion (58). Analysis of coronary atherectomy specimens from restenotic lesions after PTCA revealed that the fraction of collagen-rich sclerotic tissue was increased in lesions from patients with diabetes (59). These results suggest that diabetes increases neointimal fibrosis of arterial lesions resultant from PTCA. Diabetes has also been shown to increase the incidence of restenosis following arterial stenting and saphenous vein graft bypass (68-70).

Animal models have been utilized to examine the effect of diabetes on the neointimal response to balloon catheterization. Balloon catheter-induced injury causes endothelial denudation and arterial stretch, resulting in the formation of a neointima from the proliferative expansion of VSMC, which have migrated across the internal elastic lamina from the vessel media. Streptozotocin (STZ)-induced diabetes in rats has been shown to reduce carotid artery neointimal formation by approximately 50% compared with that in nondiabetic and insulin-treated diabetic controls in this balloon-injury model (71,72). Similarly, alloxan-induced diabetes reduced balloon catheter-induced neointimal formation in rabbits (73). STZ-induced diabetes did not affect the neointimal thickening in response to coronary stent placement in Yucatan miniature swine (74). However, diabetes was associated with increased in-stent thrombosis resulting in sudden death in this porcine model (74). These findings

indicate that hyperglycemia caused by STZ-induced diabetes does not increase neointimal hyperplasia but may increase thrombosis in injured vessels. The effects of insulin resistance and type 2 diabetes on the balloon injury–induced neointimal response have been examined in rat obesity models. These studies reveal that neointimal hyperplasia was increased in the type 2 diabetic/insulin-resistant obese Zucker rats and Otsuka Long-Evans Tokushima fatty rats compared with their lean insulinsensitive controls (72,75,76).

The interpretation of these animal studies is beset with a number of limitations. First, balloon injuries were performed on vessels with little or no preexisting vascular disease. This contrasts with clinical situations, in which revascularization is performed on restenotic vessels with advanced plaque pathologies. Second, most studies that have examined the effect of diabetes on atherosclerosis and neointimal hyperplasia in animal models have utilized the islet β -cell cytotoxins, including STZ or alloxan, to reduce insulin production. Although this approach is effective in generating hyperglycemia resulting from insulin deficiency, these models do not replicate the etiology of type 1 diabetes mediated via autoimmune destruction of β -cells. Third, rat models with obesity-induced insulin resistance have multiple endocrine abnormalities, which may contribute to the exaggerated neointimal response. Although the effects of diabetes on vascular proliferation are not fully understood, neointimal smooth muscle proliferation represents a major component of atherogenesis and an important target for emerging therapeutic strategies (77).

ENDOTHELIAL DYSFUNCTIONS IN DIABETES

The endothelium plays an integral role in vascular structure, hemodynamics, and hemostasis. Diabetes has a number of adverse effects on the vascular endothelium that impair these functions and likely facilitate atherosclerosis and thrombosis. As described above, diabetes increases the expression of leukocyte adhesion molecules that mediate binding and the infiltration of monocytes into the arterial subendothelial space. In addition, diabetes impairs endothelial barrier function, which increases transendothelial permeability and access of circulating molecules to the vascular interstitium. Diabetes also alters endothelial cell synthesis of a host of vasoactive hormones and factors that affect vascular tone, hemodynamics, coagulation, and VSMC physiology. The effects of diabetes on several key endothelial functions are described below.

Permeability of Endothelial Tight Junctions

Increased endothelial permeability is a hallmark of vascular dysfunction in diabetes (78,79). This increased permeability may facilitate penetration of proatherogenic cytokines and lipoproteins into the subendothelial space. Several mechanisms have been postulated to explain the increased transport of molecules across the endothelium in diabetes, including enhanced pinocytosis (78) and increased intercellular diffusion caused by reduced tight-junction formation (80). Diabetes can impair endothelium barrier function via the increased production of VEGF (also called vascular permeability factor) by VSMC. In this pathway, hyperglycemia and hormones, such as ATII, increase synthesis and secretion of VEGF in arterial SMC (81,82). This VEGF can act in a paracrine manner on endothelial cells, where it binds kinase insert domain-containing receptors VEGF-R2 (KDR) and stimulates phosphorylation of tight-junction proteins, such as zonula occluden 1 (83). However, although increased VEGF levels in diabetes have been shown in certain tissues, such as the retina (84),

less is known regarding the effects of diabetes on VEGF expression in cardiovascular tissues. In addition, hyperglycemia can exert additional effects on the endothelium via the activation of protein kinase C (PKC) and the increased formation of advanced glycation end-products (AGEs) and reactive oxygen species, which can act directly on endothelial cells to induce hyperpermeability (79,85).

Endothelium-Dependent Vasorelaxation

The vascular endothelium releases several factors that induce vascular smooth muscle relaxation, including nitric oxide (86), prostacyclin I₂, and one or more endothelium-derived hyperpolarizing factors (87). Of these factors, impaired endotheliumdependent vasorelaxation in diabetes has been attributed primarily to the reduced bioavailability of nitric oxide. Nitric oxide production by endothelial nitric oxide synthase (eNOS) is increased in response to shear stress and potent vasodilator hormones such as acetylcholine and bradykinin (86,88) (Fig. 52.3). Nitric oxide emanating from the endothelium acts in a paracrine manner on the vascular smooth muscle, where it binds to soluble guanylyl cyclase and thereby increases the synthesis of cyclic guanosine monophosphate (cGMP) (Fig. 52.3). Elevated cGMP levels activate cGMP-dependent protein kinases, including cGMP kinase I, which play an important role in regulating cytosolic calcium homeostasis. cGMP kinase I phosphorylates the microsomal inositol 1,4,5-trisphosphate (IP₃) receptor complex (89) and thereby inhibits IP3-stimulated calcium release from intracellular stores, resulting in SMC relaxation.

Reduced vasodilation response to infused acetylcholine (or methacholine, a long-acting muscarinic receptor agonist) and reactive hyperemia have been demonstrated in both type 1 and type 2 diabetes (90-93). Acute hyperglycemia, induced by hyperglycemic clamp, maintained at 300 mg/dL glucose levels for 6 hours, impairs methacholine-induced vasorelaxation in healthy nondiabetic subjects (94). However, although an acute increase in glucose can impair endothelial function, it is unclear whether the mechanism responsible for this effect of acute hyperglycemia is related to the chronic effects of hyperglycemia associated with diabetes. Impaired endothelium-dependent relaxation also occurs in insulin-resistant patients in the absence of overt type 2 diabetes (90,95). Thus, endothelial dysfunction in type 2 diabetes may reflect the combined adverse effects of hyperglycemia and additional metabolic and hormonal abnormalities associated with insulin resistance, such as an increase in free fatty acids and reduced insulin action (96,97). Results from studies of a variety of experimental animal models of type 1 diabetes have demonstrated that reduced endothelium-dependent relaxation occurs in ex vivo preparations of coronary, mesenteric, and carotid arteries and aorta (98-101), indicating that this dysfunction is retained in isolated vessels. Because most reports have shown a normal vasodilator response to nitric oxide donors such as sodium nitroprusside (91,102,103), the impairment of vasodilation in diabetes appears to be due mainly to an impairment in endotheliumderived nitric oxide. However, some reports have shown that vasodilator response to nitric oxide donors is also impaired in diabetes and insulin resistance (90,104), suggesting that in certain situations impaired endothelium-dependent vasorelaxation may be superimposed on impaired endothelium-independent relaxation. The mechanism or mechanisms responsible for this resistance to vasorelaxation by nitric oxide donors have not yet been defined. Potential mechanisms could be related to chronic vasoconstriction or oxidant production caused by endothelin-1 or ATII (105–107).

Reductions in both nitric oxide synthesis and stability have been proposed to explain impaired endothelium-dependent

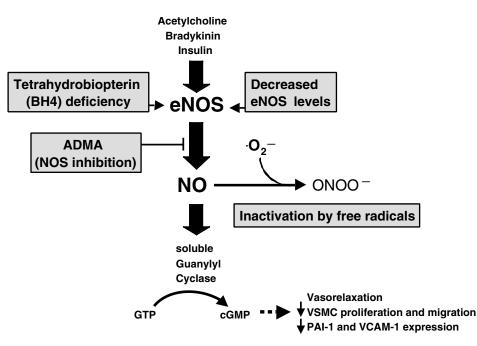

Figure 52.3. Mechanisms responsible for reduced nitric oxide (NO) bioactivity in diabetes. Mechanisms that contribute to reduced NO production include reduced endothelial nitric oxide synthase (eNOS) expression, tetrahydrobiopterin deficiency, and competitive inhibition of eNOS catalytic activity by elevated endogenous asymmetric dimethylarginine (ADMA). In addition, bioactivity of NO can also be reduced by the oxidation of NO to peroxynitrite (ONOO⁻). VSMC, vascular smooth muscle cells; PAI-1, plasminogen activator inhibitor-1; VCAM-1, vascular cell adhesion molecule-1; GTP, guanosine triphosphate; cGMP, cyclic guanosine monophosphate.

nitric oxide-mediated vasodilation in diabetes. Increased reactive oxygen species in diabetes have been suggested to decrease the half-life of nitric oxide by converting it to peroxynitrite (Fig. 52.3). Consistent with this theory, elevated vascular superoxide production in diabetes via NADPH (reduced form of nicotinamide adenine dinucleotide phosphate) oxidase has been demonstrated 101,108), and antioxidant treatments, including vitamin C, have been shown to improve endothelium-dependent vasorelaxation in diabetes (92,109). Moreover, impairment of endothelial NADPH oxidase activity by the targeted mutation of the gp91phox gene has been shown to reduce arterial oxygenradical formation and enhance endothelium-dependent vasorelaxation (110). Although there is considerable molecular and pharmacologic evidence for a role of vascular oxidants in attenuating endothelium-derived nitric oxide action, potential clinical benefits of antioxidant supplementation, such as vitamin E (RRR- α -tocopheryl acetate at 400 IU/day), for cardiovascular outcomes have not yet been identified (111). However, the potential benefits of substantially higher doses of vitamin E (1,200 IU/day), which may reduce monocyte activity and levels of soluble cell adhesion molecules (112), for cardiovascular complications remain to be examined.

Diabetes has also been reported to reduce vascular nitric oxide synthesis (98). Multiple mechanisms have been proposed to explain the decreased eNOS activity in diabetes and insulin resistance. Reduced eNOS expression has been described in adipose microvessels isolated from obese insulin-resistant Zucker rats and coronary microvessels from alloxan-induced diabetic dogs (98,113), suggesting that reduced protein levels of eNOS may contribute to lower nitric oxide production. In addition, the elevation of circulating levels of asymmetric dimethylarginine, an endogenous NOS inhibitor (114), and a deficiency in tetrahydrobiopterin (115,116), a cofactor for eNOS, have also been implicated in contributing to reduced nitric oxide generation in diabetes and insulin resistance.

The implications of reduced endothelium-derived nitric oxide bioactivity in diabetes goes beyond its hemodynamic effects. Nitric oxide, via cGMP-dependent pathways, has been shown to suppress a number of atherogenic and thrombogenic processes within the vascular wall, including neointimal SMC migration and proliferation and endothelial-leukocyte adhesion (117) (Fig. 52.2). Consistent with these possible antiatherogenic actions of nitric oxide, eNOS deficiency has been reported to increase atherosclerotic lesion size in apolipoprotein E (ApoE)–deficient mice (118). In addition, nitric oxide can also suppress the expression of thrombogenic factors, such as PAI-1 and tissue factor (119,120), which may shift the coagulation balance away from atherothrombosis.

EFFECTS OF DIABETES ON VASCULAR COMPLIANCE AND ARTERIAL STIFFNESS

Arterial stiffness is strongly associated with atherosclerosis (121). The Strong Heart Study (12) and the Atherosclerosis Risk in Communities Study (122) have reported increased arterial stiffness and reduced compliance in subjects with type 2 diabetes. Arterial compliance is also reduced in individuals with type 1 diabetes (123,124). Several theories have been proposed to explain the increased arterial stiffening in diabetes. Increased glycation of ECM proteins, such as collagen and elastin, may increase covalent intermolecular cross-linking and thereby reduce elasticity. Consistent with this theory, treatment with an AGE cross-link "breaker" has been shown to reverse diabetesinduced arterial stiffness (125). Increased arterial stiffness may also result from arterial calcification, arterial-wall thickening, or increased chronic VSMC contraction due to an imbalance in vasoactive hormone activities. Impaired arterial elasticity might contribute to atherogenesis by increasing mechanical strain and shear forces, causing endothelial damage, activation of stretchactivated mechanoreceptors, and increased release of trophic factors (126-128).

EFFECTS OF DIABETES ON COAGULATION AND THROMBOSIS

Diabetes and insulin resistance are associated with a procoagulant milieu (5,6,129,130) that may promote atherothrombosis by facilitating the expansion of nascent thrombi generated by plaque disruption. There is substantial clinical and experimental evidence that diabetes affects multiple coagulation components

and pathways, which would be expected to shift the diathesis toward thrombosis. Diabetes is associated with elevated circulating levels of prothrombin fragment 1 + 2 (F1+2) (131), a marker of thrombin generation by the prothrombinase complex, and elevated circulating levels of fibrinopeptide A (130,132), a product of fibrinogen cleavage by thrombin. Diabetes is also associated with persistent platelet activation, as reflected in part by the increases in thromboxane A2 biosynthesis (133), plateletdependent thrombin generation (134), and spontaneous platelet aggregation (135). Further evidence in support of a procoagulative state in insulin resistance and diabetes is provided by a number of reports showing increases in circulating levels of procoagulant factors and adhesion molecules. The population-based Framingham Offspring Study reported that glucose intolerance was associated with elevated plasma levels of PAI-1, tissue plasminogen activator, and von Willebrand factor (vWf) (136). Similarly, the Insulin Resistance Atherosclerosis Study reported that impaired glucose tolerance was associated with elevated PAI-1 and fibrinogen levels (137). Increased plasma PAI-1, factor VII, and P-selectin were reported in type 1 diabetes (138,139). Similarly, increased circulating levels of PAI-1, VCAM-1, and E-selectin occur in type 2 diabetes (5,140,141). These reports indicate the procoagulant milieu in diabetes is due in large part to the combination of elevated thrombin activation, impaired fibrinolysis, persistently activated platelets, and increased intercellular adhesion.

RISK FACTORS FOR CARDIOVASCULAR DISEASE IN DIABETES

Epidemiologic and clinical studies have identified a number of factors that are associated with the increased incidence of CVD in diabetes. These factors can be grouped into several different categories, including metabolic and lipid-related factors, coagulation and inflammatory factors, and vascular-related factors (Table 52.2). Although some cardiovascular risk factors appear to be associated primarily with diabetes and insulin resistance (such as hyperglycemia and hyperinsulinemia), other risk factors also appear in nondiabetic individuals.

Hyperglycemia

Several large multicenter prospective studies have shown an association between glycemic control and cardiovascular endpoints, including myocardial infarction (MI) and cardiovascularrelated mortality. The Diabetes Control and Complications Trial (DCCT) demonstrated that the conventionally treated group had nearly twice as many major macrovascular events as the

intensive treatment group, although this difference did not achieve statistical significance (p = 0.08) (142). This study reported that cardiovascular risk factors, including serum cholesterol and triglycerides, were significantly reduced in the intensively treated group. The United Kingdom Prospective Diabetes Study (UKPDS), a prospective study of vascular complications of type 2 diabetes with a mean follow-up of 10 years, demonstrated a 14% reduction in MI for each 1% reduction in glycosylated hemoglobin A_{1c} (143). This study did not detect a threshold for the association between glycemic control and MI. The UKPDS compared the effects of conventional versus intensive glycemic treatment protocols on both microvascular and macrovascular complications. This study showed that intensive control resulted in substantial reductions in microvascular disease, whereas intensive glycemic control resulted in a trend for reduced MI (p = 0.052). In addition, impaired glucose tolerance has also been identified as a risk factor for CVD, suggesting that mildly elevated hyperglycemia in the absence of overt type 2 diabetes may contribute to CVD (144).

Plasma Insulin and Insulin Resistance

Both hyperinsulinemia and insulin resistance have been identified as risk factors for CVD (145,146). The CVD risk associated with insulin has been attributed to an imbalance in the direct effects of insulin action, as well as to the confounding effects of CVD risk factors often associated with the insulin resistance syndrome. The effects of insulin on CVD in diabetes and insulin resistance are related to both systemic metabolic abnormalities and the direct effects of insulin action on the vasculature. With regard to the metabolic effects of insulin, insulin resistance results in glucose intolerance and hypertriglyceridemia, which have adverse cardiovascular effects (146). In addition, the direct actions of insulin on the vasculature have been proposed to mediate a combination of proatherogenic and antiatherogenic effects related to endothelial function and SMC growth (147). Moreover, the insulin resistance syndrome is often associated with a combination of established and emerging CVD risk factors, including hypertension, C-reactive protein (CRP), PAI-1, and fibrinogen (146,148). Hyperinsulinemia or insulin resistance or both may contribute to the elevation of these risk factors either directly in response to changes in insulin action or indirectly via imbalances in metabolites and cytokines that are associated the insulin resistance syndrome.

Lipid and Lipoproteins

Increased atherogenesis in diabetes and insulin resistance has been attributed in large part to a proatherogenic dyslipidemia,

TABLE 52.2. Cardiovascular Risk Factors Associated with Diabetes and Insulin Resistance		
Metabolic factors	Coagulation and inflammatory factors	Vascular-related factors
 Hyperglycemia Insulin resistance Hyperinsulinemia Hypertriglyceridemia Reduced HDL cholesterol Small dense LDL Hyperhomocysteinemia 	 Increased PAI-1 Increased platelet activation Increased fibrinogen Increased P-selectin, VCAM-1, and ICAM-1 Increased tissue factor and factor VII Decreased nitric oxide bioavailability Increased C-reactive protein 	 Hypertension Impaired endothelium-dependent vasorelaxation Increased arterial calcification Decreased arterial compliance

HDL, high-density lipoprotein; LDL, low-density lipoprotein; PAI-1, plasminogen activator inhibitor-1; VCAM-1, vascular cell adhesion molecule-1; ICAM-1, intercellular adhesion molecule-1.

related to hypertriglyceridemia, elevated very-low-density lipoprotein (VLDL), and decreased HDL (146,149). Although total LDL levels are not generally altered, or are only modestly increased, diabetes is associated with alterations in the buoyancy and modification of LDL particles. Insulin resistance results in increased levels of triglyceride-enriched small dense LDL particles, which have been associated with an increased risk of ischemic heart disease (150). Moreover, the combined elevation of fasting insulin, apoprotein B, and small dense LDL particles has been identified as a nontraditional risk factor cluster for ischemic heart disease (151). Additional CVD risk factors associated with diabetic dyslipidemia include increased lipoprotein(a) (152) and nonesterified fatty acids (153).

Lipid-lowering therapies, including HMG-CoA (hydroxymethylglutaryl-coenzyme A) reductase inhibitors and fibrate derivatives, have been shown to reduce coronary events in patients with type 2 diabetes. A subgroup analysis of the Cholesterol and Recurrent Events (CARE) trial revealed that pravastatin reduced total cholesterol by 20% compared with levels in the placebo groups and reduced the relative risk of coronary events in diabetic and nondiabetic patients by 25% (p = 0.05) and 23% (p < 0.001), respectively (154). Recently, the Heart Protection Study Collaborative Group reported that simvastatin reduced the occurrence of major coronary events by about 25% in diabetic patients and that this response was not dependent on preexisting elevated LDL cholesterol (>116 mg/ dL) upon entry into the study (155). The Diabetes Atherosclerosis Intervention Study has shown that treatment of patients with type 2 diabetes with fenofibrate decreased triglycerides, total cholesterol, and LDL cholesterol; increased HDL cholesterol; and reduced coronary artery diameter stenosis compared with values in the placebo group (156). These results provide important clinical evidence that amelioration of the lipid and lipoprotein abnormalities in diabetes can reduce progression of angiographic coronary disease. It should be noted that these drugs could have direct effects on vascular tissues, beyond lipid lowering, that may contribute to their beneficial cardiovascular effects. For example, HMG-CoA inhibition decreases farnesylation and geranylgeranylation of G proteins and ras family proteins and thereby directly inhibits signaling in vascular cells (157).

Circulating Adhesion Molecules

Increased CVD risk in diabetes has been attributed in part to increased circulating levels of adhesion molecules, including vWf, VCAM-1, and E-selectin (141,158-160). The endothelium synthesizes vWf, which is a glycoprotein involved in platelet adhesion and aggregation. VCAM-1 and E-selectin are expressed on the endothelium, where they contribute to leukocyte adherence and recruitment. Circulating levels of these adhesion molecules have been described both as markers of endothelial cell damage and as potential contributors to CVD risk. Although expression of adhesion molecules on the vascular endothelium mediates leukocyte and platelet adherence, the specific functions of soluble adhesion molecules have not yet been fully elucidated. Recent studies have shown that a truncated soluble mutant on Pselectin can increase procoagulant activity (161), providing direct evidence that the soluble fraction of adhesion molecules can play an important role in coagulation.

Plasminogen Activator Inhibitor-1

PAI-1 is the major physiologic regulator of the plasminogen system. Increased PAI-1 inhibits fibrinolysis and thereby reduces thrombus dissolution. An elevation in PAI-1 antigen and activity has been identified as an important risk factor for recurrent MI in both diabetic and nondiabetic subjects (4,162–164). Moreover, the elevated PAI-1 levels that are observed after acute MI are significantly higher in individuals with type 2 diabetes than in subjects without diabetes (165). Increased circulating PAI-1 activity has been correlated with the level of insulin resistance (166–169) and plasma insulin concentration (140,170–172) and has been shown to be elevated in type 2 diabetes (5,140,173,174). A decrease in fibrinolytic activity, due to increased levels of PAI-1, has also been reported in individuals with type 1 diabetes with microalbuminuria (138). The elevation of PAI-1 levels and strong correlation between elevated levels of PAI-1 and MI risk suggest that PAI-1 is an important contributor to coronary events in patients with diabetes.

C-reactive Protein

CRP is an acute-phase protein marker of inflammation that has been associated with an increased risk for CVD (175,176). Increased levels of CRP have been described in both diabetes and insulin resistance (177,178). CRP has been proposed to promote atherosclerosis and atherothrombosis by stimulating chemotactic recruitment of monocytes and upregulating endothelial-leukocyte adhesion molecules and tissue factor expression (179–181). A recent report has shown that transgenic overexpression of CRP accelerates aortic atherosclerosis in ApoE-deficient mice (182), indicating that elevated CRP levels contribute to atherogenesis.

Fibrinogen

Fibrinogen is an acute-phase protein that is elevated in inflammation and provides a number of functions in coagulation. Fibrinogen binds to glycoprotein IIb/IIIa on platelets, thereby promoting platelet aggregation, and is cleaved by thrombin to generate fibrin, a major component of thrombi matrix. Fibrinogen is an abundant plasma protein and a major contributor to blood viscosity. Fibrinogen levels are elevated in diabetes and associated with CVD risk (183–185). Increased fibrinogen levels in diabetes contribute to a procoagulative state and thereby may promote atherothrombosis.

Hyperhomocysteinemia

Homocysteine is a thiol-containing amino acid produced from methionine metabolism. Plasma homocysteine levels are elevated in insulin resistance and type 2 diabetes (186) and are associated with an increased CVD risk in patients with type 2 diabetes (187,188). Homocysteine has been proposed to exert deleterious vascular effects by increasing expression of MCP-1 and tissue factor and impairing endothelium-dependent vasodilation, possibly contributing to monocyte recruitment and thrombosis (189–191). These potential adverse cardiovascular effects of homocysteine in diabetes appear to be related primarily to type 2 diabetes, as hyperhomocysteinemia has not been observed in studies of subjects with type 1 diabetes (192,193).

Endothelium-Dependent Vasodilation

Stimulation of the vascular endothelium with a variety of agonists, such as acetylcholine and hyperemia, stimulates the release of vasorelaxative substances (including nitric oxide) that induce the vasorelaxation of underlying arterial smooth muscle. This endothelium-dependent vasodilation is impaired in type 1 and type 2 diabetes and in insulin resistance (91,92,194). Endothelial vasodilator dysfunction in coronary and brachial

arteries has been reported to be a predictive marker for cardio-vascular events (195,196).

Hypertension

Hypertension is a major CVD risk factor that often coexists with insulin resistance and diabetes (146). The UKPDS has shown that tight blood pressure control substantially reduces the risk of macrovascular events in patients with type 2 diabetes (197). This study showed that for each 10 mm Hg reduction from ≤160 to <120 mm Hg of systolic blood pressure there was an 11% reduction in MI. Within the range tested, there was no apparent threshold for blood pressure and the reduction of vascular complications. The benefits of blood pressure lowering were observed with both angiotensin-converting enzyme (ACE) inhibitors (captopril) and β -blockers (atenolol), indicating that blood pressure lowering was of primary importance. However, direct beneficial vascular effects of blocking the respective signaling pathways by these therapies cannot be excluded. The Heart Outcomes Prevention Evaluation (HOPE) trial has demonstrated that ACE inhibition can provide protective cardiovascular effects that appear to go beyond blood pressure control. In the HOPE trial, treatment with ramipril similarly reduced a composite of macrovascular outcomes in diabetic and nondiabetic patients (198).

Clustering of Risk Factors for Cardiovascular Disease

Combinations of CVD risk factors (Table 52.2) frequently coexist in individuals with insulin resistance and diabetes. An analysis of a large family study of type 2 diabetes in Finland and Sweden (the Botnia study) indicated that clustering of at least two CVD risk factors, including obesity, hypertension, dyslipidemia, and microalbuminuria, occur in ~10% of individuals with normal glucose tolerance, ~50% of subjects with impaired fasting glucose or impaired glucose tolerance, and up to 80% in subjects with type 2 diabetes (199). The clustering of these metabolic abnormalities and CVD risk factors has been termed the insulin resistance syndrome (also called syndrome X and the metabolic syndrome). The Botnia study reported that cardiovascular-related mortality was elevated sixfold in subjects with this metabolic syndrome (199). The definition of this insulin resistance/ metabolic syndrome has been expanded to include both established and emerging CVD risk factors, such as hyperinsulinemia, hyperglycemia, hypertension, central obesity, lipid/lipoprotein abnormalities, impaired endothelial-dependent relaxation, and increased PAI-1, CRP, and fibrinogen (146,148,178). Because these CVD risk factors can develop years before the onset of overt type 2 diabetes, it is likely that the pathogenesis of CVD in patients with type 2 diabetes begins well before the diagnosis of diabetes. Combinations of CVD risk factors, including hyperglycemia, hypertension, hypertriglyceridemia, microalbuminuria, impaired endothelial-dependent relaxation, and increases in circulating coagulation and adhesion molecules, also occur in type 1 diabetes. Although the etiologies of type 1 and type 2 diabetes are markedly different, the specific cardiovascular effects of type 1 diabetes compared with those of type 2 diabetes remain to be elucidated.

Comorbidity of Diabetes and Cardiovascular Disease

In addition to the adverse effects of insulin resistance and diabetes on CVD, there is growing evidence that insulin resistance/

diabetes and CVD may share components of a common etiology. For type 2 diabetes and insulin resistance, this has been described as the "common soil" hypothesis, whereby diabetes and CVD may arise from common genetic and environmental antecedents (200). There are a number of molecular mechanisms that may mediate the simultaneous development of diabetes and CVD. For example, TNF- α inhibits insulin receptor signaling and contributes to obesity-induced insulin resistance (201). TNF- α is also a proinflammatory molecule that may contribute to vascular remodeling and atherothrombosis by stimulating VSMC migration and matrix metalloproteinase, tissue factor, and PAI-1 expression (65,202,203). Another example involves the renin-angiotensin system (RAS). Both the HOPE trial (198) and Captopril Prevention Project (204) have reported that treatment with an ACE inhibitor reduced CVD endpoints as well as new diagnoses of diabetes (198,204). Although the effects of ACE inhibition on diabetes were secondary outcomes, these findings are highly suggestive that ACE inhibition can suppress the onset of type 2 diabetes. Additional factors that may independently contribute to both CVD and insulin resistance or type 2 diabetes include free fatty acids and CRP (205,206). Thus, a component of the increased pathogenesis of CVD associated with diabetes could be related to the comorbidity of these diseases, which exist in addition to the downstream effects of diabetes.

Gender

Premenopausal nondiabetic women are at lower risk of developing CVD than are nondiabetic men, and this cardiovascular protection for women is diminished by diabetes. The Rancho Bernardo Study reported that the incidence of fatal ischemic heart disease was similar in men and women with diabetes and corresponded to 1.9- and 3.3-fold increases in CVD risk compared with that in nondiabetic male and female counterparts, respectively (207). The greater relative impact of diabetes on CVD in women also was observed during the 20-year surveillance of the Framingham cohort (14). Subgroup analysis of the Nurse's Health Study at the 20-year follow-up revealed that a relative risk of 9.19 for fatal CHD in young women (<55 years) with diabetes compared with age-matched women without diabetes (16). The basis for the loss of cardiovascular protection in diabetic women is not fully understood but has been attributed in part to greater increases in triglycerides and decreases in HDL cholesterol caused by diabetes in women as compared with those increases in men (208). In addition, premenopausal women have a more robust endothelium-dependent vasodilation than that observed in men, and diabetes causes a greater impairment of this endothelial function in premenopausal women than in men (209).

BIOCHEMICAL MECHANISMS THAT CONTRIBUTE TO VASCULAR COMPLICATIONS

Effects of Hyperglycemia

Substantial evidence from both *in vitro* and *in vivo* studies has demonstrated that hyperglycemia impairs a variety of vascular functions. Exposure of cultured endothelial cells to medium containing high concentrations of glucose (~25 mM), as compared with normal glucose concentrations (~5 mM), has been shown to increase monocyte binding (37,210), endothelin-1 production (105), and intercellular permeability (211) and to decrease eNOS expression (212). Multiple mechanisms have been postulated to explain the adverse effects of glucose on vascular cells (85) (Fig. 52.4).

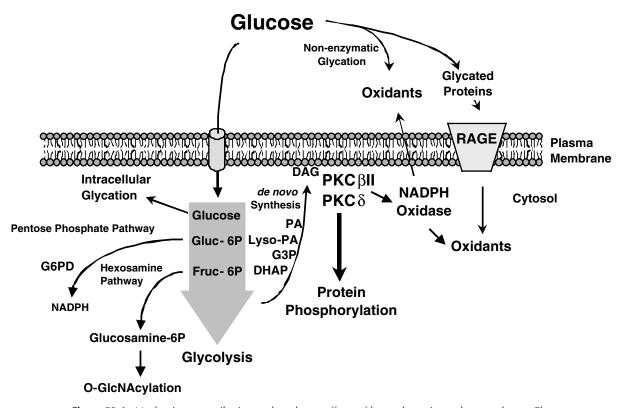

Figure 52.4. Mechanisms contributing to the adverse effects of hyperglycemia on the vasculature. Elevated glucose metabolism via glycolysis generates triose intermediates, which can increase the *de novo* synthesis of diacylglycerol (DAG) and the subsequent activation of protein kinase C (PKC). Glycolytic intermediates can be processed via the pentose phosphate pathway and alter intracellular redox via changes in NADPH (reduced form of nicotinamide adenine dinucleotide phosphate) or can be processed via the hexosamine pathway, leading to increased *O*-linked GlcNAcylation. In addition, hyperglycemia can increase the formation of advanced glycation end-products (AGE), which can generate oxidants and activate cell-surface AGE receptors (RAGE). PA, phosphatidic acid; Lyso-PA, lysophosphateidic acid; G3P, glyceraldehyde 3-phosphate; DHAP, dihydroxyacetone phosphate; G6PD, glucose 6-phosphate dehydrogenase.

One theory proposes that hyperglycemia increases glucose metabolism via glycolysis, resulting in the increased de novo synthesis of diacylglycerol (DAG). In this pathway, the glycolytic intermediate glyceraldehyde 3-phosphate is converted to dihydroxyacetone phosphate and then glycerol 3-phosphate, followed by sequential acyl group transfer by acyl-coenzyme A to yield lysophosphatidic acid and phosphatidic acid (Fig. 52.4). DAG is a cofactor for PKC, which increases the translocation to membrane and activation of a subset of PKC isoforms, including PKC β and PKC δ (213,214). These serine/threonine kinases play an integral role in cellular physiology by phosphorylating cellular targets that regulate cell growth, migration, contraction, gene expression, and metabolism. For example, glucose-induced PKC activation can increase oxygen-radical production mediated by NADPH oxidase (215). This increased oxidant production can affect endothelium function by affecting redox-sensitive signaling pathways and decreasing nitric oxide bioavailability (Fig. 52.3). Hyperglycemia-induced superoxide production in the endothelium results in the activation of poly (ADP-ribose) polymerase, increased protein nitration, and nuclear factor-kB activation (216). Tissue-specific overexpression of PKC β in the heart induces cardiac fibrosis and contractile abnormalities characteristic of diabetic cardiomyopathies (217). Selective inhibition of the PKC β isoform has been shown to ameliorate certain renal and retinal vascular dysfunctions and pathologies caused by diabetes (218). Thus, diabetes-induced PKC activation in vascular

tissues by hyperglycemia may chronically stimulate protein phosphorylation cascades that contribute to diabetic vasculopathies.

In addition, the increased flux through glycolysis induced by hyperglycemia can increase levels of intermediates, including glucose 6-phosphate and fructose 6-phosphate, which can be metabolized via alternate pathways. Glucose 6-phosphate can enter the pentose phosphate pathway by its oxidation via glucose 6-phosphate dehydrogenase (G6PD) and NADP to yield 6-phosphoglucono-1,5-lactone and NADPH. G6PD is the ratelimiting enzyme in this pathway, and its activity in endothelial cells is reduced in culture media with high glucose concentrations (219). This has been proposed to reduce the availability of NADPH, which is the primary intracellular reducing agent and a cofactor for eNOS. Fructose 6-phosphate can be converted to glucosamine 6-phosphate via glutamine:fructose-6-phosphate amidotransferase, the rate-limiting enzyme in the hexosamine pathway. This pathway leads to the synthesis of UDP-GlcNAc (uridine diphosphate-N-acetylglucosamine), which serves as a substrate for O-linked GlcNAcylation at serine and threonine residues on both cytosolic and nuclear proteins, including transcription factors such as Sp1 (220). Because O-GlcNAcylation of Sp1 inhibits its transcriptional activity, this pathway provides a mechanism for glucose-regulated gene expression (221).

Hyperglycemia can also increase nonenzymatic glycation initiated by Schiff-base formation between glucose and primary

amines on proteins and lipids. These Schiff bases undergo spontaneous rearrangements to form Amadori products and AGE. These glycation processes can occur in both extracellular and intracellular milieus (222). Increased glycation induced by high glucose levels has been proposed to adversely affect vascular function via several mechanisms. The process of glycation itself modifies protein structure and spontaneously generates reactive oxygen species. Glycated proteins and lipoproteins can act as agonists to stimulate expression of PAI-1 and tissue factor in vascular cells and monocytes (223,224). In addition, glycation of LDL can facilitate its uptake into macrophages via lipoprotein lipase (49). Reactive glycation moieties generated during rearrangements can form covalent cross-links between proteins, which can decrease the elasticity of ECM proteins. This increased cross-link-induced vascular rigidity can reduce arterial elasticity and compliance in diabetes (125). AGE-modified proteins have been reported to stimulate tissue factor and VCAM-1 expression (224,225); however, the signaling mechanisms that mediate cellular responses to AGE-modified proteins have not been elucidated. AGE-modified proteins can bind to cell-surface receptors for AGE (RAGE), which can increase oxidant stress and lead to the activation of mitogen-activated protein (MAP) kinase pathways (226). However, because glycation reactions and rearrangements can generate a large number of molecular entities, further studies are needed to define the specific molecular structures that constitute ligands for RAGE. Moreover, because RAGE represents a group of receptors including macrophage scavenger receptors (50), the cellular responses to AGE-modified proteins are likely complex. A role of nonenzymatic glycation in vascular dysfunction and pathology in diabetes is supported by a limited number of studies showing that treatment of diabetic rodents with soluble truncated RAGE can improve endothelial barrier function and reduce atherosclerosis in these rodents (79,227). These studies propose that soluble RAGE can scavenge glycated products and thereby reduce their availability to interact with vascular tissues.

Insulin Action on the Vascular Wall

The arterial wall is an insulin-sensitive tissue, which expresses both insulin and insulin-like growth factor I (IGF-I) receptors on endothelial cells and VSMC (228). Activation of the insulin receptor and IGF-I receptor pathways has been shown to affect vascular cell growth, migration, and the production of a variety of vasoactive substances, including hormones and thrombogenic factors (71,105,228-230). Because hyperinsulinemia and insulin resistance are CVD risk factors, changes in plasma insulin or vascular insulin sensitivity may alter vascular insulin action and thereby contribute to vascular dysfunctions and pathologies. Insulin can activate both insulin receptors and IGF-I receptors; however, the affinity of insulin for the IGF-I receptor is 10- to 100fold less than that for the insulin receptor (228). Although these receptors share structural and signaling characteristics, the IGF-I receptor system appears to exert greater effects on VSMC growth and migration. Normal physiologic concentrations of insulin coincide with the affinity of the insulin receptor, which mediates most insulin actions. However, at high pathophysiologic insulin concentrations associated with hyperinsulinemia, insulin may cross-react with IGF-I receptors, thereby stimulating VSMC migration and proliferation (Fig. 52.5).

The insulin/IGF-I receptor pathways also may provide protective vascular effects. Activation of the IGF-I pathway can protect VSMC from apoptosis and thereby may contribute to plaque stability (231). Insulin also provides antiapoptosis effects for endothelial cells (232). In addition, insulin action on the endothelium may provide antiatherogenic effects by increasing eNOS expression and nitric oxide production. Infusion of insulin has been shown to induce vasodilation of brachial and femoral arteries via a nitric oxide–dependent pathway (97,233). Insulin also increases nitric oxide production in endothelial cells (229). Thus, under normal physiologic insulin concentrations, the effects of insulin in promoting increased endothelial nitric oxide production may contribute to vasorelaxation and suppress atherogenesis.

Recent findings suggest that vascular tissues can display selective insulin resistance. Ex vivo studies have shown that insulin-stimulated eNOS expression is impaired in vascular tissue preparations from obese insulin-resistant Zucker rats (113). In this model, insulin-induced activation of the phosphoinositide 3kinase (PI 3-kinase) pathway is impaired, whereas insulin stimulation of the MAP kinase pathways is normal (234). These findings suggest that vascular tissues develop selective insulin resistance related to activation by insulin of the PI 3kinase/eNOS pathway. Because eNOS-derived nitric oxide provides mainly antiatherogenic effects, insulin resistance in endothelial cells leading to impairment in the eNOS/nitric oxide pathway is likely to be proatherogenic. Although insulin can also increase potentially proatherogenic factors, such as PAI-1 and endothelin-1 (230,235), the effects of the balance of hyperinsulinemia and vascular insulin resistance on the expression of these genes in endothelial cells remain to be established. Moreover, because nitric oxide can suppress these genes (119), the effects of insulin on nitric oxide may add a confounding factor to the regulation of proatherogenic gene expression in the vascular wall.

Recent studies have begun to identify mechanisms that regulate insulin signaling in vascular cells. Insulin action in the vasculature is mediated by the insulin receptor-stimulated tyrosine of insulin receptor substrate (IRS) proteins, which are adapter molecules that couple the activated insulin receptor to downstream signaling pathways (Fig. 52.5). Both ATII and endothelin-1 have been shown to inhibit insulin signaling that leads to PI 3-kinase activation in VSMC (236,237). Similarly, TNF- α has been shown to inhibit insulin signaling in endothelial cells (238). The mechanisms that inhibit insulin signaling involve the inhibition of insulin receptor-stimulated IRS-1 tyrosine phosphorylation and the subsequent docking of IRS proteins with the p85 regulatory subunit of PI 3-kinase (Fig. 52.5). The insulin-stimulated PI 3-kinase pathway has been shown to activate and upregulate eNOS in endothelial cells (229,239). Although IRS-1- and IRS-2-deficient mice display impaired endothelium-dependent vasorelaxation and enhanced neointimal expansion in response to vascular injury (240,241), it is not known whether these abnormalities are due to the absence of IRS protein expression in the vascular wall or to circulating factors associated with systemic insulin resistance. Evidence for a direct role of insulin action in the endothelium in vascular homeostasis is provided by studies showing that endothelial cell-specific insulin receptor knockout decreases both eNOS and endothelin-1 expression (242).

Renin-Angiotensin System

Although insulin resistance, insulin deficiency, hyperglycemia, and dyslipidemia likely represent the primary determinants that initiate the adverse effects of diabetes on CHD, a host of vascular hormones, cytokines, and growth factors play key roles in accelerating the progression of coronary atherosclerosis by promoting vascular remodeling, inflammation, fibrosis, and thrombosis. The role of the RAS in CVD has received considerable attention related to its systemic effects on blood pressure control and to its proinflammatory effects within plaques. The RAS involves the proteolytic processing of the protein precursor angiotensinogen to angiotensin I by renin, followed by its

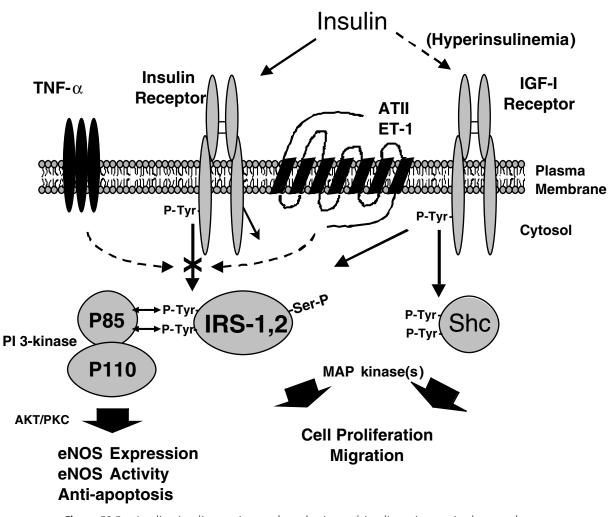

Figure 52.5. Insulin signaling, action, and mechanisms of insulin resistance in the vasculature. Insulin at normal physiologic concentrations activates the insulin receptor tyrosine kinase, which induces the phosphorylation of adapter proteins such as insulin receptor substrate (IRS)-1, -2, and Shc. Metabolic insulin resistance results in hyperinsulinemia, resulting in insulin concentrations capable of activating the insulin-like growth factor (IGF)-1 receptor. Insulin receptor signaling in vascular cells can be inhibited by tumor necrosis factor α (TNF- α), angiotensin II (ATII), and endothelin-1 (ET-1). These cytokines and hormones induce serine phosphorylation of IRS proteins and thereby can inhibit insulin receptor-activity and/or insulin receptor-IRS docking. PI 3-kinase, phosphoinositide 3-kinase; MAP kinase, mitogen-activated protein kinase; AKT, protein kinase B; PKC, protein kinase C; eNOS, endothelial nitric oxide synthase.

subsequent cleavage, primarily by ACE (dipeptidyl carboxypeptidase), to generate the octapeptide ATII. ATII signaling via the ATI receptor has been attributed to the majority of RAS action in the vasculature. The RAS plays an integral role in blood pressure regulation via a combination of mechanisms, including vasoconstriction, stimulation of renal tubular sodium resorption, and effects on the central and sympathetic nervous tissues. Inhibition of the RAS by ACE inhibitors and AT1 antagonists is widely used in the management of hypertension and its related adverse cardiovascular impact (197). In addition, there is considerable evidence that ATII is generated locally within plaques (46,243), where it may locally promote atherosclerosis and thrombosis (244,245).

Clinical trials have demonstrated that suppression of the RAS by ACE inhibitors reduces the onset and/or progression of cardiovascular complications of diabetes (197,246–249). Recent results of the HOPE trial have shown that treatment of patients at high risk for cardiovascular events with the ACE inhibitor ramipril provided protective effects against cardiovascular out-

comes in diabetic patients, even in the absence of hypertension (198,248). Although the basis for these beneficial effects has not yet been fully elucidated, a substudy of the HOPE trial that measured carotid ultrasound changes has shown that the ACE inhibitor-treated group had a reduced rate of progression in carotid intimal-medial thickness (250), consistent with a reduction in atherosclerosis. In addition, ACE inhibition can also reduce vascular PAI-1 and tissue factor expression (26,251,252), which may shift the coagulation diathesis away from thrombosis. The HOPE trial has shown that ACE inhibition provides protective cardiovascular effects for both diabetic and nondiabetic patients but does not eliminate the excessive cardiovascular risk associated with diabetes.

CONCLUSION

Although the results of the DCCT and UKPDS have shown that intensive glycemic control in type 1 and type 2 diabetes can

reduce cardiovascular complications, current therapies to normalize insulin action and glycemic control in diabetes do not eradicate its deleterious impact on the cardiovascular system. Moreover, because insulin resistance, type 2 diabetes, and CVD may arise from common genetic, metabolic, inflammatory, and hormonal antecedents, treatments to ameliorate the excessive CVD burden for diabetic patients will likely need to target the underlying causes of the metabolic syndrome. Diabetes and insulin resistance cause a combination of both systemic and intravascular abnormalities in metabolism, oxidation, inflammation, and hormone and cytokine actions that are proatherogenic and prothrombotic. In addition to intensive management of hyperglycemia, dyslipidemia, and insulin action, additional targets to slow or reverse the pathogenesis of cardiovascular disease in diabetes include strategies to preserve endothelium function, suppress vascular inflammation, reduce intravascular oxidative stress, and normalize metabolically coupled signaling cascades. The optimal use of these therapies will likely need to begin before the onset of vascular remodeling and clinical symptoms of CHD. Moreover, given the increased prevalence of obesity, insulin resistance, and type 2 diabetes, which are increasingly occurring in adolescents and young adults, strategies to preserve cardiovascular health in these individuals will need to begin in their early decades of life.

PREVENTION 897

DEFINITIONS

Hyperosmolar hyperglycemic state (HHS) and diabetic ketoacidosis (DKA) represent two distinct metabolic derangements manifested by insulin deficiency and severe hyperglycemia. HHS occurs when insulin deficiency relative to insulin requirements causes hyperglycemia, which in turn leads to dehydration, ultimately resulting in a severe hyperosmolar state. DKA occurs in the setting of more severe insulin deficiency, when low circulating levels of insulin lead not only to hyperglycemia and dehydration but also to the production of ketone bodies and acidosis. DKA is defined as the presence of all three of the following: (i) hyperglycemia (glucose >250 mg/dL), (ii) ketosis, and (iii) acidemia (pH <7.3) (1). HHS is characterized by severe hyperglycemia and hyperosmolarity. HHS and DKA are not mutually exclusive but rather two conditions that both result from some degree of insulin deficiency. They can and often do occur simultaneously. In fact, one third of patients admitted for hyperglycemia exhibit characteristics of both HHS and DKA (2).

EPIDEMIOLOGY

In one of the largest studies of the epidemiology of DKA, Faich et al. (3) reported an annual incidence of DKA in Rhode Island

of 46 cases per 10,000 persons with diabetes and of 1.4 cases per 10,000 persons in the general population. Nationally, DKA contributes to approximately 100,000 hospital admissions per year (1,4–6) and accounts for 2% to 9% of hospital admissions in persons with diabetes (1,3,7,8).

More than 20% of patients admitted for DKA had previously undiagnosed diabetes (3,9,10). Another 15% of admissions were of patients with multiple admissions for DKA (3). Several studies reported that the average age of patients admitted for DKA was 40 to 50 years (3,4), but that the risk decreased with age (10). Some studies have reported a female predominance (3,6, 9,10), possibly because young women were more likely to have repeated episodes of DKA (9,11). A slight increase in cases during the winter months has also been cited (3,9).

DKA is the leading cause of death of patients with diabetes who are younger than 24 years old, accounting for about one half of the deaths in this population group (5). Before the discovery of insulin in 1922, the mortality due to DKA was virtually 100% (12). By 1932, mortality decreased to 29% (12). By the 1950s, the reported mortality was 15%, with the improvement credited primarily to the widespread use of antibiotics, the introduction of intravenous potassium replacement, and the use of norepinephrine for blood pressure support (13). Mortality rates ranging from 2.5% to 9% among patients admitted with DKA have been reported in more recent studies (3,5,9,12). The studies reporting all-cause in-hospital mortality reported higher mortality rates than studies that reported mortality due to DKA alone and excluded deaths attributable to the factors that precipitated the DKA (11). Mortality among patients with DKA has been related to age, level of consciousness on admission, severity of acidosis, degree of hyperosmolarity, severity of azotemia, and nursing home residence (2,3,10). In addition to short-term mortality, there appears to be an increased risk of microvascular complications of diabetes with long-term follow-up of survivors of DKA (10).

One of the most interesting aspects of the epidemiologic study of hyperglycemic states is the epidemiology of DKA in various ethnic groups. In a retrospective chart review of adults with DKA admitted between 1994 and 1995 to a Texas hospital, 80% of whites admitted with DKA were classified as having type 1 diabetes (14). In contrast, only 53% of African Americans and 34% of Hispanic patients who were admitted with DKA had type 1 diabetes. By definition, patients who required insulin from the time of diagnosis of diabetes were considered to have type 1 diabetes, and patients who had prolonged treatment with either diet or oral hypoglycemic agents were considered to have type 2 diabetes. No difference was found in serum electrolytes, renal function, glucose, pH, anion gap, osmolality, or level of ketosis between those classified as having type 1 diabetes and those classified as having type 2 diabetes. Despite the conventional wisdom that DKA in type 2 diabetes usually is triggered by extreme physiologic stress, in the majority of these cases, no precipitating event could be identified.

PATHOPHYSIOLOGY

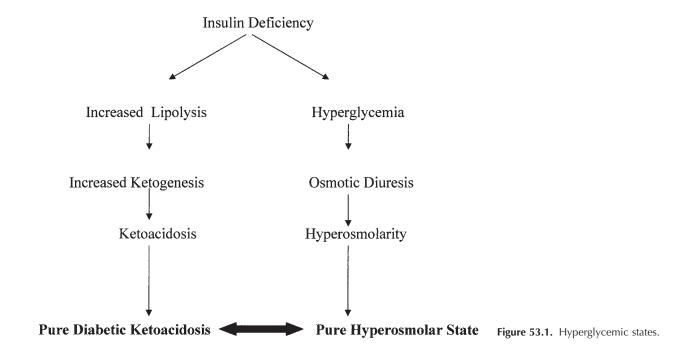

Understanding the clinical manifestations of DKA and HHS requires a thorough knowledge of the pathophysiology of these two closely related disturbances. In both DKA and HHS, relative insulin deficiency is the critical underlying defect. In both DKA and HHS, inadequate levels of circulating insulin relative to insulin requirements lead to hyperglycemia, which in turn leads to dehydration. Hyperglycemia can lead to progressive dehydration and hyperosmolarity and ultimately to HHS. If insulin deficiency is severe enough, ketosis and ultimately acidosis develop (Fig. 53.1).

Relative insulin deficiency—not absolute insulin deficiency is necessary for the development of both DKA and HHS. Even patients with type 2 diabetes and "normal" insulin levels may develop DKA if the level of insulin resistance causes a large enough increase in insulin requirements. Insulin resistance is mediated by several factors, including the underlying pathophysiology of type 2 diabetes and an increase in the levels of counterregulatory hormones, including cortisol, glucagon, epinephrine, and growth hormone (Table 53.1).

There is an extensive literature exploring the relative importance of insulin deficiency and insulin resistance due to counterregulatory hormones to the development of DKA (15–24). The facts that the incidence of DKA has decreased dramatically since the introduction of insulin in the 1920s and that insulin administration is the mainstay of therapy for DKA demonstrate the central role of insulin deficiency in the development of DKA (15). Early studies supporting insulin deficiency as the primary cause of DKA demonstrated low levels of insulin or Cpeptide or both in the face of hyperglycemia (15,16). Withdrawal of insulin from patients with type 1 diabetes results in hyperglycemia and increased levels of ketone bodies within a matter of hours, as well as in elevations in some counterregulatory hormones (17).

Despite this evidence, the impact of increased insulin resistance due to the counterregulatory hormones in the promotion of DKA and HHS must not be underestimated. Clinicians appreciate the increased risk of DKA that occurs with any physiologic stress in the patient with type 1 diabetes. Elevated levels of counterregulatory hormones have been observed during episodes of DKA (18–21). Furthermore, the severity of DKA appears to be decreased in conditions in which there is a deficiency of counterregulatory hormones (22,23).

Nevertheless, in the absence of insulin deficiency, elevated levels of counterregulatory hormones alone do not cause DKA. Gerich et al. (24) studied the effects of infusing counterregulatory hormones into insulin-dependent patients. Neither glucagon

infusion nor growth hormone infusion produced an elevation in free fatty acids or ketone bodies until insulin was withdrawn.

HYPERGLYCEMIA

Hyperglycemia occurs in both HHS and DKA. Hyperglycemia results from increased glucose production (gluconeogenesis and glycogenolysis) and decreased peripheral utilization (glycolysis, lipogenesis, and glycogen synthesis). Figure 53.2 gives an overview of these processes. Cox and Nelson (25) provide an excellent comprehensive review of the biochemistry involved in hyperglycemia.

Gluconeogenesis refers to the production of glucose from pyruvate or oxaloacetate. Glycolysis refers to the inverse-the breakdown of glucose to pyruvate. Glycolysis and gluconeogenesis utilize many, but not all, of the same enzymes; therefore, only one of these processes can occur in a tissue at any one time.

Glucose Figure 53.2. Ketogenesis.

890 JOSLIN'S DIABETES MELLITUS

Although the two pathways act in a reciprocal manner and share enzymes, each also utilizes unique enzymes. It is these unique enzymes that are critical to the control of these two pathways.

Gluconeogenesis occurs primarily in the liver. In this pathway, pyruvate is converted to oxaloacetate and then ultimately to glucose. The enzymes unique to gluconeogenesis are pyruvate carboxylase, fructose 1,6-bisphosphatase, and glucose 6-phosphatase. The pathway begins in the mitochondrion, where pyruvate is converted to oxaloacetate by pyruvate carboxylase, the first rate-limiting enzyme in the pathway. Pyruvate carboxylase is regulated by levels of acetyl-CoA (coenzyme A), which is required as a positive effector. Oxaloacetate is then reduced to malate by malate dehydrogenase and transported into the cytosol of the hepatocyte. There, malate is reoxidized into oxaloacetate. The oxaloacetate is then converted to phosphoenolpyruvate by phosphoenolpyruvate carboxykinase, another important enzyme in gluconeogenesis. Phosphoenolpyruvate is then converted to fructose 1,6-bisphosphate through a series of reactions catalyzed by enzymes shared with the glycolytic pathway.

Fructose 1,6-bisphosphate is converted to fructose 6-phosphate by another enzyme unique to gluconeogenesis, fructose 1,6-bisphosphatase. Next, fructose 6-phosphate is converted to glucose 6-phosphate by phosphohexose isomerase. Fructose 1,6-bisphosphatase is the second rate-limiting enzyme. It is induced by high levels of acetyl-CoA and suppressed by high levels of glucose 6-phosphate. Fructose 1,6-bisphosphatase is also regulated by fructose 2,6-bisphosphate. Fructose 2,6-bisphosphate is the regulator through which glucagon inhibits fructose 1,6-bisphosphatase. Glucose 6-phosphate is then dephosphorylated by glucose 6-phosphatase to glucose in the last rate-limiting step. The activity of this enzyme is suppressed by insulin.

Glycolysis occurs in cells throughout the body. The first step in the metabolism of glucose is entry of the glucose into the cytoplasm of the cell. Glucose uptake is largely insulin mediated, particularly in muscle and adipose tissue. Without insulin, cellular uptake and therefore glycolysis are greatly reduced. Once in the cytoplasm, glucose is phosphorylated by hexokinase (or glucokinase in the liver) into glucose 6-phosphate. This is the first rate-limiting step in glycolysis. Hexokinase is inhibited by its product, glucose 6-phosphate, and is induced by insulin.

Glucose 6-phosphate is converted to fructose 6-phosphate by phosphohexose isomerase. Then fructose 6-phosphate is converted to fructose 1,6-bisphosphate by phosphofructokinase-1. The activity of phosphofructokinase-1, the next rate-limiting enzyme, is regulated by glucagon through fructose 2,6-bisphosphate. Then, fructose 1,6-bisphosphate is converted through a series of reactions to phosphoenolpyruvate. In the last step, phosphoenolpyruvate is transformed by pyruvate kinase.

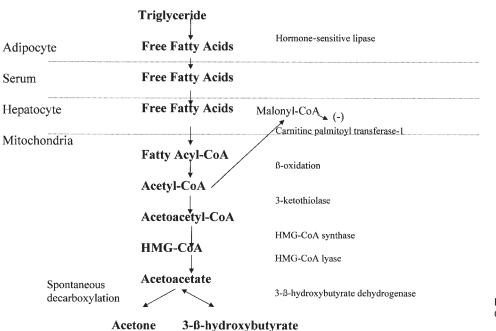

Glycogen synthesis and glycogenolysis occur primarily in liver and muscle. The key step in glycogenolysis is catalyzed by the enzyme glycogen phosphorylase a. Glycogen synthase is the key enzyme in glycogen synthesis. Glucagon and epinephrine act to inactivate glycogen synthase and activate glycogen phosphorylase, thereby inducing glycogenolysis and inhibiting glycogen synthesis.

DEHYDRATION AND HYPEROSMOLARITY

In both HHS and DKA, hyperglycemia results in an osmotic diuresis, which leads to dehydration. Hyperosmolarity develops, as the urine is relatively hypo-osmolar. Initially, the glycosuria causes an increase in the glomerular filtration rate. Once hypovolemia becomes significant, the glomerular filtration rate decreases and renal glucose losses may decrease as well. As renal clearance of glucose declines, hyperglycemia and hyperosmolarity worsen.

KETOGENESIS AND ACIDOSIS

Although the same mechanisms cause hyperglycemia and dehydration in both DKA and HHS, DKA is distinguished by ketogenesis (Fig. 53.3). Laffel (26) provides an excellent review of

Acetone

ketone metabolism. In the adipocyte, hormone-sensitive lipase converts triglycerides into diglycerides, which are then converted into free fatty acids. Hormone-sensitive lipase is stimulated by counterregulatory hormones and inhibited by insulin.

Free fatty acids are converted in the cytoplasm of the hepatocyte to fatty acyl-CoA. Fatty acyl-CoA is transported into the mitochondria of the hepatocyte by the carnitine shuttle. Glucagon inhibits the enzyme acetyl-CoA carboxylase, which leads to reduced levels of malonyl-CoA. Malonyl-CoA normally inhibits carnitine palmitoyl transferase-1 (CPT-1), the rate-limiting step in the carnitine shuttle (26). Once in the mitochondrion, the fatty acyl-CoA undergoes β-oxidation to acetyl-CoA. Acetyl-CoA is then converted in the mitochondrion to acetoacetate. The rate-limiting step is HMG-CoA (hydroxymethylglutaryl-coenzyme A) synthase. Acetoacetate, in turn, is then either spontaneously decarboxylated into acetone or converted to 3-β-hydroxybutyrate by 3-β-hydroxybutyrate dehydrogenase. Under normal circumstances, the ratio of $3-\beta-hydroxybutyrate$ to acetoacetate is about 1:1. Acetone is present in much lower quantities. In DKA, although levels of all three ketone bodies increase, the level of 3-β-hydroxybutyrate increases dramatically relative to that of acetoacetate, with ratios that may reach 10:1 (27).

Normally, ketone bodies increase insulin release from the pancreas; the insulin in turn suppresses ketogenesis. In the insulin-deficient state, the pancreatic β -cells are unable to respond, and ketogenesis proceeds unchecked.

Ketolysis occurs in the mitochondria of organs, which can use ketone bodies as an alternative energy source. Ketone bodies provide an important source of energy for the central nervous system during periods of starvation. However, skeletal muscle is probably the largest contributor to ketolysis. Acetoacetate is converted back to acetoacetyl-CoA by succinyl-CoA oxoacid transferase (SCOT). This is the rate-limiting step in ketolysis. Acetoacetyl-CoA is then converted to acetyl-CoA by methylacetoacetyl-CoA thiolase (MAT). Some ketones are also eliminated via the urine. Acetoacetate and 3- β -hydroxybutyrate are strong organic acids, which dissociate readily and account for the acidosis of DKA. Acetone does not dissociate and therefore does not worsen acidosis. It is excreted slowly via the lungs.

PRECIPITATING CAUSES OF DIABETIC KETOACIDOSIS AND HYPEROSMOLAR HYPERGLYCEMIC STATE

Infection remains the most common precipitating cause of DKA and HHS and accounts for 20% to 40% of all cases of DKA and HHS (28). The most common infections remain those of the urinary tract and lungs. Even though patients' caloric intake is decreased during intercurrent illness, most of them need to increase their insulin dose and fail to do so. Elderly patients with diabetes often neglect the increases in polyuria and polydipsia that are associated with increasing glucose concentrations during periods of intercurrent illness and present for medical attention at a more advanced stage of their illness. Up to 20% of individuals with newly diagnosed cases of type 1 diabetes, and even some with cases of type 2 diabetes, present with DKA. Some subjects with type 2 diabetes who present with DKA as the first manifestation of the disease are able to stop insulin and take oral antidiabetic agents once blood sugars have stabilized. Other precipitating causes of DKA and HHS include cerebrovascular accidents, myocardial infarction, pancreatitis, and alcohol abuse. These causes account for about 10% of all cases of DKA and HHS. Omission of insulin remains a common cause of DKA in

the adolescent population, many of whom utilize this as an opportunity to control their weight (29). This is also a common cause of DKA in African Americans (30). Drugs also may precipitate DKA and HHS, with most frequent offenders being steroids, sympathomimetic agents (dobutamine and terbutaline), and thiazides. Recently, newer antipsychotic drugs (e.g., clozapine, olanzapine, and risperidone) have been associated with the development of hyperglycemia, and patients have presented with DKA as the first manifestation of their diabetes (31–37). Therapy with interferon- α and ribavirin has been associated with the development of DKA in a patient with hepatitis C (38). DKA has been reported in association with the use of protease inhibitors and pentamidine therapy, and recreational use of cocaine and "ecstasy" has also been reported to precipitate DKA (39-43). In some patients, no obvious precipitating cause can be found.

DIAGNOSIS

History and Physical Examination

DKA usually evolves over a shorter period (usually less than 24 hours) than HHS, which tends to evolve over a few days. The symptoms of uncontrolled diabetes may be present for a number of days prior to the development of the acute metabolic decompensation. In some situations, e.g., in patients with type 1 diabetes who are using continuous subcutaneous insulin infusion pumps with regular insulin or short-acting insulin analogues, the symptoms of DKA can evolve much more rapidly—over 4 to 12 hours—if insulin delivery is disrupted. The pathophysiologic consequences of hyperglycemia, hyperketonemia, and insulin deficiency account for many of the classic symptoms and physical findings seen in DKA and HHS. High glucose levels lead to an osmotic diuresis, dehydration, and ultimately hypotension. The high ketone concentrations are responsible for the metabolic acidosis and also cause an osmotic diuresis because the renal threshold for ketones is low and ketones are osmotically active substances. The anionic charge on the ketones leads to excretion of positively charged ions, including sodium, potassium, calcium, and magnesium, to maintain electrical neutrality. The high solute excretion further impairs reabsorption of water from the renal tubule and loop of Henle, resulting in further loss of water and electrolytes. Insulin per se promotes reabsorption of water and sodium from the renal tubules. Insulin deficiency promotes further loss of water and electrolytes. The average amounts of electrolytes and fluids lost in patients with DKA are shown in Table 53.2. Losses of potassium and phosphate are further exacerbated by the acidosis, which leads to loss of intracellular potassium and phosphate. This may complicate therapy (see below). Ketone production by the liver leads to the metabolic acidosis. Hyperglycemia leads to an increase in serum osmolality, which in

TABLE 53.2.	Average Fluid and Electrolyte Losses in
Diabeti	c Ketoacidosis and Hyperosmolar
	Hyperglycemic State

Sodium	500 mEg	
Chloride	350 mEq	
Potassium	300–1000 mEq	
Calcium	50–100 mmol	
Phosphate	50–100 mmol	
Magnesium	25–50 mmol	

turn causes a further shift of fluid out of cells and leads to intracellular dehydration (44,45).

On the basis of the above pathophysiology, patients with DKA and HHS present with increasing polyuria and polydipsia, loss of weight, nausea, vomiting, increasing malaise, and dehydration. Patients with HHS tend to be more dehydrated at the time of presentation than patients with DKA. Abdominal pain is a common symptom in patients with DKA and may be due to the ketosis per se (with no evidence of intraabdominal pathology) or sometimes may be related to the cause of DKA. Fever is often present but may be absent even in the presence of infection because of the vasodilation that accompanies a metabolic acidosis. Patients may be alert at the time of presentation, but changes in mental status are common and may vary from drowsiness to coma. It is important to inquire about symptoms of the precipitating cause of the acute metabolic decompensation, such as symptoms of a urinary tract infection; the presence of cough, fever, or chills; the recent introduction of new medications; or chest pain. All women of reproductive age should be asked about possible pregnancy and have a pregnancy test at the time of presentation.

On examination, patients usually are dehydrated and have evidence of Kussmaul respiration if there is underlying acidosis. Assessment of the degree of dehydration is important. Decreased tissue turgor suggests 5% dehydration. An orthostatic change in pulse alone suggests that there has been loss of approximately 10% of extracellular fluid volume (~2 L), whereas an orthostatic change in pulse and blood pressure (>15/10 mm Hg) suggests a 15% to 20% fluid deficit (3 to 4 L). Supine hypotension, when present, suggests either severe dehydration and a decrease in extracellular fluid volume of more than 20% or underlying sepsis. Assessment of degree of dehydration may be difficult in the elderly and those with underlying autonomic neuropathy, who may have orthostatic hypotension at baseline. Fever may be present in those who have an underlying infection. The absence of fever, however, does not rule out infection-acidosis is associated with vasodilation and may lead to hypothermia. Hypothermia is an ominous finding and represents a poor prognostic sign. At the time of presentation, patients may be alert or have various degrees of change in mental status, ranging from drowsiness to stupor to coma. The level of consciousness correlates more closely with the underlying serum osmolality than with the degree of acidemia. Up to 25% of patients with DKA and HHS complain of vomiting at the time of presentation. Some of these patients have acute gastritis and may be vomiting brown-colored fluid or blood when they are seen in the emergency department. Diffuse abdominal pain and tenderness may be present. It is important to differentiate this as a manifestation of DKA from other causes of acute abdominal pain that may have precipitated the acute metabolic illness. Neck stiffness may be present even in the absence of underlying meningitis. When underlying meningeal infection is a possibility, examination of the CSF is essential. Examination for signs of the precipitating illness is important; this includes thorough examination of the skin, throat, and chest for infection. Table 53.3 summarizes the important clinical features that need to be reviewed when assessing a patient with severe hyperglycemia.

Laboratory Investigations

Initial laboratory evaluations of the patient with DKA or HHS must include plasma glucose, electrolytes, blood urea nitrogen (BUN) and creatinine, CO₂, serum and urine ketones, calculation of the anion gap, arterial blood gas (for DKA), complete blood count and differential, and electrocardiogram. Cultures

of urine, blood, and throat should be done if clinically indicated, and a chest radiograph should be obtained if there is any concern about an underlying cardiopulmonary problem. Measurement of glycosylated hemoglobin (HbA1C) may provide information about the underlying degree of metabolic control. The initial laboratory investigations that should be performed on patients with DKA or HHS are summarized in Table 53.4.

The serum sodium level may be low or normal. It may even be elevated in patients who are severely dehydrated even though total body sodium is depleted. The acidosis leads to a shift of potassium out of the cells. Serum potassium levels at presentation may be high, normal, or low even though total body potassium may be depleted. Unless the initial serum potassium is elevated above 5.5 mEq/L or the patient is in acute renal failure or oliguric, potassium replacement is required when treatment is initiated, because resolution of the acidosis will lead to cellular reuptake of potassium and the potential for hypokalemia and the risk of cardiac arrhythmia.

Calculations for determining the effective serum osmolality and anion gap are presented in Table 53.5. As noted above, the level of consciousness correlates more closely with serum osmolality than with pH (45). Coma in an individual whose serum osmolality is less than 320 mOsm/kg warrants further evaluation for other causes of the coma.

Serum amylase and lipase levels may be elevated even in the absence of pancreatitis. In a recent study, serum amylase and lipase levels were nonspecifically elevated in 16% to 25% of cases of DKA (46). The cause of this elevation is not known.

TABLE 53.4. Laboratory Evaluation of the Patient with Suspected Diabetic Ketoacidosis and Hyperosmolar Hyperglycemic State

• SMA 7

- Complete blood count
- Serum ketones
- Calculate serum osmolality and anion gap based on glucose and clinical findings
- Measure osmolar gap if ingestion of osmotically active substances other than glucose suspected

- Acid–base assessment if indicated by clinical findings
- HbA_{1c}

HCG, human chorionic gonadotropin; HbA1c, glycosylated hemoglobin.

TABLE 53.5.Commonly Used Calculations in the
Evaluation of Patients with Severe Hyperglycemia

• Calculation of effective serum osmolality:

$$2[Na + K] + \frac{(glucose in mg/dL)}{18} + \frac{BUN}{2.8} + \frac{ETOH}{4.6}$$

• Calculation of the anion gap:

$$[Na] - [CI + HCO_3]$$

• Correction of serum sodium:

Corrected Na = [Na] + 1.6 $\times \frac{[g|ucose in mg/dL] - 100}{100}$

• Uncomplicated metabolic acidosis:

 Δ anion gap: Δ bicarbonate = 1

• Metabolic acidosis and metabolic alkalosis:

 Δ anion gap: Δ bicarbonate = <1

BUN, blood urea nitrogen; ETOH = ethyl alcohol.

Although serum lipase measurement is more specific for the diagnosis of pancreatitis, this is not true in DKA, and elevations of either amylase or lipase to more than three times normal do not confirm the diagnosis of pancreatitis in these situations. It should be noted, too, that coexisting acute pancreatitis may be present in 10% to 15% of patients with DKA (47).

Leukocytosis may occur in DKA in the absence of infection, thereby making it more difficult to diagnose infection. The mechanism for this finding is not clearly understood.

Differential Diagnosis

Other causes of ketoacidosis need to be considered when patients with diabetes present with ketosis. These include starvation ketosis and alcoholic ketoacidosis. Starvation does not usually cause acidosis. Pregnant patients are more likely to develop ketoacidosis due to starvation because pregnancy is associated with an accelerated state of starvation and lipolysis and ketogenesis may be more accentuated and start within 6 hours of fasting (48). Alcohol may be associated with ketoacidosis. In this condition, plasma glucose levels are not always elevated. Serum ketones as measured by the nitroprusside reaction are not always significantly positive, because there is increased production of β -hydroxybutyrate in alcoholic ketosis and this is not measured in the nitroprusside reaction.

Other causes of an anion gap metabolic acidosis need to be considered in the differential diagnosis of DKA. These include lactic acidosis, uremia, and drugs (salicylates, methanol, ethylene glycol, and paraldehyde). Table 53.6 summarizes the salient findings in patients with other causes of ketosis and an anion gap acidosis.

Unusual Clinical and Laboratory Findings

Although the majority of people presenting with DKA and HHS have plasma glucose levels above 250 mg/dL, some patients may have lower plasma glucose levels at the time of presentation. "Euglycemic ketoacidosis" was originally described in situations in which the plasma glucose concentration was less than 300 mg/dL and the plasma bicarbonate concentration was 10 mEq/L or lower, but serum glucose levels lower than this have been reported (49). Euglycemic ketoacidosis has been reported in patients using continuous subcutaneous insulin infusion pumps, which contain short-acting insulin (regular- or shortacting analogues lispro or aspart). In these patients, interruption of insulin delivery results in the rapid development of ketosis, as patients become profoundly insulin deficient within 2 to 4 hours of cessation of insulin delivery. Euglycemic DKA has also been reported during pregnancy and in subjects using "conventional" insulin regimens (50,51). In these patients, the excretion of larger amounts of glucose in the urine or lower rates of hepatic glucose production may account for the relatively "normal" glucose concentrations. These patients are usually alert and, if they are not vomiting, can sometimes be managed with frequent administration of subcutaneous insulin rather than intravenous insulin infusions (see below).

Serum ketones may be negative in some situations, such as alcoholic ketoacidosis or DKA associated with hypoxia. In

								Methanol or
	Starvation ketosis	Pregnancy ketosis	Diabetic ketoacidosis	Alcoholic ketoacidosis	Lactic acidosis	Uremic acidosis	Salicylate intoxication	ethylene glycol ingestion
рН	Normal	Normal or decreased	Decreased	Decreased	Decreased	Slight decrease	Decreased or increased	Decreased
Plasma glucose	Normal	Normal or increased	Increased	Normal	Normal	Normal	Normal	Normal
Anion gap	Normal	Normal to increased	Increased	Increased	Increased	Increased	Increased	Increased
Serum ketones	Slight increase	Slight increase	Increased	Normal to increased ^a	Normal to slight increase	Normal	Normal	Normal
Serum osmolality	Normal	Normal	Increased	Normal	Normal	Increased	Normal	Increased markedly Measure serum levels

these circumstances, the nitroprusside reaction fails to detect β -hydroxybutyrate, which is the dominant ketone present. Under "normal" conditions, the ratio of β -hydroxybutyrate to acetoacetate is 3:1. This increases to 8:1 in alcoholic ketoacidosis or DKA associated with severe hypoxia.

Serum creatinine may be spuriously elevated in DKA; the ketones interfere with the measurement of creatinine when measured by the alkaline picrate (Jaffe) assay, resulting in a falsely elevated level (51). Treatment of the ketoacidosis leads to resolution of the problem.

Although the most common acid-base disturbance seen in DKA is an uncomplicated, partially compensated metabolic acidosis, other abnormalities of acid-base status may occur (52). These can range from a hyperchloremic acidosis (associated with no anion gap) to a metabolic alkalosis associated with vomiting. In the typical patient with DKA, the increase in the anion gap (ΔAG) is usually equivalent to the decrease in the serum bicarbonate concentration (ΔCO_2). The ratio of the ΔAG to ΔCO_2 (Δ : Δ ratio) is equal to 1 in uncomplicated DKA. Hyperchloremic acidosis may occur at any stage during the course of DKA but is more likely to occur during treatment with fluids that include saline. Loss of ketoanions in the urine is associated with a decrease in the serum bicarbonate concentration. During treatment, large amounts of fluid and NaCl are administered. Chloride is reabsorbed to maintain electrical neutrality. This may lead to excess chloride and a hyperchloremic acidosis, which is associated with a normal anion gap. The Δ : Δ ratio in this situation is not equal to 1 (44). Excessive vomiting in DKA may lead to excess loss of hydrogen ions and a metabolic alkalosis, which is characterized by a decrease in the chloride concentration and a normal serum bicarbonate level. Once again the Δ : Δ ratio is not equal to 1 (see Table 53.5) (53,54).

TREATMENT

Treatment of both DKA and HHS is based on correcting the underlying pathophysiologic defects, correcting the fluid and electrolyte imbalance, normalizing the blood glucose, correcting the acid–base disturbance, treating the precipitating cause, and determining what factors need to be addressed to prevent a recurrence. The fluid and electrolyte abnormalities are treated with saline, water, and potassium; the hyperglycemia is treated with insulin; and the acidosis is treated with insulin and sometimes bicarbonate.

Fluids

Fluid and electrolyte losses are considerable in most patients with DKA or HHS. Initially, fluid replacement is aimed at correcting the volume deficit rather than restoring serum osmolality to normal. Restoration of intravascular volume lowers blood sugar (independent of insulin) and decreases the counterregulatory hormones, improving insulin sensitivity. Normal saline (osmolar concentration, 308 mOsm/kg) is recommended for initial fluid therapy. Even though this fluid is isotonic, it is relatively hypotonic compared with the osmolality of the patient's serum. If the patient is in shock or has an inadequate blood pressure response to normal saline, colloid may sometimes be used together with normal saline (55). The initial rate of fluid administration depends on the degree of volume depletion and the patient's underlying cardiac status and ranges from 2 to 4 L during the first hour of therapy to 1 L per hour (15 to 20 mL/kg per hour). There is some debate concerning the optimal time to change from normal saline to 0.45% normal saline. Once the corrected sodium is normal or elevated and most of the initial

volume deficit is replaced, most clinicians would change treatment to 0.45% normal saline. The rate of fluid replacement must take into account ongoing urinary losses and be administered at a rate that will correct the fluid deficits in 24 hours (56). Osmolality should be corrected at a rate of approximately 3 mOsm/kg per hour. Once serum glucose has dropped to less than 250 mg/dL, dextrose-containing fluids should be used (5% dextrose in 0.45% saline) and the insulin infusion rate adjusted to maintain blood glucose levels in the 120 to 180 mg/dL range.

Fluids are administered to children at a rate of 10 to 20 mL/kg per hour during the first hour of treatment, usually not exceeding 50 mL/kg during the first 4 hours of therapy. The rate of fluid replacement is calculated so that the fluid deficit is replaced over 48 hours. Too-rapid correction of the fluid deficit or osmolality does not appear to increase the risk for the development of cerebral edema, a rare but devastating complication of DKA, which is more common in children (57).

Potassium replacement is started as soon as the initial serum potassium is known, providing that it is less than 5.5 mEq/L and the patient is passing urine and not in acute renal failure. Guidelines for fluid correction are provided in Table 53.7.

Insulin

For many years there has been debate about the optimal method and dose of insulin administration for patients with DKA or HHS. There is clear evidence that patients with DKA are insulin resistant and require supraphysiologic doses of insulin to ensure suppression of lipolysis and hepatic gluconeogenesis. Intravenously administered insulin has a half-life of 4 to 5 minutes, whereas regular insulin administered via the intramuscular or subcutaneous route has a half-life of ~2 or 4 hours, respectively.

After the discovery of insulin, patients with DKA were treated with small, frequent doses of intravenous or intramuscular insulin, but this soon gave way to "high-dose" bolus insulin therapy. It was later realized that even "low" doses of insulin administered by intravenous infusion (doses of 4 to 8 units per hour) were sufficient to suppress lipolysis and hepatic gluconeogenesis by 100% and were associated with serum insulin levels of approximately 100 μ U/mL, concentrations significantly higher than those in the average nondiabetic person. Large doses of insulin given intravenously intermittently

TABLE 53.7. Suggested Fluid Replacement in Patients with Diabetic Ketoacidosis and Hyperosmolar Hyperglycemic State^a

Administer NS as indicated to maintain hemodynamic status, then follow general guidelines:

• NS for first 4 hr.

- · Consider half NS thereafter.
- Change to D5 half NS when blood glucose ≤250 mg/dL.

Hours	Volume
1st half-hour to 1 hour	1 L
2nd hr	1 L
3rd hr	500 mL–1 L
4th hr	500 mL–1 L
5th hr	500 mL–1 L
Total 1st 5 hr	3.5–5 L
6th–12th hr	250–500 mL/hr

^aMay need to adjust type and rate of fluid administration in the elderly and in patients with congestive heart failure or renal failure. NS, normal saline; D5, 5% dextrose in water.

TABLE 53.8. Guidelines for Insulin Management in Diabetic Ketoacidosis and Hyperosmolar Hyperglycemic State

- Regular insulin 10 U i.v. stat (for adults) or 0.15 U/kg i.v. stat.
 - Start regular insulin infusion 0.1 U/kg per hour or 5 U per hour.
- Increase insulin by 1 U per hour every 1–2 hr if less than 10% decrease in glucose or no improvement in acid–base status.
- Decrease insulin by 1–2 U per hour (0.05–0.1 U/kg per hour) when glucose ≤250 mg/dL and/or progressive improvement in clinical status with decrease in glucose of >75 mg/dL per hour.
- Do not decrease insulin infusion to <1 U per hour.
- Maintain glucose between 140 and 180 mg/dL.
- If blood sugar decreases to <80 mg/dL, stop insulin infusion for no more than 1 hr and restart infusion.
- If glucose drops consistently to <100 mg/dL, change i.v. fluids to D10 to maintain blood glucose between 140 and 180 mg/dL.
- Once patient is able to eat, consider change to s.c. insulin:

Overlap short-acting insulin s.c. and continue i.v. infusion for 1-2 hr. For patients with previous insulin dose: return to prior dose of insulin. For patients with newly diagnosed diabetes: full-dose s.c. insulin based on 0.6 U/kg per day.

every hour lead to much higher peak insulin levels that wane within approximately 30 minutes of the administration of insulin and result in minimal biologic effects for at least 15 minutes every hour. Thus, continuous infusion of "low-dose" insulin has become the standard of treatment in most medical centers. Such treatment is associated with fewer metabolic complications (i.e., hypoglycemia, hypokalemia, hypophosphatemia, hypomagnesemia, hyperlactatemia, and osmotic dysequilibrium) than is therapy with large, intermittent doses. Intermittent low-dose intramuscular insulin (5 units) given every hour or every 2 hours after an initial intramuscular loading dose of 20 units is also acceptable treatment for DKA, especially in centers where it is difficult to monitor low-dose intravenous infusions, and is associated with serum insulin levels of 60 to 90 μ U/mL. With this treatment regimen, the initial decline in glucose is usually not as rapid as with intravenous insulin. Subcutaneous insulin can also be used in DKA, but because it takes longer to achieve peak insulin concentrations, it is associated with a less rapid initial decline in glucose concentrations and may cause late hypoglycemia more frequently than intramuscular insulin.

Therefore, for the majority of patients, insulin is given simultaneously with intravenous fluids, starting with an intravenous loading dose of 0.15 U/kg body weight (usually 10 U in adults), followed by a continuous infusion of insulin at a rate of 0.1 U/kg per hour (usually 5 to 7 U per hour in adults) (58). If the patient is in shock or the initial serum potassium level is less than 3.3 mEq/L, resuscitation with intravenous fluids or potassium replacement or both is instituted before commencing the insulin infusion. An insulin infusion of 5 to 7 U per hour should lower serum glucose concentrations by 50 to 75 mg/dL per hour and is usually sufficient to inhibit lipolysis, stop ketogenesis, and suppress hepatic gluconeogenesis (59-67). The insulin infusion rate should be continually reassessed and increased if the rate of decrease in glucose is less than 50 mg/dL per hour, providing that other causes for the lack of response to therapy have been excluded. These include worsening of the acidosis and inadequate hydration. Once the serum glucose has decreased to less than 250 mg/dL, the rate of infusion may often be decreased to 0.05 to 0.1 U/kg per hour until the patient is able to take fluids and food by mouth. At this stage, a subcutaneous insulin regimen can be commenced, ensuring that the intravenous infusion is continued for at least 1 to 2 hours after the subcutaneous administration of short-acting insulin. Recommendations for insulin administration are summarized in Table 53.8.

Milder forms of DKA and HHS can be treated with subcutaneous or intramuscular insulin. Comparison of intravenous, subcutaneous, and intramuscular regimens for treatment of mild DKA has shown no significant difference in outcomes except for a more rapid decrease in ketones and glucose during the first 2 hours of treatment with intravenous insulin (68–74).

Potassium

Most patients with DKA and HHS have already lost considerable amounts of potassium at the time of presentation. Despite this, total body losses of serum potassium may be low, normal, or elevated (75,76). Intracellular dehydration and the metabolic acidosis lead to intracellular depletion of potassium, which is largely an intracellular cation. Correction of the fluid deficit and acidosis in combination with insulin therapy leads to a shift of potassium back into the cells and a decrease in the serum potassium concentration. To prevent hypokalemia, potassium supplementation is started if the initial serum potassium is less than 5.5 mEq/L and urine output is adequate. Guidelines for potassium replacement are shown in Table 53.9. Usually 20 to 30 mEq of potassium is added to each liter of fluid. Some authors prefer to use potassium chloride, and others use twothirds potassium chloride and one-third potassium phosphate. Larger concentrations of potassium are used if the serum potassium drops below 3.5 mEq/L. If the initial serum potassium is less than 3.3 mEq/L, potassium replacement is required before initiating the insulin infusion, which is started only when the potassium has risen to above 3.5 mEq/L.

Bicarbonate

The serum insulin concentrations achieved with the low-dose insulin infusion during treatment of DKA usually are sufficient to suppress lipolysis and reverse ketogenesis. In most situations, treatment with insulin results in resolution of the acid–base abnormality. No studies to date have shown any benefit of bicarbonate therapy in patients with DKA whose pH is between 6.9 and 7.1 (77–79). Severe acidosis, however, is associated with a number of adverse vascular effects, including hypotension, decreased cardiac output, decreased peripheral vascular resistance, increased pulmonary arterial resistance, bradycardia, and arrhythmias. It also causes renal and mesenteric ischemia, cerebral vasodilatation, increased cerebrospinal

>5.5

	tassium Replacement in Diabetic Ketoacidosis molar Hyperglycemic State			
 Do not administer potassium if serum potassium >5.5 mEq/L or patient is anuric. Use KCl but alternate with KPO₄ if there is severe phosphate depletion and patient is unable to take phosphate by mouth. Add i.v. potassium to each liter of fluid administered unless contraindicated. 				
Serum K (mEq/L)	Additional K required			
<3.5 3.5–4.5 4.5–5.5	40 mEq/L 20 mEq/L. 10 mEq/L			

Stop K infusion

fluid pressure, and coma; decreases the buffer reserve considerably; and also may increase insulin resistance (80). Potential adverse effects of bicarbonate therapy, on the other hand, include an overshoot alkalosis, paradoxical cerebrospinal fluid acidosis, hypokalemia, volume overload, alteration in tissue oxygenation, and overproduction of ketoacids. Thus, treatment with bicarbonate should be considered only in patients whose pH is less than 7.0 unless some of the adverse clinical manifestations of acidemia are present. Usually 100 mL of sodium bicarbonate is mixed with 400 mL sterile water and administered at a rate of 200 mL per hour intravenously. The venous pH should be checked 30 minutes later and treatment repeated if the pH remains below 7.0 (Table 53.10).

Phosphate

Phosphate depletion is common in DKA and HHS. Intracellular phosphate is lost, and renal phosphate excretion is increased. During treatment with insulin, phosphate is taken up intracellularly with resultant hypophosphatemia (81). Hypophosphatemia is associated with a number of clinical sequelae, including decreased cardiac output, respiratory muscle weakness, rhabdomyolysis, central nervous system depression, seizures and coma, acute renal failure, and hemolysis. Intravenous phosphate therapy may lead to hypocalcemia. Thus, the degree of phosphate replacement and type of phosphate treatment required in DKA and HHS remain controversial. Most studies have not shown any obvious benefit of routine phosphate replacement in DKA (82). Phosphate replacement, therefore, should be reserved for those with severe hypophosphatemia of 1.5 mg/dL or less and in whom serum calcium concentrations are normal. The use of small amounts of potassium phosphate with potassium chloride given intravenously appears to be safe and effective. Oral phosphate repletion is always preferable to intravenous repletion and should be commenced as soon as patients are able to take food by mouth.

TABLE 53.10. Guidelines for Bicarbonate Therapy in Diabetic Ketoacidosis

- Use clinical judgment in deciding if bicarbonate therapy is indicated.
- If pH is <7.0, give 100 mL NaHCO3 over 45 min.
- Check acid-base status 30 min later and repeat if pH remains <7.0.

Ongoing Monitoring

Successful management of DKA and HHS requires frequent clinical and laboratory reassessment. Blood glucose should be checked hourly (either fingerstick capillary blood glucose or venous plasma glucose), and electrolytes and acid-base status should be reviewed every 2 to 4 hours as indicated. Measurement of venous pH is acceptable for those in whom there is no need to assess arterial PO2 or PCO2. The venous pH is approximately 0.03 unit less than the arterial pH (83). BUN and creatinine should be checked every 4 hours. Frequent measurement of serum or urine ketones is usually not necessary, providing that the patient is responding to treatment. During treatment of the acidosis, β -hydroxybutyrate is converted to acetoacetate, which may result in an apparent increase in the ketone concentration. Thus, frequent measurement of ketones (measuring acetoacetate) may be misleading. Bedside patient blood ketone testing that measures β -hydroxybutyrate has recently become available. Measurement of the rate of decline of β-hydroxybutyrate with this technique may facilitate treatment (84). Use of a flow chart documenting clinical status (blood pressure, intake and output of fluids, and level of consciousness if indicated), serum glucose, electrolytes, and anion gap is recommended. An example of a flow chart is shown in Table 53.11. If pneumonia is suspected and the initial chest radiograph shows no evidence of consolidation, a repeat chest radiograph should be performed after at least 4 L of fluid has been administered. Pregnancy testing should be considered for women of reproductive age because of the potential deleterious consequences of DKA and uncontrolled diabetes on fetal well-being.

Once the patient is able to tolerate oral fluids and start eating, the shift from intravenous to subcutaneous insulin should be undertaken. When changing to subcutaneous insulin, the intravenous infusion of insulin should be continued for 1 to 2 hours after the subcutaneous insulin has been administered, and the dextrose infusion should be continued until the patient has eaten a meal. The initial dose of subcutaneous insulin should contain some short- or rapid-acting insulin. Stopping the insulin infusion for more than 30 to 60 minutes without administering short- or rapid-acting subcutaneous insulin should be avoided because the half-life of intravenous insulin is 2 to 4 minutes and ketoacidosis may recur rapidly in the absence of exogenous insulin.

Complications of Therapy

Hypoglycemia and hypokalemia remain common complications of therapy. Both can be avoided by ensuring appropriate glucose and potassium administration as recommended earlier

TABLE 53.11. Suggested Flow Chart for Use in Management of Diabetic Ketoacidosis/Hyperosmolar Hyperglycemic State																
Date Time	Mental status	Blood pressure	Pulse	Glucose	Na	к	Cl	HCO ₃	Ca	PO ₄	Anion gap	Ketones	Blood gas	Insulin dose units/hr	IV fluids	Urine output

in the chapter. Hypophosphatemia may occur during therapy. There are no data supporting the use of intravenous potassium phosphate routinely during treatment of DKA and HHS. Intravenous phosphate should be given judiciously, but oral phosphate repletion should commence as soon as the patient is able to tolerate food and fluids by mouth. Persistent acidosis that does not respond to therapy may be caused by hypophosphatemia, sepsis, and inadequate insulin administration.

Hyperchloremia and hyperchloremic acidosis may occur during treatment of DKA. Chloride losses are less than sodium losses during DKA. Because replacement solutions have equal parts of sodium and chloride, relative hyperchloremia will occur during treatment. This is usually of no clinical consequence, and normalization of the anion gap during treatment with persistent reduction of bicarbonate is not an unexpected finding during the course of treatment.

Hypocalcemia may occur during treatment, especially during therapy with phosphate. Serum calcium levels should be checked before phosphate supplementation is started.

Pulmonary edema or respiratory distress syndrome or both may occur during treatment of DKA and HHS. Elderly patients are at risk for this complication, which may be caused by excessive fluid replacement, left ventricular dysfunction, or a capillary leak syndrome. Ongoing assessment of oxygen saturation and fluid balance, sometimes with invasive hemodynamic monitoring, is critical during treatment.

Cerebral edema is a rare complication of treatment of DKA. Clinically significant cerebral edema is more likely to occur in children, affecting approximately 1% of all children with DKA, but it is very rare in adults (85). Children at risk for the development of cerebral edema include those with lower PCO₂ and high BUN concentrations at presentation, those whose serum sodium level rises more slowly during therapy, and those who require bicarbonate therapy. The rate of fluid administration and rate of decline of glucose concentrations do not appear to be associated with the development of cerebral edema in children (57). Sudden deterioration of level of consciousness in a

child being treated for DKA should arouse clinical suspicion for cerebral edema. Hyperosmolar therapy remains the treatment of choice for these situations.

Venous thrombosis and pulmonary embolism are rare "complications" of DKA and HHS (85). Patients presenting with dehydration and electrolyte imbalance are in a hypercoagulable state. Prophylaxis for venous thromboembolism should be considered in those most at risk, including the elderly and obese patients.

PREVENTION

DKA and HHS are preventable disorders. Infection and inadequate insulin administration (inappropriate reduction or omission of insulin and noncompliance with insulin regimens) remain the most common causes of DKA and HHS. Patient education and 24-hour access to advice and care remain the cornerstone of preventative therapy. Patients should be taught how to manage their diabetes during periods of stress or intercurrent infection ("sick-day" rules) and should understand the importance of frequent monitoring of blood glucose concentrations, urine ketones, temperature, and, if necessary, blood pressure, pulse, and weight during these times. They should have access to healthcare providers who are trained to manage diabetes during these periods and who are familiar with guidelines for referral to an emergency department, should home management be unsuccessful or should vomiting develop. Education programs have been shown to reduce the rate of episodes and admissions for DKA in susceptible groups of patients.

The elderly patient living in a nursing home, who is unable to keep up with fluid losses or is unaware of fluid losses during intercurrent illness, is particularly at risk for the development of HHS. Education of caregivers who should learn to recognize signs and symptoms of increasing hyperglycemia will reduce the incidence of severe HHS. These people should also know when

898 **IOSLIN'S DIABETES MELLITUS**

to increase the frequency of blood glucose monitoring in those at risk and should have access to specialty care if indicated.

CONCLUSIONS 921

Ocular complications in diabetes are frequent, distressing and destined to become one of the challenging problems of the future.

These prophetic words of Dr. Howard Root opened the chapter on ocular complications in the 1935 edition of Joslin's *The Treatment of Diabetes Mellitus* (1). Indeed, as insulin increased the life span of persons with diabetes, diabetic retinopathy became a major cause of severe visual loss in the United States and in other industrialized countries of Europe and the Americas. By the 1960s, diabetic retinopathy was recognized as the leading cause of new, severe visual loss in the United States among persons 21 to 74 years old. Diabetic retinopathy is still neither preventable nor curable.

Dedicated efforts by researchers and patients, however, have established treatment and surgical modalities that can reduce

¹The reports of the Early Treatment Diabetic Retinopathy Study (17–39), which form the basis of the discussion of diabetic retinopathy, and other key retinopathy studies are widely quoted and paraphrased and set the standards of care for patients with diabetic retinopathy. Frequently used terms and abbreviations are given in Table 54.1. Portions of this chapter appear in *Principles and Practices of Ophthalmology: The Harvard System,* 2nd ed. Philadelphia: WB Saunders, 2000, and the *Journal of the American Optometric Association* 1990;61:533–543.

the 5-year risk of severe visual loss (visual acuity 5/200 or worse) from proliferative diabetic retinopathy (PDR) to less than 2% and the 5-year risk of moderate visual loss (a doubling of the visual angle; e.g., 20/20 reduced to 20/40) from diabetic macular edema to 12% or less.

Ongoing research efforts continue to hold promise that diabetic retinopathy eventually will be curable or preventable. Presently, however, clinical goals must concentrate on identifying eyes at risk of visual loss and ensuring that appropriate and timely laser surgery is offered. If patients with diabetes receive currently recommended care, remarkable preservation of vision can be achieved.

SIGNIFICANCE OF APPROACHING/REACHING HIGH-RISK PROLIFERATIVE DIABETIC RETINOPATHY AND CLINICALLY SIGNIFICANT MACULAR EDEMA

In 1969, the first evidence of the effectiveness of scatter (panretinal) laser photocoagulation surgery in the treatment of dia-

TABLE 54.1. Abbreviations of Commonly Used Terms

CSME	Clinically significant macular edema
DRS	Diabetic Retinopathy Study
DRVS	Diabetic Retinopathy Vitrectomy Study
ETDRS	Early Treatment Diabetic Retinopathy Study
FPD	Fibrous proliferations on or within 1 disc diameter of disc margin
FPE	Fibrous proliferations elsewhere—not FPD
H/Ma	Hemorrhages and/or microaneurysms
HE	Hard exudates
IRMA	Intraretinal microvascular abnormalities
MVL	Moderate visual loss: a doubling of the visual angle
	(e.g., 20/40 to 20/80 at two consecutive, completed 4-month follow-up visits)
NPDR	Nonproliferative diabetic retinopathy
NVD	Neovascularization of the disc: new vessels on or
	within 1 disc diameter of disc margin
NVE	Neovascularization elsewhere: new vessels elsewhere in the retina outside of disc and more than 1 disc diameter from disc margin
PDR	Proliferative diabetic retinopathy
SE	Soft exudates (cotton-wool spots)
SVL	Severe visual loss: visual acuity equal to or less than
JVL	5/200 at two consecutive, completed 4-month follow-up visits
VB	Venous beading

glycosylated hemoglobin (HbA_{1c}) levels, can reduce the risk of onset and progression of diabetic retinopathy.

Nevertheless, diabetic retinopathy remains a leading cause of blindness in the United States for persons between the ages of 20 and 74 years (56-58). This blindness usually results from nonresolving vitreous hemorrhage, traction retinal detachment, or diabetic macular edema. However, the 5-year risk of severe visual loss can be reduced to less than 2% if a person with diabetic retinopathy approaching or just reaching high-risk proliferative retinopathy, as defined below, undergoes scatter (panretinal) laser photocoagulation surgery (59,60). Furthermore, people with clinically significant diabetic macular edema (CSME) can reduce the risk of moderate visual loss by 50% or more, to approximately 12% or less, if they receive appropriate focal laser surgery (17). Because diabetic retinopathy is often asymptomatic in its most treatable stages, early detection of diabetic retinopathy through regularly scheduled ocular examination is critical.

This chapter reviews prognostic implications of the lesions of diabetic retinopathy and the risks of progression of retinopathy, placing particular emphasis on identifying patients at risk of visual loss and in need of laser surgery. The laser treatment techniques are described in only general terms in this chapter but are carefully detailed in ETDRS reports 3 and 4 (19,20). Nonretinal ocular complications of diabetes mellitus and alterations in visual function also are discussed.

EPIDEMIOLOGY OF DIABETIC RETINOPATHY

betic retinopathy was promulgated in the ophthalmologic and medical communities (2). Since these promising beginnings, dramatic strides have been made in treating diabetic retinopathy and macular edema through the effective use of scatter (panretinal) laser and other surgical techniques. The value of these techniques has received strong support from the findings of three major nationwide, randomized, and controlled clinical trials in the United States: the Diabetic Retinopathy Study (DRS) (3–16), the Early Treatment Diabetic Retinopathy Study (ETDRS) (17–39), and the Diabetic Retinopathy Vitrectomy Study (DRVS) (40–44). With proper diagnosis and treatment, the 5-year risk of severe visual loss from PDR could be virtually eliminated. Additionally, clinical trials in the United States (45–52), Japan (53), and the United Kingdom (54,55) have demonstrated that intensive control of diabetes, as measured by

An estimated 16 to 17 million Americans have diabetes mellitus (diabetes), but approximately 6 million of these cases have not been diagnosed (61). Among the American population with diabetes, 5% to 10% have type 1 diabetes (insulin-dependent diabetes), which is usually diagnosed before the age of 40 years. The majority of diabetic patients, however, have type 2 diabetes (non–insulin-dependent diabetes), which is usually diagnosed after the age of 40 years; these patients may or may not be treated with insulin. While those with type 1 diabetes experience a high incidence of severe ocular complications and are more likely to develop significant ocular problems during their lifetimes, those with type 2 diabetes account for the majority of clinical cases of diabetic eye disease because of their larger overall number.

TABLE 54.2. Medical Problems Presenting Significant Risk for Development of Diabetic Retinopathy or Affecting Its Course

Condition	Comment
RISK INDICATORS OF DIA	BETIC RETINOPATHY
Joint contractures	Association of retinopathy and contractures has been established. Eye examination is indicated. Care of joint contractures is important.
Neuropathy	Peripheral neuropathy may result in difficulty in handling contact lenses. Neuropathy in lower extremities may alter mobility; therefore, restoration and maintenance of as much vision as possible is important.
CONDITIONS THAT MAY	AFFECT COURSE OF DIABETIC RETINOPATHY
Hypertension	Appropriate medical treatment is indicated for prevention of cardiovascular disease, stroke, and death. Hypertension itself may result in hypertensive retinopathy superimposed on diabetic retinopathy.
Elevated lipids	Appropriate management to normalize lipids is important. Proper diet and drug treatment may result in less retinal vessel leakage and hard exudate.
Proteinuria; elevated creatinine level	Aggressive management of renal disease is indicated to avoid renal retinopathy, which may increase risk of progression of diabetic retinopathy and of neovascular glaucoma.
Cardiovascular disease	Increased risk of peripheral vascular disease, particularly coronary vascular disease, is often associated with an increase in the attenuation and arteriosclerotic closure of the arterial system of the retina. A decreased risk of hemorrhage into the vitreous may result, but there also may be a decrease in retinal function with associated decrease in vision. Aggressive management of cardiovascular risk factors theoretically could relieve some of the ischemic process in the retina.

Diabetic retinopathy is a highly specific vascular complication of both type 1 and type 2 diabetes, and the duration of diabetes is a significant risk factor for the development of retinopathy (62). After 20 years of diabetes, nearly all patients with type 1 diabetes and more than 60% of those with type 2 diabetes have some degree of retinopathy. Laser surgery and other surgical modalities help minimize the risk of moderate and severe visual loss from diabetes mellitus and, in some cases, restore useful vision for those who have suffered visual loss. These surgical modalities, particularly laser surgery, are most effective if initiated when a person approaches or just reaches high-risk PDR or before a person has lost visual acuity from diabetic macular edema (26).

The 5-year risk of severe visual loss from high-risk PDR may be as high as 60%, and the risk of moderate visual loss from CSME may be as high as 30%. Because PDR and macular edema may cause no ocular or visual symptoms when the retinal lesions are most amenable to treatment, a major clinical goal is to identify eyes at risk of visual loss and ensure that patients are referred for laser surgery at the appropriate time. Even minor errors in diagnosis of the level of retinopathy can result in a significant increase in a person's risk of visual loss.

Furthermore, collateral health and medical problems present a significant risk for the development and progression of diabetic retinopathy (Table 54.2) (63). These factors include pregnancy (64–66), chronic hyperglycemia (45–55,67–70), hypertension (54,71), renal disease (69), and hyperlipidemia (37,72). Patients with these conditions require careful medical evaluation and follow-up for the progression of diabetic retinopathy and optimization of their medical status.

CLINICAL TRIALS OF DIABETIC RETINOPATHY: SCIENTIFIC BASIS FOR MANAGEMENT

In the United States, the results of four nationwide randomized clinical trials have determined in large part the strategies for appropriate clinical management of patients with diabetic retinopathy. The United Kingdom Prospective Diabetes Study (UKPDS) adds significant information to supplement the findings of the studies in the United States.

Diabetic Retinopathy Study

The DRS (3–16) (Table 54.3) conclusively demonstrated that scatter (panretinal) photocoagulation significantly reduces the

risk of severe visual loss from PDR, particularly when high-risk PDR is present.

Early Treatment Diabetic Retinopathy Study

The ETDRS (17–39) provided valuable information concerning the timing of scatter (panretinal) laser surgery for advancing diabetic retinopathy and conclusively demonstrated that focal photocoagulation for CSME reduces the risk of moderate visual loss by 50% or more (Table 54.4). Furthermore, the ETDRS demonstrated that both early scatter (panretinal) laser surgery (before high-risk PDR) and deferral of treatment "until and as soon as high-risk PDR developed" are effective in reducing the risk of severe visual loss. Scatter laser surgery, therefore, should be considered as an eye approaches the high-risk stage and "usually should not be delayed if the eye has reached the highrisk proliferative stage" (26). For patients with type 2 diabetes mellitus or type 1 diabetes mellitus of long standing, early photocoagulation should be considered.

Diabetic Retinopathy Vitrectomy Study

The DRVS (40-44) provided guidelines for the most opportune time for vitrectomy surgery for patients with type 1 and type 2 diabetes who suffered from vitreous hemorrhage (40,41,44) or from severe PDR in eyes with useful vision (Table 54.5) (42,43). In these early years of pars plana vitrectomy, early vitrectomy for eyes with recent severe vitreous hemorrhage and a visual acuity of less than 5/200 was beneficial, especially for patients with type 1 diabetes. Furthermore, the chance of achieving visual acuity of 10/20 or better was increased by early vitrectomy in eyes with severe proliferating neovascular retinopathy, again especially for patients with type 1 diabetes. However, surgical tools and techniques for vitrectomy in patients with diabetic retinopathy have evolved significantly over the past two decades, making precise prediction of clinical outcome for the DRVS data potentially less applicable and present surgical outcomes probably more favorable.

Diabetes Control and Complications Trial

The Diabetes Control and Complications Trial (DCCT) (45–52) conclusively demonstrated that intensive control of glycemic levels, as reflected by measurements of HbA_{1c}, significantly reduces the risk of onset of diabetic retinopathy, progression of preexisting retinopathy, and the need for laser surgery for persons with type 1 diabetes. Intensive therapy reduced the risk of

TABLE 54.3. Diabetic Retinopathy Study

Major eligibility criteria

Visual acuity ≥20/100 in each eye

PDR in at least one eye or severe NPDR in both eyes

Both eyes suitable for photocoagulation

Major design features

One eye of each patient assigned randomly to photocoagulation [scatter (panretinal), local (direct confluent treatment of surface new vessels)]; other eye assigned to follow-up without photocoagulation

The eye assigned to treatment then randomly assigned to argon laser or xenon arc

Major conclusions

Photocoagulation reduced risk of SVL by ≥50% (SVL = visual acuity ≤5/200 at two consecutively completed 4-month follow-up visits) Modest risks of decrease in visual acuity (usually only one line) and constriction of visual field (risks greater with xenon than argon) Treatment benefit outweighs risks for eyes with high-risk PDR (50% 5-year rate of SVL in such eyes without treatment reduced to 20% by treatment)

For abbreviations, see Table 54.1. Table prepared by Matthew D. Davis, M.D., and the ETDRS Research Group for the Diabetes 2000 Program of the American Academy of Ophthalmology.

904 JOSLIN'S DIABETES MELLITUS

TABLE 54.4. Early Treatment Diabetic Retinopathy Study

```
Major eligibility criteria
```

Visual acuity $\geq 20/40$ ($\geq 20/400$ if reduction caused by macular edema)

Mild NPDR to non-high-risk PDR, with or without macular edema

Both eyes suitable for photocoagulation

Major design features

One eye of each patient assigned randomly to early photocoagulation and the other to deferral (careful follow-up and photocoagulation if high-risk PDR develops)

Patients assigned randomly to aspirin or placebo

Major conclusions

Focal photocoagulation (direct laser for focal leaks and grid laser for diffuse leaks) reduced risk of MVL (doubling of the visual angle) by ≥50% and increased the chance of a small improvement in visual acuity

Both early scatter with or without focal photocoagulation and deferral followed by low rates of severe visual loss (5-year rates in deferral subgroups 2%–10%; in early photocoagulation groups, 2%–6%)

Focal photocoagulation should be considered for eyes with CSME

Scatter photocoagulation not indicated for mild to moderate NPDR but should be considered as retinopathy approaches high-risk PDR and usually should not be delayed when this high-risk stage is present

Aspirin had no effect on progression of retinopathy, frequency of vitreous hemorrhage, or cataract development

For abbreviations, see Table 54.1.

Table prepared by Matthew D. Davis, M.D., and the ETDRS Research Group for the Diabetes 2000 Program of the American Academy of Ophthalmology.

onset of retinopathy by 76% and resulted in a 63% reduction in the risk of progression of retinopathy. There was a 47% reduction in the risk of developing severe nonproliferative diabetic retinopathy (NPDR) or PDR, a 23% reduction in the risk of developing clinically significant macular edema, and a 56% reduction in the risk of requiring laser surgery for those on intensive therapy. Significantly, these benefits persisted for 4 years after the period of intensive control, despite convergence of glycemic control for both groups after 4 years (52). Similar reduction of risks was identified for other microvascular complications of diabetes, such as renal disease and neuropathy.

United Kingdom Prospective Diabetes Study

The UKPDS (54,55) and studies in Japan (53) demonstrated similar reduction in risk for onset and progression of diabetic retinopathy for persons with type 2 diabetes. The UKPDS enrolled 3,867 patients with newly diagnosed type 2 diabetes. Intensive therapy to control blood glucose, using either sulfonylureas or insulin, resulted in a 17% risk reduction for progression of diabetic retinopathy, a 29% risk reduction in the need for laser photocoagulation surgery, a 23% risk reduction for the development of vitreous hemorrhage, and a 16% risk reduction in legal blindness.

TABLE 54.5. Diabetic Retinopathy Vitrectomy Study
RECENT SEVERE VITREOUS HEMORRHAGE (GROUP H)
Major eligibility criteria
Visual acuity ≥5/200
Vitreous hemorrhage consistent with visual acuity, duration 1–6 months
Macula attached by ultrasound
Major design features
In most patients, only one eye eligible
Eligible eye(s) assigned randomly to early vitrectomy or conventional management (vitrectomy if center of macula detaches or if vitreous
hemorrhage persists for 1 year; photocoagulation as needed and as possible) Major conclusions
Chance of recovery of visual acuity $\geq 10/20$ increased by early vitrectomy, at least in patients with type 1 diabetes, who were younger and
had more severe PDR (in most severe PDR group, $\geq 10/20$ at 4 years in 50% of early vitrectomy group vs. 12% in conventional
management group)
VERY SEVERE PDR WITH USEFUL VISION (GROUP NR)
Major eligibility criteria
Visual acuity ≥10/200
Center of macula attached
Extensive, active, neovascular or fibrovascular proliferations
Major design features
Same as group H (except conventional management included vitrectomy after a 6-month waiting period in eyes that developed severe vitreous hemorrhage)
Major conclusions
Chance of visual acuity $\geq 10/20$ increased by early vitrectomy, at least for eyes with very severe new vessels
Note: The DRVS was conducted prior to the advent of several surgical advances such as endolaser, now commonly used during
vitreoretinal surgery in patients with diabetic retinopathy. Caution is therefore warranted if extrapolating DRVS results to patients
receiving such current therapeutic modalities. For abbreviations, see Table 54.1. Table prepared by Matthew D. Davis, M.D., and the ETDRS Research Group for the Diabetes 2000 Program of the American Academy
of Ophthalmology.

DIAGNOSIS, CLASSIFICATION, AND MANAGEMENT OF DIABETIC RETINOPATHY

Retinal Lesions

The processes by which diabetes mellitus results in retinopathy and maculopathy are not fully understood. It is apparent in studies with laboratory animals, however, that hyperglycemia itself, even in animals not genetically diabetic, is sufficient to cause diabetic retinopathy (73). The elevated blood glucose level is thought to induce structural, physiologic, and hormonal changes that affect the retinal capillaries. The retinal capillary mural cells become less functional and endothelial cell dysfunction results (74–76). Alteration in retinal blood flow is observed early in the course of diabetes (77,78).

Basic pathophysiologic processes in the development of diabetic retinopathy include (a) loss of pericytes associated with retinal capillaries, (b) thickening of the basement membrane, (c) changes in retinal blood flow, (d) outpouching of capillary walls to form microaneurysms, (e) closure of retinal capillaries and arterioles leading to retinal nonperfusion, (f) breakdown of the blood/retinal barrier with increased vascular permeability of retinal capillaries, (g) proliferation of new retinal and/or iris vessels, (h) development of fibrovascular tissue, and (i) contraction of vitreous and fibrous proliferation with subsequent vitreous hemorrhage and/or retinal detachment as a result of traction.

HEMORRHAGES AND/OR MICROANEURYSMS

The various diabetic retinal lesions and their severity, both alone and in aggregate, are excellent predictors of the risk of progression of retinopathy and visual loss (Table 54.6) (29). The development of the various lesions of diabetic retinopathy is believed to result from the occurrence of various pathologic processes and interactions during the course of diabetes and development of diabetic eye disease. The retinal pericytes, which are intimately associated within the basement membrane of the retinal endothelial cells, are normally present in a one-toone ratio with the endothelial cells themselves. This is a ratio higher than that found anywhere else in the body. This finding and other cell-culture data have suggested that the retinal pericytes are critical supporting cells for the retinal capillaries (79,80). The loss of the retinal pericytes is thought, therefore, to be a factor contributing to the development of endothelial cell dysfunction and weakness of the retinal capillary wall, possibly contributing to the formation of microaneurysms, which, along with venous dilatation, is one early clinical sign of diabetic retinopathy (15,19,20).

TABLE 54.6.	Proliferative Diabetic Retinopathy at 1-Year Visit,
	By Severity of Individual Lesion

Lesion	Grade	PDR in 1 year, %
H/Ma	Present in 2–5 fields	9
	Very severe	57
IRMA	None	9
	Moderate in 2–5 fields	57

	Present in 2-5 fields	59

See Table 54.1 for abbreviations

From Early Treatment Diabetic Retinopathy Study Research Group. Fundus photographic risk factors for progression of diabetic retinopathy: ETDRS report no. 12. *Ophthalmology* 1991;98[Suppl 5]:823–833.

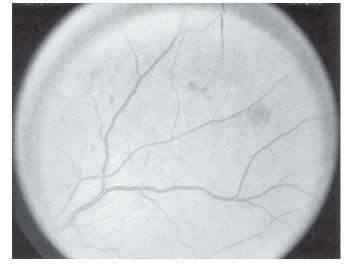

Figure 54.1. Standard photograph 2A of the modified Airlie House classification of diabetic retinopathy demonstrating a moderate degree of hemorrhage and/or microaneurysms.

The early clinical signs of diabetic retinopathy are microaneurysms, which are saccular outpouchings of retinal capillaries (Fig. 54.1). Ruptured microaneurysms, leaking capillaries, and intraretinal microvascular abnormalities can result in intraretinal hemorrhages. The clinical appearance of these hemorrhages reflects the retinal architecture at the retinal level of the hemorrhage. Hemorrhages in the nerve-fiber layer assume a more flame-shaped appearance, coinciding with the structure of the nerve-fiber layer that runs parallel to the retinal surface. Hemorrhages deeper in the retina, where the arrangement of cells is approximately perpendicular to the surface of the retina, assume a pinpoint or dot shape and are more characteristic of diabetic retinopathy.

The term "dot/blot hemorrhages" has been used to describe these small intraretinal hemorrhages characteristic of diabetic retinopathy. Because it is very difficult, if not impossible, to distinguish small dot/blot hemorrhages from microaneurysms, and because critical evaluation of these lesions has determined that little additional clinically significant information is obtained by differentiating these two lesions, they are classically evaluated together and referred to as "hemorrhages and microaneurysms."

VENOUS CALIBER ABNORMALITIES

Venous caliber abnormalities (Fig. 54.2) are early indicators of diabetic retinopathy and are often indicators of severe retinal hypoxia. These abnormalities can be venous dilatation, beading, or loop formation. These venous changes usually occur where there are large areas of nonperfusion adjacent to the veins. Treatment with scatter (panretinal) photocoagulation may cause these abnormal veins to become more normal in appearance over time.

INTRARETINAL MICROVASCULAR ABNORMALITIES

Intraretinal microvascular abnormalities (IRMAs) (Fig. 54.3) are preexisting vessels with endothelial cell proliferation that some consider new vessel growth within the retina that become "shunts" through areas of nonperfusion. IRMAs may be seen adjacent to cotton-wool spots, which result from microinfarcts in the nerve-fiber layer of the retina. IRMAs are often associated with a severe stage of nonproliferative retinopathy, and frank

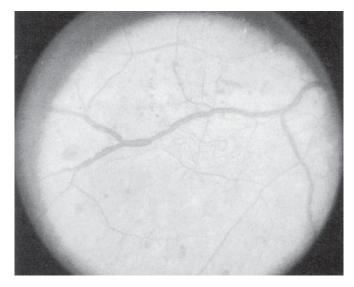

Figure 54.2. Standard photograph 6B of the modified Airlie House classification of diabetic retinopathy demonstrating venous beading.

neovascularization is likely to appear on the surface of the retina or optic disc within a short time.

RETINAL NEOVASCULARIZATION

PDR (Fig. 54.4) is marked by the development of new, abnormal retinal vessels. The rate of growth of these new vessels is variable. These vessels grow either at or near the optic disc [neovascularization of the disc (NVD)] or elsewhere on the surface of the retina [neovascularization elsewhere (NVE)]. Translucent fibrous tissue is often associated with the new vessels. This fibroglial tissue appears opaque and becomes adherent to the adjacent vitreous.

Patients with high-risk PDR require immediate scatter laser photocoagulation. High-risk PDR is characterized by any one or more of the following lesions: (a) NVD approximately one fourth to one third the disc area or more in size (i.e., greater than or equal to NVD in ETDRS standard photo 10A) (9,27) (Fig. 54.4); (b) NVD less than one fourth the disc area in size if fresh

Figure 54.4. Standard photograph 10A of the modified Airlie House classification of diabetic retinopathy demonstrating neovascularization of the optic disc covering approximately one fourth to one third of the disc area.

vitreous or preretinal hemorrhage is present; or (c) NVE greater than or equal to one half the disc area in size if fresh vitreous or preretinal hemorrhage is present (Fig. 54.5). Because identification of high-risk characteristics is critical for determining delivery of sight-saving care, careful attention must be paid to the presence or absence of new vessels, the location of new vessels, the severity of new vessels, and the presence or absence of preretinal or vitreous hemorrhage (5).

Levels of Diabetic Retinopathy

Scatter (panretinal) laser photocoagulation surgery should be considered as retinopathy approaches or reaches the high-risk stage of PDR. An eye is considered to be approaching the highrisk stage when there are retinal signs of severe or very severe NPDR or new vessels not fulfilling the definition of high-risk PDR (see Proliferative Diabetic Retinopathy), especially if associated with very severe NPDR. The baseline level of retinopathy

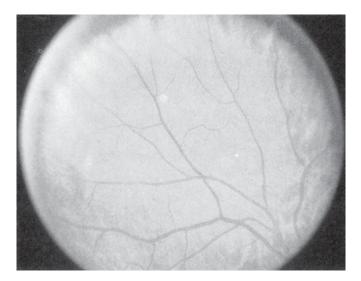

Figure 54.3. Standard photograph 8A of the modified Airlie House classification of diabetic retinopathy demonstrating intraretinal microvascular abnormalities.

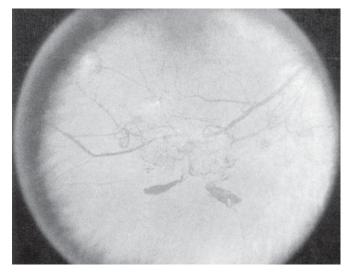

Figure 54.5. Standard photograph 7 of the modified Airlie House classification of diabetic retinopathy demonstrating neovascularization elsewhere in the retina greater than one half disc area with fresh hemorrhage present.

is a strong indicator of the risk of progression from the NPDR stage to both early PDR and high-risk PDR (Tables 54.6, 54.7, and 54.8) (29).

NONPROLIFERATIVE DIABETIC RETINOPATHY

Diabetic retinopathy is broadly classified as NPDR and PDR. Diabetic macular edema can occur with either NPDR or PDR and is discussed separately. Accurate diagnosis of a patient's "diabetic retinopathy level" is critical because the risk of progression to PDR and high-risk PDR varies and is closely correlated with the specific level of NPDR (Table 54.8, Fig. 54.6).

Mild NPDR is marked by at least one retinal microaneurysm, but hemorrhages and microaneurysms are less than those in ETDRS standard photograph 2A (Fig. 54.1) in all four retinal quadrants (Fig. 54.1 and Table 54.7). No other retinal lesions or abnormalities associated with diabetes are present. Those with mild NPDR have a 5% risk of progression to PDR within 1 year and a 15% risk of progression to high-risk PDR within 5 years (Table 54.8).

Moderate NPDR (Table 54.7) is characterized by hemorrhages and/or microaneurysms (H/Ma) greater than those pictured in ETDRS standard photograph 2A in at least one quadrant but in less than four retinal quadrants, with or without venous beading and IRMA to a mild degree. The risk of progression to PDR

907 54: OCULAR COMPLICATIONS OF DIABETES MELLITUS

within 1 year is 12% to 27%, and the risk of progression to highrisk PDR within 5 years is 33% (Table 54.8).

Patients with mild or moderate NPDR generally are not candidates for scatter (panretinal) laser surgery and can be followed safely at 6- to 12-month intervals as determined by the examiner. The presence of macular edema, even with mild or moderate degrees of NPDR, requires follow-up in a shorter period. If CSME is present, focal laser treatment is advisable (Table 54.8). Coincident medical problems or pregnancy will necessitate more frequent reevaluation.

Severe NPDR is based on the severity of H/Ma, IRMA, and/or venous beading and is determined by any one of the following lesions (Table 54.7): (a) H/Ma greater than ETDRS standard photo 2A (Fig. 54.1) in four quadrants, (b) venous beading (Fig. 54.2) in two or more quadrants, or (c) IRMA greater than ETDRS standard photo 8A (Fig. 54.3) in at least one quadrant.

Eyes with severe NPDR have a 52% risk of developing PDR within 1 year and a 60% risk of developing high-risk PDR within 5 years. These patients require follow-up evaluation in 2to 4-month intervals. Because the clinical effectiveness of laser photocoagulation for clinically significant macular edema in the presence of PDR may be reduced compared with treatment of clinically significant macular edema alone, treatment of clinically significant macular edema in patients with severe or very severe NPDR is indicated because of a high risk of developing PDR and requiring scatter (panretinal) laser surgery in a relatively short time. In addition, scatter (panretinal) laser surgery can worsen macular edema-another reason for optimizing the macular edema status of these patients who are likely to require scatter (panretinal) laser photocoagulation in the near term (Table 54.8).

Eyes with very severe NPDR (Table 54.7) have two or more lesions of severe NPDR but no frank neovascularization. These eyes have a 75% risk of developing PDR within 1 year. Patients with severe or very severe NPDR may be candidates for scatter (panretinal) laser surgery, particularly those with type 2 diabetes, and macular edema, if present, often requires treatment. Frequent reevaluation at 2- to 3-month intervals is important for these eyes (Table 54.8).

PROLIFERATIVE DIABETIC RETINOPATHY

Diabetic retinopathy marked by new vessel growth on the optic disc (NVD) or elsewhere (NVE) on the retina or by fibrous-tissue proliferation is designated PDR. Early PDR does not meet the definition of high-risk PDR (Table 54.7). Eyes with early PDR (less than high risk) have a 75% risk of developing high-risk PDR within a 5-year period. These eyes may require scatter (panretinal) laser surgery. Macular edema, even if not clinically significant, may benefit from focal treatment before scatter is initiated, as discussed above (nonproliferative diabetic retinopathy) (Table 54.8).

In patients with early PDR (less than high-risk PDR), early scatter (panretinal) laser surgery should be considered if any of the associated findings are present: (a) any new vessels accompanied by severe or very severe NPDR, (b) elevated new vessels, (c) or NVD. In the presence of macular edema, patients with severe NPDR or worse should be considered for focal treatment of macular edema whether or not the macular edema is clinically significant, in preparation for the impending future need of scatter laser photocoagulation (Table 54.8).

In patients with severe or very severe NPDR or early PDR, the patient's type of diabetes is important. It has been demonstrated in the ETDRS that patients with type 2 diabetes have their risk of severe visual loss or vitrectomy surgery reduced by 50% if scatter (panretinal) laser surgery is initiated prior to the development of high-risk PDR. In contrast, patients with type 1

diabetes showed no significant difference in the risk of severe visual loss or vitrectomy if laser surgery is delayed until the development of PDR with high-risk characteristics (59,60).

Diabetic Macular Edema

Diabetic macular edema may be present at any level of retinopathy (Table 54.8). Alterations in the structure of the macula observed in diabetes include (a) macular edema (a collection of intraretinal fluid in the macula with or without lipid exudates and with or without cystoid changes); (b) nonperfusion of parafoveal capillaries with or without intraretinal fluid; (c) traction in the macula by fibrous-tissue proliferation causing dragging of the retinal tissue, surface wrinkling, or detachment of the macula; (d) intraretinal or preretinal hemorrhage in the macula; (e) lamellar or full-thickness retinal hole formation; (f) various combinations of the above.

The clinical definition of macular edema is retinal thickening within two disc diameters of the center of the macula. This definition is not based on the presence of fluorescein leakage. Retinal thickening or hard exudates with adjacent retinal thickening that threaten or involve the center of the macula are considered to be clinically significant. CSME as defined by the ETDRS includes any one of the following lesions (Table 54.7): (a) retinal thickening at or within 500 µm from the center of the macula (Fig. 54.7), (b) hard exudates at or within 500 µm from the cen-

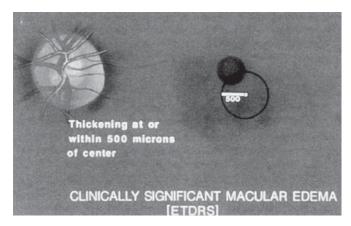

Figure 54.7. Schematic showing clinically significant macular edema with thickening of the macular less than 500 µm from the center of the macula. (Schematic courtesy of Robert Murphy, M.D., with permission.)

ter of the macula if there is thickening of the adjacent retina (Fig. 54.8), or (c) an area or areas of retinal thickening at least one disc area in size, at least part of which is within one disc diameter of the center of the macula (Fig. 54.9).

In managing CSME, there are particular retinal lesions identified on fluorescein angiography that are amenable to treatment. These "treatable lesions" associated with macular edema include (a) focal leaks more than 500 μ m from the center of the macula thought to be causing retinal thickening and/or hard exudates (Fig. 54.10); (b) focal leaks 300 to 500 μ m from the center of the macula thought to be causing retinal thickening and/or hard exudates, if the treating ophthalmologist does not believe that treatment is likely to destroy the remaining perifoveal capillary network (Fig. 54.11), and visual acuity is 20/40 or worse; (c) areas of diffuse macular leakage (Fig. 54.12) from extensive numbers of microaneurysms or from many IRMAs; or (d) avascular zones other than the normal foveal avascular zone, not previously treated (Fig. 54.12).

Focal laser surgery for CSME consists of "direct" laser treatment, "grid" laser treatment, or "combination" focal laser and grid laser treatment. These treatment methods are described in detail elsewhere (18,20). Table 54.8 summarizes the management recommendations for CSME at the various retinopathy levels.

International Classification of Diabetic Retinopathy

While the classification of diabetic retinopathy used in the ETDRS is evidence-based and unparalleled for clinical research involving diabetic retinopathy, this classification is at times challenging to employ, especially clinically. In order to simplify classification and standardize communication between retinal specialists and ophthalmologists and other healthcare providers worldwide, in 2001 the American Academy of Ophthalmology initiated a project to establish a consensus International Classification of Diabetic Retinopathy and Diabetic Macular Edema (80a,b). The consensus panel included 31 participants from 16 countries. The consensus panel relied on evidence-based studies, including the Early Treatment Diabetic Retinopathy Study (ETDRS) and the Wisconsin Epidemiologic Study of Diabetic Retinopathy. This International Classification of Diabetic Retinopathy and Diabetic Macular Edema described five clinical levels of diabetic retinopathy: no apparent retinopathy (no abnormalities), mild NPDR (microaneurysms only), moderate NPDR (more than microaneurysms only but less than severe NPDR), severe NPDR (any of the following: >20 intraretinal hemorrhages in each 4 quadrants, definite VB in 2+ quadrants, prominent IRMA in 1+ quadrant and no PDR), and PDR (one or more of retinal neovascularization, vitreous hemorrhage, or preretinal hemorrhage). Table 54.9 compares levels of DR in the International Classification of DR with ETDRS levels of DR.

Additionally, the International Classification identified two broad levels of diabetic macular edema (DME): *macular edema apparently absent* (no apparent retinal thickening or hard exudates [HE] in the posterior pole) and *macular edema apparently present* (some apparent retinal thickening or HE in the posterior pole); if present, macular edema was subclassified as *mild DME* (some retinal thickening or HE in the posterior pole but distant from the center of the macula), *moderate DME* (retinal thickening or HE approaching the center of the macula but not involv-

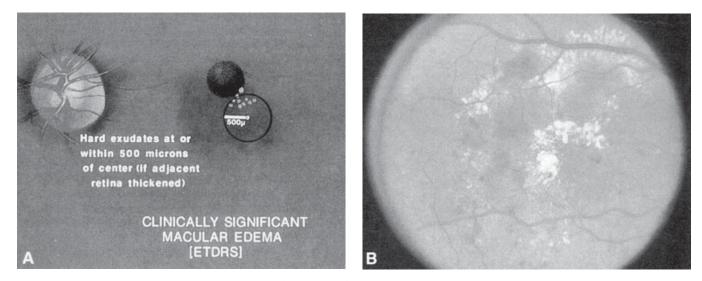

Figure 54.8. A: Schematic showing clinically significant macular edema (CSME) with hard exudates at or within 500 μ m from the center of the macula, with thickening of the retina adjacent to the exudates (Schematic courtesy of Robert Murphy, M.D., with permission.) **B**: Clinical appearance of hard exudates less than 500 μ m from the center of the macula. There is thickening of the adjacent retina, not appreciated without stereoscopic observation.

ing the center), or *severe DME* (retinal thickening or HE involving the center of the macula). Table 54.10 (page 913) compares levels of DME in the International Classification with ETDRS levels of DME.

Overall, the International Classification of Diabetic Retinopathy and Diabetic Macular Edema reduces the number of levels of DR, simplifies descriptions of the categories, and describes the levels without relying on reference to the standard photographs of the Airlie House Classification of DR. While the classification does simplify clinical levels of DR, the International Classification of Diabetic Retinopathy and Diabetic Macular Edema is not a replacement for ETDRS levels of DR in large-scale clinical trials or studies in which precise retinopathy classification is required.

Role of Clinical Fluorescein Angiography in Management of Diabetic Retinopathy

Fluorescein angiography of the macula in the presence of CSME is valuable for the detection of treatable lesions, as previously described. However, its use for identifying lesions such as NVE or feeder vessels on NVD is usually not necessary because the lesions are clinically evident and scatter (panretinal) laser

surgery is the method of choice for the treatment of diabetic retinopathy as it approaches or reaches the high-risk stage.

Angiographic risk factors for progression of NPDR to PDR have been identified (28,30). Analysis of data for the untreated (deferred) eyes in the ETDRS indicates that the following lesions are independently related to outcome: (a) fluorescein leakage, (b) capillary loss on fluorescein angiography, (c) capillary dilatation on fluorescein angiography, and (d) the following color fundus photographic risk factors: IRMA, venous beading, and H/Ma. Hard and soft exudates have an inverse relationship to progression. It is widely accepted that capillary loss as documented on fluorescein angiography is a risk factor for progression of NPDR to PDR (28,30,74–76). However, capillary dilatation on fluorescein angiography, fluorescein leakage,

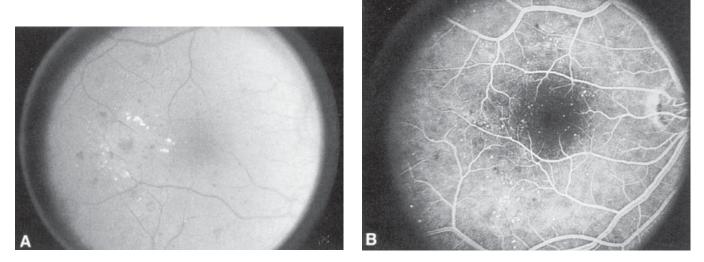

Figure 54.10. A: Clinical picture showing macular edema more than 500 μm from the center of the macula (edema not appreciated without stereoscopic evaluation). **B:** Fluorescein angiogram showing focal leaks from microaneurysms more than 500 μm from the center of the macula.

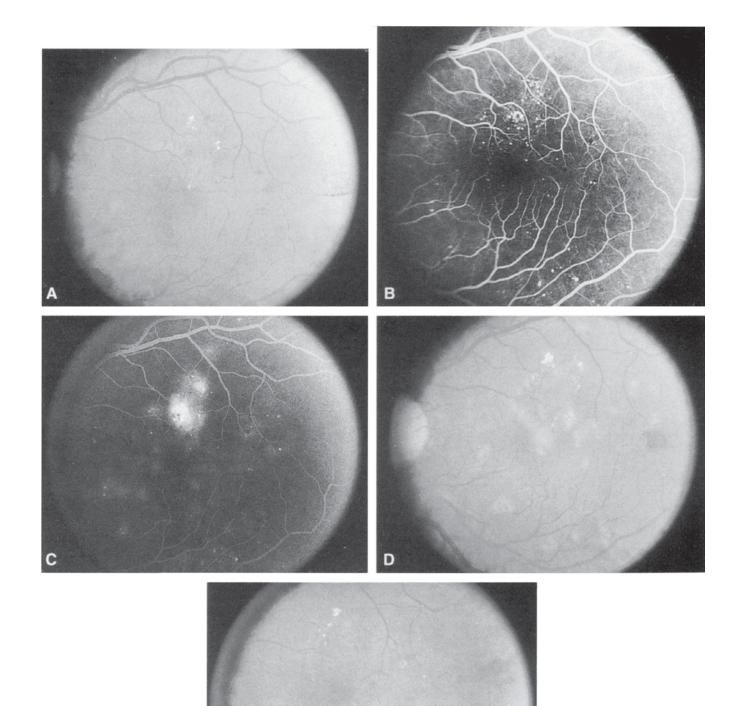

Figure 54.11. A: There is a small area of retinal thickening just above the center of the macula (poorly appreciated without stereopsis), detectable monocularly because of blurring of the choroidal pattern. Several microaneurysms are visible within the thickened area. There is a little hard exudate around the edges of the edematous patch, some of which extends almost to the center of the macula. Thickening extends to within 500 µm of the center of the macula (clinically significant macular edema). Visual acuity was 20/15. **B:** In the 17- to 18-second phase of the fluorescein angiogram, microaneurysms and slightly dilated capillaries are visible in the area of thickening. **C:** The 7-minute phase of the angiogram shows leakage into the retina from the two groups of microaneurysms noted in **B. D:** Treatment has been applied to most of the microaneurysms. **E:** Four months later the appearance of the retina is satisfactory, with flattening of the center of the macula and disappearance of the thickening noted before the treatment. Visual acuity remains at 20/15.

Ε

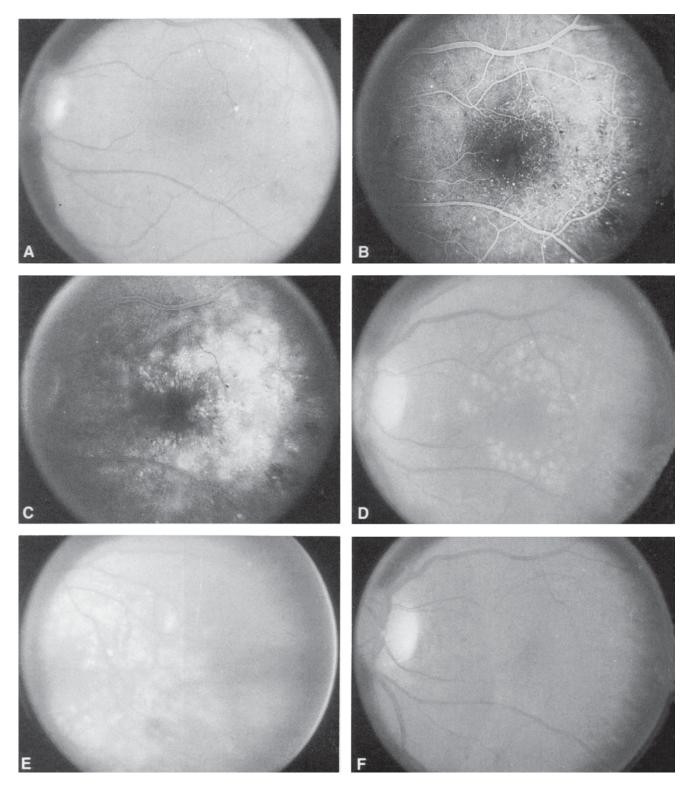

Figure 54.12. A: Clinical picture showing retinal thickening temporal to the center of the macula extending just to the center. Visual acuity is 20/40. **B:** Early phase of the angiogram shows capillary loss adjacent to the foveal avascular zone, capillary dilatation, and scattered microaneurysms. **C:** The 7-minute phase of the angiogram shows extensive small cystoid spaces temporal to the center of the macula and above and below it. The center appears uninvolved. **D:** The microaneurysms have been treated focally and, in addition, laser burns have been applied in a grid pattern in the areas of diffuse leakage. **E:** The temporal extent of the grid laser treatment. **F:** Four months after treatment, hemorrhages and hard exudates have decreased and the retinal thickening can no longer be detected. Visual acuity was 20/25.

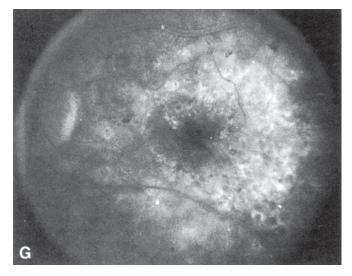

Figure 54.12. *(continued)* **G:** The 7-minute phase of the angiogram showing disappearance of most of the cystoid space visible in **C**.

capillary loss on fluorescein angiography, and the ETDRS color fundus photographic retinopathy are all closely correlated. Although the fluorescein angiography abnormalities provide additional prognostic information, the color fundus photographic grading of retinopathy levels of both eyes gives the same prognostic results (29,30). Therefore, the increase in power to predict progression from NPDR to PDR by fluorescein angiography is "not of significant clinical importance to warrant routine fluorescein angiography" (30).

Periodic follow-up retinal examinations, however, are necessary. The appropriate interval can be determined by skillful grading of seven standard-field stereo color fundus photographs and/or retinal evaluation by an examiner experienced in the management of diabetic eye disease. Because the level of diabetic retinopathy as derived from color fundus photography or retinal ophthalmic evaluation is closely correlated with the rate of progression of diabetic retinopathy, the accurate determination of the level of retinopathy becomes of paramount clinical importance and determines the appropriate retinal reevaluation interval. Also, since fluorescein angiography classification cannot "identify all cases destined to progress," and because initiation of scatter (panretinal) laser photocoagulation should be considered as diabetic retinopathy approaches (before or just as it reaches) the high-risk stage, "periodic follow-up of all patients with diabetic retinopathy continues to be of fundamental clinical importance" (30). Table 54.8 summarizes the appropriate use of fundus photography and fluorescein angiography in monitoring and treating diabetic retinopathy and macular edema.

LASER PHOTOCOAGULATION

Timing of Photocoagulation

In the ETDRS, the 3-year risk of moderate visual loss from macular edema without focal laser treatment was 30%. Focal laser surgery for CSME reduced this risk to 15% or less (17), a reduction in risk of approximately 50%, and focal treatment also increased the chance of improvement in visual acuity of one line or more. On the other hand, scatter (panretinal) laser surgery was not effective in managing diabetic macular edema and in some cases may have had a deleterious effect on the progression of macular edema.

Eyes with CSME and retinopathy approaching high-risk PDR are best treated first with focal photocoagulation for the macular edema 6 to 8 weeks before initiating scatter (panretinal) laser surgery. Eyes with mild or moderate NPDR and CSME respond best to prompt focal photocoagulation, with scatter treatment delayed unless severe or very severe NPDR or PDR occurs. Delaying scatter photocoagulation while focal treatment is being completed is unlikely to increase the risk of severe visual loss, provided the retinopathy is not progressing rapidly and careful follow-up can be maintained. Delaying scatter photocoagulation while focal treatment is completed in eyes with high-risk PDR usually is not advisable, and the macular edema will usually be treated at the first treatment session of scatter photocoagulation.

Focal treatment was not attended by adverse effects on central visual field or color vision in comparison with eyes assigned to deferral of focal treatment in the ETDRS (18). Any harmful effects of early photocoagulation as reflected by constriction of the peripheral visual fields seem to be due mostly to scatter photocoagulation. Because the principal benefit of treatment is the prevention of a further decrease in visual acuity, focal laser surgery should be considered in all eyes with CSME, especially if the center of the macula is threatened or involved, even if visual acuity is normal. However, it should be noted that macular edema that is not particularly extensive may resolve

Disease severity level	Findings	DME vs. ETDRS scale
DME apparently absent	No apparent retinal thickening or hard exudates (HE) in posterior pole	
DME apparently present	Some apparent retinal thickening or HE in posterior pole	 Mild DME: some retinal thickening or HE in posterior pole but distant from center of the macul (ETDRS: DME but not CSME) Moderate DME: retinal thickening or HE approaching the center but not involving the center (ETDRS: CSME) Severe DME: retinal thickening or HE involving the center of the macula (ETDRS: CSME)

Data from Wilkinson CP, Ferris FL III, Klein RE, et al. Proposed international clinical diabetic retinopathy and diabetic macular edema disease severity scales. *Ophthalmology* 2003;110:1677–1682; and Early Treatment Diabetic Retinopathy Study Research Group. Photocoagulation for diabetic macular edema; Early Treatement Diabetic Retinopathy Study report no. 1. *Arch Ophthalmol* 1985;103:1796–1806. spontaneously in as many as 30% of patients. Thus, in cases where visual acuity is excellent, the fovea is not particularly threatened by edema, hard exudates, or subretinal fibrosis, the likelihood for requiring scatter (panretinal) photocoagulation in the near future is low, and the patient demonstrates excellent compliance with follow-up evaluations, the edema may, at the discretion of the patient and the treating physician, be monitored carefully without immediate focal photocoagulation. However, should the visual acuity show signs of deterioration, the macular edema show signs of progression, or the level of retinopathy advance to a stage where scatter (panretinal) laser photocoagulation is likely in the near future, prompt focal laser surgery for the macular edema is indicated.

The DRS demonstrated in 1976 that scatter (panretinal) photocoagulation was effective in reducing the risk of severe visual loss from high-risk PDR (3). Because the DRS did not provide a clear choice between prompt treatment or deferral of treatment unless there was progression to high-risk PDR, one question of concern for the ETDRS was whether earlier scatter photocoagulation, before the development of high-risk PDR, justified the side effects and risks of laser surgery (Table 54.11).

In the ETDRS, early treatment, compared with "deferral" of photocoagulation until the development of high-risk PDR (26), was associated with a small reduction in the incidence of severe visual loss; however, the 5-year rates of severe visual loss were low for both the early-treatment group and the group assigned to "deferral" of treatment (2.6% and 3.7%, respectively). Provided that careful follow-up can be maintained, scatter laser surgery is not recommended for eyes with mild or moderate NPDR (26). When retinopathy is more severe (i.e., severe or very severe NPDR and early PDR), scatter photocoagulation should be "considered and usually should not be delayed if the eye has reached the high-risk proliferative stage" (26).

As retinopathy approaches the high-risk stage (very severe NPDR or early PDR), the benefits and risks of early photocoagulation may be roughly balanced. Initiating scatter photocoagulation early in at least one eye seems particularly appropriate when both of the patient's eyes are approaching the high-risk stage, as optimal timing of photocoagulation may be difficult if both eyes require photocoagulation simultaneously. Also, prompt scatter photocoagulation of the retina should be considered for eyes with neovascularization in the anterior chamber angle, whether or not high-risk PDR is present (26). It has been demonstrated in the ETDRS that patients with type 2 diabetes have their risk of severe visual loss or vitrectomy surgery reduced by 50% if scatter (panretinal) laser surgery is initiated prior to the development of high-risk PDR. In contrast, patients with type 1 diabetes showed no difference in the risk of severe visual loss or vitrectomy if laser surgery was delayed until the development of high-risk PDR (59,60).

Treatment Program

The treatment program (Table 54.8) for diabetic retinopathy consists of (a) initial scatter laser photocoagulation surgery as the diabetic retinopathy approaches or reaches the high-risk stage, (b) careful follow-up at 3- to 4-month intervals following the treatment, (c) re-treatment of persistent or recurrent treatable lesions, and (d) focal laser photocoagulation treatment for macular edema prior to scatter (panretinal) photocoagulation to reduce the risk of progression of macular edema secondary to scatter photocoagulation (see above).

As high-risk PDR is reached, the major threat for severe visual loss (SVL; visual acuity $\leq 5/200$ at two consecutive, completed 4-month follow-up visits) is traction retinal detachment. A lesser threat of persistent visual loss, but a more common

Secondary retinal hole and rhegmatogenous retinal detachment

Secondary retinal hole and rhegmatogenous retinal detachment Retinopathy progression to traction retinal detachment

complication, is vitreous hemorrhage. The primary goal of the scatter laser surgery is the prevention of traction retinal detachment, particularly involving the macula.

Various strategies are involved in follow-up treatment. The ocular lesions to be considered for follow-up photocoagulation include new flat neovascularization or elevated neovascularization and new, persistent, or recurrent CSME. The treatment methods include additional scatter laser treatment, local laser to NVE, focal laser for CSME, *pars plana* vitrectomy for recurrent hemorrhages with fibrovascular proliferation causing traction, and, when appropriate, continued observation. Further scatter treatment may be placed between previously placed laser scars as long as these scars do not become confluent and the extent of the scatter treatment is not such as to totally destroy retinal function.

Although laser surgery often is considered painless, some patients may experience discomfort in association with the treatment. There usually is some discomfort or pain in all patients when the peripheral retina is treated. Complications and side effects of laser photocoagulation are summarized in Table 54.11.

In summary, scatter treatment significantly reduces the risk of severe visual loss from PDR. Both early scatter treatment prior to development of high-risk PDR and deferral of treatment until the development of high-risk PDR reduce the risk of severe visual loss. The rates of severe visual loss are low for each group after treatment. Consequently, it is recommended that scatter laser treatment not be used for mild to moderate NPDR. For severe NPDR and early PDR, scatter treatment is appropriate when close follow-up is unlikely, the disease process is progressing rapidly, or in patients with type 2 diabetes.

NONRETINAL OCULAR COMPLICATIONS

Clinical Significance

The potentially devastating effects of diabetes on the retina and the attendant threat of visual loss are generally well recognized (81). All structures of the eye, however, are susceptible to the deleterious effects of diabetes (Table 54.12). Some of these effects are of little consequence and go unnoticed by both the patient and the physician. Other effects, while not sight-threatening, result in uncomfortable vision or other symptoms interfering with normal visual function. Still other effects, while perhaps most prevalent with diabetes, require evaluation to rule out potentially life-threatening underlying causes other than diabetes.

Complications

MONONEUROPATHIES

Mononeuropathies of the third, fourth, or sixth cranial nerves may arise in association with diabetes (81,82) (see Chapter 56). These nerve palsies are usually of serious concern to the patient and present a significant diagnostic challenge, because misdiagnosis may keep a life-threatening lesion from being treated. On the other hand, a full neurologic evaluation, including computed tomography, magnetic resonance imaging, and other tests, may prove unwarranted and unnecessary. In one review of cranial nerve palsies treated in a diabetic patient population in 1967, 42% of mononeuropathies were not diabetic in origin (82). This finding underscores the danger of routinely attributing mononeuropathies, even in a diabetic person, to the diabetic condition itself without carefully ruling out other potential causes. The percentage of all extraocular muscle palsies attributable to diabetes mellitus is estimated at 4.5% to 6% (83-85).

Histopathologic studies of diabetic third-nerve palsies suggest that they are secondary to ischemic infarction of the nutrient vessels to the oculomotor nerve within the cavernous sinus or subarachnoid space (86,87). By extension, vascular infarct with resulting ischemia to any of the cranial nerves serving the extraocular muscles is generally accepted as the cause of diabetes-related cranial-nerve palsies.

The trochlear or fourth cranial nerve is the least likely to be affected by diabetes (81,82,84) (Table 54.13). Palsies of the oculomotor or third cranial nerve are more frequent and are usually accompanied by a ptosis of the affected eye, which may block or mask a horizontal and vertical diplopia. The ptosis itself, however, is usually sufficient to cause a person to seek medical evaluation. Characteristically, the affected eye has an exotropic and hypotropic posture (down and out). Pain may be associated with the onset of the palsy, which is usually acute (82,88–91). The pupil is usually unaffected or spared in diabetic third-nerve palsy, although there may be pupillary involvement in up to 20% of diabetes-induced third-nerve palsies (92,93). Pupillary involvement suggests external pressure on the nerve by a mass lesion or aneurysm and is sufficient reason to arrange immediate consultation for neurologic evaluation. In one series, 19.2% of all oculomotor-nerve palsies were associated with diabetes (94).

Paralysis of the abducens or sixth cranial nerve occurs at least as often as third-nerve palsies in diabetes (81,83,84). Patients with sixth-nerve palsies usually complain of horizontal diplopia, sometimes only on extreme lateral gaze to the side of the affected eye. The affected eye is generally esotropic and frequently cannot be moved past the midline. The sixth cranial nerve has a lengthy path, and there are many causes of abducens nerve insult, some of which are life-threatening.

Mononeuropathies also may be the initial presenting sign of new-onset diabetes. Diabetes should therefore be considered in the differential diagnosis of any mononeuropathy affecting the extraocular muscles, even in patients who do not claim a history of diabetes. Diabetes-induced third-, fourth-, and sixthnerve palsies are usually self-limited and should resolve spontaneously in 2 to 6 months, although more or less time may be needed and the palsies may recur or subsequently develop in the contralateral eye.

Treatment involves patching one eye to eliminate diplopia, if symptoms warrant, and a mild analgesic if needed. In monocular patients, or in patients with poor vision in one eye, the maintenance of vision, especially when ptosis obstructs the visual axis of the eye with better sight, may present a challenge. Taping of the lid or the use of a ptosis crutch may be required, although the problems of corneal drying associated with diabetes-induced corneal hypoesthesia and poor epithelial adhesions are significant.

PERIORBITAL AND ORBITAL STRUCTURES

Waite and Beetham (81) reported a slightly higher frequency of xanthelasma in their diabetic patients than in their nondiabetic patients. The xanthelasma are usually of no clinical significance. A far more serious complication is orbital infection, usually at the apex of the orbit, with fungi of the order Mucorales (see Chapter 60). Although rare, mucormycosis (also called phycomycosis) is a fungal infection that develops in the adjacent periorbital sinuses in predisposed persons (95,96). Schwartz and coworkers found that 80% of their patients with the disorder had diabetes; most had diabetic ketoacidosis (96). The condition is frequently fatal, and prompt diagnosis is crucial. The patient typically has internal and external ophthalmoplegia, as well as decreased vision, proptosis, and ptosis. Treatment of the diabetic condition and aggressive treatment of the infectious

TABLE 54.13. Diabetic Nerve Palsies

Cranial nerve	Symptoms and signs
III (oculomotor)	Complete or partial ptosis
	Horizontal and vertical diplopia Affected eye "down and out"
	Possible supraorbital pain
	Pupillary sparing (80% of cases)
	Decreased sursumduction and adduction
IV (trochlear)	Vertical diplopia with associated esotropia
	Vertical deviation increases in downward
	gaze or when head is tilted to side of affected muscle
	Vertical deviation decreases with abduction
	of the affected eye
	Esotropia increases with downward gaze
VI (abducens)	Lateral or horizontal diplopia
	Esotropia of the affected eye
	Decreased abduction
	Possible head turn in the direction of the affected eye

organism with amphotericin B may result in recovery, although the survival rate still remains at only 57% (97,98).

CONJUNCTIVA AND LACRIMAL SYSTEM

Changes in the microcirculation of the bulbar conjunctiva of diabetic persons have been identified. In one series, microaneurysms of the bulbar conjunctiva were observed before cataract surgery in 63.6% of 22 eyes of diabetic patients (99). Histologically, these conjunctival microaneurysms show a thickened basement membrane, proliferation of endothelium, and lamellated hyaline deposits similar to the retinal microaneurysms in diabetic retinopathy (100). Diurnal variations in the dilation of conjunctival veins have also been noted (101). Insulin use itself appears to affect the composition of tears, sometimes resulting in a decrease in their lysozyme content (102).

Conjunctivitis and other disorders of the conjunctiva and lacrimal system need to be treated aggressively. Mild infections or marginal dry-eye syndromes potentially can cause serious ocular injuries, particularly in the presence of neuropathies or compromised corneal integrity.

CORNEA

The cornea of the diabetic person is often more susceptible to injury and slower to heal after injury than is the cornea of a nondiabetic person. A potential threat to corneal integrity is the measured reduction of corneal sensitivity in the diabetic individual (103). In animal studies, measured corneal sensitivity was significantly lower in dogs with poorly controlled diabetes than in nondiabetic dogs and diabetic dogs with good blood glucose control (104). The decrease in corneal sensitivity was also more marked with increased duration of diabetes in the dogs with poorly controlled diabetes.

The reduction of corneal sensitivity results in elevated tactile corneal thresholds (105). This reduction usually affects both eyes symmetrically and is the result of diffuse polyneuropathy of the trigeminal nerve and its branches. Other studies have suggested that panretinal photocoagulation can reduce corneal sensitivity caused by inadvertent thermal injury to the sensory nerves to the cornea between the choroid and the sclera (106). The reduction of corneal sensitivity may predispose a person to the development of neurotrophic corneal ulcerations (107). Furthermore, there is mounting evidence supporting the clinical impression that once corneal abrasions develop, the cornea in the diabetic patient is slower to heal than the cornea in the nondiabetic patient, presumably due to alterations in the basement membrane of the epithelium in patients with diabetes (108–110).

Waite and Beetham (81) found disorders in the deeper layers of the cornea as well, and subsequent research has verified the presence of these wrinkles in Descemet membrane layer in persons with diabetes (111,112). Subsequent studies demonstrated increased corneal thickness in diabetic individuals compared with that in nondiabetic control individuals (113,114), changes representing minimal corneal swelling, possibly as the result of increased corneal hydration.

Potential corneal complications affect contact-lens wear for diabetic patients. The person with diabetes may be a poor candidate for contact lenses, because discomfort from a poorly fitting or damaged lens may be absent because of a reduction in corneal sensitivity. Corneal abrasions or minor erosions that may be detected in an otherwise healthy cornea may develop into significant ulcerations. Long-term (1 week) extended-wear contact lenses should be used with extreme caution and careful monitoring and reserved only for patients with optimal conditions and specific needs, such as aphakia. All diabetic users of contact lenses should be properly educated about potential problems, early signs of lens rejection and infection, and corneal abrasion. The risk of corneal abrasion and the delay of corneal wound healing apparent in diabetic persons because of irregularities in the corneal basement epithelium dictate careful and selective contact-lens wear, although diabetes itself is not a contraindication for the use of either rigid or soft contact lenses. Many of the programmed-replacement or flexible-wear lenses provide adequate safeguards for successful adaptation to contact-lens wear.

The tendency for corneal abrasion may necessitate the use of artificial tears, particularly in dry environments. In chronic cases not remedied by tear replacement therapy, punctal plugs or punctal cauterization may be indicated. Patients with diabetes should be alerted to the potential side effects of contact lenses, and follow-up evaluations need to be frequent and thorough. The necessity of wearing safety glasses and goggles for appropriate work and sport environments should be emphasized. For ocular examination and treatment, care must be exercised to avoid corneal insult when treating or examining the retina with a corneal contact fundus lens, particularly if the patient has had a corneal abrasion in the past.

There have been no studies evaluating the risk of keratorefractive surgery to reduce myopia or hyperopia for persons with diabetes; however, diabetic persons should be evaluated carefully prior to undergoing LASIK (laser-assisted *in situ* keratomileusis), PRK (photoreactive keratectomy), or other keratorefractive surgical techniques.

IRIS

Diabetic complications affecting the iris have been well documented and the subject of much study. Glycogen deposits in the pigment epithelial cells of the iris can cause thickening of ocular tissue and depigmentation of the epithelial layer of the iris (81). Similar glycogen deposition occurs in the retina, optic nerve, epithelium of the lens capsule, and ciliary body (81,115,116). The most serious diabetic complication affecting the iris is neovascularization of the iris (NVI) or rubeosis iridis, a growth of new blood vessels on the iris (Fig. 54.13). Usually these vessels are first observed at the pupillary border and may resemble grape clusters. Neovascularization may already exist in the filtration angle without evidence of neovascularization at the pupillary border or on the iris surface. If NVI progresses, a fine network of vessels may grow over the iris tissue and into the filtration angle of the eye. Fibrous tissue accompanying the new vessels may contract and pull the underlying pigmented

layer of the iris forward through the pupillary opening, resulting in ectropion uveae. Fibrovascular growth in the filtration angle may result in peripheral anterior synechiae. Closure of the angle by the fibrovascular network results in neovascular glaucoma, although intraocular pressure may be elevated prior to angle involvement because of protein and cellular leakage from the proliferating vessels (117,118). Neovascular glaucoma is difficult to manage and requires aggressive treatment. Usually NVI is first seen around the pupillary margin, although the vessels can grow initially in or near the filtration angle. Evaluation with a slit-lamp biomicroscope is necessary to observe and evaluate these vessels. The development of neovascular glaucoma in one eye is strongly correlated with the development of the same condition in the patient's other eye.

Diabetes is the second leading cause of neovascular glaucoma, accounting for 32.2% of cases, as opposed to 36.1% of cases resulting from retinal venous obstructive disease (119–122). This neovascularization of the anterior segment occurs in 4% to 7% of diabetic eyes and may be present in up to 40% to 60% of eyes with proliferative retinopathy that have not been treated with scatter laser photocoagulation (95–97).

Treatment for NVI and neovascular glaucoma includes scatter (panretinal) laser photocoagulation; goniophotocoagulation with a green or yellow laser; topical antiglaucoma medications; systemic antiglaucoma medications; antiglaucomatous filtration surgery, including Molteno valve implants; or, usually, a combination of one or more of the above therapies (2,123–127).

GLAUCOMA

Open-angle glaucoma is 1.4 times more common in the diabetic population than in the nondiabetic population (128–131). The prevalence of glaucoma increases with age and duration of diabetes, but medical therapy for open-angle glaucoma is gener-

ally effective. Choice of treatment of open-angle glaucoma in diabetic individuals must be influenced by the patient's general medical condition. Caution must be exercised with the use of topical β -adrenergic blockers in masking hypoglycemic symptoms or affecting concurrent cardiovascular disease. Systemic acetazolamide or other carbonic anhydrase inhibitors (CAIs) may be used if needed, but since these medications can cause metabolic acidosis, electrolyte monitoring should be done more frequently. The presence of renal disease may influence how these and other pressure-lowering drugs may be used, and close cooperation with the internist is important. Topical CAIs and recently available antiglaucoma eye drops have added safe additional medication for the treatment of glaucoma. Argon laser trabeculoplasty may normalize intraocular pressures in some if medical therapy proves ineffective.

Narrow-angle glaucoma and acute angle-closure glaucoma are comparatively rare. Narrow-angle glaucoma does not seem to be more common in persons with diabetes than in the general population, but investigations suggest that the shallower the anterior chamber of the patient's eye, the more likely the patient is to respond abnormally to an oral glucose-tolerance test (132). The postulated mechanism for this association is autonomic dysfunction within the anterior segment of the eye resulting in a hypersensitivity to both sympathetic and parasympathetic autonomic mediators, with the iris-lens diaphragm moving forward and closing the angle. Anterior chambers generally become shallower with age.

In acute angle-closure glaucoma, the outflow angle in the anterior chamber of the eye formed by the iris plane and the posterior corneal surface becomes closed, blocking outflow to the outflow channels of the trabecula meshwork. The result is a dramatic and rapid rise in intraocular pressure, with ocular pain, decreased vision, colored halos around lights, and, fre-

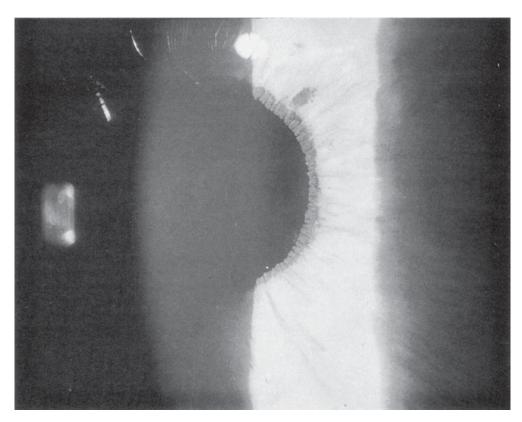

Figure 54.13. Neovascularization of the iris (rubeosis iridis) around the pupillary margin.

918 JOSLIN'S DIABETES MELLITUS

quently, nausea and vomiting. Angle-closure glaucoma should be considered as part of the differential diagnosis for a diabetic patient presenting with nausea and vomiting.

Angle-closure glaucoma is considered a medical emergency. Treatment consists of attempts to break the angle closure medically with miotic drops and to lower the pressure with either systemic or topical medications. A peripheral iridectomy or laser iridotomy can restore the normal aqueous outflow and prevent future episodes of angle closure. Because pupil dilation can trigger an angle-closure attack, care needs to be exercised before dilation of any pupil.

LENS

Diabetic effects on the crystalline lens can result in transitory refractive changes and cataracts.

Refractive Changes

Refractive changes related to fluctuation of blood glucose levels are readily acknowledged by all clinicians, and diabetes has also been found to affect accommodation ability.

Blood Glucose Levels

The mechanism of such refractive changes due to fluctuations in blood glucose levels is only poorly understood. Myopic or hyperopic shifts with changes of blood glucose levels or as an initial symptom or sign of undiagnosed diabetes are common in the phakic eye (81). These refractive shifts can be of several diopters or more and are thought to be the result of osmotic swelling of the crystalline lens. Rapid shifting of blood glucose levels may result in uncorrectable blurring of vision.

Sudden refractive shifts are frequently the presenting symptom for a person with new diabetes. Patients who were able to see clearly at a distance either with or without their glasses may complain that their distance vision is now blurry. On the other hand, those who required reading glasses or who were experiencing difficulty with close work may now find they can read more easily without their glasses, misinterpreting the change as "an improvement" in their eyes. Patients with uncontrolled or poorly controlled blood glucose levels should be encouraged to postpone the purchase of eyeglasses until their blood glucose levels have stabilized. This stabilization may take 4 to 6 weeks to occur, although the effects of a rise in blood glucose level on refractive state are generally recognized as being more sudden. Any coexisting physical condition that impacts on blood glucose level, such as infection or stress, is reason not to prescribe glasses, especially if a person recognizes recent or sudden fluctuations in vision.

The proposed cause of such refractive shifts in phakic eyes involves fluid absorption by the crystalline lens. The galactitol and sorbitol pathways have been implicated, and rat models have shown that osmotic changes caused by the accumulation of galactitol in the lenses of rats fed with galactose leads to lens swelling and premature cataract development (133–140). The sorbitol pathway, however, is most likely beneficial in protecting the lens against glucose-generated osmotic changes (138).

Accommodation

While discussions of refractive changes associated with diabetes most frequently are directed to refractive shifts related to elevated blood glucose levels, there is evidence that diabetes alters accommodative ability. Waite and Beetham (81) demonstrated transitory paresis of accommodation in 21% of the diabetic patients in their study. This paresis was most predominant in the 20- to 50-year-old group and resolved with improvement of the diabetic condition. Transient accommodative paralysis

accompanied with hyperopia may be associated with either a rise or fall in blood glucose levels, most frequently after insulin treatment has been started, and may be present even in young individuals (140).

Reduced accommodative ability and diminished pupillary response have been demonstrated following heavy panretinal argon laser photocoagulation (141). It is postulated that this internal ophthalmoplegia following heavy panretinal laser photocoagulation is the result of direct or indirect injury to the parasympathetic motor fibers to the ciliary body and the iris. These fibers enter the globe at the posterior pole and course forward between the sclera and the choroid. As the fibers course forward, the choroid becomes thinner, providing less protection against the heat generated in the retinal pigment epithelium from the laser surgery. Unlike the paresis of accommodation associated with uncontrolled diabetes, the internal ophthalmoplegia associated with scatter (panretinal) photocoagulation surgery is generally irreversible, since the laser burns cause permanent damage to the underlying parasympathetic nerve fibers.

Diabetic persons frequently demonstrate presbyopia at an earlier age than nondiabetic persons, and the loss of accommodative ability frequently progresses more rapidly for diabetic persons. Consequently, it is not uncommon for myopic contact-lens wearers, who need to accommodate more through contact lenses than through spectacle lenses, or hyperopic individuals to demonstrate difficulty in reading or in close tasks. Identifying these problems may be difficult because of refractive changes secondary to fluctuation in blood glucose levels. These changes in accommodation are irreversible with age.

Cataracts

Cataracts occur earlier in life and progress more rapidly in the presence of diabetes (137–142). Cataracts are 1.6 times more common in people with diabetes than in those without diabetes (142-144). Incidence of cataract surgery in the nondiabetic population in the Beaver Dam Eye Study (150) was one-fifth to onehalf the incidence of cataract in the Wisconsin Epidemiologic Study of Diabetic Retinopathy in each age stratum studied (145). This increased risk of cataract development for the diabetic person occurs both in persons with earlier-onset diabetes and those with later-onset diabetes. In persons diagnosed with diabetes at age 30 years or older, cataract is the most common cause of visual impairment. Several studies suggested that aspirin use can reduce the risk of cataract for persons with diabetes (146–149). Other studies do not support this finding (148,149). The ETDRS results do not support the use of 650 mg of aspirin per day to reduce the risk of cataract development in the ETDRS patient population (32). In the Beaver Dam Eye Study, persons with older-onset diabetes were significantly more likely to have cortical lens opacities or prior cataract surgery than persons without diabetes in the same age group (150). Many factors are correlated with cataract development, including duration of diabetes and retinopathy status in the patient with earlier-onset diabetes, the use of diuretics, and the HbA_{1c} level (139). In patients with lateronset diabetes, age of the patient, severity of retinopathy, use of diuretics, lower intraocular pressure, smoking, and lower diastolic blood pressure may be risk factors (150,151).

Fortunately, cataract extraction is 90% to 95% successful in restoring useful vision, but the surgery is not without potential complications unique to diabetes, such as delayed wound healing, acceleration of diabetic retinopathy, iris or retinal neovascularization, and macular edema. Cataracts obscuring retinal examination may need to be removed surgically to permit retinal examination and, in some cases, appropriate laser photocoagulation surgery. Diabetic patients undergoing simultaneous kidney/pancreas transplantation are at an increased risk of developing all types of cataract, independent of the use of corticosteroids after transplantation (152).

Reversible lenticular opacities related to diabetes mellitus have also been reported (153–160). These reversible cataracts can occur in different layers of the lens and are most frequently related to poor metabolic control of diabetes. The so-called true diabetic cataracts are usually bilateral and are characterized by dense bands of white, subcapsular spots that are snowflake in appearance or fine, needle-shaped opacities (161) (Fig. 54.14). Because these diabetic cataracts are related to prolonged periods of severe hyperglycemia and untreated diabetes mellitus, they are only rarely now seen in the United States and other industrialized countries.

Management of diabetic cataract involves the same treatment strategies as those for age-related cataracts. For visual impairment not requiring surgery, optimal refractive correction is beneficial. Glare-control lenses and the use of sunglasses may relieve cataract-induced visual symptoms. Surgically, intraocular lens implants provide the most natural postsurgical refractive correction, depending on retinopathy status (162). Both phacoemulsification and extracapsular cataract extraction provide appropriate surgical approaches to cataract extraction and intraocular lens implantation; however, in one study, phacoemulsification was generally associated with better postoperative visual acuity, less postoperative inflammation, and reduced need for capsulotomy (163). A retrospective review of 150 eyes of 119 diabetic patients comparing phacoemulsification surgery to other surgical techniques did not demonstrate significant differences in postoperative visual acuity or rate of progression of diabetic retinopathy (164). In each study, the principal determinant of postoperative vision and progression of retinopathy was related to the preoperative presence of diabetic macular edema and level of nonproliferative diabetic retinopathy.

VITREOUS

Problems with the vitreous in the diabetic patient are intimately related to retinal disease (165–174). PDR is associated with an increased incidence of posterior vitreous detachment, although frequently a partial vitreous detachment, rather than a total posterior vitreous detachment, is present (166). Partial vitreous detachment may result in vitreous hemorrhage, an increase in retinal neovascularization, and tractional retinal detachment (174).

OPTIC DISC

Although the optic disc usually is discussed only in relation to PDR and neovascularization at the disc, it can be affected in a variety of other ways by diabetes. Optic disc edema unrelated to anterior ischemic optic neuropathy or other neurologic disorders can occur with diabetes mellitus (175,176). The condition seems to be related to a vasculopathy of the most superficial layer of capillaries of the optic disc (177) and is more common in younger patients with type 1 diabetes. Although transient optic disc edema usually leaves little or no lasting effect on visual acuity or visual fields, especially in younger patients, some residual disc pallor may follow resolution of the disc edema. One or both eyes may be affected.

Diabetic papillopathy must be distinguished from other causes of disc swelling, such as true papilledema from increased intracranial pressure; pseudopapilledema, such as optic nerve head drusen; toxic optic neuropathies; neoplasm of the optic nerve; and hypertension (178).

Optic disc pallor can occur following spontaneous remission of proliferative retinopathy or remission following scatter (panretinal) laser photocoagulation (179). This disc pallor does not result in a change of the cup/disc ratio. Since diabetes poses an increased risk for the development of open-angle glaucoma and anterior ischemic optic neuropathy, the disc pallor following remission of retinopathy or panretinal photocoagulation must

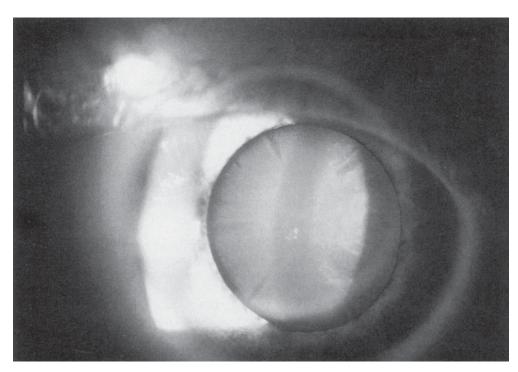

Figure 54.14. Diabetic cataract in a 16-year-old girl.

be considered when evaluating the optic-nerve head for openangle glaucoma or low-tension glaucoma (179).

FUTURE HORIZONS

Molecular and Cellular Advances

Over the past several decades, remarkable advances in our understanding of the basic mechanisms underlying diabetes and diabetic retinopathy have been achieved. These new insights into the processes underlying the fundamental molecular and cellular changes ultimately resulting in sight-threatening complications of diabetic retinopathy are permitting the development of new interventional approaches. These new therapeutic modalities hold great promise for further reducing or eliminating the complications of diabetic eye disease. Advances have been made in understanding many areas, including the changes in the sorbitol pathway, the development of oxidative stress, the production of advanced glycosylation end-products (AGEs), and the activation of protein kinase C. Each of these various pathways has been associated with a variety of the complications of diabetes, and they are often intimately related.

An area of substantial study has been the increased flux through the sorbitol pathway in cells exposed to a hyperglycemic environment. Consequently, aldose reductase inhibitors have been evaluated extensively for their potential use in ameliorating diabetic retinopathy. A multicenter clinical trial, the Sorbinil Retinopathy Trial (180,181), tested whether a daily dose of sorbinil could reduce the complications of diabetes mellitus. Over a 3-year period, the drug had no clinically important effect on the course of diabetic retinopathy in adults with type 1 diabetes of moderate duration (180,181). However, the group taking sorbinil did show a slight lowering in the number of microaneurysms. Unfortunately, there were complications in nearly 7% of the initial 202 participants taking the drug. These adverse reactions included toxic epidermal necrolysis, erythema multiforme, and Stevens-Johnson syndrome. Because of this lack of efficacy in humans and the associated side effects, no aldose reductase inhibitors are currently being used on a routine clinical basis for the treatment of diabetic retinopathy.

A variety of studies has also looked at antioxidants as a potential ameliorator of oxidative stress present under the diabetic condition. Preliminary data on antioxidants such as vitamin E have been promising with regard to preventing or reversing early changes in retinal circulation in animals and in correcting the abnormal retinal blood flow present in patients with short-duration diabetes and minimal diabetic retinopathy (78,182,183).

When proteins are exposed to high levels of glucose for extended periods, AGEs may be formed (184). Recent studies have suggested that these AGEs can cause a variety of changes in cellular processes and may contribute to diabetic ocular complications. Inhibitors of AGEs are being evaluated for clinical usefulness.

A promising area of research involves the activation of protein kinase C by diabetes (185). Activation of this enzyme can result in wide-ranging effects underlying endothelial dysfunction in the eye and other organs. In addition, protein kinase C is a key mediator of signaling processes induced by other growth factors involved in retinal neovascularization, diabetic macular edema, and perhaps earlier stages of diabetic retinopathy as well. A particular isoform (the β isoform) of protein kinase C appears to specifically mediate many of the complications arising in the eye. Consequently, inhibitors of protein kinase C β have been evaluated in animal models, with documented ability to normalize retinal blood flow, suppress retinal permeability, prevent retinal neovascularization, and normalize retinal blood flow in patients with no or mild nonproliferative retinopathy. These agents are currently in clinical trials to determine whether they can prevent or slow the progression of diabetic retinopathy and/or diabetic macular edema. Results from these studies are expected in the next few years.

Another promising area of investigation is the evaluation of the various growth factors mediating the later-stage complications of diabetic retinopathy. Numerous angiogenic agents, such as vascular endothelial growth factor, have been identified as key modulators of the retinal neovascular response and the increase in retinal vascular permeability. Several inhibitors of these agents have been developed with very promising results observed in animal models and over the next few years may add significantly to our therapeutic armamentarium. In addition, preliminary results from small uncontrolled studies suggest that intravitreal administration of steroids may have a significant effect in reducing diabetic macular edema and may actually improve vision in a subset of these patients. Currently, a number of these agents are in clinical trials.

Patient Access to Eye Care

Despite demonstrated methods of reducing vision loss from diabetes, many patients are deprived of sight-saving care. Enhanced and facilitated access to quality eye care can have a substantial impact on preserving human vision and eliminating blindness as a complication of diabetes. In addition to saving of vision, substantial savings in health costs would also be achieved. There are many barriers to quality eye care, including ignorance of the importance of such care, a shortage in caregivers, geographic isolation and distances, socioeconomic challenges, and cultural patterns.

Telemedicine initiatives hold great theoretical potential for surmounting these barriers. One system that has been studied is the Joslin Vision Network (JVN), a telemedicine-enabling technology for remote-site diagnosis and management of chronic-disease care of diabetes mellitus within the Joslin Diabetes Eye Health Care Model (186–188). Evaluation for level of diabetic retinopathy using the JVN compares favorably with evaluation using the current gold standard, 35-mm stereoscopic color slide of seven standard retinal fields as used in the ETDRS. Such validated systems are uniquely positioned to provide efficient, cost-effective eye examination and medical intervention strategies for persons with diabetes, increasing access to quality eye care and treatment and providing a database warehouse for clinical trials, treatment outcomes, and population-based studies (186–188).

Deployment of this type of technology in a communitybased and community-owned program enhances the potential to reach patients who do not have access to specialty eye care. This approach can be implemented in culturally sensitive diabetes healthcare programs in geographically diverse communities. These programs would screen for undiagnosed diabetes in the general population, access the retina at appropriate intervals to diagnose the level of diabetic retinopathy for timely medical and surgical treatment as necessary, manage diabetes medically, and collect data for population-based studies and clinical research.

GUIDELINES

Until modalities are in place to prevent or cure diabetic retinopathy and other complications, the clinical emphasis must be placed on identification, careful follow-up, and timely laser photocoagulation for patients with diabetic retinopathy and diabetic eye disease. Proper care will result in reduction of personal suffering, as well as in a substantial cost savings for the individuals with diabetes, their families, and society in general (189–191). Therefore, strict guidelines have been established for the ocular care of people with diabetes (Tables 54.8 and 54.14).

All patients with diabetes should be informed of the likelihood of developing retinopathy and the associated threat of visual loss. The natural course and treatment of diabetic retinopathy should be discussed, including the asymptomatic nature of early disease and the importance of routine examination. Patients should be informed of the relationship between glycemic control and the risk of developing ocular and other medical complications. Patients must be made aware that diabetic nephropathy, as manifest by proteinuria, requires aggressive early treatment with proper diet and blood pressure control, especially with angiotensin-converting enzyme (ACE) inhibitors, to reduce renal disease and avoid superimposed renal retinopathy (and the possible associated risk of neovascular glaucoma). The association of joint contractures, hypertension, cardiovascular disease, elevated lipid levels, and neuropathy with onset and progression of diabetic retinopathy should be discussed.

Women with diabetes who are contemplating pregnancy should have a complete eye examination before they conceive. Pregnant women with diabetes should ideally have their eyes examined early in each trimester of their pregnancy or more frequently, as indicated by level of retinopathy, and 6 weeks after delivery. Because pregnancy may exacerbate existing retinopathy and be associated with hypertension, careful medical and ocular observation during pregnancy is crucial. In women with PDR, cesarean delivery may be considered in some cases rather than vaginal delivery to reduce the risk of vitreous hemorrhage. Close communication among the various members of the healthcare team is essential.

Patients with diabetic retinopathy, even in its mildest form, must be informed of the availability and benefits of early and timely laser photocoagulation therapy in reducing the risk of visual loss. The management program outlined in Table 54.8 is fundamental. Furthermore, patients with visual impairment of any degree, legal blindness, or total blindness should be informed of the availability of visual, vocational, and psychosocial rehabilitation programs.

CONCLUSIONS

In its earliest stages, diabetic retinopathy usually causes no symptoms. Visual acuity may be very good at the time of diagnosis of diabetic retinopathy, even when significant ocular disease is present. It is crucial at this stage for a patient's physician to initiate a careful program of education and medical and ocular follow-up.

54: OCULAR COMPLICATIONS OF DIABETES MELLITUS 921

As retinal disease progresses, visual acuity may become compromised by macular edema, episodes of vitreous hemorrhage, macular nonperfusion, or traction retinal detachment. The resulting loss of visual acuity can cause significant difficulties in the work or home environment. This loss often puts extreme psychologic stress on patients with diabetes and their families. The healthcare provider should identify some stresses, and appropriate support for the patients should be offered. In many cases, the patient will experience a significant drop in visual acuity for a period of time. Although in many cases excellent vision can ultimately be obtained and retained for many decades, the period during which the patient experiences this visual decline can lead to great uncertainty and anxiety.

It is of critical importance that the level of ocular disease be monitored carefully and appropriate observation, laser treatment, vitreoretinal surgery, or other intervention be applied promptly when indicated. If these approaches are followed, most patients can now retain excellent vision with many decades of stable ocular status once the diabetic retinopathy has become quiescent. New therapies on the horizon promise even better outcomes.

Thus, it is obvious that a very close interaction between the patient and a diverse healthcare team is essential. The healthcare team will commonly require services of both the ophthalmologist and internist, as well as the diabetologist, nurse practitioner, diabetes educator, dietician, psychosocial worker, and many other specialties, depending on the particular situation. With such access, careful lifelong and routine ophthalmic follow-up, optimization of glycemic and systemic medical control, and timely laser photocoagulation, the risk of blindness in persons with diabetes mellitus can essentially be eliminated.

POSSIBLE APPROACHES TO THE COMPLETE PREVENTION OR CURE OF DIABETIC NEPHROPATHY 946

SUMMARY OF RECOMMENDATIONS 946

The management of patients with diabetic nephropathy has become both increasingly complex and increasingly rewarding in the past 10 years. The elucidation of at least some of the underlying mechanisms has led to a number of therapeutic interventions that, when applied aggressively, will lead to a highly significant reduction in the number of patients who progress to end-stage renal disease (ESRD). Although these approaches have not led to either the complete prevention or cure of diabetic nephropathy, they have produced dramatic improvements in patients' quality of life and mortality rates and have decreased healthcare costs. Much research remains to be done, but the promise of even more effective therapeutic approaches is on the horizon. This chapter reviews the current approaches to treatment and briefly anticipates future therapies.

The seriousness of diabetic nephropathy is demonstrated by the following. First, patients with diabetic nephropathy have a reduced life span. Second, diabetic patients with nephropathy have more comorbid events (such as worse cardiac and peripheral vascular disease) than do diabetic patients without nephropathy, events that significantly affect the patient's lifestyle and ability to work. Third, diabetic nephropathy is now the major cause of ESRD in the United States and throughout most of the world (1). Fourth, the financial costs of caring for these patients are rapidly increasing, as treatment of ESRD (dialysis and transplantation) is paid for by national healthcare systems such as Medicare in the United States (2). Thus, for reasons of quality of life, morbidity and mortality, and financial costs, the prevention or slowing of the progression of diabetic nephropathy will significantly benefit both the patient and public heath.

In this chapter, we will review the current approaches to therapy. Although we cover all therapeutic interventions, our focus is primarily on hypertension and the use of medications that block the actions of angiotensin. The approach to hypertension and the use of angiotensin-blocking drugs has had a dramatic impact on the progression of both type 1 and type 2 diabetes. The use of these drugs in providing optimal treatment of diabetic nephropathy has increased in importance and complexity. Thus, a detailed analysis of these drugs follows.

DIAGNOSIS, SCREENING, AND NATURAL HISTORY

Diabetic kidney disease takes years to develop. It is rare to see diabetic nephropathy earlier than 3 years after the diagnosis of diabetes; it usually is seen after 5 to 15 years in patients with type 1 diabetes (2). For patients with type 1 diabetes, this time course is well understood because these patients present with very clear symptoms at diagnosis. The natural history of kidney disease in type 2 diabetes is less well understood, as patients can have relatively mild symptoms for quite some time before a diagnosis is made. It is likely, however, that in type 2 diabetes, as in type 1 diabetes, kidney disease develops only after a number of years of diabetes. From the physician's standpoint, the practical difference is that screening for kidney disease is not necessary before at least 3 years and usually not until 5 years after the diagnosis in patients with type 1 diabetes but should begin at the time of diagnosis in patients with type 2 diabetes because the duration of their disease is unknown.

The earliest known manifestation of diabetic kidney disease is the presence of small amounts of albumin in the urine, called microalbuminuria (3). Protein excretion in the urine normally does not exceed 100 to 200 mg per 24 hours. Much of this protein comes from the tubules, but a percentage is filtered through the glomeruli. Studies done 20 years ago showed that urinary excretion of albumin, which is normally excreted in amounts of less than 30 mg per 24 hours, increases even before total urinary protein levels increase (4). This very important insight allowed physicians to detect diabetic nephropathy much earlier than they had in the past, thus permitting earlier therapeutic interventions to prevent progression. Microalbuminuria is the presence in the urine of 30 to 300 mg of albumin per 24 hours. When albumin levels exceed 300 mg per 24 hours, this condition is called proteinuria or overt nephropathy. Microalbuminuria has been called "early diabetic nephropathy" or "incipient nephropathy," which to some suggests early, possibly insignificant, disease that does not require therapeutic intervention. It must be stressed, however, that microalbuminuria is the earliest marker we are aware of. Clearly, mechanistic changes over a number of years in the glomeruli of the kidney are now being expressed as the presence of albumin in the urine. An ideal situation would be to look at renal glomeruli during the course of diabetes to detect changes even before microalbuminuria is present (as ophthalmologists can detect early retinal pathology). Because this is not possible, we use as a marker a point at which the glomerular filter has been sufficiently damaged to permit the passage of albumin. The point is that microalbuminuria is kidney disease that needs to be treated and not simply monitored. It should be noted that not all patients with microalbuminuria progress to overt proteinuria and renal failure. Although a variety of attempts have been made to find markers (both genetic and physiologic) that can determine who will progress to overt proteinuria and kidney failure and who will not, there is not yet a standard that lets us ascertain this. Thus, at this time we strongly recommend treating all patients who have microalbuminuria as if they are going to progress to more severe kidney disease because preventing it from worsening has clear benefits and the treatments are all reasonably safe and prudent.

As previously noted, patients with type 1 diabetes should be screened 3 to 5 years after diagnosis, and patients with type 2 diabetes should be screened at the time of diagnosis. Patients should be tested yearly by examining the urine for albumin. At this time, we recommend using the albumin/creatinine ratio in a spot urine test, as this accurately reflects 24-hour total excretion in most circumstances. Although a 24-hour urine test for albumin can be done, it has a few drawbacks, including inconvenience for the patient and the possibility of an incomplete collection. The ratio has been shown to be quite accurate for both diagnosis and follow-up (3). The albumin/creatinine ratio is normally less than 30 µg of albumin per milligram of creatinine. A ratio of more than 30 µg of albumin per milligram of creatinine is abnormal. The current recommendation is to repeat the albumin measurement on two more occasions during a 3- to 6month period; if microalbuminuria persists, the patient has diabetic nephropathy (5). Some causes of transient increases in albuminuria include exercise, dietary intake, pregnancy, drugs, and other factors that can alter both protein delivery and glomerular hemodynamics. Although transient increases of up to 300 mg of albumin in 24 hours have been seen, levels of greater than 150 to 200 mg per 24 hours usually remain elevated

after one or two more measurements. Of note, dipsticks used in standard urinalysis for the determination of protein in urine are not sensitive enough to measure albumin excretion of greater than 300 μ g per milligram of creatinine and thus are not sufficiently sensitive to measure levels of microalbuminuria of 30 to 300 μ g per milligram of creatinine.

The diagnosis of diabetic nephropathy is usually quite evident in the appropriate clinical setting, but it is important to be aware of associations that support the diagnosis or suggest the possibility of another diagnosis for a patient with diabetes and renal disease. A diagnosis of diabetic kidney disease is supported by the following. First, a large majority of patients have albuminuria. It has been suggested that up to 100% of patients with diabetic nephropathy have albuminuria; however, this is clearly not the case. The absence of albuminuria should certainly prompt a search for an alternate diagnosis, but in the absence of clear signs to seek an alternate diagnosis, there is usually nothing else to consider. Second, the urinary sediment is characteristically unremarkable-i.e., there are usually no casts, no white blood cells, and no red blood cells-although red blood cells (2 to 15 per high-power field) may be seen in up to 30% of patients. Third, the majority of patients have retinopathy before the onset of diabetic kidney disease. Fourth, as previously noted, the duration of the disease is also important; it is relatively unusual to diagnose diabetic nephropathy before 5 years of diabetes. Deviations from any of the above associations should prompt a search for alternate diagnoses in a patient with diabetes and kidney disease. It is rarely, if ever, necessary to obtain a renal biopsy to make a diagnosis of diabetic nephropathy. Renal biopsy in a patient with diabetes is used principally when there is a question about whether the kidney disease is due to a disorder other than diabetes.

EPIDEMIOLOGY

Diabetic nephropathy occurs in 30% to 50% of patients with type 1 or type 2 diabetes (5). In the past, except in select ethnic populations, the incidence and prevalence of nephropathy have been lower in patients with type 2 diabetes than in those with in type 1 diabetes. In recent years, however, the incidence and prevalence of diabetic nephropathy have been steadily increasing, so that the percentage of patients with type 2 diabetes who have nephropathy is approaching that seen in patients with type 1 diabetes (6). ESRD due to hypertension and glomerulonephritis is relatively unchanged, but there has been an inexorable increase in the cases of ESRD due to diabetic nephropathy such that almost 50% of all cases of ESRD are caused by diabetes. The increasing incidence of diabetic nephropathy in patients with type 2 diabetes is in part the result of the greater success in decreasing mortality due to type 2 diabetes. Improved management of the cardiovascular complications of type 2 diabetes through better control of lipids and improved and more stringent blood pressure control has significantly increased life expectancy and has allowed time for other complications to develop. The increased prevalence of diabetic nephropathy is due in part to the current worldwide epidemic of diabetes.

Specific ethnic populations are at unusually high risk for developing diabetic nephropathy. Native Americans (e.g., the Pima Indians of the southwestern United States) (7) and African Americans have a high prevalence of diabetes and diabetic nephropathy (8,9). The reasons for the increased risk have not been clearly identified. It is likely that there is a very strong genetic basis for the observed susceptibility. But factors such as hypertension and diet also may play a role. In any event, a concerted effort to understand the specific susceptibility of these groups is of great importance to the prevention of the increased In general, the incidence of diabetic nephropathy follows a pattern of increase about 5 years after diagnosis, with the highest incidence 5 to 15 years after diagnosis of type 1 diabetes. There is a gradual decline in the incidence of diabetic nephropathy with increased duration of type 1 diabetes so that by 20 to 25 years after the diagnosis the incidence of diabetic nephropathy decreases. The natural history of diabetic nephropathy in type 2 diabetes is less well characterized because of the indefinite start of the disease.

WHO IS GOING TO PROGRESS FROM MICROALBUMINURIA TO MORE SEVERE RENAL DISEASE?

A major question surrounding therapy is who will progress from microalbuminuria to frank proteinuria (>300 mg/24 hours) and to ESRD. Because not all patients progress, perhaps not all of them need to be treated aggressively. Although this is an important question, the answer is not clear. A few studies have tried to determine markers for progression. A recent study by Caramori et al. (10) suggested that the rate of increase of albuminuria was predictive; i.e., a rapid rate was predictive of subsequent progression of disease. However, although the correlation is good, the albumin excretion rate was too variable to be used routinely for clinical decision making. Also, Thomas and colleagues (11) reviewed data from the Diabetes Complication and Control Trial (DCCT) to evaluate the relationship between an increase in blood pressure and progression to albuminuria. The retrospective analysis showed that an increase in albumin excretion routinely preceded an increase in blood pressure to a hypertensive range (140/90 mm Hg). They concluded that an increase in blood pressure was not a good marker for progression. Interestingly, this relationship was observed only in the conventionally treated group; in the intensively treated group, an increase in blood pressure preceded an increase in albuminuria. Thus, at this time there are no clear markers for progression, and even the intensity of treatment may affect markers. Considering the potential seriousness of worsening disease and the negative effect of increased albuminuria and frank proteinuria on cardiovascular and renal outcomes, we recommend very aggressive treatment of any patient with established microalbuminuria or frank proteinuria. The study by Thomas et al. (11) also illustrates the important point that the changing treatments for diabetes are possibly altering the phenotypic expression of diabetic nephropathy. For example, diabetic nephropathy (biopsy proven) with no albuminuria and no preceding retinopathy is now being diagnosed in more patients.

CREATININE CLEARANCE SHOULD BE ESTIMATED IN PATIENTS WITH KIDNEY DISEASE TO ACCURATELY ASSESS KIDNEY FUNCTION

An important consideration when evaluating patients with diabetic nephropathy is the relation between serum creatinine and the actual glomerular filtration rate (GFR). The creatinine clearance overestimates the actual GFR because a percentage of the creatinine is secreted into the tubule rather than filtered. Nevertheless, the creatinine clearance offers a highly useful approximation of GFR. A 24-hour urine test to determine creatinine clearance can be done, but a number of formulas use a combination of weight (as a marker of muscle mass), age, sex, and other factors to estimate creatinine clearance (12). An excellent and relatively simple formula is the Cockcroft-Gault calculation of the estimate of creatinine clearance.

Estimated CrCl = (140 - age)/(Serum Cr) $\times (\text{wt in kg}/72) \times 0.85 \text{ (if female)}$

This formula often provides surprises to non-nephrologists, as the creatinine clearance determined is considerably lower than expected (especially in older women). For example, the clearance for a 70-year-old woman with a serum creatinine of 1.5 mg/dL and a weight of 50 kg is

Estimated CrCl = $(140 - 70)/1.5 \times (50/72) \times 0.85 = 27.5$ mL/min

Determining the creatinine clearance is important for evaluating the severity of diabetic kidney disease and knowing with certainty that the patient is receiving proper dosages of drugs. For example, treatment with metformin is not recommended for patients with creatinine clearances of less than 50 mL per minute, and the dosages of many medications need to be adjusted for patients with impaired renal function.

As noted above, the creatinine clearance (measured either by 24-hour urine assessment or by a formula) is quite useful but overestimates the GFR. The overestimate may be greater for patients with diabetic kidney disease than for patients with nondiabetic kidney disease. The reason for this difference is unclear (although it may be due to a reduction in muscle mass and thus in the production of creatinine in patients with diabetes as compared with that in nondiabetic patients). In any event, it is important to be aware of the relationship between serum creatinine and GFR, as some patients with apparently "normal" serum creatinine values actually have significantly impaired renal function.

TREATMENTS

Control of Blood Glucose Levels

For many years, controversy existed over how stringent blood glucose control should be to prevent the development or progression of diabetic nephropathy. A number of studies have illustrated that intensive control of blood glucose levels is beneficial to kidney function. But the landmark DCCT study definitively demonstrated that tight control of the blood glucose significantly reduced the development of diabetic nephropathy and slowed progression of type 1 diabetes (13). In that study, 1,441 patients with type 1 diabetes were evaluated for a mean of 6.5 years and assigned either to a conventional therapy group [median hemoglobin A_{1c} (HbA_{1c}) of 9.1%] or to an intensive therapy group (median HbA_{1c} of 7.2%). Intensive therapy led to a decrease in the presentation of microalbuminuria (defined as >40 mg per 24 hours) by 39% and led to a decrease in progression to albuminuria (defined as >300 mg per 24 hours) by 54% (Fig. 55.1). This dramatic reduction in the development and progression of diabetic nephropathy was achieved by diet, use of an external insulin pump, and/or the injection of three or more daily insulin injections associated with frequent monitoring of blood glucose level. A recent publication studied the same group of patients 4 years after the DCCT study to determine whether benefits of the DCCT persisted after completion of the trial (14). At the end of the DCCT, the patients in the conventional therapy group were offered intensive therapy, and the care of all patients was transferred to their own physicians. Nephropathy was evaluated on the basis of urine specimens obtained from 1,302 patients, approximately half from each group, during the third or fourth year. The median HbA_{1c} values of the conventional therapy group (8.2%) and intensive therapy group (7.9%) were closer than in the original DCCT study. The authors reported that microalbuminuria was detected for the first time in 11% of 573 patients in the former

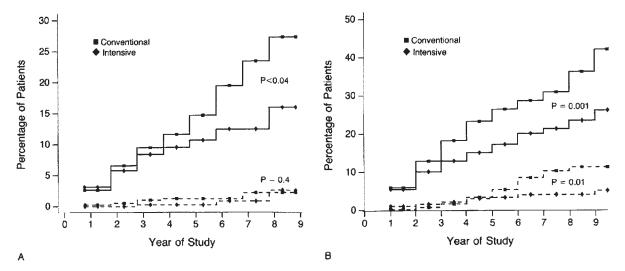

Figure 55.1. Changes in albuminuria in group receiving intensive treatment versus group receiving conventional treatment for primary prevention of albuminuria (**A**) and for secondary prevention of progression to overt albuminuria (**B**). (Reprinted from The Diabetes Control and Complications Trial Research Group. *N Engl J Med* 1993;329:977–986, with permission. Copyright © 1993 Massachusetts Medical Society. All rights reserved.)

conventional therapy group as compared with 5% of 601 patients in the former intensive therapy group, representing a 53% odds reduction. The risk of new albuminuria was reduced by 86% in the intensive therapy group. Although blood glucose control worsened in the intensive therapy group, the importance of intensive control was still evident. Two significant observations can be made about these studies: Control of blood glucose to levels as close to normal as possible (without causing repeated hypoglycemic events) is beneficial; worsening of blood glucose control over years of diabetes therapy is quite common. This worsening of blood glucose control likely reflects a combination of increasing ineffectiveness of insulin due to multiple factors (e.g., changing metabolic requirements, resistance to effects of injected insulin, difficulty in maintaining the strict intensive regimen, age of the patient, genetic factors, and other as yet unanticipated factors). Thus, target blood glucose and HbA1c levels should be aimed for but may not be achieved. The chief adverse events associated with intensive therapy were a twofold to threefold increase in episodes of severe hypoglycemia and weight gain. In any event, the data strongly support the aggressive pursuit of close-to-normal blood glucose levels through an intensive mixture of diet, exercise, and insulin therapy in order so slow the progression of renal disease.

For type 2 diabetes, control of the blood glucose is also critical. A number of studies have shown he benefit of tight control of blood glucose in patients with type 2 diabetes with diabetic nephropathy (15). The large, comprehensive UK Prospective Diabetes Study Group (UKPDS) trial is of great importance (16). Patients in the conventional therapy group had an average HbA_{1c} of 7.9%, whereas the average was 7.0% in the intensively treated group. In the intensively treated group, the reduction in risk for developing microalbuminuria was 11%, and the risk reduction for progression of microalbuminuria to proteinuria was 3.5%. Although these reductions are modest, the number of patients studied was large and the improvements were highly significant. The change in HbA1c was also relatively modest, and it is likely that greater reductions would have a greater protective effect on kidney function. The recommendation for blood glucose control in diabetic nephropathy in both type 1 and type 2 diabetes is to aim for HbA_{1c} values of less than 7%.

Considering the central importance of hyperglycemia to the development of diabetic complications, it would appear that intensive control of blood glucose alone should be adequate to protect against the development or progression of diabetic kidney disease, but that is clearly not the case. Blood glucose control is only part of the management profile; blood pressure control is of paramount importance. In patients with type 2 diabetes in the UKPDS, controlling blood pressure was more important than lowering glucose levels in protecting the kidney. The next sections discuss in depth the management of hypertension, an essential part of treating a patient with diabetic nephropathy.

Management of Hypertension

More than 11 million people in the United States have coexistent diabetes mellitus and hypertension; however, hypertension in patients with diabetes remains underrecognized and undertreated. Hypertension and the risk of nephropathy form a continuum (17), so that all diabetic persons with hypertension, and even those with high normal blood pressure, are in a high-risk category (18). In addition, hypertension and diabetes combined are devastating to the cardiovascular system.

Hypertension is particularly prevalent in diabetic patients with nephropathy. Hypertension is now considered an early abnormality, not a late complication, of nephropathy. In patients with type 1 diabetes, a rise in systemic pressure may precede or predict the presence of diabetic nephropathy. In patients with type 2 diabetes, hypertension is common even without nephropathy, so that many patients with microalbuminuria and most of those with proteinuria are hypertensive (19) or are receiving treatment for hypertension (Table 55.1).

Several factors contribute to hypertension in type 1 and type 2 diabetes (20) (Fig. 55.2). The role of genetic factors in the clinical management of the diabetic patient with nephropathy has not yet been adequately defined.

Of further clinical importance is the link between hypertension and cardiovascular disease. Although diabetes and hypertension are both independent risk factors for cardiovascular disease, more than doubling the risk of cardiovascular mortality,

TABLE 55.1. Prevalence of Arterial Hypertension in Patients with Diabetes Mellitus				
Type of diabetes	Stage	Number of patients	Prevalence of hypertension, ^a % (mean)	Prevalence of antihypertensive treatment, ^b %
1	Normoalbuminuria	562	42	8
	Microalbuminuria	215	52	12
	Proteinuria	180	79	48
2	Normoalbuminuria	323	71	30
	Microalbuminuria	151	90	39
	Proteinuria	75	93	65

^aHypertension is defined according to The Sixth Report of the Joint National Committee on Prevention, Detection, Evaluation, and Treatment of High Blood Pressure (JNC-VI) as blood pressure \geq 140/90 mm Hg. ^bRates of antihypertensive treatment are relatively low.

Modified from Deedwania PC. Hypertension and diabetes: new therapeutic options. *Arch Intern Med* 2000;160:1585–1594, with permission. Copyright 2000, American Medical Association.

the risk is even greater when nephropathy is present. Cardiovascular causes account for more than half of the mortality associated with nephropathy (21). The diabetic patient with hypertension is already burdened with a greater prevalence of cardiovascular risk factors, such as dyslipidemia, hyperuricemia, thrombotic tendency, and left ventricular hypertrophy. The additional cardiovascular risk attributed to nephropathy is not adequately understood. However, aggressive therapy provides the opportunity to reduce excessive deaths due to cardiovascular disease (19).

Effective antihypertensive therapy is generally regarded as the best inhibitor of diabetic nephropathy (22,23) almost regardless of the class of agent used (24,25). Convincing data now strongly support a role of hypertension in the progression of diabetic renal insufficiency, both for type 1 and for type 2 diabetes (26,27), as well as the benefit of early control of hypertension (Figs. 55.3 to 55.5). Although many studies of type 1 diabetic nephropathy have clearly demonstrated the benefit of controlling hypertension, the benefit in type 2 diabetes is not as clear. In a recent meta-analysis of 100 controlled and uncontrolled trials, about one third of the studies included only patients with type 2 diabetes. Overall, each 10 mm Hg decrease in mean arterial pressure was associated with an increase in GFR of about 4 mL per minute, which otherwise declined by 8 mL per minute (28). Angiotensin-converting enzyme (ACE) inhibitors were used in almost half of the groups. However, the

duration of the study was greater than 1 year in only 13% of the study groups.

Hypertension, which exacerbates all the vascular complications of diabetes, worsens albuminuria and accelerates the decline in GFR. Because the afferent arteriole fails to autoregulate normally in patients with diabetic nephropathy, any increase in mean systemic pressure can be transmitted to the glomeruli (29). Further increases in glomerular capillary pressure derive from the effect of the increase in efferent arteriolar resistance by angiotensin (30).

Important management decisions that clinicians now face concerning the hypertensive diabetic patient with nephropathy include the following three questions (31,32):

1. When should treatment be initiated following the JNC-VI (Sixth Report of the Joint National Committee on Prevention, Detection, Evaluation, and Treatment of High Blood Pressure) guidelines, in which hypertension is still defined as 140/90 mm Hg?

The blood pressure levels of diabetic patients need to be lower than those generally recommended to maximize the reduction in risk of renal disease. The JNC-VI recommended that all diabetic patients with blood pressure in excess of 130/85 mm Hg (mean arterial pressure, 100 mm Hg) be treated with both lifestyle modifications and drugs (Table 55.2). These guidelines were based on clinical trial results available in 1997 and have been supported by additional trials since the

guidelines were issued (33). Patients with hypertension and diabetes should be treated as if they already have target organ damage. Convincing studies conducted over more than two decades show that hypertension should be corrected at all levels of kidney function because aggressive control of hypertension is of key importance in slowing the loss of renal function. The effectiveness of blood pressure control appears to

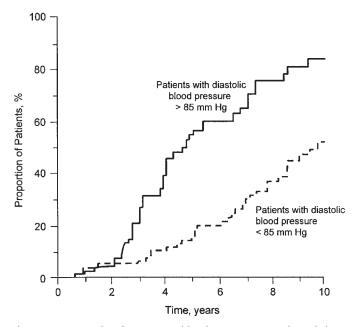

Figure 55.4. Benefit of aggressive blood pressure control in diabetic nephropathy. Renal endpoint (loss of 40% of glomerular filtration rate) was less likely when diastolic blood pressure was lower than 85 mm Hg. (Reprinted from Ismail N, Becker B, Strzelczyk P, et al. Renal disease and hypertension in non-insulin-dependent diabetes mellitus. *Kidney Int* 1999;55:1–28, with permission.) Data are from [32].

be related to the blood pressure achieved. A measurable decrease in proteinuria, a likely sign of renal protection, is also achievable by a reduction in systemic blood pressure.

2. What should the target blood pressure be?

Although the unique sensitivity of diabetic nephropathy to systemic pressure has gained acceptance, the target blood pressure is still a source of some confusion (34). The primary goal is to lower blood pressure to the desired target levels. Guidelines of the JNC-VI (The 1997 report) reduced the target blood pressure for patients with diabetes to 130/85 mm Hg, values below those for nondiabetic hypertensive patients. Furthermore, recent treatment recommendations by a working group of the National Kidney Foundation based on subsequent tests have urged a slightly lower target blood pressure, 130/80 mm Hg, to better preserve kidney function.

Adults with proteinuria of greater than 1 g per 24 hours should maintain pressure goals as low as 125/75 mm Hg in the absence of contraindications (35). Clinical trial data confirm that the mean arterial pressure should be lowered to at least 92 mm Hg (corresponding to a blood pressure of about 130/70 mm Hg) for optimal renal protection (36). The lower the pressure, as tolerated, the greater the potential for preservation of renal function. Data from the Modification of Diet in Renal Disease (MDRD) study (37), the Hypertension Optimal Treatment (HOT) trial (38), the UKPDS (39), and the Appropriate Blood Pressure Control in Diabetes (ABCD) trial (40) have demonstrated that reducing the target blood pressures can preserve renal function or reduce cardiovascular events. (However, no trials that target the lower values of 125/75 mm Hg have been completed.) Concern for increased cardiovascular risk at lower blood pressures (J-curve) has so far not been supported by evidence (41,42). In fact, although recommendations for target blood pressure have been based on the effect of lowering systemic pressure on renal function, it is now evident that reductions in blood pressure decrease associated cardiovascular morbidity and mortality (43). In the diabetic subgroup of the HOT study, for example, the groups with the lowest target blood pressure (diastolic ≤80 mm Hg) had the lowest rate of cardiovascular events (38). Tight control of blood pressure also reduced the overall rate of complications in the UKPDS study, in which tight blood pressure control (144/82 mm Hg) was associated with a 37% reduction in microvascular endpoints and a 44% reduction in the rate of stroke (39).

3. Which classes of drugs are preferable?

Successful blood pressure correction is more important than the specific treatment used. However, agents in specific classes of antihypertensive drugs have been investigated in clinical trials involving patients with type 1 and type 2 diabetes with various stages of diabetic nephropathy. Treatment with ACE inhibitors, calcium antagonists, and β-blockers may have similar effects on mean arterial pressure (29) (see following discussion), with no class having a greater antihypertensive effect than other classes (Fig. 55.6), and all are effective in reducing cardiovascular events (43). Most patients will require an "antihypertensive cocktail" that includes several drugs. Nonetheless, the quality of blood pressure control remains poor (44,45), and adequate control is seldom achieved, with only a minority of patients achieving the lower blood pressure goals for diabetic patients with nephropathy (46). Among the barriers that must be overcome to achieve target levels include cultural, emotional, and economic issues contributing to noncompliance by the patient (47); insufficient knowledge base and time limitations among physicians; and the inadequacy of blood pressure measurement outside the medical setting (48). Many hypertensive patients with persistent proteinuria should be referred to a nephrologist.

The subsequent sections will review ACE inhibitors and comparable therapies (49). Blood pressure reduction can be achieved by several classes of drugs. There are many special considerations in selecting antihypertensive therapy for the patient with diabetes (Table 55.3). Therapy with a diuretic, although no longer justified as monotherapy for the diabetic patient, is frequently required for the hypertensive diabetic with nephropathy. Loop diuretics are necessary for patients with impaired renal function. Potential side effects limit their benefit, including deleterious metabolic effects on lipids, glucose, and electrolytes. In addition to these unwanted

Change in Mean Arterial Pressure, mmHg

Figure 55.6. Meta-analysis of blood pressure–lowering effects of different antihypertensive agents in type 1 and type 2 diabetes. Blood pressure reductions with ACE inhibitors, calcium antagonists, and β -blockers were similar, as were reductions with different ACE inhibitors (not shown). (Reprinted from Kasiske BL, Kalil RS, Ma JZ, et al. Effect of antihypertensive therapy on the kidney in patients with diabetes: a meta-regression analysis. *Ann Intern Med* 1993;118:129–138, with permission.)

side effects, diuretics could also cause reactive stimulation of the renin-angiotensin system (RAS). Potassium-sparing diuretics are contraindicated in the presence of impaired renal function because of the risk of hyperkalemia. Adequate long-term data are not available on protection from diabetic complications such as nephropathy with other classes of antihypertensive drugs, such as α -blockers, central α -agonists, and β -blockers. Although their use in diabetic patients is discouraged, the effectiveness of β -blockers (50) is supported by the UKPDS study, in which atenolol was as effective as captopril in lowering blood pressure and protecting against microvascular complications (39). A recently suggested algorithm for reaching blood pressure goals in diabetic patients with renal insufficiency is shown if Figure 55.7.

Antihypertensive agents that both lower blood pressure and decrease proteinuria (see further on) include ACE inhibitors, angiotensin-receptor blockers, nondihydropyridine calcium–channel blockers, and β -blockers (51). High sodium intake reduces the antiproteinuric effect of both ACE inhibitors and calcium–channel blockers (33). Furthermore, ACE inhibitors,

Drug class	Special considerations
Diuretic	Edema common in diabetic nephropathy, thiazides not effective in renal insufficiency
Angiotensin-	Treatment of choice
converting enzyme (ACE) inhibitor	Reduce proteinuria and protect from progression
	Risk of hyperkalemia
	Risk of worsening renal function No adverse effects on glucose or lipid levels
	Avoid in renal failure
Angiotensin receptor blocker	Alternative to ACE inhibitor
Calcium-channel blocker	May use in combination with ACE inhibitor
	Variable effects on diabetic nephropathy
β-Blocker	No long-term data on diabetic nephropathy
	Increased risk of hypoglycemia
	May mask warning signs of hypoglycemia
	Use if history of myocardial infarction or tachycardia
α-Blockers	Never shown to reduce disease progression
	Neutral effect on proteinuria
	Orthostatic hypotension
	Neutral on lipids and glucose intolerance
	Recent concern about congestive heart failure

TABLE 55.3. Special Considerations in Selecting Antihypertensive Therapy for the Diabetic Patient with Nephropathy

angiotensin-receptor blockers, and nondihydropyridine calciumchannel blockers attenuate both the abnormal permeability of the glomerular basement membrane and the morphologic damage associated with diabetic nephropathy. ACE inhibitors attack a fundamental abnormality in the hypertensive diabetic—capillary vasoconstriction—and pro-vide nearly uniform renal protective effects that surpass those of blood pressure control along (51,53). ACE inhibitors should be titrated to moderate or high doses as tolerated.

Many diabetic patients will tolerate angiotensin-receptor blockers better than they do ACE inhibitors. Several studies, primarily in patients without diabetes, have indicated that the renal protective effects of angiotensin-receptor blockers are similar to those of ACE inhibitors in reducing proteinuria. At present, comparative studies with ACE inhibitors are incomplete.

The ability of conventional antihypertensive agents to lower proteinuria is intermediate between that of ACE inhibitors and no therapy (Fig. 55.8), and conventional agents may have no effect on proteinuria independent of that due to blood pressure reduction. Renal protection provided by calcium-channel blockers is less uniform (see further on); first-generation dihydropyridine calcium-channel blockers, for example, may increase renal progression despite blood pressure control, and their use is more controversial because of safety concerns (40,54). The selection of additional agents will depend on the presence of extracellular volume expansion, in which case diuretics should be added, and on secondary issues such as metabolic profiles, drug safety, and comorbid conditions (43). ACE inhibitors (55), nondihydropyridine calcium-channel blockers (56), and probably

angiotensin-receptor blockers do not adversely affect glucose or lipid metabolism, which might worsen microvascular and macrovascular complications. Combination therapy will generally be required and can be more effective than monotherapy (57). The lower blood pressure goals recommended by JNC-VI not only may be effective in slowing renal progression and cardiovascular events but also may be costeffective in the long run (46).

Angiotensin-Converting Enzyme Inhibitors

The optimal drug management of diabetic nephropathy is still evolving (58–60). ACE inhibitors have, in recent years, gained widespread acceptance as first-line therapy to improve the prognosis for hypertensive diabetic patients with early or advanced nephropathy (5,61,62). Several lines of evidence, including animal models and human clinical trials, have led to the conclusion that ACE inhibitors, a class that includes more than 20 comparable compounds, provide selective protection in diabetic nephropathy independent of their ability to lower systemic blood pressure. Furthermore, the benefit of ACE inhibitors in patients with diabetes appears to exceed that in patients without diabetes. In contrast, other antihypertensive agents have little or no effect after beneficial influences on blood pressure are accounted for (28,63).

Nonetheless, several unresolved issues remain. The more definitive ACE inhibitor trials have generally been placebo controlled rather than comparisons with other available agents, although additional drugs frequently were necessary for blood pressure control. Not all patients will benefit equally from therapy with an ACE inhibitor (64,65), and questions about the accuracy of the assumption that all ACE inhibitors are equivalent remain unanswered (66,67). Critical review suggests that these agents may merely postpone ESRD rather than prevent it indefinitely. As a result, multiple interventions are likely to be necessary, particularly with current low blood pressure targets, and an individualized approach is necessary for maximum benefit to slow long-term progression. Furthermore, although three large trials in patients without progressive renal disease [ABCD (40), Captopril Prevention Project (CAPPP) (68), and Fosinopril versus Amlodipine Cardiovascular Events Randomized Trial (FACET) (54)] suggest a special advantage of ACE inhibitors for cardiovascular events, the most common determinants in diabetic patients with nephropathy (68), the overall long-term efficacy and safety profiles of ACE inhibitors in diabetic patients with nephropathy have not been determined.

Studies continue to elaborate on the complex role of angiotensin in diabetic glomerulosclerosis. As the key player in the pathophysiology of diabetic nephropathy, angiotensin II (ATII) has important hemodynamic and nonhemodynamic actions (70). The direct effects of ATII on increasing systemic vascular resistance and vascular tone have a unique role when applied to renal hemodynamics, in which vasoconstriction of the outgoing efferent glomerular arteriole causes increased glomerular capillary pressure. Brenner (71) proposed that the resulting glomerular hypertension is the basis for renal damage and glomerular proteinuria in diabetic nephropathy. Angiotensin also has direct structural and functional effects independent of those on renal hemodynamics. Exposure of proximal tubular, mesangial, and smooth muscle cells to ATII stimulates matrix molecular synthesis and cell hypertrophy, predominantly in response to increased production of transforming growth factor- β (TGF- β) by ATII itself. Angiotensin also stimulates filtration of proteins across the glomerular capillary wall. Metabolically, angiotensin may help reduce blood glucose levels by serving as an insulinsensitizing vasoactive hormone (72).

These effects occur despite the apparent suppression of the circulating RAS in diabetes. However, the kidney may be exposed to excessive intrarenal actions by ATII through compartmental localization of the intrarenal RAS (73). Significant angiotensin may also be generated by pathways alternative to the ACE pathway; in patients with diabetes, more than one third of ATII formation may occur through these alternative routes.

These complex effects suggest that the actions of ACE inhibitors, the most important clinical innovation for slowing

the progression of diabetic nephropathy, are complicated (Table 55.4). The benefits, clarified in experimental and animal studies, are due not only to control of blood pressure but also to renal hemodynamic and cellular effects. ACE inhibitors are known to decrease levels of ATII and inhibit actions mediated by the ATII receptor. ACE inhibitors block circulating and tissue levels of ATIIs. Systemically, ACE inhibitors decrease vascular resistance by antagonizing ATII-mediated vasoconstriction, potentiating the vasodepressor kinin system, and inhibiting effects of the sympathetic nervous system. Although the renal effects of ACE inhibitors may not be completely understood (74), ACE inhibitors, more than other antihypertensive drugs, complement their systemic hypotensive action by lowering the high intraglomerular pressure that is fundamental to diabetic nephropathy. ACE inhibitors also inhibit the effects of ATII on renal cells independent of hemodynamics. They retard glomerular basement membrane thickening (75) and tubular interstitial injury (76) in diabetic rats without hypertension, modulate intrinsic properties of the glomerular basement membrane (68) such as functional clearance of neutral dextran molecules, and ameliorate glomerular size-selective dysfunction. Nonhemodynamic benefits also include the blocking of the growth factor properties of ATII (77) and morphologic protection (78) through reduced matrix protein synthesis, decreased formation of matrix collagen, and decreased glomerular cytokine release (TGF-β, platelet-derived growth factor, and endothelin). Recent laboratory data indicate that activation of TGF-β may mediate some of the hypertrophic and proliferative effects of ATII on the diabetic kidney (79). Data also suggest that reduction in the production of TGF-β by ACE inhibitors may mediate some of these beneficial effects (80). In animal models of nephropathy, ACE inhibitors reduce glomerular production of TGF- β coincident with slowing the progression of renal disease. In patients with type 1 diabetes, ACE inhibitors-related reduction in serum levels of TGF-β correlate with long-term renal protection (79). Of particular importance for diabetic patients, ACE inhibitors may improve insulin sensitivity.

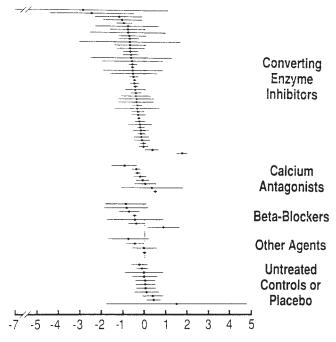

Experimental studies in animal models preceded important clinical trials in patients with type 1 and type 2 diabetes (82). Early studies by Zatz et al. (83) clearly established a beneficial effect of ACE inhibitors in experimental diabetes. Other data have shown that ACE inhibitors decrease the detrimental

effects of ATII in the kidney (84) and ameliorate functional and structural changes that produce clinical renal failure.

Human interventional trials, the largest of which have used the ACE inhibitors captopril and enalapril, are best classified by the type of diabetes and stage of nephropathy. Long-term trials have recently increased the emphasis on the significance of reductions in proteinuria as a surrogate renal outcome, which may correlate with conventional outcome measures such as creatinine clearance or GFR. Proteinuria is now considered to be an independent risk factor for progression of renal disease. Although it has yet to be proven that a reduction in proteinuria indicates a better a long-term prognosis in diabetic nephropathy, proteinuria is increasingly accepted as a promoter of progressive loss of renal function by directly damaging the kidneys (85) through tubular cell injury and interstitial damage. Proteinuria increases over time in untreated patients. Higher levels of proteinuria correlate with decreased GFR in diabetic patients (86).

Serving as a sign of earlier renal disease, microalbuminuria predicts the development of persistent proteinuria and a later decline in renal function. Data suggest that microalbuminuria may progress to proteinuria in about half of patients (4), especially if microalbuminuria develops within the first 10 years of diabetes (87). Studies suggest that reduction in proteinuria is an indicator of therapeutic response. Infrequently, nonproteinuric renal disease occurs in diabetes, usually with a nonglomerular microvascular pathology.

Agents to reduce proteinuria are now essential components in the treatment of chronic renal failure (88,89) (Fig. 55.9). Reductions in microalbuminuria or proteinuria are consistent effects of therapy with ACE inhibitors. Compared with conventional

Change in Proteinuria [In (treatment/baseline)]

Conventional

Ca-Antagonist

diuretic therapy with or without a β -blocker, ACE inhibitors produce the greatest reduction in urinary protein excretion, independent of mean arterial pressure reduction (Fig. 55.10). Proteinuria is reduced even before systemic pressure is lowered significantly, and patients with the most severe proteinuria appear to benefit the most from ACE inhibitor therapy. The attributes of ACE inhibitors that reduce urinary protein losses include reductions in systemic pressure, in filtration of proteins across the glomerular capillary wall (90), and in glomerular membrane permeability (74). The renal protective effect appears to be present for all agents in the ACE inhibitor class. A recent meta-analysis found no significant difference among ACE inhibitors in the reduction of proteinuria (28). Potential clinical differences might derive from decreased compliance in patients receiving short-acting agents or differences in tissue penetration among ACE inhibitors.

DIABETIC NEPHROPATHY IN PATIENTS WITH TYPE 1 DIABETES

Patients without Microalbuminuria. Treating patients with type 1 diabetes who have normal urinary albumin excretion and normal systemic pressure with ACE inhibitors for primary prevention is premature. Only about one third of patients with type 1 diabetes will develop nephropathy, and those at risk are difficult to identify. Although available studies were not adequately designed or powered to answer this question, stratified analysis in a large trial by the EUCLID (EURODIAB Controlled Trial of Lisinopril in Insulin Dependent Diabetes) Study Group suggested that those whose albumin excretion rate is within the higher range of normal, who are at risk for progression to microalbuminuria, might benefit from early initiation of therapy (91). A small difference in blood pressure in the ACE inhibitor group, also seen in many other trials, could have accounted for some of the reduction in albuminuria.

Patients with Microalbuminuria. Because the risk of progression of microalbuminuria (incipient nephropathy) to overt nephropathy is significant, several organizations, including the American Diabetes Association, now recommend ACE inhibitor therapy for all patients with type 1 diabetes with microalbuminuria, even if their blood pressure is not elevated above normal (92–94). This is especially true when the patient's microalbuminuria is worsening despite having achieved strict glycemic control.

Patients with type 1 diabetes are almost always normotensive if their urinary albumin excretion is normal. Blood pressure usually begins to rise subtly within the normal range after the onset of microalbuminuria. The incidence of overt hypertension is approximately 20% among all patients with type 1 diabetes with microalbuminuria (increasing as the patient progresses to overt nephropathy). A minority will be expected to develop hypertension each year. Increases in microalbuminuria are closely related to increases in blood pressure (35). Along with glycemic control, several studies have shown reversal of microalbuminuria with early antihypertensive treatment (95). Glycemic control and hypertension are the dominant clinical factors predicting the risk of progression of microalbuminuria. The natural course of albumin excretion is to increase by 10% to 30% each year. Response to therapy would be evident by stabilization or even reduction in microalbuminuria rates.

A number of studies support the recommendation to use ACE inhibitors in normotensive patients with microalbuminuria to attenuate expected increases in albuminuria over 1 (96), 2 (97, 98), or 4 years (99). Although ACE inhibitors are effective in reducing microalbuminuria levels in normotensive patients with type 1 diabetes (25), the guidelines have been based largely on studies comparing ACE inhibitors with placebo and with alternative antihypertensive therapy. The one available study, by Crepaldi et al. (100), did not resolve the question of whether ACE inhibitors have specific renal protective effect in microalbuminuria. Reduction of risk of progression tends to occur during the first year or so of therapy. Because renal function does not clearly decline when microalbuminuria is stable, no benefits with regard to long-term functional loss have been reported. In a recent report of normotensive patients with microalbuminuria, only those progressing to overt proteinuria showed a decline in GFR after several years, but functional benefit was not specific to treatment with an ACE inhibitor (101).

Additional analysis suggests limitations in studies of ACE inhibitor therapy. In the microalbuminuria subgroup of patients in the EUCLID Study, lisinopril lowered urinary albumin excretion by 49% over 2 years. Blood pressure was significantly lower in the treated group, and the reduction in albuminuria in the treatment group did not reach statistical significance in subgroup analysis. In studies by the North American Microalbuminuria Study Group (98), captopril prevented an increase in albuminuria and produced a small but significant decrease in blood pressure relative to changes with placebo. In the European Microalbuminuria Study Group, both lisinopril and nifedipine caused a 53% reduction in risk of progression from microalbuminuria to clinical proteinuria that persisted after statistical adjustment was made for blood pressure differences (100). It is essential that study groups have similar blood pressure levels because of the influence of systemic pressure on both proteinuria and preservation of renal function.

In hypertensive patients with microalbuminuria, the therapeutic advantage of an ACE inhibitor probably diminishes as hypertension is corrected (102). Interventional trials show the same effect of ACE inhibitors and placebo at lower mean arterial pressures. Several large clinical trials have documented that patients with microalbuminuria and hypertension respond to antihypertensive therapy with a reduction in risk of progression to overt nephropathy (see above section).

A meta-analysis has strengthened the case for the use of ACE inhibitors in patients with microalbuminuria (49). Nine trials (seven in patients with type 1 diabetes) were identified that evaluated (Fig. 55.11) the progression to proteinuria from microalbuminuria in patients with diabetic nephropathy with at least 1 year of follow-up. In about half of the studies, patients were hypertensive at baseline. For individuals treated with an

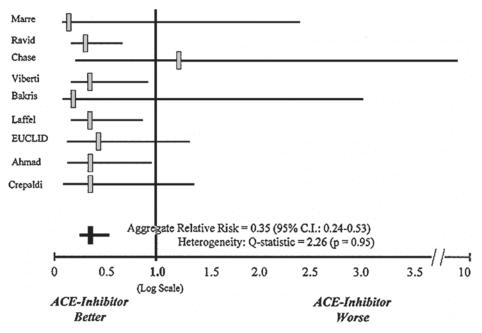

Figure 55.11. Meta-analysis of angiotensinconverting enzyme (ACE) inhibitors in seven trials in patients with type 1 diabetes with renal disease. (The studies of patients with type 2 diabetes reported in the meta-analysis are omitted.) Only one study failed to show a reduction in risk to progression to microalbuminuria with ACE inhibitor compared with placebo. EUCLID, EURODIAB Controlled Trial of Lisinopril in Insulin Dependent Diabetes. (Modified from Kshirsagar AV, Joy MS, Hogan SL, et al. Effect of ACE inhibitors in diabetic and nondiabetic chronic renal disease: a systematic overview of randomized placebo-controlled trials. *Am J Kidney Dis* 2000;35:695–707, with permission.) ACE inhibitor (captopril, enalapril, or lisinopril), the relative risk of progression from microalbuminuria to proteinuria was 0.35 compared with those treated with placebo. However, in eight of nine trials reviewed, mean arterial pressures were slightly lower in the group treated with an ACE inhibitor at the end of therapy.

In response to ACE inhibitor therapy, urinary albumin excretion typically falls during the first 3 months and then remains constant. Doses of ACE inhibitors should be increased if albumin excretion rates remain elevated but only if the systemic blood pressure is not low and hyperkalemia or worsening renal function tests do not necessitate a dosage reduction or cessation of therapy.

Cigarette smoking has also been associated with the development and progression of microalbuminuria (95), and patients should be encouraged to discontinue smoking.

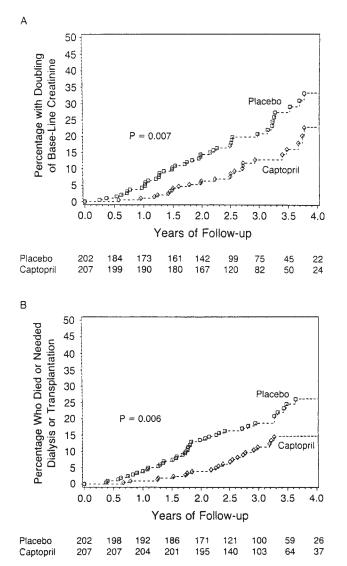

Figure 55.12. Effect of angiotensin-converting enzyme inhibitor (captopril, 25 mg t.i.d.) on retarding loss of renal function in type 1 diabetic nephropathy. Cumulative incidence curves for primary endpoint **(A)** and secondary endpoint **(B)** are shown according to baseline serum creatinine level. *P* values are captopril versus placebo. (Reprinted from Lewis EJ, Hunsicker LG, Bain RP, et al. The effect of angiotensin-converting-enzyme inhibition on diabetic nephropathy. *N Engl J Med* 1993;329:1456–1462, with permission. Copyright © 1993 Massachusetts Medical Society. All rights reserved.)

Patients with Overt Nephropathy. The Collaborative Study Group trial, published by Lewis et al. in 1999 (36), was the definitive randomized trial of ACE inhibitors in adult patients with type 1 diabetes with overt nephropathy. In this frequently cited study, 409 patients with proteinuria and mild renal dysfunction were randomized to captopril or placebo. Treatment with captopril was associated with a 40% reduction in risk of progression in renal dysfunction (i.e., doubling of serum creatinine) and a 50% reduction in the defined endpoints of kidney dialysis, transplantation, or death (Fig. 55.12). Slowing of the rate of loss of kidney function was achieved during roughly the first year of exposure, with little apparent benefit thereafter. Previously hypertensive patients did not attain lower blood pressures with captopril during the trial, whereas the average blood pressures of the one fourth who were normotensive at entry were 5 mm Hg lower with ACE inhibitor therapy. The median reduction in the proteinuria was ~3 g per 24 hours. Hyperkalemia was not significant in the group receiving an ACE inhibitor. The group who entered the trial with near-normal renal function (serum creatinine <1.5 mg/dL) did show a significant benefit from therapy with an ACE inhibitor. A separate cost-benefit model of the trial results indicated that captopril would result in an absolute cost savings of \$32,550 per patient with type 1 diabetic nephropathy over the course of a lifetime (103).

As noted above, results indicating an advantage of ACE inhibitor therapy in general have been partly confounded by the lower blood pressure results compared with placebo groups. In addition, data on enhancement of life expectancy have been limited (68). One recent small prospective trial, however, showed a cumulative death rate of 11% 10 years after onset of nephropathy in patients receiving ACE inhibitors, compared with an expected mortality of 50% to 75% from historical data (86).

DIABETIC NEPHROPATHY IN PATIENTS WITH TYPE 2 DIABETES

For several reasons, the optimal therapy for patients with type 2 diabetes with nephropathy, including the use of ACE inhibitors, is less clear than that for patients with type 1 diabetes with nephropathy. In patients with type 2 diabetes, the course of renal dysfunction is more heterogeneous (104), and the natural progression less well characterized than in patients with type 1 diabetic nephropathy. The transition from normal albumin excretion to microalbuminuria is less certain in patients with type 2 diabetes, although levels similar to those in patients with type 1 diabetes are considered clinically significant. Progression from microalbuminuria to overt nephropathy and ESRD in type 2 diabetic nephropathy is more variable compared with the uniformly high proportion of progression in type 1 diabetic nephropathy.

Proteinuria, especially at low levels, may be a less specific finding in type 2 diabetic nephropathy. Nonetheless, recent recognition of the importance of microalbuminuria in type 2 diabetic nephropathy has emerged. Several consensus groups have recommended screening for microalbuminuria in patients with type 2 diabetes as a preventive strategy (94). Although microalbuminuria is not as predictive of progression to overt nephropathy in type 2 diabetes as in type 1 diabetes, it has additional benefits as an independent marker of atherosclerotic disease and premature death in patients with type 2 diabetes (105). Microalbuminuria is frequently associated with mild elevations in cholesterol and triglycerides, recognized risk factors for cardiovascular disease. In addition, the development of microalbuminuria may be linked to systemic abnormalities in glucose and lipid metabolism, hemostasis, and coagulation.

In addition, the relationship between renal structure and function is less secure in type 2 than type 1 diabetic nephropathy. Recent data suggest that the majority of patients with type 2 diabetes with microalbuminuria have nonspecific changes in biopsy specimens or even normal-appearing glomeruli (106). Only subsets of patients with microalbuminuria or proteinuria have structural damage limited to diabetic nephropathy. Glomerular histology is often atypical for diabetic nephropathy, with more advanced arterial and/or tubulointerstitial lesions.

The benefits of ACE inhibitors are less well substantiated than in type 1 diabetic nephropathy, and the level of renal protection appears to be lower in type 2 diabetic nephropathy (107). One effect of ACE inhibitor therapy in type 1 diabetic nephropathy, the improvement in glomerular size-selective dysfunction, is not reproduced in type 2 diabetic nephropathy, even when pure diabetic-type glomerular lesions are present (108). Nonetheless, ACE inhibitors are considered desirable in several stages of nephropathy.

Patients without Microalbuminuria. Observational data suggest that patients with type 2 diabetes without albuminuria who are treated with an ACE inhibitor are less likely to progress to microalbuminuria than are those treated with conventional therapy. Data on the advantage of ACE inhibitors in slowing the development (as opposed to progression) of microalbuminuria in type 2 diabetes are limited. Ravid et al. (109) evaluated patients without either hypertension or microalbuminuria in a prolonged trial published in 1998. One hundred fifty-six patients with type 2 diabetes with normal blood pressure and mean urine albumin losses of only 12 mg per day received either enalapril 10 mg daily or a placebo over 6 years. Enalapril limited the increase in microalbuminuria to 12 to 16 mg per day as compared with an increase of 11 to 27 mg per day in the placebo group. Three times as many (19%) in the placebo group crossed the threshold to microalbuminuria. The fall-off in renal function was small in the placebo group (14 mL per minute in >6 years), but even less (9 mL per minute) in the ACE inhibitor group. After 6 years, renal function was better preserved and proteinuria was lower in patients treated with the ACE inhibitor than in those treated with placebo, although the absolute reduction in risk of microalbuminuria was a modest 12.5%. This low-risk population did not provide data on risk reduction for progression to overt nephropathy.

A recent computerized model of medical decision analysis indicated that routine ACE inhibitor therapy in all Pima Indians with type 2 diabetes, who have an extremely high rate of ESRD, would provide more cost-savings than would screening for microalbuminuria (110). The simple strategy of treating all patients with type 2 diabetes with an ACE inhibitor, based on a model of patients who are 50 years of age with diagnosed type 2 diabetes and a prevalence of microalbuminuria of 11% and proteinuria of 3%, provided increased quality-adjusted life expectancy at a modest cost (111).

Patients with Microalbuminuria. Early ACE inhibitor therapy at the onset of microalbuminuria has been recommended, even in patients with type 2 diabetes. Prospective controlled trials indicate that, as in patients with type 1 diabetes, progression to overt proteinuria is reduced. However, this is an even smaller subset in patients with type 2 diabetes, because most are hypertensive. In an extended placebo-controlled trial versus enalapril 10 mg daily, a steady, gradual increase in levels of microalbuminuria occurred over 5 years in the placebo group, for an overall increase of 2.5-fold and a 13% increase in plasma creatinine levels (112). In contrast, levels of microalbuminuria in the group treated with enalapril remained stable, as did renal function (Fig. 55.13). In the enalapril group, the risk of progression to overt proteinuria was reduced to one-third that in the placebo group (12% versus 42%). Mean blood pressure remained normal. When 2 years of unblinded follow-up were included, ACE

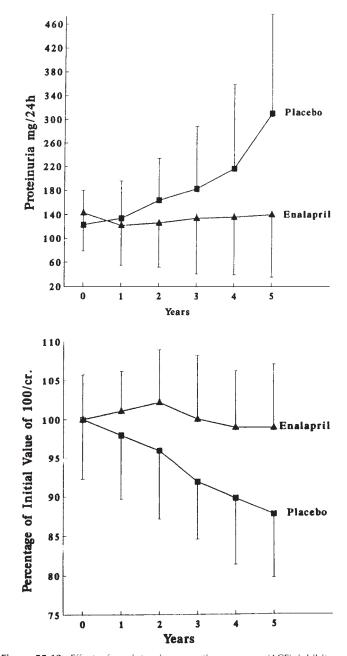

Figure 55.13. Effect of angiotensin-converting enzyme (ACE) inhibitor (enalapril, 10 mg daily) on stabilizing proteinuria **(top)** and renal function **(bottom)** in a 5-year period in normotensive patients with type 2 diabetes with microalbuminuria. The risk of progression to overt proteinuria was also reduced. Kidney function declined by 13% in the placebo group and remained stable in the ACE inhibitor group. (Reprinted from Ravid M, Savin H, Jutrin I, et al. Long-term stabilizing effect of angiotensin-converting enzyme inhibition on plasma creatinine and on proteinuria in normotensive type II diabetic patients. *Ann Intern Med* 1993;118:577–581, with permission.)

inhibitor therapy resulted in an absolute risk reduction of 42%. On the basis of these data, ACE inhibitors are preferred therapy in microalbuminuric patients with type 2 diabetes even in the absence of hypertension.

The benefits of early intervention have also been shown in hypertensive patients with type 2 diabetes with subclinical proteinuria. During two and a half years of maintenance enalapril therapy, patients with an initial baseline urinary albumin excretion rate of less than 300 mg per 24 hours demonstrated better preservation of renal function than did those receiving an antihypertensive regimen that excluded an ACE inhibitor, although, as in several other clinical trials, the mean systemic blood pressure was lower in the enalapril group (110). Another prospective trial of hypertensive type 2 patients included a subset with overt albuminuria. In patients with microalbuminuria, the rate of deterioration in renal function was better stabilized in those treated with enalapril than in those treated with nifedipine (114).

Patients with Overt Nephropathy. No adequate prospective controlled study has documented a benefit from therapy with an ACE inhibitor using accepted renal endpoints in patients with type 2 diabetes with overt nephropathy (proteinuria >300 mg per 24 hours). One small study compared lisinopril and atenolol in patients with type 2 diabetes with overt nephropathy and hypertension. The study, which was double blinded for only 12 months, showed that the loss of glomerular rate was slowed by about half in both groups after the first 6 months, while the ACE inhibitor produced greater reductions in proteinuria (115). Although a meta-analysis of several independent clinical trials [ABCD (40), CAPPP (68), and FACET (54)] has shown significant cardiovascular benefits of ACE inhibitor therapy in hypertensive patients with type 2 diabetes, no trial in patients with nephropathy has provided adequate information.

RISKS

Although as a class ACE inhibitors have a relatively safe adverse event profile, concerns about safety and tolerability may account for the use of relatively low doses in clinical practice. Cough and angioedema are not primarily dose related. The most common adverse outcomes are hyperkalemia and increased azotemia.

Hyperkalemia, a well-recognized complication of ACE inhibitor therapy (116), results when levels of serum aldosterone decrease and potassium clearance by the kidney is diminished. Previous studies indicate that ACE inhibitors in general raise serum potassium levels by about 15% (117). Patients with impaired renal function are at particular risk because the adaptive increase in potassium excretion by surviving nephrons is mediated in part by increased adrenal production of aldosterone. Aldosterone levels are acutely suppressed by ACE inhibitors, but the reduction in serum aldosterone levels with an ACE inhibitor throughout the course of therapy is variable. Differences in pharmacokinetic properties of ACE inhibitors may account for this variability.

The most common cause of renal deterioration in patients receiving an ACE inhibitor is relative hypotension, which results in impaired renal perfusion. The effect is compounded in diabetic patients with renal impairment because the function of the nephrons is not maximized when perfusion pressure falls. In the presence of advanced renal insufficiency, aggressive blood pressure control may lead to a critical increase in serum creatinine levels (118). The decline in renal function is more slowly reversible when ACE inhibitor therapy is halted. Severe deterioration may occur in the added presence of volume depletion or the use of nonsteroidal antiinflammatory drugs. More severe deterioration in renal function, i.e., a greater than 50% increase in serum creatinine level, also occurs when renal perfusion is already further stressed in patients with underlying chronic renal failure or renal artery stenosis.

Angiotensin-Receptor Blockers

The angiotensin-receptor (AR) blockers are currently being evaluated as alternatives to ACE inhibitors for managing diabetic nephropathy (119). Although AR blockers may be broadly similar to ACE inhibitors, there are significant clinical differences (Table 55.4). Clinical trials have demonstrated the efficacy of AR blockers in reducing blood pressure (120), with a potency equal to that of ACE inhibitors, calcium-channel blockers, and β -blockers (121).

It is reasonable to expect that these agents might reproduce the beneficial renal effects of ACE inhibitors (74) and broaden the therapeutic options for the physician. In fact, by blocking ATII activity at the ATI receptor site responsible for all the known clinical actions of ATII (122), AR blockers could more effectively block the RAS, because more than one third of ATII formation is generated by pathways alternative to the ACE pathway. Although ACE inhibitors also result in accumulation of bradykinin by inactivating a kinin-degrading enzyme, data suggest that kinins do not contribute to renal protection in a diabetic model. AR blockers may antagonize the effects of ATII generated by any pathway, while having no effect on bradykinin metabolism.

Although no long-term comparative trials with ACE inhibitors have been completed, AR blockers are known to be similar to ACE inhibitors in their effects on renal hemodynamics and proteinuria. Data suggest that AR blockers may produce greater renal vasodilatation than ACE inhibitors, suggesting more complete inhibition of angiotensin. Whether this is a class effect is unknown. AR blockers are known to diminish glomerulosclerosis in diabetic rats (123), blocking the development of albuminuria and hypertension (124) and protecting against glomerular histologic injury (125,126). AR blockers, similar to ACE inhibitors, also affect glomerular permeability. Several small studies have shown that AR blockers reduce proteinuria unrelated to diabetes as effectively as do ACE inhibitors and have similar effects on glomerular size-selective functions that are mediated by ATII. AR blockers do not appear to duplicate the acute hemodynamic benefit of ACE inhibitors in diabetic hyperfiltration. However, a crossover trial comparing AR blockers with ACE inhibitors in patients with type 1 diabetes with overt nephropathy and hypertension that was published in 2000 revealed similar reductions in proteinuria and systemic blood pressure (125). Renal function, with an average baseline GFR of 90 mL per minute, remained stable with both treatments. The ACE inhibitor group showed a slight increase in serum potassium, although still within the normal range.

In short-term trials in humans, AR blockers appear to have beneficial renal effects in type 2 diabetic nephropathy. A 12-week pilot study of 47 hypertensive patients with type 2 diabetes with nephropathy who were treated with irbesartan indicated a mild increase in creatinine clearance and a reduction in proteinuria as compared with the group treated with the calciumchannel blocker amlodipine (126). A second small and shortduration trial demonstrated a reduction by about half in levels of microalbuminuria. A longer-term clinical study in early type 2 diabetic nephropathy (most with microalbuminuria) compared the effects of the ATI receptor antagonist losartan with those of the ACE inhibitor enalapril. During 52 weeks of active treatment, both were effective in reducing clinical and ambulatory blood pressure, although the former fell short of currently recommended target blood pressures. Both treatments reduced urinary albumin excretion significantly-by about one half. Renal function declined by about 10% in each group. Fourteen percent of the enalapril group, but none of the losartan group, developed a cough (127). These results have formed the basis of three large placebo controlled clinical trials, the ABCD-V2 trial, the Irbesartan Diabetic Nephropathy Trial, and the Losartan Renal Protection Study (58).

The appropriate blood pressure control in diabetes, the second part of the ABCD trial (ABCD-V2), is a continuation of the completed ABCD trial and uses valsartan as the initial antihy-

pertensive treatment. The Irbesartan Diabetic Nephropathy Trial (IDNT) compared irbesartan, amlodipine, and a placebo in hypertensive patients with type 2 diabetes with nephropathy (128). The Losartan Renal Protection Study (RENAAL) (129) compared losartan with placebo in patients with type 2 diabetes with nephropathy. The results of these trials were reported in 2001 (130-132). Treatment with losartan (130) and irbesartan (131,132) significantly reduced progression of renal disease, as evaluated by increasing proteinuria, doubling of serum creatinine level, and ESRD. These results strongly support the use of AR blockers in patients with type 2 diabetes with kidney disease. It is likely that ACE inhibitors and AR blockers are equally effective in patients with type 1 and type 2 diabetes with diabetic kidney disease. The larger studies will not be done because of a confluence of economic and political factors preventing a head-to-head trial comparing ACE inhibitors with AR blockers. Recent evidence also suggests that the use of an ACE inhibitor and an AR blocker in combination offers a further benefit in reducing proteinuria.

The increasing use of AR blockers for renal protection is based on expectations not only of benefits comparable to those with ACE inhibitors but also of a more favorable side-effect profile (133,134). Clinical trials support the remarkable safety of AR blockers. Kinin-associated cough is avoided, and angioedema has rarely been reported. The comparative risk of causing renal dysfunction is probably similar to that of ACE inhibitors. The risk of hyperkalemia appears to be comparable to or lower than that with ACE inhibitors. Previous data indicated that AR blockers raised the serum potassium levels by less than 10% over a 1-month period in hypertensive patients with renal disease (135). A recent randomized crossover trial comparing hemodynamically equipotent doses of valsartan and lisinopril reported that, in the presence of renal insufficiency, the AR blocker did not raise serum potassium to the same degree as did the ACE inhibitor (136). The trial apparently did not include patients with diabetes, however. Like ACE inhibitors, AR blockers are contraindicated during pregnancy. The AR blocker losartan has a uricosuric effect that lowers serum uric acid levels, but this is of uncertain benefit. AR blockers have been used in combination with other agents, such as calcium-channel blockers. In general, AR blockers in combination with ACE inhibitors would provide better inhibition of the RAS and less elevation of bradykinin levels than either one alone.

Calcium-Channel Blockers

Supplemental or alternative therapy is frequently required in patients treated with ACE inhibitors or AR blockers. Either may produce an insufficient decline in blood pressure, particularly with the current low blood pressure goals for hypertensive patients with diabetes. Other patients will require alternative therapy because of hyperkalemia, drug intolerance, or refractory proteinuria, or for cardiac indications.

With the predominance of ACE inhibitor and AR blocker therapy in recent years, there has been a shift away from β -blockers and toward calcium-channel blockers (137,138). Some calciumchannel blockers can even be given as alternatives to ACE inhibitors (139). More commonly, calcium-channel blockers are used in combination therapy. However, unlike the ACE inhibitors, their efficacy in preventing progressive renal dysfunction is controversial (140), and their effects on the kidney are not uniform within the class (141).

Two subclasses of calcium-channel blockers have reached the stage of clinical use, the dihydropyridines, such as nifedipine and related agents; and the nondihydropyridines, consisting of phenylalylkamines (such as verapamil) and benzothiazepines (such as diltiazem) (142). These calcium-channel blockers have in common the blockade of voltage-operated calcium channels, including those involving postreceptor effects of ATII itself (143). By preventing calcium entry, calcium-channel blockers prevent some actions of ATII. Calcium is known to be an important intracellular messenger.
