The operator delivers the baby and then the placenta. Recent evidence has demonstrated that blood loss is reduced by massaging the uterus to allow for spontaneous placental expulsion rather than by manually separating and extracting the placenta. Both methods are performed. After delivery of the placenta, the uterus should be massaged and oxytocin dilute intravenous solution at a rate sufficient to maintain a firm contraction. The uterine cavity is wiped clean with gauze to remove any retained membranes. The uterus is exteriorized, and active bleeding sinuses are clamped with either hemostats or ring forceps.

Closure of the Uterine Incision

The closure of the uterine incision is dependent upon the type of incision that is made. In general, the entire thick myometrium should be closed. The two types of uterine incisions used most often and discussed here are the classical incision and the low-transverse uterine incision.

CLASSICAL CESAREAN SECTION

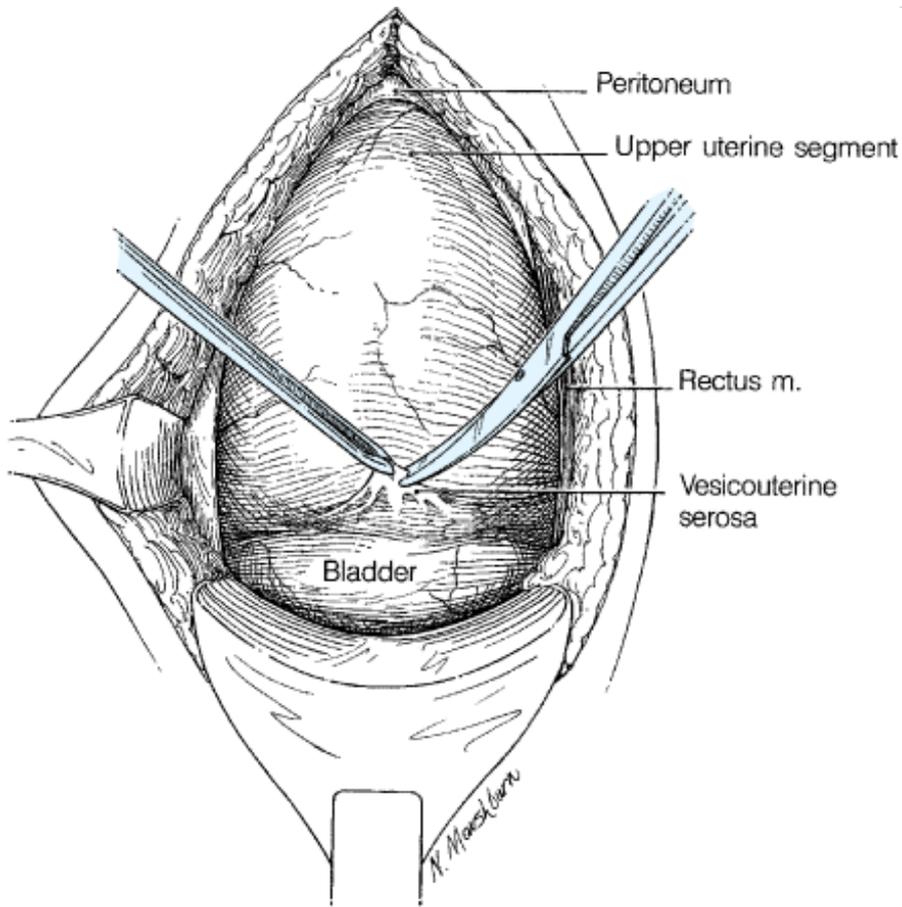

This is the simplest to perform. However, it is associated with the greatest loss of blood and may result in uterine rupture in subsequent pregnancies. The currently accepted indications for classical cesarean section are placenta previa, transverse lie (especially back down), and preterm delivery in which the lower uterine segment is poorly developed. A classical cesarean may be preferred if extremely rapid delivery is needed, because this type of incision offers the quickest means of delivering the baby. Nonetheless, the hazards of this procedure must be weighed against the additional minute or so needed to move away from the lower uterine segment and to make the transverse semilunar low-transverse incision.

In performing a classic procedure, a vertical incision is made in the corpus. A scalpel is used to enter the uterine cavity. The incision is enlarged with bandage scissors. The fetus is delivered through the incision. After the placenta and membranes are removed, the uterine defect is repaired with 3 layers of running, interlocking absorbable suture. Number 0 suture is used for the 2 deeper layers and 2-0 suture is used for the superficial layer to reapproximate the serosal edges.

LOW-TRANSVERSE CESAREAN SECTION

Because the low-transverse uterine incision (Figs 30-10, 30-11, 30-12, 30-13, 30-14, 30-15, 30-16, and 30-17) results in less blood loss and the risk of subsequent uterine rupture is less than with a classic cesarean section, this type of cesarean is performed more frequently. After the peritoneal cavity is opened and the uterus identified, the bladder fold is reflected up with tissue forceps and incised transversely. The bladder is bluntly separated from the anterior aspect of the uterus by a distance of 3–4 cm. The bladder is held away from this area by a specially designed bladder retractor. A transverse incision is made through the anterior uterine wall with the scalpel. Using either bandage scissors or fingers, the transverse incision is made in a semilunar fashion and extended superiorly at the lateral edges in order to avoid the uterine vessels.

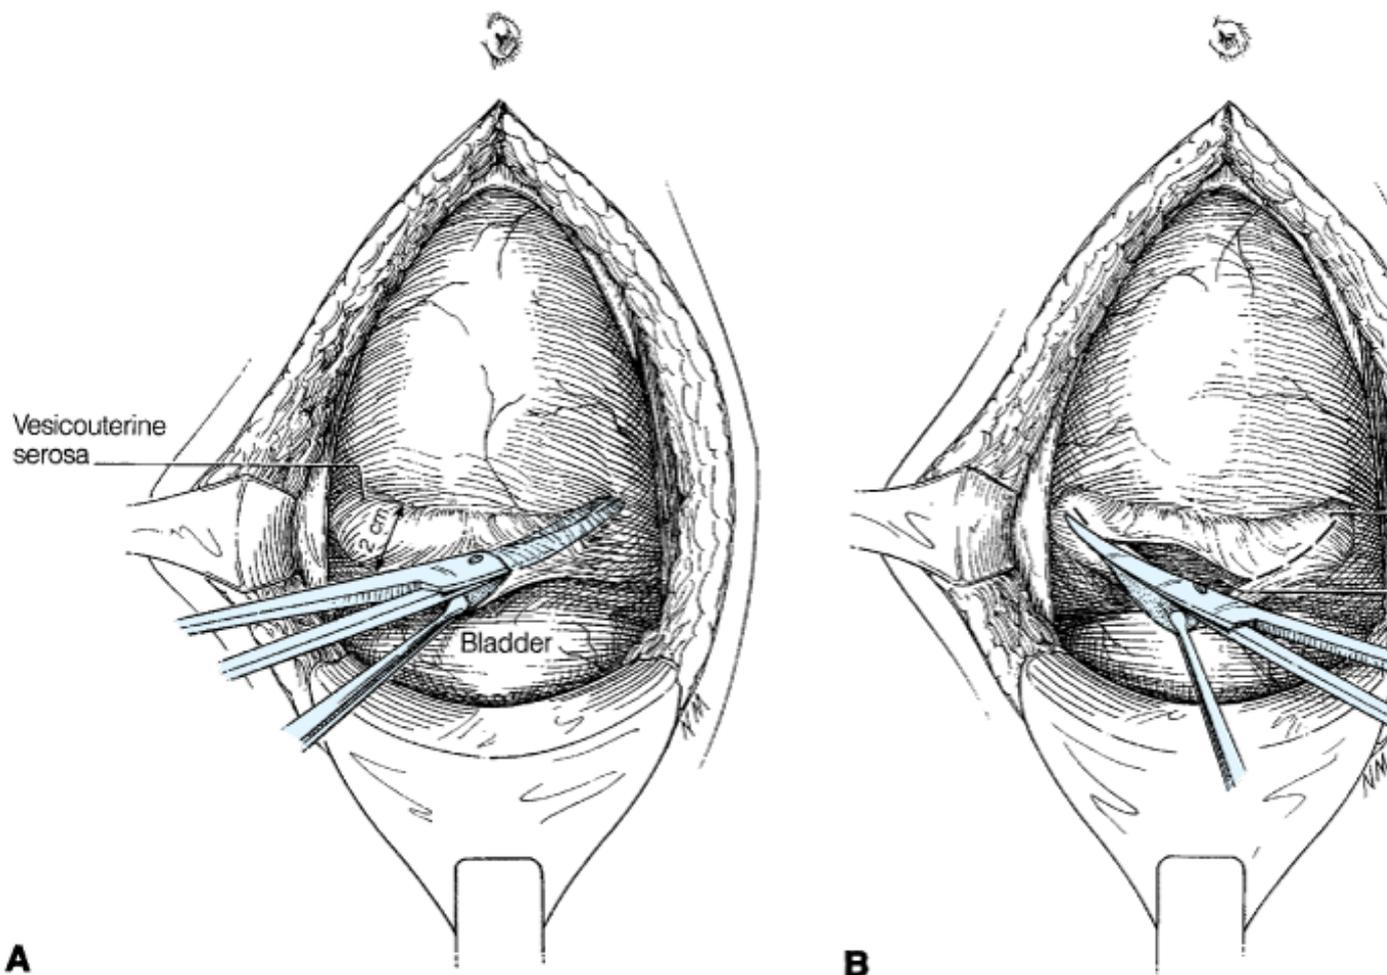

Figure 30–10.

The loose vesicouterine serosa is grasped with the forceps. The hemostat tip points to the upper margin of the retractor is firmly positioned against the symphysis. (m. = muscle.)

Placenta bulging through the uterine incision as the uterus contracts.

Figure 30–17.

The cut edges of the uterine incision are approximated with a running-lock suture.

If the maneuver can be easily done, the fetal presenting part is elevated with the hand, making sure not to flex increasing the possibility of extension of the incision inferiorly towards the cervix. If the head is located deep in can safely be pushed up by an assistant inserting a hand into the vagina to elevate the fetal head for ease of de and placenta are delivered, the uterus is exteriorized and clamps are placed on the cut edge of the uterus in are bleeding from the uterine sinuses. The uterine incision is generally closed in 2 layers using number 0 chromic ca absorbable suture. After adequate hemostasis has been achieved, the bladder peritoneum either is reapproxima left in place. Before the uterus is returned to the peritoneal cavity, the adnexa should be inspected for the prese pathology, such as ovarian cysts. Some practitioners prefer to close the anterior peritoneum with absorbable sut prefer to leave it alone. The fascia, subcutaneous tissue, and skin are reapproximated in standard fashion.

COMPLICATIONS

The most common complications that result from cesarean section are postpartum hemorrhage, endometritis, and Administering prophylactic antibiotics and ensuring hemostasis prior to closure of the abdomen have helped dec of these complications. The major factors affecting healing of the uterine incision are hemostasis, accuracy of ap amount of suture material, and avoidance of infection and tissue strangulation. It can generally be stated that th operative procedure, the greater the likelihood of postoperative complications. Disasters following cesarean sect clearly are not preventable. Others are the direct result of faulty surgical technique, especially lack of attention t or ill-chosen anesthesia, inadequate blood product replacement or transfusion of mismatched blood, and delayec mismanagement of infection.

Unfortunately, little information about the integrity of a particular scar in a subsequent pregnancy is gained by ir

presence or absence of postoperative infection and location of the incision. In a later pregnancy, pain in the area suggest dehiscence. Approximately 50% of all ruptures of classic uterine scars occur before the onset of labor. The uterine rupture is approximately 4–9% of classic scars and 0.7–1.5% of low-transverse scars. Rupture of a classic is catastrophic, occurring suddenly, totally, and with partial or total extrusion of the fetus into the abdominal cavity. Internal hemorrhage is a prominent sign. Rupture of the low-transverse scar usually is more subtle and almost always occurs during active labor. The most common presenting sign (present in more than 80% of cases) is a change in the fetal heart rate. A newly recognized finding of variable decelerations or late decelerations should alert the obstetrician. Additional findings that signal uterine rupture include vaginal bleeding, abdominal pain (especially over the prior incision site), and loss of fetal station. If uterine rupture is suspected, the patient must undergo surgery as soon as possible.

PERINATAL MORBIDITY AND MORTALITY

Although it may appear on the surface that cesarean delivery is the safest for the baby, this may not be entirely true. Usually benign, transient tachypnea of the newborn is more common with cesarean section than with vaginal delivery. Fetal hemorrhage and hypoxia is present when the placenta is encountered below the uterine incision and is inadequately transected, and there is the potential risk for laceration of the baby at the time the uterine incision is made. Laceration is reported to occur rather infrequently at a rate of approximately 0.2–0.4% of all cesarean sections. Lacerations of the face, in the area of the cheek, but it also may occur on the buttock, ear, head, or any other body site under the skin. Therefore it is of great importance that care be taken when incising the layers of the uterus. This is especially true during labor, in which the uterus may be very thin. Because of the potential complications to the baby inherent with each cesarean, each infant must be examined by a trained professional as soon as possible after delivery.

CESAREAN HYSTERECTOMY

A major indication for cesarean hysterectomy is the inability to stop bleeding. The most common reason for performing a hysterectomy is abnormal placental implantation, such as placenta accreta, increta, and percreta. As the cesarean continues to escalate, these complications are becoming more common. Other indications for cesarean hysterectomy include intractable uterine atony, inability to repair a ruptured uterus, and large uterine myomas. Cesarean hysterectomy is a morbid procedure because of increased blood loss and potential for injury to the bladder or ureter.

The technical aspects of hysterectomy at the time of cesarean section are similar to those of hysterectomy in the nonpregnant patient except that all structures, cleavage planes, and pedicles are highly vascular. Therefore, there is significant blood loss and the need for transfusion of blood products. At least 4 units of packed red blood cells should be available. It has been demonstrated that cesarean hysterectomy performed on a nonemergent basis is much safer than cesarean hysterectomy on an emergent basis. Specifically, injury to bladder and ureter and the need for blood transfusions are more common with cesarean hysterectomy if performed emergently.

Current OB/GYN > Chapter 31. Postpartum Hemorrhage & the Abnormal Puerperium >

POSTPARTUM HEMORRHAGE

Definition

Postpartum hemorrhage denotes excessive bleeding (> 500 mL in vaginal delivery) following delivery. Hemorrhage may occur before, during, or after delivery of the placenta. Actual measured blood loss during uncomplicated vaginal deliveries averages 700 mL, and blood loss often may be underestimated. Nevertheless, the criterion of a 500-mL loss is acceptable on historical grounds.

Blood lost during the first 24 hours after delivery is *early postpartum hemorrhage*; blood lost between 24 hours and 6 weeks after delivery is *late postpartum hemorrhage*.

Incidence

The incidence of excessive blood loss following vaginal delivery is 5–8%. Postpartum hemorrhage is the most common cause of excessive blood loss in pregnancy, and most transfusions in pregnant women are performed to replace blood lost after delivery. Hemorrhage is the third leading cause of maternal mortality in the United States and is directly responsible for approximately one-sixth of maternal deaths. In less-developed countries, hemorrhage is among the leading obstetric causes of maternal death.

Morbidity & Mortality

Although any woman may suffer excessive blood loss during delivery, women already compromised by anemia or intercurrent illness are more likely to demonstrate serious deterioration of condition, and anemia and excessive blood loss may predispose to subsequent puerperal infection. Major morbidity associated with transfusion therapy (eg, viral infection, transfusion reactions) is infrequent but is not insignificant. Moreover, other types of treatment for anemia may involve some risk.

Postpartum hypotension may lead to partial or total necrosis of the anterior pituitary gland and cause postpartum panhypopituitarism, or Sheehan's syndrome, which is characterized by failure to lactate, amenorrhea, decreased breast size, loss of pubic and axillary hair, hypothyroidism, and adrenal insufficiency. The condition is rare (< 1 in 10,000 deliveries). A woman who has been hypotensive postpartum and who is actively lactating probably does not have Sheehan's syndrome. Hypotension also can lead to acute renal failure and other organ system injury. In extreme hemorrhage, sterility will result from hysterectomy performed to control intractable postpartum hemorrhage.

Etiology

Causes of postpartum hemorrhage include uterine atony, obstetric lacerations, retained placental tissue, and coagulation defects.

UTERINE ATONY

Postpartum bleeding is physiologically controlled by constriction of interlacing myometrial fibers that surround the blood vessels supplying the placental implantation site. Uterine atony exists when the myometrium cannot contract.

Atony is the most common cause of postpartum hemorrhage (50% of cases). Predisposing causes

include excessive manipulation of the uterus, general anesthesia (particularly with halogenated compounds), uterine overdistention (twins or polyhydramnios), prolonged labor, grand multiparity, uterine leiomyomas, operative delivery and intrauterine manipulation, oxytocin induction or augmentation of labor, previous hemorrhage in the third stage, uterine infection, extravasation of blood into the myometrium (Couvelaire uterus), and intrinsic myometrial dysfunction.

OBSTETRIC LACERATIONS

Excessive bleeding from an episiotomy, lacerations, or both causes approximately 20% of postpartum hemorrhages. Lacerations can involve the uterus, cervix, vagina, or vulva. They usually result from precipitous or uncontrolled delivery or operative delivery of a large infant; however, they may occur after any delivery. Laceration of blood vessels underneath the vaginal or vulvar epithelium results in hematomas. Bleeding is concealed and can be particularly dangerous because it may go unrecognized for several hours and become apparent only when shock occurs.

Episiotomies may cause excessive bleeding if they involve arteries or large varicosities, if the episiotomy is large, or if a delay occurred between episiotomy and delivery or between delivery and repair of the episiotomy.

Persistent bleeding (especially bright red) and a well-contracted, firm uterus suggests bleeding from a laceration or from the episiotomy. When cervical or vaginal lacerations are identified as the source of postpartum hemorrhage, repair is best performed with adequate anesthesia.

Spontaneous rupture of the uterus is rare. Risk factors for this complication include grand multiparity, malpresentation, previous uterine surgery, and oxytocin induction of labor. Rupture of a previous cesarean section scar after vaginal delivery may be an increasingly important cause of postpartum hemorrhage.

RETAINED PLACENTAL TISSUE

Retained placental tissue and membranes cause 5–10% of postpartum hemorrhages. Retention of placental tissue in the uterine cavity occurs in placenta accreta, in manual removal of the placenta, in mismanagement of the third stage of labor, and in unrecognized succenturiate placenta.

Ultrasonographic findings of an echogenic uterine mass strongly support a diagnosis of retained placental products. The technique probably is better used in cases of hemorrhage occurring a few hours after delivery or in late postpartum hemorrhage. Transvaginal duplex Doppler imaging also is effective in evaluating these patients. Some evidence indicates that sonohysterography may aid in the diagnosis of residual trophoblastic tissue. If the endometrial cavity appears empty, unnecessary dilatation and curettage may be avoided.

COAGULATION DEFECTS

Coagulopathies in pregnancy may be acquired coagulation defects seen in association with several obstetric disorders, including abruptio placentae, excess thromboplastin from a retained dead fetus, amniotic fluid embolism, severe preeclampsia, eclampsia, and sepsis. These coagulopathies may present as hypofibrinogenemia, thrombocytopenia, and disseminated intravascular coagulation. Transfusion of more than 8 U of blood in itself may induce a dilutional coagulopathy.

Von Willebrand's disease, autoimmune thrombocytopenia, and leukemia may occur in pregnant women.

Risk Factors

Prevention of hemorrhage is preferable to even the best treatment. All patients in labor should be evaluated for risk of postpartum hemorrhage. Risk factors include coagulopathy, hemorrhage, or blood transfusion during a previous pregnancy; anemia during labor; grand multiparity; multiple gestation;

large infant; polyhydramnios; dysfunctional labor; oxytocin induction or augmentation of labor; rapid or tumultuous labor; severe preeclampsia or eclampsia; vaginal delivery after previous cesarean birth; general anesthesia for delivery; and forceps delivery.

Management

PREDELIVERY PREPARATION

All obstetric patients should have blood typed and screened on admission. Patients identified as being at risk for postpartum hemorrhage should have their blood typed and cross-matched immediately. The blood should be reserved in the blood bank for 24 hours after delivery. A large-bore intravenous catheter should be securely taped into place after insertion. Delivery room personnel should be alerted to the risk of hemorrhage. Severely anemic patients should be transfused as soon as cross-matched blood is ready.

With concerns associated with blood transfusion, autologous blood donation in obstetric patients at risk for postpartum hemorrhage has been advocated. Despite careful evaluation for risk factors, with the exception of cases of placenta previa, our ability to predict which patients will have hemorrhage and require blood transfusion remains poor; therefore, the cost of such an approach may not be justified.

DELIVERY

Following delivery of the infant, the uterus is massaged in a circular or back-and-forth motion until the myometrium becomes firm and well contracted. Excessive and vigorous massage of the uterus before, during, or after delivery of the placenta may interfere with normal contraction of the myometrium and instead of hastening contraction may lead to excessive postpartum blood loss.

THIRD STAGE OF NORMAL LABOR; PLACENTAL SEPARATION

The placenta typically separates from the uterus and is delivered within 5 minutes of delivery of the infant. Attempts to speed separation are of no benefit and may cause harm. Spontaneous placental separation is impending if the uterus becomes round and firm, a sudden gush of blood comes from the vagina, the uterus seems to rise in the abdomen, and the umbilical cord moves down out of the vagina.

The placenta then can be removed from the vagina by gentle traction on the umbilical cord. Prior to placental separation, gentle steady traction on the cord combined with upward pressure on the lower uterine segment (Brandt-Andrews maneuver) ensures that the placenta can be removed as soon as separation occurs and provides a means of monitoring the consistency of the uterus. Adherent membranes can be removed by gentle traction with ring forceps. The placenta is inspected for completeness immediately after delivery.

Manual Removal of the Placenta

Opinion is divided about the timing of manual removal of the placenta. In the presence of hemorrhage, it is unreasonable to wait for spontaneous separation, and manual removal of the placenta should be undertaken without delay. In the absence of bleeding, many advocate removal of the placenta 30 minutes after delivery of the infant.

Efforts to promote routine manual removal of the placenta were often made in the past. The rationale includes shortening the third stage of labor, decreasing blood loss, developing experience in manual removal as practice for dealing with placenta accreta, and providing a way to simultaneously explore the uterus. Evidence now indicates that manual removal of the placenta may be a risk factor for postpartum endometritis. These real or potential benefits must be weighed against the discomfort caused to the patient, the risk of infection, and the risk of causing more bleeding by interfering with normal mechanisms of placental separation.

Technique: The uterus is stabilized by grasping the fundus with a hand placed over the abdomen. The

other hand traces the course of the umbilical cord through the vagina and cervix into the uterus to palpate the edge of the placenta. The membranes at the placental margin are perforated, and the hand is inserted between the placenta and the uterine wall, palmar side toward the placenta. The hand is then gently swept from side to side and up and down to peel the placenta from its attachments to the uterus. When the placenta has been completely separated from the uterus, it is grasped and pulled from the uterus.

The fetal and maternal sides of the placenta should be inspected to ensure that it has been removed in its entirety. On the fetal surface, incomplete placental removal is manifested as interruption of the vessels on the chorionic plate, usually shown by hemorrhage. On the maternal surface, it is possible to see where cotyledons have been detached. If evidence of incomplete removal is observed, the uterus must be re-explored and any small pieces of adherent placenta removed. The uterus should be massaged until a firm myometrial tone is achieved. Depending on the patient's other risk factors for postpartum endometritis, prophylactic antibiotics can be given at the time of manual removal of the placenta.

Immediate Postpartum Period

Uterotonic agents can be administered as soon as the infant's anterior shoulder is delivered. Recent studies show a significantly lowered incidence of postpartum hemorrhage in patients receiving oxytocin (either low-dose IV or IM) at the time of delivery of the anterior shoulder and controlled cord traction compared to patients receiving IV oxytocin following placental delivery. There was no greater incidence of placental retention. However, populations without ultrasound screening for twins have a potential risk for entrapment of an undiagnosed second twin, and oxytocin should only be given after placental delivery. Routine administration of oxytocics during the third stage reduces the blood loss of delivery and decreases the chances of postpartum hemorrhage by 40%. Oxytocin, 10–20 U/L of isotonic saline, or other intravenous solution by slow intravenous infusion or 10 U intramuscularly can be used. Bolus administration should not be used because large doses (> 5 U) can cause hypotension. Ergot alkaloids (eg, methylergonovine maleate 0.2 mg intramuscularly) also can be routinely used, but they are not more effective than oxytocin and pose more risk because they rarely cause marked hypertension. This occurs most commonly with intravenous administration or when regional anesthesia is used. Ergot alkaloids should not be used in hypertensive women or in women with cardiac disease.

Repair of Lacerations

If bleeding is excessive before placental separation, manual removal of the placenta is indicated. Otherwise, excessive manipulation of the uterus should be avoided.

The vagina and cervix should be carefully inspected immediately after delivery of the placenta, with adequate lighting and assistants available. The episiotomy is quickly repaired after massage has produced a firm, tightly contracted uterus. A pack placed in the vagina above the episiotomy helps to keep the field dry; attaching the free end of the pack to the adjacent drapes reminds the operator to remove it after the repair is completed.

The tendency of bleeding vessels to retract from the laceration site is the reason for 1 of the cardinal principles of repair. Begin the repair above the highest extent of the laceration. The highest suture is also used to provide gentle traction to bring the laceration site closer to the introitus. Hemostatic ligatures are then placed in the usual manner, and the entire birth canal is carefully inspected to ensure that no additional bleeding sites are present. Extensive inspection also provides time to confirm that prior hemostatic efforts have been effective.

A cervical or vaginal laceration extending into the broad ligament should not be repaired vaginally. Laparotomy with evacuation of the resultant hematoma and hemostatic repair or hysterectomy is

required.

Large or expanding hematomas of the vaginal walls require operative management for proper control. The vaginal wall is first exposed by an assistant. If a laceration accompanies the hematoma, the laceration is extended so that the hematoma can be completely evacuated and explored. When the bleeding site is identified, a large hemostatic ligature can be placed well above the site. This ensures hemostasis in the vessel, which is likely to retract when lacerated. The hematoma cavity should be left open to allow drainage of blood and ensure that bleeding will not be concealed if hemostasis cannot be achieved.

If no laceration is present on the vaginal side wall when a hematoma is identified, then an incision must be made over the hematoma to allow treatment to proceed as outlined.

Following delivery, recovery room attendants should frequently massage the uterus and check for vaginal bleeding.

Evaluation of Persistent Bleeding

If vaginal bleeding persists after delivery of the placenta, aggressive treatment should be initiated. It is not sufficient to perform perfunctory uterine massage, for instance, without searching for the cause of the bleeding and initiating definitive treatment. The following steps should be undertaken without delay:

1. Manually compress the uterus.
2. Obtain assistance.
3. If not already done, obtain blood for typing and cross-matching.
4. Observe blood for clotting to rule out coagulopathy.
5. Begin fluid or blood replacement.
6. Carefully explore the uterine cavity.
7. Completely inspect the cervix and vagina.
8. Insert a second intravenous catheter for administration of blood or fluids.

MEASURES TO CONTROL BLEEDING

Manual Exploration of the Uterus

The uterus should be explored immediately in women with postpartum hemorrhage. Manual exploration also should be considered after delivery of the placenta in the following circumstances: (1) when vaginal delivery follows previous cesarean section; (2) when intrauterine manipulation, such as version and extraction, has been performed; (3) when malpresentation has occurred during labor and delivery; (4) when a premature infant has been delivered; (5) when an abnormal uterine contour has been noted prior to delivery; and (6) when there is a possibility of undiagnosed multiple pregnancy—to rule out twins.

Ensure that all placental parts have been delivered and that the uterus is intact. This should be done even in the case of a well-contracted uterus. Exploration performed for reasons other than evaluation of hemorrhage also should confirm that the uterine wall is intact and should attempt to identify any possible intrauterine structural abnormalities. Manual exploration of the uterus does not increase febrile morbidity or blood loss.

Technique: Place a fresh glove over the glove on the exploring hand. Form the hand into a cone and gently introduce it by firm pressure through the cervix while stabilizing the fundus with the other hand. Sweep the backs of the first and second fingers across the entire surface of the uterus, beginning at the fundus. In the lower uterine segment, palpate the walls with the palmar surface of 1 finger. Uterine

lacerations will be felt as an obvious anatomic defect. All exploration should be gentle because the postpartum uterus is easily perforated.

Uterine rupture detected by manual exploration in the presence of postpartum hemorrhage requires immediate laparotomy. A decision to repair the defect or proceed with hysterectomy is made on the basis of the extent of the rupture, the patient's desire for future childbearing, and the degree of the patient's clinical deterioration.

Bimanual Compression and Massage

The most important step in controlling atonic postpartum hemorrhage is immediate bimanual uterine compression, which may have to be continued for 20–30 minutes or more. Fluid replacement should begin as soon as a secure intravenous line is in place. Typed and cross-matched blood is given when it is available. Manual compression of the uterus will control most cases of hemorrhage due to uterine atony, retained products of conception (once the products are removed), and coagulopathies.

Technique: Place a hand on the patient's abdomen and grasp the uterine fundus; bring it down over the symphysis pubis. Insert the other hand into the vagina and place the first and second fingers on either side of the cervix and push it cephalad and anteriorly. The pulsating uterine arteries should be felt by the fingertips. Massage the uterus with both hands while maintaining compression. Prolonged compression (20–30 minutes) may be required but almost always is successful in controlling bleeding.

Insert a Foley catheter into the bladder during compression and massage because vigorous fluid and blood replacement will cause diuresis. A distended bladder will interfere with compression and massage, will contribute to the patient's discomfort, and may itself be a major contributor to uterine atony.

Curettage

Curettage of a large, soft postpartum uterus can be a formidable undertaking because the risk of perforation is high and the procedure commonly results in increased rather than decreased bleeding. The suction curette, even with a large cannula, covers only a small area of the postpartum uterus, and its size and shape increase the likelihood of perforation. A large blunt curette, the "banjo" curette, probably is the safest instrument for curettage of the postpartum uterus. It can be used when manual exploration fails to remove fragments of adherent placenta.

Curettage should be delayed unless bleeding cannot be controlled by compression and massage alone. Overly vigorous puerperal curettage can result in focal complete removal of the endometrium, particularly if the uterus is infected, with subsequent healing characterized by formation of adhesions and Asherman's syndrome (amenorrhea and secondary sterility due to intrauterine adhesions and uterine synechiae). If circumstances permit, ultrasonic evaluation of the postpartum uterus may distinguish those patients who will benefit from curettage from those who should be managed without it.

Uterine Packing

Although once widely used for control of obstetric hemorrhage, uterine packing is no longer favored. The uterus may expand to considerable size after delivery of the placenta, thus accommodating both a large volume of packing material and a large volume of blood. The technique also demands considerable technical expertise because the uterus must be packed uniformly with 5 yards of 4-inch gauze, sometimes with the aid of special instrumentation (Torpin packer). However, this method has been used successfully, avoiding conversion to laparotomy in 9 reported cases. As a last resort, uterine packing may be particularly appropriate in centers where an interventional radiologist is not immediately available.

Uterotonic Agents

Oxytocin 20–40 U/L of crystalloid should be infused, if not already running, at a rate of 10–15 mL/min. Methylergonovine 0.2 mg can be given intramuscularly but is contraindicated if the patient is

hypertensive. Intramyometrial injection of prostaglandin F₂ (PGF₂) to control bleeding was initially described in 1976. Intravaginal or rectal prostaglandin suppositories, intrauterine irrigation with prostaglandins, and intramyometrial injection of prostaglandins also have been reported to control hemorrhage from uterine atony. Intramuscular administration of 15-methylprostaglandin analogue was successful in treating 85% of patients with postpartum hemorrhage due to atony. Failures in these series occurred in women who had uterine infections or unrecognized placenta accreta. Side effects usually are minimal but may include transient oxygen desaturation, bronchospasm, and, rarely, significant hypertension. Transient fever and diarrhea may occur. A recent randomized controlled trial showed excellent efficacy of 800 µg of rectal misoprostol, a prostaglandin E₁ analogue, in the treatment of primary postpartum hemorrhage secondary to atony.

Radiographic Embolization of Pelvic Vessels

Embolization of pelvic and uterine vessels by angiographic techniques is increasingly common and has success rates from 85–95% in experienced hands. In institutions with trained interventional radiologists, the technique is worth considering in women of low parity as an alternative to hysterectomy. With the patient under local anesthesia, a catheter is placed in the aorta and fluoroscopy is used to identify the bleeding vessel. Pieces of absorbable gelatin sponge (Gelfoam) are injected into the damaged vessel or into the internal iliac vessels if no specific site of bleeding can be identified. If bleeding continues, further embolization can be performed. This technique has the advantage of being effective even when the cause of hemorrhage is extrauterine and in the presence or absence of uterine atony. Many authors recommend embolization before internal iliac ligation, because ligation obstructs the access route for angiography. Adequate recanalization can occur to maintain fertility, although fertility rates following embolization are not known.

Operative Management

The patient's wishes regarding further childbearing should be made clear as soon as laparotomy is contemplated for the management of postpartum hemorrhage. If the patient's wishes cannot be ascertained, the operator should assume that the childbearing function is to be retained. Whenever possible, the spouse or family members should also be consulted prior to laparotomy.

PRESSURE OCCLUSION OF THE AORTA

Immediate temporary control of pelvic bleeding may be obtained at laparotomy by pressure occlusion of the aorta, which will provide valuable time to treat hypotension, obtain experienced assistants, identify the source of bleeding, and plan the operative procedure. In the young and otherwise healthy patient, pressure occlusion can be maintained for several minutes without permanent sequelae.

UTERINE ARTERY LIGATION

During pregnancy, 90% of the blood flow to the uterus is supplied by the uterine arteries. Direct ligation of these easily accessible vessels can successfully control hemorrhage in 75–90% of cases, particularly when the bleeding is uterine in origin. Recanalization can occur, and subsequent pregnancies have been reported.

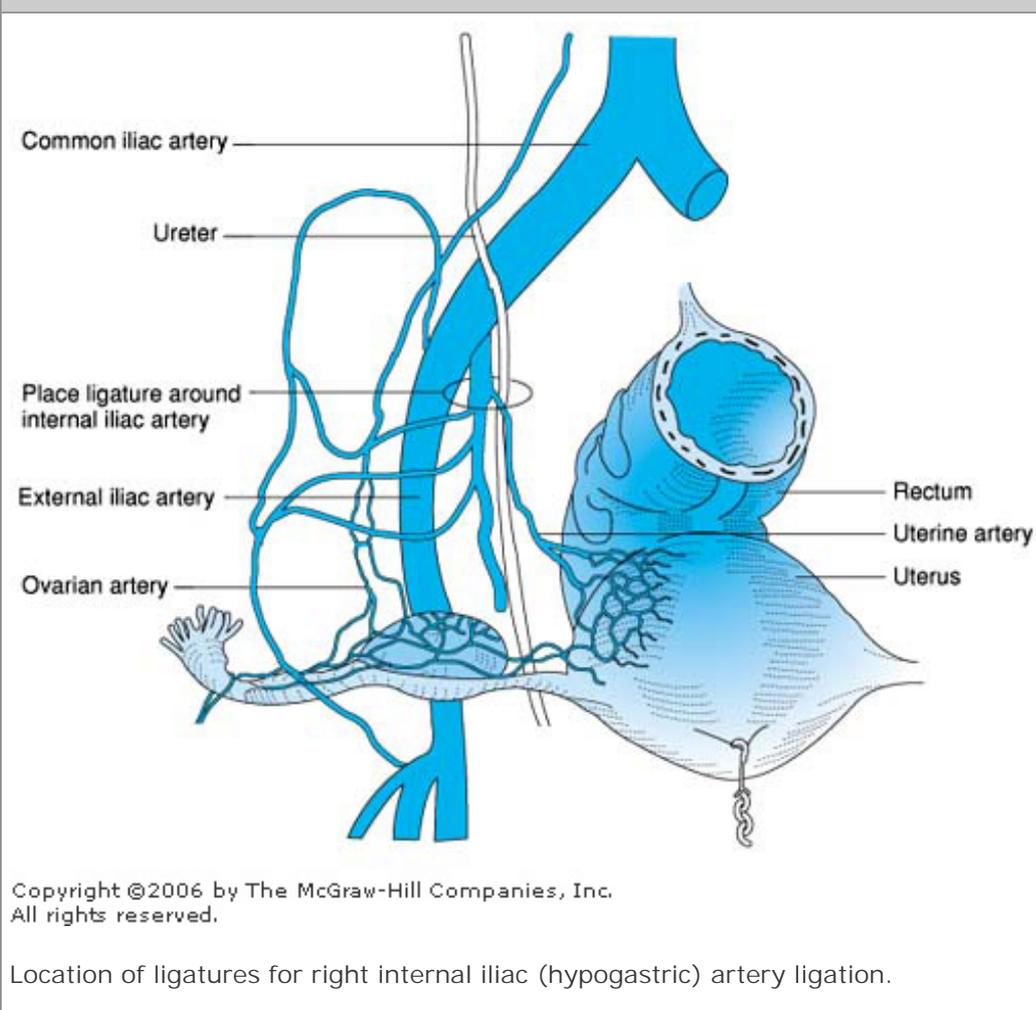

Technique: The uterus is lifted upward and away from the side to be ligated. Absorbable suture on a large needle is placed around the ascending uterine artery and vein on 1 side of the uterus, passing through the myometrium 2–4 cm medial to the vessels and through the avascular area of the broad ligament. The suture includes the myometrium to fix the suture and to avoid tearing the vessels. The same procedure is then performed on the opposite side. If the ligation is performed during cesarean section, the sutures can be placed just below the uterine incision under the bladder flap. It is not necessary to mobilize the bladder otherwise. Bilateral uteroovarian artery ligation can also be performed in an attempt to reduce blood flow to the uterus. This technique should be performed with absorbable

suture near the point of anastomoses between the ovarian artery and the ascending uterine artery at the uteroovarian ligament.

INTERNAL ILIAC ARTERY LIGATION

Bilateral internal iliac (hypogastric) artery ligation is the surgical method most often used to control severe postpartum bleeding (Fig 31–1). Exposure can be difficult, particularly in the presence of a large boggy uterus or hematoma. Failure rates of this technique can be as high as 57% but may be related to the skill of the operator, the cause of the hemorrhage, and the patient's condition before ligation is attempted.

Figure 31–1.

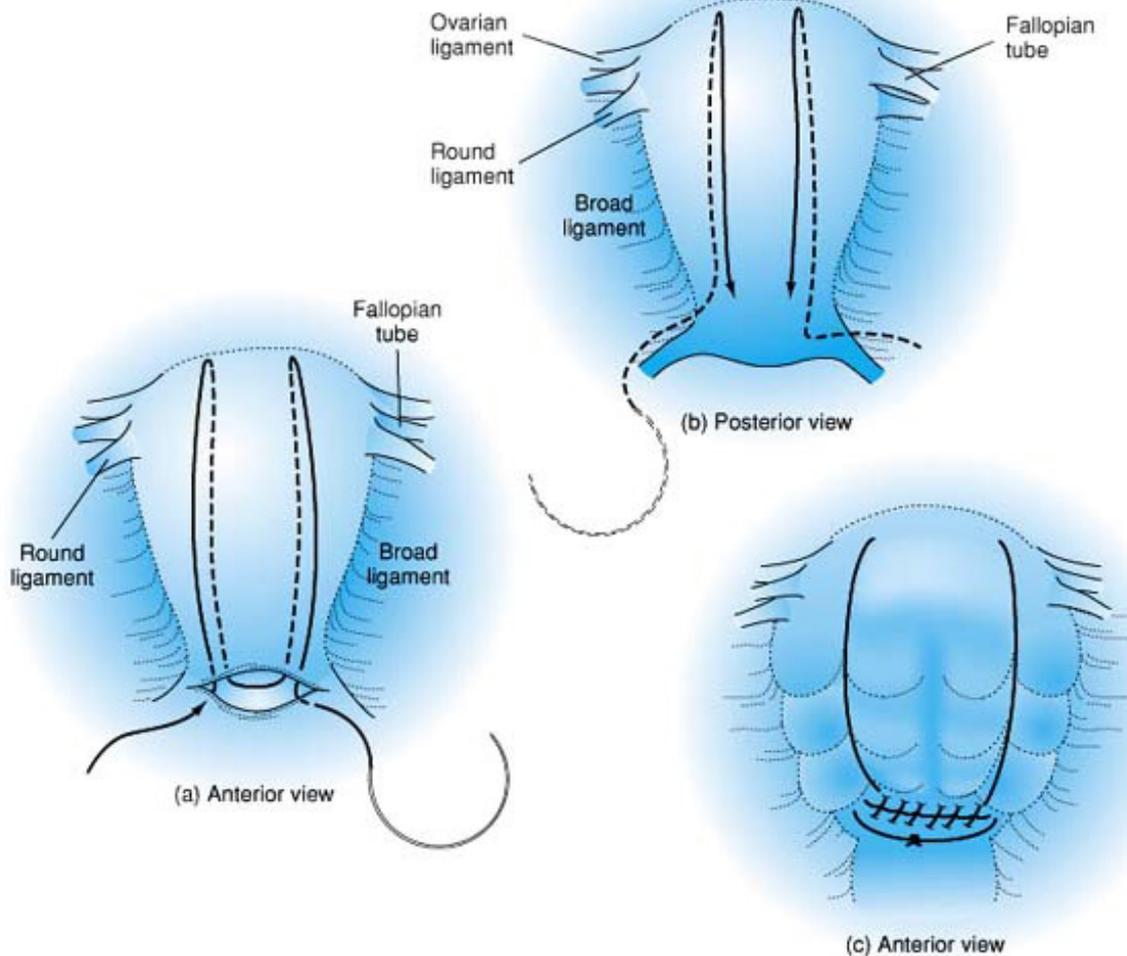

Technique: The peritoneum lateral to the infundibulopelvic ligament is incised parallel with the ligament, or the round ligament is transected. In either case, the peritoneum to which the ureter will adhere is dissected medially, which removes the ureter from the operative field. The pararectal space is then enlarged by blunt dissection. The internal iliac artery on the lateral side of the space is isolated and doubly ligated (but not cut) with silk ligatures at its origin from the common iliac artery. The operator must be careful not to tear the adjacent thin veins. Blood flow distally to the uterus, cervix, and upper vagina is not occluded, but the pulse pressure is sufficiently diminished to allow hemostasis to occur by in situ thrombosis. Fertility is preserved, and subsequent pregnancies are not compromised.

B-LYNCH BRACE SUTURE

An alternative to the vessel ligation techniques is placement of a brace suture to compress the uterus in

cases of diffuse bleeding from atony or percreta (Fig 31–2). A small case series shows success and avoidance of hysterectomy using this novel approach.

Figure 31–2.

B-Lynch brace suture (see text for details).

Technique: Laparotomy is made in the standard way for cesarean section, and a low-transverse uterine incision is made after the bladder is taken down. The uterus is exteriorized. To test the effectiveness of the method, the uterus is compressed manually and another operator checks the vagina for decreased bleeding. Using no. 2 catgut, the uterus is punctured 3 cm from the right lower incision and 3 cm from the right lateral border. The suture is threaded to emerge 3 cm above the upper incision margin and 4 cm from the lateral border. The catgut is now visible anteriorly as it is passed over to compress the uterine fundus approximately 34 cm from the right cornual border. The suture is fed posteriorly and vertically to enter the posterior wall of the uterine cavity at the same level as the previous entry point. After manual compression, the suture is tightened and then passed posteriorly on the left side and passed around the uterine fundus again, this time on the left. The suture is brought anteriorly to puncture the uterus at the upper part of the left uterine incision and then reemerge below the lower

incision in a symmetric fashion. With 1 operator providing compression, the other throws the knot. The hysterotomy is closed in the standard fashion for a cesarean section.

HYSTERECTOMY

Hysterectomy is the definitive method of controlling postpartum hemorrhage. Simple hemostatic repair of a ruptured uterus with or without tubal ligation in a woman of high parity or in poor condition for more extensive surgery may be preferred unless she has intercurrent uterine disease. The procedure is undoubtedly lifesaving.

Blood Replacement

Blood and fluid replacement are required for successful management of postpartum hemorrhage. Massive transfusions may be necessary in patients with severe hemorrhage. Component therapy is advocated, with transfusion of packed cells, platelets, fresh-frozen plasma, and cryoprecipitate when indicated. Blood products should be obtained and given without delay when needed, because postponing transfusion may only contribute to the development of disseminated intravascular coagulation.

MANAGEMENT OF DELAYED POSTPARTUM HEMORRHAGE

Delayed postpartum hemorrhage (bleeding \geq 2 weeks after delivery) is almost always due to subinvolution of the placental bed or retained placental fragments. Involution of the placental site is normally delayed when compared with that of the rest of the endometrium. However, for unknown reasons, in subinvolution the adjacent endometrium and the decidua basalis have not regenerated to cover the placental implantation site. The involutinal processes of thrombosis and hyalinization have failed to occur in the underlying blood vessels, so bleeding may occur with only minimal trauma or other (unknown) stimuli. Although the cause of subinvolution is unknown, faulty placental implantation, implantation in the poorly vascularized lower uterine segment, and persistent infection at the implantation site have been suggested as possible factors. Uterine compression and bimanual massage, as previously described, control this type of bleeding, but it may be necessary to continue compression and massage for 30–45 minutes or longer. As previously mentioned, transvaginal ultrasound may aid in diagnosis of retained placental products. If imaging studies suggest intracavitary tissue, curettage is warranted.

Broad-spectrum antibiotics should be started when resuscitation allows. Oxytocin 10 U intramuscularly every 4 hours or 10–20 U/L intravenous solution by slow continuous infusion, 15-methyl PGF_2 (Prostin 15M) 0.25 mg intramuscularly every 2 hours, or ergot alkaloids, such as methylergonovine maleate 0.2 mg orally every 6 hours, should be administered for at least 48 hours.

PLACENTA ACCRETA

A layer of decidua normally separates the placental villi and the myometrium at the site of placental implantation. A placenta that directly adheres to the myometrium without an intervening decidual layer is termed *placenta accreta*.

Classification

BY DEGREE OF ADHERENCE

Placenta Accreta Vera

Villi adhere to the superficial myometrium.

Placenta Increta

Villi invade the myometrium.

Placenta Percreta

Villi penetrate the full thickness of the myometrium.

BY AMOUNT OF PLACENTAL INVOLVEMENT

Focal Adherence

A single cotyledon is involved.

Partial Adherence

One or several cotyledons are involved.

Total Adherence

The entire placenta is involved.

Incidence

Estimates of the incidence of placenta accreta (all forms) vary from 1 in 2000 to 1 in 7000 deliveries. Placenta accreta vera accounts for approximately 80% of abnormally adherent placentas, placenta increta accounts for 15%, and placenta percreta accounts for 5%. The rate has risen slightly over the last 2 decades, paralleling the cesarean section rate.

Morbidity & Mortality

The immediate morbidity associated with an abnormally adherent placenta is that associated with any type of postpartum hemorrhage. Massive blood loss and hypotension can occur. Intrauterine manipulation necessary to diagnose and treat placenta accreta may result in uterine perforation and infection. Sterility may occur as a result of hysterectomy performed to control bleeding.

Recurrence may be common with lesser degrees of adherence.

Etiology

Both excessive penetrability of the trophoblast and defective or missing decidua basalis have been suggested as causes of placenta accreta. Histologic examination of the placental implantation site usually demonstrates the absence of the decidua and Nitabuch's layer. Cases of placenta accreta have been seen in the first trimester, suggesting that the process may occur at the time of implantation and not later in gestation.

Although the exact cause is unknown, several clinical situations are associated with placenta accreta, such as previous cesarean section, placenta previa, grand multiparity, previous uterine curettage, and previously treated Asherman's syndrome.

These conditions share a common possible defect in formation of the decidua basalis. The incidence of placenta accreta in the presence of placenta previa after 1 prior uterine incision is between 14% and 24%, after 2 is 23–48%, and after 3 is 35–50%. The incidence of placenta accreta after successful treatment of Asherman's syndrome may be as high as 15%.

Diagnosis

Adverse effects from placenta accreta in pregnancy or during the course of labor and delivery are uncommon. Rarely, intra-abdominal hemorrhage or placental invasion of adjacent organs prior to labor has occurred, with the diagnosis made at laparotomy.

The diagnosis of placenta increta prior to delivery based on the lack of the sonolucent area normally seen beneath the implantation site during ultrasonographic examination is a finding confirmed in several reports. Sonographic antenatal diagnosis of the less invasive placental accreta also has been reported. Color Doppler imaging appears to be particularly helpful in diagnosis. Magnetic resonance imaging has also aided in the diagnosis of placenta accreta. The diagnosis is more often established when no plane of cleavage is found between the placenta or parts of the placenta and the myometrium in the presence of postpartum hemorrhage. Retained placental parts prevent the myometrium from contracting and thereby

achieving hemostasis. Bleeding can be brisk. Inspection of the already separated placenta shows that portions are missing, and manual exploration may produce additional placental fragments.

Delayed spontaneous separation of the placenta is also an indication of an unusually adherent placenta. Focal or partial involvement may be manifested as difficulty in establishing a cleavage plane during manual removal of the placenta. Removal of a totally adherent placenta is difficult. Persistent efforts to manually remove a totally adherent placenta are futile and waste time, and they result in even more blood loss. Preparation for hysterectomy should begin as soon as the diagnosis is suspected.

Management

Fluid and blood replacement should begin as soon as excessive blood loss is diagnosed. Insertion of a second large-bore intravenous catheter may be necessary. Evaluation of puerperal hemorrhage should be performed as outlined in Evaluation of Persistent Bleeding.

Conservative treatment of placenta accreta in women of low parity has occasionally succeeded. The placenta (or portions of it) is left in situ if bleeding is minimal and will later slough off. Successful subsequent pregnancies have been reported, although the risk of recurrence of placenta accreta may be high. In up to 72% of cases of placenta accreta, particularly those associated with placenta previa, hysterectomy is required.

Successful conservative treatment of placenta percreta is rare, but the conservative approach may be a reasonable option if only focal defects are present, blood loss is not excessive, and the patient wishes to preserve fertility. In anticipated cases of severe placenta accreta, preoperative balloon occlusion and embolization of the internal iliac arteries may minimize intraoperative blood losses. Successful embolization in unpredicted cases of placenta accreta has been reported. However, additional resection of adjacent organs, such as partial cystectomy, may be necessary in placenta percreta.

UTERINE INVERSION

Definition

Uterine inversion is prolapse of the fundus to or through the cervix so that the uterus is in effect turned inside out. Almost all cases of uterine inversion occur after delivery and may be worsened by excess traction on the cord before placental separation. Nonpuerperal uterine inversion is rare and usually is associated with tumors (eg, polypoid leiomyomas).

Classification

If the uterus is inverted but does not protrude through the cervix, the inversion is *incomplete*. In *complete* inversion, the fundus has prolapsed through the cervix. Occasionally, the entire uterus may prolapse out of the vagina.

Puerperal inversion has also been classified on the basis of its duration. Acute inversion occurs immediately after delivery and before the cervix constricts. Once the cervix constricts, the inversion is termed *subacute*. Chronic inversion is noted more than 4 weeks after delivery. Today, nearly all cases of uterine inversion are of the acute variety and are recognized and treated immediately after delivery.

Incidence

In series reported within the past 30 years, the incidence of uterine inversion has varied from 1 in 4000 to 1 in 100,000 deliveries; an incidence of 1 in 20,000 is frequently cited. One worker reported no inversions in more than 10,000 personally conducted deliveries. More recent reviews indicate a greater incidence of uterine inversion, approximately 1 in 2000 to 1 in 2500 deliveries.

Morbidity & Mortality

The morbidity and mortality associated with uterine inversion correlate with the degree of hemorrhage, the rapidity of diagnosis, and the effectiveness of treatment.

The immediate morbidity is that associated with any postpartum hemorrhage; however, endomyometritis frequently follows uterine inversion. The intestines and uterine appendages may be injured if they are entrapped by the prolapsed uterine fundus. Death has occurred from uterine inversion, although with prompt recognition, definitive treatment, and vigorous resuscitation, the mortality rate in this condition should be quite low.

Etiology

The exact cause of uterine inversion is unknown, and the condition is not always preventable. The cervix must be dilated and the uterine fundus must be relaxed for inversion to occur. Rapid uterine emptying may contribute to uterine relaxation.

Conditions that may predispose women to uterine inversion include fundal implantation of the placenta, abnormal adherence of the placenta (partial placenta accreta), congenital or acquired weakness of the myometrium, uterine anomalies, protracted labor, previous uterine inversion, intrapartum therapy with magnesium sulfate, strong traction exerted on the umbilical cord, and fundal pressure.

Many cases of uterine inversion result from mismanagement of the third stage of labor in women who already are at risk for developing uterine inversion. The following maneuvers are to be avoided: excessive traction on the umbilical cord, excessive fundal pressure, excessive intra-abdominal pressure, and excessively vigorous manual removal of the placenta.

Diagnosis

The diagnosis of uterine inversion usually is obvious. Shock and hemorrhage are prominent, as is considerable pain. A dark red–blue bleeding mass is palpable and often visible at the cervix, in the vagina, or outside the vagina. A depression in the uterine fundus or even an absent fundus is noted on abdominal examination. Partial inversion in which the fundus stays within the vagina can escape immediate notice if the attendant is not aware of this complication.

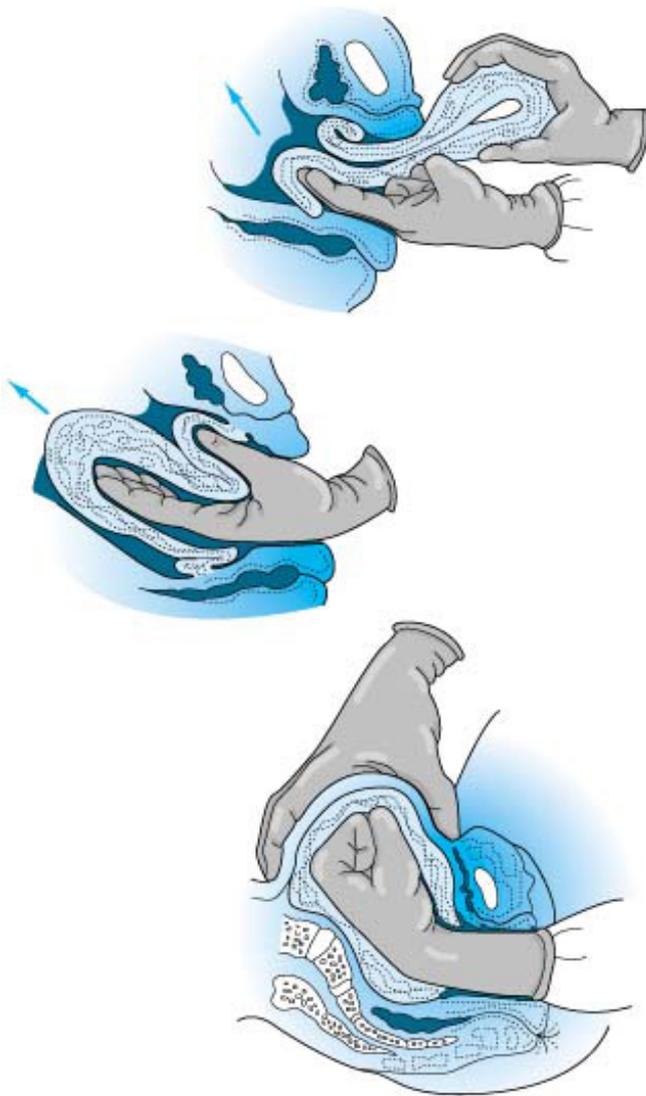

Treatment

Successful management of patients with uterine inversion depends on prompt recognition and treatment. If initial measures fail to relieve the condition, it may progress to the point at which operative treatment or even hysterectomy is necessary. Shock associated with uterine inversion typically is profound. Hemorrhage can be massive, and hypovolemia should be vigorously treated with fluid and blood replacement.

MANUAL REPOSITIONING OF THE UTERUS

Treatment should begin as soon as the diagnosis of uterine inversion is made. Assistance is vital. An initial attempt should be made to reposition the fundus. The inverted fundus, along with the placenta if it is still attached, is slowly and steadily pushed upward in the axis of the uterus (Fig 31–3). If the placenta has not separated, do not remove it until an adequate intravenous infusion has been established.

Figure 31–3.

Replacement of an inverted uterus.

If the initial attempt fails, induce general anesthesia, preferably with a halogenated agent (eg, halothane) to provide uterine relaxation. Alternatively, 50 μ g of IV nitroglycerin can be given as a bolus to relax the uterus and avoid intubation. The dose can be repeated at least once. While awaiting anesthesiology assistance, easily available tocolytics may be used effectively. Either intravenous magnesium sulfate or terbutaline 0.25 mg given as a bolus dose intravenously has been used successfully to achieve uterine relaxation in subacute inversion, and neither has been associated with bleeding.

Technique: The operator's fist is placed on the uterine fundus, and the fundus is gradually pushed back into the pelvis through the dilated cervix. The general anesthetic or uterine relaxant is discontinued. Infusion of oxytocin or ergot alkaloids is started and fluid and blood replacement continued. Alternatively, prostaglandins can be used to effect uterine contraction after repositioning. Bimanual uterine

compression and massage are maintained until the uterus is well contracted and hemorrhage has ceased. The placenta can then be removed.

Antibiotics should be started as soon as is practical. Oxytocics or ergot alkaloids are continued for at least 24 hours. Frequent determinations of the hematocrit level should be made to ascertain the need for further blood replacement. Iron supplements should begin with resumption of oral intake.

SURGICAL REPOSITIONING OF THE UTERUS

Surgical repositioning of the uterus is rarely necessary in contemporary medical practice in the United States. However, when all other efforts have failed to reposition the everted uterus, operative intervention may be lifesaving. This is generally accomplished by a vertical incision through the lower uterine segment directly posterior. The uterus is repositioned by either pulling from above or, very rarely, pushing from below (using a sterile glove). The incision is then repaired as would be any uterine incision. Blood replacement, antibiotics, and careful monitoring are necessary for successful perioperative management.

ABNORMALITIES OF THE PUERPERIUM: INTRODUCTION

When compared with the dramatic and climactic events of delivery, the puerperium may seem uneventful. Nevertheless, significant physiologic changes occur during this interval, and they undoubtedly influence many of the problems that often arise rapidly and without warning. Hypotension and shock demand urgent treatment and careful follow-up. Cardiac monitoring and insertion of Swan-Ganz or central venous pressure catheters may be prudent to permit rapid evaluation of hemodynamic status. Appropriate medical and surgical consultation are also recommended.

POSTPARTUM & PUERPERAL INFECTIONS

Infections are among the most prominent puerperal complications. An improved understanding of the natural history of female genital infections and the availability of powerful antibiotics may have produced a complacent attitude toward puerperal infections that is unrealistic. Postpartum infections still are costly to both patients and society, and they are associated with an admittedly small but not negligible threat of serious disability and death.

Puerperal morbidity due to infection has occurred if the patient's temperature is higher than 38 °C (100.4 °F) on 2 separate occasions at least 24 hours apart following the first 24 hours after delivery. Overt infections can and do occur in the absence of these criteria, but fever of some degree remains the hallmark of puerperal infection, and the patient with fever can be assumed to have a genital infection until proved otherwise.

Incidence

Puerperal infectious morbidity affects 2–8% of pregnant women and is more common in those of low socioeconomic status, who have undergone operative delivery, with premature rupture of the membranes, with long labors, or who have multiple pelvic examinations.

Morbidity & Mortality

Postpartum infections are responsible for much of the morbidity associated with childbirth, and they either are directly responsible for or contribute to the death of approximately 8% of all pregnant women who die each year. The costs are considerable, not only in additional days of hospitalization and medications but also in time lost from work.

Sterility may result from the sequelae of postpartum infections, such as periadnexal adhesions. Hysterectomy occasionally is required in patients with serious postpartum or postoperative infection.

Pathogenesis

The flora of the birth canal of pregnant women is essentially the same as that of nonpregnant women, although variations in culture techniques and in the study populations have produced markedly different results. The vaginal flora typically includes aerobic and anaerobic organisms that are commonly considered pathogenic (Table 31–1). Several mechanisms appear to prevent overt infection in the genital tract, such as the acidity of the normal vagina; thick, tenacious cervical mucus; and maternal antibodies to most vaginal flora.

Table 31–1. Percentage of Organisms Isolated from the Vagina or Cervix in Normal Pregnant and Nonpregnant Women.

Organism	Percentage Isolated
Aerobic bacteria	
<i>Lactobacillus</i>	17–97
Diphtheroids	14–83
<i>Staphylococcus epidermidis</i>	7–67
<i>Staphylococcus aureus</i>	0–12
α-Hemolytic streptococci	2–53
β-Hemolytic streptococci	0–93
Nonhemolytic streptococci	4–37
Group D streptococci	4–44
<i>Escherichia coli</i>	0–28
<i>Gardnerella vaginalis</i>	40–43
<i>Neisseria gonorrhoeae</i>	1–7
<i>Mycoplasma</i>	15–72
<i>Ureaplasma</i>	40–95
Anaerobic bacteria	
<i>Lactobacillus</i>	11–72
<i>Bacteroides fragilis</i>	0–20
<i>Bacteroides</i> species	0–50
<i>Fusobacterium</i> species	0–18
<i>Peptococcus</i> species	0–71
<i>Peptostreptococcus</i> species	12–40
<i>Veillonella</i> species	0–27
<i>Clostridium</i> species	0–17
<i>Bifidobacterium</i> species	0–32
<i>Eubacterium</i> species	0–36

During labor and particularly after rupture of the membranes, some of the protective mechanisms are no longer present. Examinations and invasive monitoring apparatus probably facilitate the introduction of

vaginal bacteria into the uterine cavity. Bacteria can be cultured from the amniotic fluid of most women undergoing intrauterine pressure monitoring, but overt postpartum infection is seen in fewer than 10% of these cases. Contractions during labor may spread bacteria present in the amniotic cavity to the adjacent uterine lymphatics and even into the bloodstream.

The postpartum uterus initially is devoid of mechanisms that keep it sterile, and bacteria may be recovered from the uterus in nearly all women in the postpartum period. Whether or not disease is clinically expressed depends on the presence of predisposing factors, the duration of uterine contamination, and the type and amount of microorganisms involved. The necrosis of decidua and other intrauterine contents (lochia) promotes an increase in the number of anaerobic bacteria, heretofore limited by lack of suitable nutrients and other factors necessary for growth.

Sterility of the endometrial cavity returns by the third or fourth postpartum week. Granulocytes that penetrate the endometrial cavity and the open drainage of lochia are effective in preventing infection in most patients.

Etiology

Almost all postpartum infections are caused by bacteria normally present in the genitalia of pregnant women. The lochia is an excellent culture medium for organisms ascending from the vagina. In women who have undergone cesarean section, more devitalized tissue and foreign bodies (sutures) are present, providing additional fertile ground for possible contamination and subsequent infection. Approximately 70% of puerperal soft-tissue infections are mixed infections consisting of both aerobic and anaerobic organisms; infections occurring in women undergoing cesarean section are more likely to be serious.

General Evaluation

The source of infection should be identified, the likely cause determined, and the severity assessed. Most women with fever in the postpartum period have endometritis. Urinary tract infection is the next most common infection. Neglected or virulent endomyometritis may progress to more serious infection. Generalized sepsis, septic pelvic thrombophlebitis, or pelvic abscess may be the end result of an initial infection of the endometrial cavity.

Endometritis

Etiology

All of the following circumstances have led to higher than normal postpartum infection rates: prolonged rupture of the membranes (> 24 hours), chorioamnionitis, an excessive number of digital vaginal examinations, prolonged labor (> 12 hours), toxemia, intrauterine pressure catheters (> 8 hours), fetal scalp electrode monitoring, preexisting vaginitis or cervicitis, operative vaginal deliveries, cesarean section, intrapartum and postpartum anemia, poor nutrition, obesity, low socioeconomic status, and coitus near term.

Cesarean section and low socioeconomic class are consistently associated with higher rates of postpartum infection, and cesarean section is easily the most common identifiable risk factor for development of puerperal infection. Some series report an infection rate of 40–80% following cesarean section delivery. Postpartum infection is more likely to be serious after cesarean section than after vaginal delivery. A history of bacterial vaginosis confers a higher risk of postcesarean endometritis.

Clinical Findings

SYMPTOMS AND SIGNS

Fever and a soft, tender uterus are the most prominent signs of endometritis. The lochia may or may not have a foul odor. Leukocytosis (white blood cell count > 10,000/ μ L) is seen. In more severe disease, high

fever, malaise, abdominal tenderness, ileus, hypotension, and generalized sepsis may be seen. Movement of the uterus causes increased pain.

Fever

Although the puerperium is a period of high metabolic activity, this factor should not raise the temperature above 37.2 °C (99 °F) and then only briefly in the first 24 hours postpartum. Modest temperature elevations may occur with dehydration. Any woman with a fever over 38 °C (100.4 °F) at any time in the puerperium should be evaluated.

Endometritis results in temperatures ranging from 38 °C to over 40 °C (100.4 °F to > 104 °F), depending on the patient, the causative microorganism, and the extent of infection. The lower range of temperatures is more common. Endometritis usually develops on the second or third postpartum day. Early fever (within hours of delivery) and hypotension are almost pathognomonic for infection with β -hemolytic streptococci.

Uterine Tenderness

The uterus is soft and exquisitely tender. Motion of the cervix and uterus may cause increased pain.

Abdominal tenderness is generally limited to the lower abdomen and does not lateralize. A carefully performed baseline examination should include an adnexal evaluation. Adnexal masses palpable on abdominal or pelvic examination are not seen in uncomplicated endometritis, but tubo-ovarian abscess may be a later complication of an infection originally confined to the uterus. Bowel sounds may be decreased and the abdomen distended and tympanitic.

Pelvic examination confirms the findings disclosed by abdominal examination.

LABORATORY FINDINGS

Hematologic Findings

Leukocytosis is a normal finding during labor and the immediate puerperal period. White blood cell counts may be as high as 20,000/ μ L in the absence of infection, so higher counts can be anticipated in infection. Bacteremia is present in 5–10% of women with uncomplicated endometritis. *Mycoplasma* is frequently recovered from the blood of patients with postpartum fever. Infections with *Bacteroides* as the predominant organism are frequently associated with positive blood cultures.

Urinalysis

Urinalysis should be routinely performed in patients thought to have endometritis because urinary tract infections are often associated with a clinical picture similar to that of mild endometritis. If pyuria and bacteria are noted in a properly collected specimen, appropriate antibiotic therapy for urinary tract infections should be started and a portion of the specimen sent for culture.

Lochia Cultures

Bacteria colonizing the cervical canal and ectocervix almost always can be recovered from lochia cultures, but they may not be the same organisms causing endometritis. Accurate cultures can be achieved only if specimens obtained transcervically are free from vaginal contamination. Material should be obtained using a speculum to allow direct visualization of the cervix and a gloved culture device (a swab that is covered while it is passed through a contaminated area, then uncovered to obtain a culture from the desired area). Transabdominal aspiration of uterine contents does secure an uncontaminated specimen, but routine use of this technique probably is not justified, and confirmation of placement within the uterine cavity may be difficult. Unless special means are taken to prevent cervical contamination and to ensure the recovery of anaerobic species, results of lochia cultures must be interpreted with great care.

Bacteriologic Findings

Although the organisms responsible for puerperal infections vary considerably among hospitals, most

puerperal infections are due to anaerobic streptococci, gram-negative coliforms, *Bacteroides* spp., and aerobic streptococci. *Chlamydia* and *Mycoplasma* are also implicated in many postpartum infections, but clinical isolates are rare because of the difficulty in culturing these organisms. Gonococci are recovered in varying degrees. The percentage of representative microorganisms recovered from women with endometritis is given in Table 31–2.

Table 31–2. Percentage of Organisms Recovered from Women with Postpartum Endomyometritis.

Organism	Percentage Isolated
Aerobic bacteria	
Group A streptococci	2–6
Group B streptococci	6–21
Group D streptococci	3–14
<i>Enterococcus</i>	12–21
Other streptococci	32
<i>Staphylococcus epidermidis</i>	28
<i>Staphylococcus aureus</i>	10
<i>Escherichia coli</i>	13–36
Gonococci	1–40
<i>Gardnerella vaginalis</i>	16
Anaerobic bacteria	
<i>Bacterioides fragilis</i>	19–75
<i>Bacteroides</i> species	17–100
<i>Peptococcus</i>	4–40
<i>Peptostreptococcus</i>	15–54
<i>Veillonella</i> species	10
<i>Clostridium</i> species	4–32

Patterns of bacterial isolates in puerperal infections in the patient's hospital are more important in guiding selection of appropriate antibiotics than are studies from the literature.

AEROBIC BACTERIA

Group A streptococci are no longer a major cause of postpartum infection, but infection with these organisms still occurs occasionally. If more than an isolated instance of infection due to these streptococci occurs, immediate measures should be taken to halt a potential epidemic. Penicillin is highly effective.

In as many as 30% of women with clinically recognized endometritis, group B streptococci are partly or wholly responsible for the infection. Classic presenting signs are high fever and hypotension shortly after delivery. However, group B streptococci are commonly recovered from the vaginas of pregnant women whether or not they have endometritis. Why some women with positive cultures develop serious illness whereas others do not undoubtedly depends on the presence of predisposing factors as well as other, as yet unknown, elements. It is interesting that positive cultures in women do not correlate well with the

incidence of streptococcal infection in their newborns. Penicillin is the treatment of choice for patients with endometritis.

Group D streptococci, which include *Streptococcus faecalis*, are common isolates in endometritis. Ampicillin in high doses is the treatment of choice. Aminoglycosides are also effective against this group.

Staphylococcus aureus is not commonly seen in cultures from women with postpartum infections of the uterus. *Staphylococcus epidermidis* is frequently recovered from women with postpartum infections. These organisms are typically not seen in pure culture. When established staphylococcal infections require treatment, nafcillin, cloxacillin, or cephalosporins should be used.

Among the gram-negative aerobic organisms likely to be recovered in postpartum uterine infections, *Escherichia coli* is the most common. In postpartum uterine infections, *E coli* is more likely to be isolated from seriously ill patients, whereas in urinary tract infections, it is the most commonly isolated organism but is not necessarily found in the sickest patients. Hospital-acquired *E coli* is most susceptible to aminoglycosides and cephalosporins.

The incidence of *Neisseria gonorrhoeae* is 2–8% in pregnant women antepartum. Unless repeat screening examinations and treatment of patients with positive cultures are undertaken in women near term, the incidence of asymptomatic endocervical gonorrhea at delivery probably is only slightly less, and it is reasonable to believe that some cases of puerperal endometritis are gonococcal in origin.

Gardnerella vaginalis, a cause of vaginitis, is seen in isolates from women with postpartum infections, usually in those with a polymicrobial cause, although pure isolates have been reported.

Other gram-negative bacilli that are commonly encountered on medical and surgical wards (eg, *Klebsiella pneumoniae*, *Enterobacter*, *Proteus*, and *Pseudomonas* spp.) are uncommon causes of endometritis.

ANAEROBIC BACTERIA

Anaerobic bacteria are involved in puerperal infections of the uterus in at least 50% and perhaps as many as 95% of cases. They are much less commonly seen in urinary tract infections. Anaerobic Peptostreptococci and Peptococci are commonly recovered in specimens from women with postpartum infection, particularly with other anaerobic species. Clindamycin, chloramphenicol, and the newer cephalosporins are active against these organisms.

Bacteroides spp., particularly *Bacteroides fragilis*, are commonly found in mixed puerperal infections. These are likely to be the more serious infections (eg, puerperal pelvic abscess, cesarean section wound infections, and septic pelvic thrombophlebitis). When infection with this organism is suspected or confirmed, clindamycin, chloramphenicol, or third-generation cephalosporins should be used.

Gram-positive anaerobic organisms are represented only by *Clostridium perfringens*, which is not infrequently isolated from an infected uterus but which is a rare cause of puerperal infection.

OTHER ORGANISMS

Mycoplasma and *Ureaplasma* spp. are common genital pathogens that have been isolated from the genital tract and blood of postpartum women both with and without overt infection. These pathogens are frequently found in the presence of other bacteria. The role of these organisms in puerperal infections is unknown.

Chlamydia trachomatis is now thought to be the leading cause of pelvic inflammatory disease in some populations. Because the population most at risk for pelvic inflammatory disease is the same as that most likely to become pregnant, it is not surprising that *Chlamydia* is in some way involved in puerperal infections, but it is infrequently isolated as a cause of early postpartum endometritis. *Chlamydia* is more frequently associated with mild late-onset endometritis, so cultures for this organism should be obtained

from patients with endometritis diagnosed several days after delivery. *Chlamydia* is difficult to culture, and it is possible that as more effective culture techniques become available, the place of this organism in the morbidity associated with postpartum infections will be clarified.

Differential Diagnosis

In the immediate postpartum period, involuntary chills are common and are not necessarily an indication of overt infection. Lower abdominal pain is common as the uterus undergoes involution with continuing contractions.

Extragenital infections are much less common than endometritis and urinary tract infections. Most of these infections can be effectively ruled out by history and examination alone. Patients should be asked, at a minimum, about coughing, chest pain, pain at the insertion site of intravenous catheters, breast tenderness, and leg pain. Examination of the breasts, chest, intravenous catheter insertion site, and leg veins should determine whether these areas might be the source of the postpartum fever. Chest x-ray films are rarely of benefit unless signs and symptoms point to a possible pulmonary cause of the fever.

Treatment

The choice of antibiotics for treatment of endometritis depends on the suspected causative organisms and the severity of the disease. If the illness is serious enough to require antibiotics, initial therapy should consist of intravenous antibiotics in high doses. Factors reinforcing the need for this approach include the large volume of the uterus, the expanded maternal blood volume, the brisk diuresis associated with the puerperium, and the difficulty in achieving adequate tissue concentrations of the antibiotic distal to the thrombosed myometrial blood vessels. Clindamycin plus an aminoglycoside is a standard first-line regimen. Good evidence now indicates that once-a-day dosing of gentamicin is as effective as the traditional thrice-daily regimen. Single-agent therapy with second- or third-generation cephalosporins is an acceptable alternative.

The response to therapy should be carefully monitored for 24–48 hours. Deterioration or failure to respond determined both clinically and by laboratory test results requires a complete re-evaluation. Ampicillin is added when the patient has a less than adequate response to the usual regimen, particularly if *Enterococcus* spp. are suspected.

Intravenous antibiotics are continued until the patient has been afebrile for 24–48 hours. Randomized and prospective trials have shown that additional treatment with oral antibiotics after intravenous therapy is unnecessary. Patients with documented concurrent bacteremia can be treated similarly, unless they have persistently positive blood cultures or a staphylococcal species cultured. If the patient remains febrile despite the standard antibiotic regimens, further evaluation should be initiated to look for abscess formation, hematomas, wound infection, and septic pelvic thrombophlebitis.

For patients known to be infected or at extremely high risk for infection at the time of delivery, initial therapy with 2- or 3-drug regimens in which 1 of the agents is clindamycin is prudent. Single-agent intravenous infusion of broad-spectrum agents such as piperacillin or ceftiofex appears to be equally effective.

Urinary Tract Infection

Approximately 2–4% of women develop a urinary tract infection postpartum. Following delivery, the bladder and lower urinary tract remain somewhat hypotonic, and residual urine and reflux result. This altered physiologic state, in conjunction with catheterization, birth trauma, conduction anesthesia, frequent pelvic examinations, and nearly continuous contamination of the perineum, is sufficient to explain the high incidence of lower urinary tract infections postpartum. In many women, preexisting

asymptomatic bacteria, chronic urinary tract infections, and anatomic disorders of the bladder, urethra, and kidneys contribute to urinary tract infection postpartum.

Clinical Findings

SYMPTOMS AND SIGNS

Urinary tract infection usually presents with dysuria, frequency, urgency, and low-grade fever; however, an elevated temperature is occasionally the only symptom. White blood cells and bacteria are seen in a centrifuged sample of catheterized urine. A urine culture should be obtained. The history should be reviewed for evidence of chronic antepartum infections. If a woman had an antepartum urinary tract infection, then her postpartum infection likely is caused by the same organism. Repeated urinary tract infections call for careful postpartum evaluation. Urethral diverticulum, kidney stones, and upper urinary tract anomalies should be ruled out.

Urinary retention postpartum in the absence of regional anesthesia or well after its effects have worn off almost always indicates urinary tract infection.

Pyelonephritis may be accompanied by fever, chills, malaise, and nausea and vomiting. Characteristic signs of kidney involvement associated with pyelonephritis include costovertebral angle tenderness, dysuria, pyuria, and, in the case of hemorrhagic cystitis, hematuria.

LABORATORY FINDINGS

E coli is easily the most common organism isolated from infected urine in postpartum women (approximately 75% of cases). Other gram-negative bacilli are much less likely to be recovered. *E coli* is less likely to be the causative organism in women who had repeated urinary tract infections in the recent past.

Treatment

Antibiotics with specific activity against the causative organism are the cornerstone of therapy in uncomplicated cystitis. These drugs include sulfonamides, nitrofurantoin, trimethoprim-sulfamethoxazole, oral cephalosporins (cephalexin, cephradine), and ampicillin. Some hospitals report a high incidence of microbial resistance to ampicillin. The oral combination of amoxicillin-clavulanic acid provides a better spectrum of bacterial sensitivity. Sulfa antibiotics can be used safely in women who are breastfeeding if the infants are term without hyperbilirubinemia or suspected glucose-6-phosphate dehydrogenase deficiency. High fluid intake should be encouraged.

Pyelonephritis requires initial therapy with high doses of intravenous antibiotics, such as ampicillin 8–12 g/d or first-generation cephalosporins (cefazolin 3–6 g/d, cephalothin 4–8 g/d). An aminoglycoside can be added when resistant organisms are suspected or when the patient has clinical signs of sepsis. A long-acting third-generation cephalosporin, such as ceftriaxone 1–2 g every 12 hours, also can be used. The response to therapy may be rapid, but some women respond with gradual defervescence over 48 hours or longer. Urine cultures should be obtained to guide any necessary modifications in drug therapy if the patient's response is not prompt. Even with prompt resolution of fever, antibiotic therapy should be continued intravenously or orally for a total of 10 days. Urine for culture should be obtained at a postpartum visit after therapy has been completed.

Pneumonia

Women with obstructive lung disease, smokers, and those undergoing general anesthesia have an increased risk for developing pneumonia postpartum.

Clinical Findings

SYMPTOMS AND SIGNS

Symptoms and signs are the same as those of pneumonia in nonpregnant patients: productive cough, chest pain, fever, chills, rales, and infiltrates on chest x-ray film. In some cases, careful differentiation from pulmonary embolus is required.

X-RAY AND LABORATORY FINDINGS

Chest x-ray film confirms the diagnosis of pneumonia. Gram-stained smears of sputum and material for culture should be obtained.

Streptococcus pneumoniae and *Mycoplasma pneumoniae* are the 2 most likely causative organisms. *S pneumoniae* can easily be identified on gram-stained smears. Infection with *M pneumoniae* can be suspected on clinical grounds.

Treatment

Appropriate antibiotics, oxygen (if the patient is hypoxic), intravenous hydration, and pulmonary toilet are the mainstays of therapy.

Cesarean Section Wound Infection

Incidence

Wound infection occurs in 4–12% of patients following cesarean section.

Etiology

The following risk factors predispose to subsequent wound infection in women undergoing cesarean section: obesity, diabetes, prolonged hospitalization before cesarean section, prolonged rupture of the membranes, chorioamnionitis, endomyometritis, prolonged labor, emergency rather than elective indications for cesarean section, and anemia.

Clinical Findings

SYMPTOMS AND SIGNS

Fever with no apparent cause that persists to the fourth or fifth postoperative day strongly suggests a wound infection. Wound erythema and tenderness may not be evident until several days after surgery. Occasionally, wound infections are manifested by spontaneous drainage, often accompanied by resolution of fever and relief of local tenderness. Rarely, a deep-seated wound infection becomes apparent when the skin overtly separates, usually after some strenuous activity by the patient.

LABORATORY FINDINGS

Gram-stained smears and culture of material from the wound may be helpful in guiding selection of the initial antibiotic. Blood cultures may be positive in the patient with systemic sepsis due to wound infection. The organisms responsible for most wound infections originate on the patient's skin. *S aureus* is the organism most commonly isolated. *Streptococcus* species, *E coli*, and other gram-negative organisms that may originally have colonized the amniotic cavity are also seen. Occasionally, *Bacteroides*, which comes only from the genital tract, is isolated from material taken from serious wound infections.

Rarely, necrotizing fasciitis and the closely related synergistic bacterial gangrene can involve cesarean section incisions. They are recognized by their intense tissue destruction, lack of sensation in the involved tissues, and rapid extension. Radical debridement of necrotic and infected tissue is the cornerstone of treatment.

Treatment

INITIAL EVALUATION

The incision should be opened along its entire length and the deeper portion of the wound gently

explored to determine whether fascial separation has occurred. If the fascia is not intact, the wound is dissected to the fascial level, debrided, and repaired. Wound dehiscence has a high mortality rate and should be treated aggressively. Dehiscence is uncommon in healthy patients and with Pfannenstiel incisions. The skin can be left open to undergo delayed closure or to heal by primary intention.

If the fascia is intact, the wound infection can be treated by local measures.

DEFINITIVE MEASURES

Mechanical cleansing of the wound is the mainstay of therapy for cesarean wound infection. Opening the wound encourages drainage of infected material. The wound can be packed with saline-soaked gauze 2–3 times per day, which will remove necrotic debris each time the wound is unpacked. The wound can be left open to heal, or it can be closed secondarily when granulation tissue has begun to form.

Antibiotic Prophylaxis for Cesarean Section

The high rate of infection (averaging 35–40%) following cesarean section is sufficient reason to consider prophylactic perioperative antibiotic administration in high-risk patients. If possible, a single drug should be used because of the convenience. The drug should have a wide spectrum of activity, including reasonably good activity against pathogens likely to be present at the incision site. The dosage regimen should be designed to ensure adequate tissue levels at the time the operation begins or shortly thereafter. The drug should not be one that is used to treat serious, established infections. The duration of therapy should be short. (Antibiotics administered for > 48 hours can hardly be called prophylactic.) The drug should be free of major side effects and should be relatively inexpensive.

One drug commonly used is cefazolin 1 g intravenously when the umbilical cord is clamped, followed by 2 similar doses at 6-hour intervals. A single dose has been shown to be as effective as a 3-dose regimen. Almost all studies on the use of prophylactic antibiotics in patients with cesarean section deliveries have shown significant reductions in the incidence of infection, regardless of the drugs, doses, and schedules used. However, no regimen has provided total protection against the incidence of fever and associated morbidity, nor has one completely prevented serious postoperative infections. Low-risk women, that is, those undergoing elective cesarean section who are not in active labor, do not benefit to the same degree from prophylactic antibiotics.

Episiotomy Infection

It is surprising that infected episiotomies do not occur more often than they do, because contamination at the time of delivery is universal. Subsequent contamination during the healing phase also should be common, yet infection and disruption of the wound are infrequent (0.5–3%). The excellent local blood supply is suggested as an explanation for this phenomenon.

Etiology

In general, the more extensive the laceration or episiotomy, the greater the chances for infection and breakdown of the wound. More tissue is devitalized in a large episiotomy, thereby providing greater opportunity for contamination. Women with infections elsewhere in the genital area probably are at greater risk for infection of the episiotomy.

Clinical Findings

SYMPTOMS AND SIGNS

Pain at the episiotomy site is the most common symptom. Spontaneous drainage is frequent, so a mass rarely forms. Incontinence of flatus and stool may be the presenting symptom of an episiotomy that breaks down and heals spontaneously.

Inspection of the episiotomy site shows disruption of the wound and gaping of the incision. A necrotic

membrane may cover the wound and should be debrided if possible. A careful rectovaginal examination should be performed to determine whether a rectovaginal fistula has formed. The integrity of the anal sphincter should be evaluated.

LABORATORY FINDINGS

Infection with mixed aerobic and anaerobic organisms is common. *Staphylococcus* may be recovered from cultures of material from these infections. Culture results frequently are misleading because the area of the episiotomy typically is contaminated with a wide variety of pathogenic bacteria.

Treatment

Initial treatment should be directed toward opening and cleaning the wound and promoting the formation of granulation tissue. Warm sitz baths or Hubbard tank treatments help the debridement process. Attempts to close an infected, disrupted episiotomy are likely to fail and may make ultimate closure more difficult. Surgical closure by perineorrhaphy should be undertaken only after granulation tissue has thoroughly covered the wound site. There is an increasing trend towards early repair of episiotomy wound dehiscence, in contrast to conventional wisdom, which suggests a 3- to 4-month delay. Several large case series show excellent results once initial infection is treated.

Mastitis

Congestive mastitis, or breast engorgement, is more common in primigravidas than in multiparas. Infectious mastitis and breast abscesses also are more common in women pregnant for the first time and are seen almost exclusively in nursing mothers.

Etiology

Infectious mastitis and breast abscesses are uncommon complications of breastfeeding. They almost certainly occur as a result of trauma to the nipple and the subsequent introduction of organisms from the infant's nostrils to the mother's breast. *S aureus* contracted by the infant while in the hospital nursery is the usual causative agent.

Clinical Findings

SYMPTOMS AND SIGNS

Breast engorgement usually occurs on the second or third postpartum day. The breasts are swollen, tender, tense, and warm. The patient's temperature may be mildly elevated. Axillary adenopathy can be seen.

Mastitis presents 1 week or more after delivery. Usually only 1 breast is affected and often only 1 quadrant or lobule. It is tender, reddened, swollen, and hot. There may be purulent drainage, and aspiration may produce pus. The patient is febrile and appears ill.

LABORATORY FINDINGS

The organism responsible for infectious mastitis and breast abscess almost always is *S aureus*. *Streptococcus* spp. and *E coli* are occasionally isolated. Leukocytosis is evident.

Treatment

CONGESTIVE MASTITIS

The form of treatment depends on whether or not the patient plans to breastfeed. If she does not, tight breast binding, ice packs, restriction of breast stimulation, and analgesics help to relieve pain and suppress lactation. Medical suppression of lactation probably does not hasten involution of congested breasts unless the drug is taken very early after delivery. Bromocriptine 2.5 mg twice daily orally for 10 days is an effective regimen, although concerns about its side-effect profile have curtailed its use. For the

woman who is breastfeeding, manually emptying the breasts following infant feeding is all that is necessary to relieve discomfort.

INFECTIOUS MASTITIS

Infectious mastitis is treated in the same way as congestive mastitis. Local heat and support of the breasts help to reduce pain. Cloxacillin, dicloxacillin, nafcillin, or a cephalosporin—antibiotic with activity against the commonly encountered causative organisms—should be administered. Infants tolerate the small amount of antibiotics in breast milk without difficulty. It may be prudent to check the infant for possible colonization with the same bacteria present in the mother's breast.

If an abscess is present, incision and drainage are necessary. The cavity should be packed open with gauze, which is then advanced toward the surface in stages daily. Most authorities recommend cessation of breastfeeding when an abscess develops. Antistaphylococcal antibiotics should be prescribed. Inhibition of lactation is also recommended.

DISORDERS OF LACTATION

Inhibition & Suppression of Lactation

Anatomic alteration of the breasts during pregnancy prepares them for sustained milk production shortly after delivery. The rapid decrease of serum estrogen and progesterone levels postpartum does not occur in prolactin levels, which decrease much more slowly. The breast is no longer subject to the inhibitory effects of the steroid hormones and now comes under the influence of high prolactin levels to begin sustained milk production.

Colostrum is secreted in late pregnancy and for the first 2–3 days postpartum. It is higher in protein (much of which may be antibodies) and minerals and lower in carbohydrates and fat than is later breast milk. Prior to full milk production, from the second to the fourth postpartum days, the breasts become enlarged, engorged, and tender. The breast lobules enlarge, and alveoli and blood vessels proliferate. Milk production truly begins around the third or fourth postpartum day. Fortuitously, infants may frequently take this long to feel a sensation of hunger and to develop the neuromuscular control necessary to successfully empty the breast.

In spite of the manifold benefits of breastfeeding for both infants and mothers, at least one-third of all women who give birth today do not wish to nurse, and perhaps an additional 10–20% discontinue attempts within a few weeks of delivery. For these women, inhibition of lactation for relief of breast congestion and tenderness may be necessary.

PHYSICAL METHODS OF SUPPRESSION OF LACTATION

Inhibition of physical stimuli that encourage milk secretion can prevent lactation. Tight breast binding, avoidance of any tactile breast stimulation, ice packs, and mild analgesics (eg, aspirin or ibuprofen) are effective in inhibiting lactation and relieving the symptoms of breast engorgement in 50% of women. Physical methods successfully inhibit lactation and prevent breast engorgement either before the onset of lactation or after it has been established for some time.

HORMONAL SUPPRESSION OF LACTATION

Large doses of estrogen alone have been used to suppress lactation; they do inhibit milk production, probably by acting directly on the breast. Estrogens are somewhat more successful than physical methods alone. Side effects are tolerable in young women who have had vaginal deliveries, but increased rates of thrombophlebitis and pulmonary embolism are seen in women older than 35 years, in those who have undergone cesarean section, and in women with difficult deliveries. For these reasons, pure estrogens are no longer used for suppression of lactation as they once were. Furthermore, drug-induced suppression of lactation is not very effective after lactation has been established.

The ergot derivative bromocriptine has strong prolactin-inhibiting and thus lactation-inhibiting properties. In the dosage ranges used to suppress lactation, the drug is relatively free of serious side effects. Minor side effects include nausea and nasal congestion. More serious associations with hypertension, cerebrovascular accidents, and myocardial infarction have been reported. The risks seem to be reported frequently when bromocriptine is used in patients with pregnancy-induced hypertension. Drawbacks of bromocriptine therapy include the necessity for prolonged treatment (10–14 days) and a more rapid resumption of ovulation. A significant number of women have rebound lactation (18–40%). The Food and Drug Administration (FDA) removed painful breast engorgement as an indication for bromocriptine use in 1989. The FDA noted that although there is no clear proof of adverse effects of these medications, there is no proved health benefit, so even minor safety concerns become significant because of their potential unfavorable effects on the benefit/risk ratio. Bromocriptine may be a reasonable treatment option in women with severe congestive mastitis.

Inappropriate Lactation

Lactation is physiologic in late pregnancy and for a considerable period after delivery. In the woman who has not lactated for 1 year or more or who has never been pregnant, lactation may indicate a significant endocrinopathy.

POSTPARTUM MONITORING

Serious and acute obstetric and postanesthetic complications often occur during the first few hours immediately following delivery. Therefore the patient should be transferred to a recovery room where she can be constantly attended to and where observation of bleeding, blood pressure, pulse, and respiratory change can be made every 15 minutes for at least 1–2 hours after delivery or until the effects of general or major regional anesthesia have disappeared. On return to the patient's room or ward, the patient's blood pressure should be taken and the measurement repeated every 12 hours for the first 24 hours and daily thereafter for several days. Preeclampsia–eclampsia, infection, or other medical or surgical complications of pregnancy may require more prolonged and intensive postpartum care.

POSTPARTUM COMPLICATIONS

Complications of Anesthesia

The most common respiratory complications that follow general anesthesia and delivery are airway obstruction or laryngospasm and vomiting with aspiration of vomitus. Bronchoscopy, tracheostomy, and other related procedures must be performed promptly as indicated. Hypoventilation and hypotension may follow an abnormally high subarachnoid block. Because serum cholinesterase activity is lower during labor and the postpartum period, hypoventilation during the early puerperium may follow the use of large amounts of succinylcholine during anesthesia for cesarean section. Brief postpartum shivering is commonly seen after completion of the third stage of labor and is no cause for alarm. The cause of the shivering is unknown, but it may be related to loss of heat, or it may be a sympathetic response. Subcutaneous emphysema may appear postpartum after vigorous bearing-down efforts. Most cases resolve spontaneously.

If preeclampsia has been ruled out, hypertension in the immediate puerperium may be due to excessive use of vasopressor or oxytocic drugs. It must be treated promptly with a vasodilator. Hydralazine 5 mg administered slowly intravenously usually reduces the blood pressure.

Postanesthetic complications that manifest themselves later in the puerperium include postsubarachnoid puncture headache, atelectasis, renal or hepatic dysfunction, and neurologic sequelae.

Postpuncture headache usually is located in the forehead, deep behind the eyes; occasionally, the pain

radiates to both temples and to the occipital region. It usually begins on the first or second postpartum day and lasts 1–3 days. Because new mothers frequently develop various types of headache, the correct diagnosis is essential. An important characteristic of postspinal puncture headache is increased pain in the sitting or standing position and significant improvement when the patient is supine. The mild form is relieved by aspirin or other analgesics. Headache is due to leakage of cerebrospinal fluid through the site of dural puncture into the extradural space. It is advisable to supplement the daily oral intake of fluids with at least 1 L of 5% glucose in saline intravenously. Administration of 7–10 mL of the patient's own blood into the thecal space at the point of previous needle insertion will "patch" the leaking point and relieve the headache in most patients. Subdural hematoma is a rare complication of chronic leakage of cerebrospinal fluid and resultant loss of support to intracranial structures.

A small percentage of women who develop headaches during this time also show symptoms of meningeal irritation. Headache due to aseptic chemical meningitis is not relieved by lying down. Lumbar puncture reveals a slightly elevated pressure and an increase in spinal fluid protein and white blood cells but no bacteria. Symptoms usually disappear 1–3 days later, and the spinal fluid returns to normal within 4 days with no sequelae. Treatment is conservative and includes supportive measures, analgesics, and fluids.

Neurologic problems in the puerperium sometimes follow traumatic childbirth, such as injury to the femoral nerve caused by forceps when the patient was in the lithotomy position. Such complications are rarely bilateral, which aids in the differential diagnosis of a spinal cord lesion. Evidence of more serious neurologic sequelae following regional or general anesthesia for delivery requires consultation with the anesthesiologist or a neurologist.

Postpartum Cardiac Problems

The puerperium is relatively complicated for the patient with congenital or acquired heart disease. Following delivery, the cardiovascular system responds with sharply increased cardiac output as a result of unimpeded venous return from the lower extremities and pelvis. This produces a relative bradycardia that may persist for several days. For the initial few days after delivery, the intracellular water and sodium retained during pregnancy are mobilized and contribute to increasing cardiac output. A concomitant postpartum diuresis gradually mitigates the bradycardia and increases cardiac output (see Chapter 7).

Valvular Heart Disease

The management principles underlying treatment of valvular heart disease in the postpartum period are those instituted in the intrapartum period: antibiotic prophylaxis of bacterial endocarditis, careful fluid and electrolyte administration, accurate (often continuous invasive) monitoring, and frequent physical examinations to detect changes in cardiovascular status. Return to an ambulatory state soon after delivery reduces the possibility of thrombophlebitis. The postpartum period is also a time for the patient to carefully consider further childbearing options in light of the fetal outcome and the possible progression of heart disease during the antecedent pregnancy.

Women whose valvular heart disease required systemic anticoagulation before delivery should continue the treatment postpartum; however, oral anticoagulants can be used instead of heparin. There are no reports of problems in term breastfed infants of women taking warfarin or dicumarol. Other oral anticoagulants are contraindicated if the patient is breastfeeding.

Postpartum Cardiomyopathy

A cardiomyopathy unique to the latter half of pregnancy and the puerperium has been described by numerous investigators. The incidence is estimated to be 1 in 4000 deliveries. Congestive heart failure, cardiomegaly, and cardiac arrhythmias develop in otherwise healthy young women. This problem is

addressed in Chapter 22A on cardiac disease in pregnancy.

Postpartum Pulmonary Problems

Return to nonpregnant pulmonary physiology occurs by 6 weeks after delivery. Except for women undergoing general anesthesia, the puerperium is not a time of special concern. The factors placing pregnant women at risk for highly destructive chemical aspiration pneumonitis (gastric pH < 2.5 and fasting gastric contents > 25 mL) persist for at least 48 hours after delivery. Thus, women undergoing general anesthesia in the puerperium (eg, for tubal ligation) are at high risk for aspiration. A nonparticulate antacid should be used preoperatively for women undergoing general anesthesia in the puerperal period as well as other anesthetic techniques (rapid sequence induction of anesthesia, endotracheal intubation, and preanesthetic fasting) designed to prevent aspiration of gastric contents.

Pulmonary hypertension, either primary or secondary to congenital heart disease, is an overt threat to the mother's life in the intrapartum and postpartum periods. The most important management principle is to use invasive monitoring to avoid hypovolemia (see Chapter 22A).

Postpartum Thyroiditis

Thyroid abnormalities, particularly of immunologic origin, are common in the postpartum period. Although racial differences exist, between 3% and 17% of women will develop postpartum thyroiditis, and over half of these women will have positive microsomal antibody titers. Patients with known Graves' disease are at particular risk; even if they are euthyroid at time of delivery, approximately 10% will experience postpartum hyperthyroidism. Postpartum thyroiditis usually presents with mild transient hyperthyroidism 3–8 months postpartum, followed by mild and transient hypothyroidism, although simple hypothyroidism or hyperthyroidism may be seen. Suppression of hyperthyroid symptoms or temporary thyroid hormone supplementation may be necessary, but most women recover completely and are euthyroid within 6–9 months after delivery. The recurrence risk for postpartum thyroiditis in a subsequent pregnancy is 10–25%.

Postpartum Thrombophlebitis & Thromboembolism

Historically, the puerperium has been known as the time for occurrence of severe thrombophlebitic conditions and pulmonary embolism, probably as a result of the once-prevalent recommendation of prolonged bed rest following parturition. Even though contemporary postpartum management encourages early ambulation, puerperal thrombophlebitis and thromboembolism remain a serious problem.

Thrombophlebitis requires careful and prolonged medical management. The risk of recurrence in a subsequent pregnancy is substantial, and a history of thrombophlebitis may prohibit the future use of oral contraceptives and replacement estrogens.

The incidence of thrombophlebitic conditions is difficult to estimate because the clinical diagnosis of these disorders is highly unreliable. One study of venographically confirmed deep venous thrombosis reported 1.3 antepartum cases per 10,000 deliveries and 6.1 postpartum cases per 10,000 deliveries. Most studies confirm that the incidence of superficial thrombophlebitis, deep vein thrombosis, and pulmonary embolism is 2–6 times higher in the postpartum period than in the antepartum period, although these data may be influenced by the effects of the prolonged postpartum bed rest once advocated. (Methods of diagnosis and treatment of thromboembolic conditions are discussed in Chapter 26.)

Postpartum Neuropsychiatric Complications

Peripheral Nerve Palsy

Nerve palsies involving pelvic nerves or parts of the lumbosacral plexus result from pressure by the presenting part or trauma by obstetric forceps. Typically, the palsy occurs after prolonged labor in a nullipara and presents as unilateral footdrop noted when ambulation resumes after delivery. Most cases resolve spontaneously in a matter of days or weeks. A few may have a more protracted course. Electromyography may help in predicting the course of the disorder.

Seizures

Postpartum seizures immediately raise the possibility of eclampsia, but if the interval since delivery is more than 48 hours, other etiologies should be considered. In the absence of a history of epilepsy or signs of pregnancy-induced hypertension, a thorough evaluation to determine the cause of the seizures must be performed.

Postpartum Depression

Considering the excitement, anticipation, and tension associated with imminent delivery, the marked hormonal alterations following delivery, and the substantial new burdens and responsibilities that result from childbirth, it is not surprising that some women experience depression after delivery. The incidence of postpartum depression is difficult to estimate, but the disorder is common. The disorder in its usual form is self-limited and benign. However, hypothyroidism is emerging as a cause of some cases of postpartum depression, and screening for this disorder should be considered if suggested by clinical presentation.

In women who suffered from depression before they became pregnant and in those without effective support mechanisms, the severity of depression may be more profound and the consequences far more serious. An openly psychotic state may develop within a few days after delivery and render the woman incapable of caring for herself or her newborn. In some cases she may harm her infant and herself.

Psychiatric consultation should be obtained for the postpartum woman who shows symptoms of severe depression or overt psychosis. Nursery personnel are often the first to notice that the new mother does not devote the usual amount of attention to her newborn (see Chapter 62).

Current OB/GYN >Chapter 32. The Resuscitation & Care of the Newborn at Risk>

THE RESUSCITATION & CARE OF THE NEWBORN AT RISK: INTRODUCTION

Delivery of a high-risk fetus requires multidisciplinary prenatal decision making to ensure the best outcome for the newborn and mother. Obstetricians, neonatologists, and, in appropriate cases, pediatric medical and/or surgical subspecialists must work together to determine an appropriate plan of care for the fetus and delivery of the newborn and provide counseling for the family. Discovery of a significant complication during pregnancy often warrants referral of the mother to a perinatologist for further evaluation and possible treatment. When circumstances allow, the mother of a high-risk fetus should be transferred to a tertiary care center with experience in high-risk obstetric and neonatal care prior to delivery. Numerous studies have shown improved outcomes for low-birth-weight (LBW) infants (< 2500 g) with delivery at a center with a higher level of neonatal care.

Successful transition from fetal to ex utero life involves a complex series of hormonal and physiologic changes, many of which occur or begin before birth. Events such as cord compression, placental abruption, meconium aspiration, and premature delivery or the presence of infection or major congenital malformations may alter or prevent the essential postnatal transition. Any process that prevents or hinders the newborn from inflating the lungs with air, establishing effective ventilation, oxygenation, and/or circulation will result in a depressed newborn in need of resuscitation for survival.

RESUSCITATION OF THE HIGH-RISK INFANT

The American Academy of Pediatrics (AAP) guidelines mandate that at least 1 skilled person capable of carrying out resuscitation of a newborn be present at every delivery. When a delivery is identified as high risk, 2 or more skilled people may be required to provide adequate care. Often it is useful to assign roles to the resuscitation staff to ensure that the resuscitation flows as smoothly as possible. The equipment required for resuscitation, such as the bag and mask used for ventilation, the blender for oxygen and air delivery, the suction equipment, the radiant warmer, and the monitors, should be checked prior to the delivery. Communication between the obstetric and neonatal staff and the maternal medical and obstetric history as well as the prenatal history of the fetus is essential to ensure that the neonatal team can anticipate and interpret the problems the newborn may have in the delivery room.

Delivery Room Management

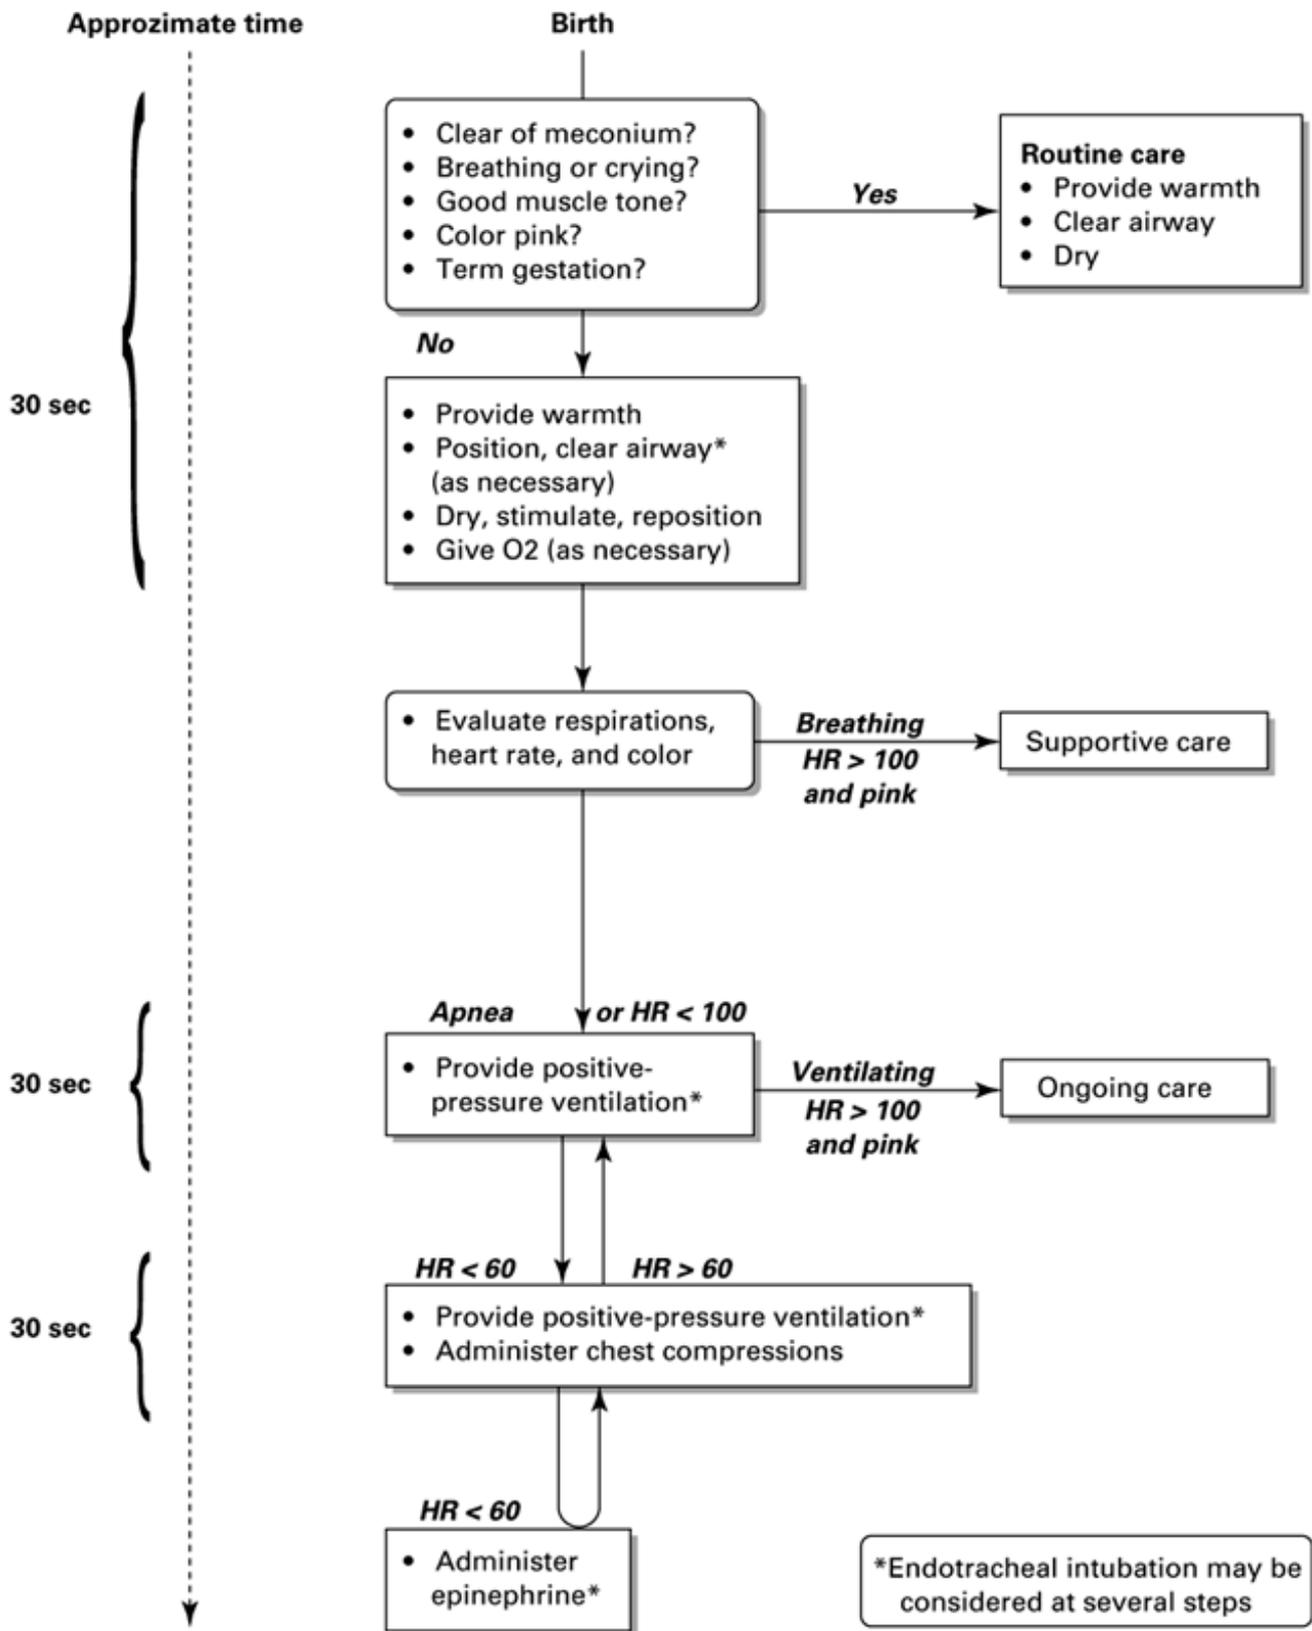

Although the expectations may be different and the need for resuscitation more common, the same principles apply to a high-risk delivery as to a routine delivery: the newborn should be kept warm and rapidly assessed to determine the need for intervention.

The initial evaluation and resuscitation may take place in the delivery room or, in centers with a high-risk delivery service, preferentially in an adjacent room specifically designed for high-risk resuscitations. Typically the newborn is brought immediately to a radiant warmer, although some institutions weigh extremely premature infants prior to transfer to the warmer bed in order to determine the birth weight if viability is in question. The infant is dried with prewarmed towels to prevent heat loss. At some centers LBW newborns are put into polyurethane bags or wrapped with polyethylene occlusive wrap after delivery; these measures have been shown to significantly improve

temperature stability during stabilization and transport to the neonatal intensive care unit (NICU). In addition, a hat is used to prevent heat loss from the head. Preterm infants are at increased risk for thermal instability given greater body surface area to weight ratio, thinner skin, and relative paucity of subcutaneous fat compared to term infants. Hypothermia (body temperature < 36 C) can occur rapidly in the preterm infant and may cause complications such as hypoglycemia and acidosis.

After rapidly drying the infant and removing the wet towels, the resuscitation team should position and clear the airway. The team then assesses the newborn's respiratory effort, heart rate, color and activity to determine the need for intervention. Figure 32–1 depicts the most recent AAP algorithm for neonatal evaluation and resuscitation. Drying the patient and suctioning the airway usually provide adequate stimulation for the newborn to breathe. Rubbing the back or flicking the soles of the feet may be done to provide additional stimulus if initial respirations are irregular.

Algorithm for resuscitation of the newborn.

As illustrated in Figure 32–1, positive-pressure ventilation (PPV) should be started if the newborn is apneic or has a heart rate less than 100 bpm. Figure 32–2 shows the correct positioning of the neck and placement of the mask will not be effective if the airway is not extended slightly and the mask is not applied to the face in the correct manner, with a tight seal around the nose and mouth. In addition, sufficient pressure must be given to produce adequate chest wall movement. A pressure manometer should be attached to the bag to monitor the amount of pressure that is being delivered. Overdistention of the lung causes significant trauma to the lung parenchyma and may cause complications such as a pneumothorax or lead to development of pulmonary interstitial emphysema especially in the very-low-birth-weight (VLBW) neonate (birth weight < 1500 g). Inability to move the chest wall at high pressures may indicate the lack of a good seal between the mask and the face, an airway obstruction, or significant pulmonary or extrapulmonary pathology compromising ventilation, such as pleural effusions, a congenitally enlarged chest or abdominal mass, or a congenital diaphragmatic hernia (CDH). If the infant's respiration is markedly depressed, endotracheal intubation should be considered.

Technique of bag and mask ventilation of the newborn. The neck should be slightly extended. An anesthesia bag should have a manometer attached; a self-inflating bag should have an oxygen reservoir attached.

Chest compressions should be initiated if the heart rate is less than 60 bpm after 30 seconds of effective PPV. Figure 32–3 shows the acceptable methods for administering compressions to a neonate. Pressure should be applied to the sternum to depress it one-third of the anteroposterior diameter of the chest. Compressions should be coordinated with breaths: a single cycle should consist of 3 compressions followed by a single breath, and each cycle should last for 2 seconds. Compressions should be continued until the heart rate rises above 60 bpm. PPV should be continued until the heart rate is > 100 bpm and the patient is showing adequate respiratory effort. If the heart rate remains < 60 bpm after 30 seconds of compressions, administration of epinephrine is indicated. Failure to respond to PPV and chest compressions is a clear indication for endotracheal intubation; intubation should be attempted at this time if it has not already been performed. Figure 32–4 shows the landmarks used to guide placement of the endotrachea (ETT) between the vocal cords.

Landmarks for placement of the laryngoscope.

Epinephrine can be given via an ETT or an umbilical venous catheter. The standard dose of epinephrine in neonate is 0.01–0.03 mg/kg. The 2006 American Academy of Pediatrics (AAP) guideline recommends using a higher dose of 0.05 mg/kg/dose of the 1:10,000 concentration solution administered rapidly if epinephrine is delivered via the ETT (

32–1). The dose can be repeated every 3–5 minutes until the heart rate rises above 60 bpm.

Table 32–1. Neonatal Resuscitation and Newborn Infant Drug Doses.

Epinephrine

(1:10,000) 0.2 mL/kg IV or ET. Give rapidly. Dilute 1:1 with saline for ET use.

Volume Expansion

(Whole blood, saline, 5%albumin, Ringer's lactate) 10 mL/kg. Give over 5–10 minutes.

NaHCO₃

(0.5 mEq/mL) 1–2 mEq/kg IV. Give slowly, only if ventilation adequate.

Naloxone

(0.4 mg/mL) 0.1 mg/kg = 0.25 mL/kg IV, ET, IM, SQ. Give rapidly.

Glucose

D₁₀ W 2 mL/kg IV. Give over 1–2 minutes.

When the infant's response to resuscitation is poor, other factors that may be complicating successful resuscitation of a newborn should be considered. Naloxone should be considered if respiratory depression is thought to be secondary to maternal narcotic administration within 4 hours of delivery and there is no history of maternal narcotic abuse during pregnancy. Naloxone can cause symptoms of withdrawal, including seizures, if given to the child of a mother addicted to narcotics. Hypovolemia should be suspected if there is a perinatal history consistent with blood loss (e.g., placental abruption, placenta previa) or sepsis, and the baby is hypotensive and pale, with weak pulses and cool extremities. A 10 cc/kg IV infusion of normal saline, lactated Ringer's solution, or O-negative blood, if available and anemia is suspected, can be given to treat the suspected hypovolemia. The dose can be repeated if there is minimal improvement with the initial bolus. Metabolic acidosis may be present at birth if the baby was significantly distressed in utero or may develop after birth if oxygenation and/or perfusion are compromised. Although use of bicarbonate resuscitation is somewhat controversial, significant acidosis will cause pulmonary vasoconstriction and poor myocardial contractility and should be treated. The umbilical artery can be catheterized to provide ongoing access to blood samples for determination of the extent of acidosis and the response to treatment during resuscitation. The recommended dose of bicarbonate is 2 mEq/kg IV of a 0.5 mEq/mL (4.2%) solution. Bicarbonate should be given slowly via an intravenous line (IV) and should be used only after ventilation is established so that the CO₂ produced with bicarbonate administration can be removed. Otherwise, bicarbonate administration may result in a significant increase in intracellular acidosis. Tromethamine (Tham) may be used as an alternative to bicarbonate when there is documented or suspected hypercapnia, as occurs in neonates with conditions resulting in pulmonary hypoplasia. Tham is a buffer that increases bicarbonate while lowering PaCO₂ levels.

Apgar scores are assigned at 1 and 5 minutes of life and continued at 5-minute intervals for up to 20 minutes as long as the score remains below 7. However, the Apgar score does not determine the need for resuscitation. Although a depressed or distressed newborn likely will receive a low Apgar score, assessment of the need for intervention with PPV should already have been made by the time the 1-minute Apgar score was assigned, and the score may not accurately reflect the newborn's clinical status. The initial assessment of the newborn and assignment of the Apgar score are discussed in further detail in Chapter 11.

Although 100% oxygen is the current standard for neonatal resuscitation, this treatment has recently been called into question. Oxygen is known to have numerous toxic effects, and there is concern among many neonatologists that the use of 100% oxygen during resuscitation may actually cause cellular injury, particularly to the brain, via products of oxygen-derived free radicals. In addition, a recent study of more than 50,000 children showed a slightly higher rate of a certain type of leukemia in children exposed at birth to oxygen for more than 3 minutes compared to unexposed children. A Cochrane Database meta-analysis published in 2005 analyzed the results of several clinical trials comparing neonatal resuscitation with room air (21% oxygen) versus 100% oxygen. The results showed a signif

decrease in mortality in the group resuscitated with room air and no difference between the rates of moderate or severe hypoxic–ischemic encephalopathy (HIE) in the room air and 100% oxygen groups. The single study with follow-up (at 18–24 months) that was included in the meta-analysis showed no difference in neurodevelopmental outcome between the groups. However, given the small number of studies to date and the use of backup 100% oxygen in many of the infants studied, the authors concluded there currently is not enough evidence to recommend standard use of room air instead of 100% oxygen for resuscitation when oxygen is available. The debate continues but it is clear that every effort should be made to avoid hyperoxia and to minimize any unnecessary exposure to oxygen.

Specific Considerations in the Delivery Room

MECONIUM

Meconium-stained fluid is present in 10–20% of deliveries. It is extremely rare if delivery takes place prior to 34 weeks' gestation. Passage of meconium in utero usually indicates fetal distress, and those personnel present at delivery should be alerted by the presence of meconium to the possibility that the newborn may be depressed at birth.

It is no longer recommended by the AAP that all meconium-stained babies receive intrapartum suctioning. An alert, crying, well-appearing infant does not require endotracheal intubation regardless of the presence of meconium staining or the thickness of the meconium. If the newborn is in distress or has depressed respiratory effort, the appropriate intervention is to intubate and suction the trachea before stimulating the baby in any way. If no meconium is suctioned from the airway, resuscitation should proceed according to the standard algorithm. If meconium is suctioned from the trachea, another attempt should be made to intubate the patient and suction the trachea again. However, if the patient has significant bradycardia it may be appropriate to defer repeated suctioning and provide PPV.

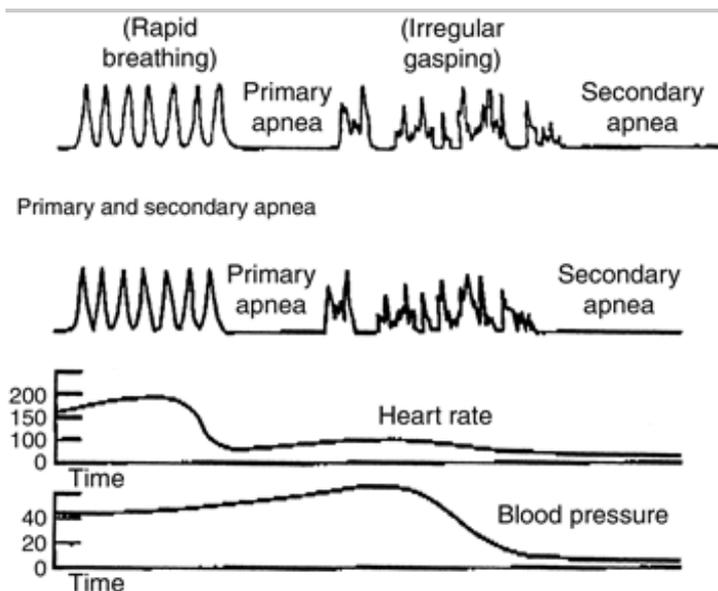

The majority (94–97%) of infants born through meconium-stained fluid will not develop meconium aspiration syndrome, but when it does occur, infants are often critically ill. Meconium can block the airway and prevent the newborn's lungs from filling with oxygen, which is a vital step in normal transitioning. Meconium aspiration into the lungs can cause obstruction of the small airways and consequently areas of atelectasis, gas trapping, and overdistention in addition to a chemical pneumonitis. The infant born through meconium may have pulmonary hypertension and inadequate oxygenation and requires close observation and early initiation of treatment when appropriate.

ASPHYXIA

Despite optimal prenatal care, some infants sustain injury prior to or during delivery that results in asphyxia. Perinatal asphyxia is characterized by the presence of hypoxemia, hypercapnia, and metabolic acidemia. It is the result of compromised oxygen delivery and blood flow to the fetus, either chronically or acutely, that stems from processes such as placental insufficiency, cord compression, trauma, and placental abruption.

If significant prepartum or peripartum hypoxic–ischemic injury has occurred, the infant likely will be depressed at birth and may not respond to initial interventions to establish respiration. The initial response in the newborn to oxygen is rapid breathing, followed shortly thereafter by a period of apnea, termed *primary apnea*. Drying the infant and rubbing the back or flicking the soles of the feet is sufficient to stimulate respiration during the primary apnea phase. However, without intervention at this point, continued oxygen deprivation will lead to a series of gasps followed by a period of secondary apnea. It is important to recognize that an infant who does not respond to stimulation likely is in secondary apnea and requires further intervention. Respiration will not resume with stimulation if secondary apnea has begun and positive pressure is necessary to reverse the process. As Figure 32–5 demonstrates, heart rate changes typically begin toward the end of primary apnea, whereas blood pressure typically is maintained until the period of secondary apnea.

Figure 32–5.

Heart rate and blood pressure changes during apnea.

Effective resuscitation of an asphyxiated newborn usually requires treatment of acidosis. Perinatal asphyxia may be complicated by hypoglycemia and hypocalcemia. Myocardial dysfunction may be present, and fluid boluses or continuous infusion of inotrope may be required for adequate blood pressure support. However, in the presence of significant myocardial dysfunction, repeated volume boluses will worsen the cardiovascular status. In these cases, early administration of an inotrope (eg, dobutamine) with or without low to moderate doses of a vasopressor (eg, dopamine) is the appropriate approach. In addition, seizures may occur in the newborn with perinatal asphyxia. Seizures usually are the result of hypoxic–ischemic injury to the cerebral cortex, but hypoglycemia and hypocalcemia also may cause seizure activity in the depressed neonate. In the newborn, phenobarbital (15–20 mg/kg IV) typically is given as the first-line treatment of seizures not caused by hypoglycemia or hypocalcemia. An additional 5–10 mg/kg bolus can be given to control status epilepticus. Asphyxiated infants are at increased risk for persistent pulmonary hypertension (discussed in detail later in the section Pathology and Care of the High Risk Term Neonate).

The severity of the insult sustained by the newborn can be difficult to assess in the neonatal period. The presence of abnormal findings on the neurologic examination and the severity and persistence of those abnormalities are the most useful measures for assessing the degree of brain injury sustained. Laboratory (umbilical cord and baby blood gases, serum creatinine level, liver function tests, blood lactate level, cardiac enzyme levels) studies, radiographic (brain magnetic resonance imaging [MRI]) studies, and electroencephalographic (EEG) findings provide additional information to help predict the likelihood and anticipated extent of an adverse neurodevelopmental outcome. Early onset of seizure activity has been shown to increase the likelihood of a poor outcome. Infants with severe HIE, who is characterized by absent reflexes, flaccid muscle tone, seizures, and a markedly altered level of consciousness, either die within several days of birth or have significant neurologic sequelae. It is a misconception that perinatal asphyxia is the cause of cerebral palsy. A minority of the cases of cerebral palsy are actually attributable to intrapartum complications. Selective hypothermia, or brain cooling, currently is under investigation as a possible intervention to improve outcome after asphyxia. Therapies aimed at inhibiting free-radical production also may play a role in preventing adverse outcomes of asphyxia in the future.

SHOCK

The newborn who fails to respond to initial attempts at resuscitation may be in circulatory shock. A number of different pathophysiologic processes can result in shock in the delivery room. Circulatory collapse can result from absolute (hemorrhage, capillary leak) or relative (vasodilatation) hypovolemia, cardiac dysfunction (asphyxia,

congenital heart disease [CHD]), abnormal peripheral vasoregulation (prematurity, asphyxia, sepsis), or a combination of these factors. The peripartum history often helps pinpoint the etiology. The presence of risk factors for sepsis (prolonged rupture of membranes, maternal fever, chorioamnionitis), hemorrhage (placenta previa, placental abruption, trauma), or perinatal asphyxia may be informative. Pallor or peripheral hyperemia, weak pulse with tachycardia, and cool or warm extremities are present on examination. Hypotension in the newborn immediately following delivery is commonly defined as a mean arterial pressure that is equal to or less than the gestational age. It is worth noting that blood pressure is normal in the early (compensated) phase of shock; hypotension may only develop as the process progresses.

As mentioned in Delivery Room Management, a 10 cc/kg normal saline bolus typically is given to the newborn with hypotension. An additional 10–20 cc/kg is often given if the improvement in circulation is inadequate. Unmatched negative blood can be transfused in 10–15 cc/kg aliquots if severe anemia from blood loss is suspected. Volume should be administered slowly and judiciously to preterm infants who lack the mechanisms to autoregulate cerebral blood flow and protect the brain against reperfusion injury. Excessive volume may worsen the patient's status if cardiac dysfunction is the cause of hypotension. As discussed earlier, administration of sodium bicarbonate or Tris is frequently indicated to treat metabolic acidosis in the newborn in shock. Vasopressor/inotrope infusions should be initiated in neonates who do not respond to volume resuscitation.

CYANOSIS

Although acrocyanosis (cyanosis of the hands and feet) often is normal in the newborn, central cyanosis is not. Cyanosis is due to inadequate oxygen delivery to the tissue, either as a result of poor blood flow (peripheral vasoconstriction in acrocyanosis or low cardiac output in cardiogenic shock) or insufficiently oxygenated blood (pulmonary hypertension or severe parenchymal lung disease). Free-flow oxygen can be administered if a newborn has central cyanosis despite regular respirations. Free-flow oxygen can be delivered by holding a mask or oxygen tubing that is connected to a flowing source of 100% oxygen close to the baby's nose and mouth. Oxygen can be gradually withdrawn when the newborn turns pink. PPV is often indicated if the baby remains cyanotic despite free-flow oxygen. Lack of improvement of central cyanosis with administration of free-flow oxygen necessitates an evaluation of the cause of cyanosis. As discussed earlier, provision of 100% oxygen may have significant side effects if it is used for newborn resuscitation.

PREMATURITY

The delivery of a preterm infant requires a skilled multidisciplinary resuscitation team that has an understanding of the myriad problems associated with preterm delivery and has experience handling VLBW newborns. The presence of physicians, nurses, and a respiratory therapist trained in newborn resuscitation will optimize the care of the newborn. Details of the delivery room care of the preterm infant are discussed in the section Delivery Room Management earlier in this chapter.

The neonatal team should meet with the family prior to delivery whenever possible. The parents should be informed about the prognosis for the fetus and need for intensive care admission if appropriate. It is critical that the family understand the plan for resuscitation in the delivery room and the anticipated short- and long-term problems the newborn may face. Often it is helpful to families to discuss the emotional impact of the admission and the possibility of a prolonged stay of their newborn in the ICU. If the fetus is at the limits of viability, currently considered 23–24 weeks' gestation and/or weight < 500 g, it is essential that the parents understand the considerable risk of death and the serious cognitive, motor, and pulmonary complications that may occur if the newborn does survive. The neonatal team must have a clear conversation with the parents about the possible options for postnatal management. Unfortunately, it often is difficult to make definitive plans given that the margin of error for prenatal determination of birth weight and gestational age is wide enough to have a significant impact on the viability of the fetus. Although many physicians have strong feelings of their own, it is vital that the course of resuscitation of a newborn at the limits of viability incorporates the family's wishes. Nevertheless, parents should understand that the fetus' viability

will be reassessed after delivery, and that the maturity of the newborn, the newborn's condition at delivery, and response to the resuscitative efforts made, in combination with available outcomes data, ultimately will determine management in the delivery room.

ABDOMINAL WALL DEFECTS

Gastroschisis is the herniation of abdominal contents through an abdominal wall defect. The defect in gastroschisis usually is small and to the right of the umbilicus, and the intestines are unprotected by the peritoneal sac.

Omphalocele also involves the herniation of abdominal contents through the abdominal wall, but the defect is in the umbilical portion of the abdominal wall, and the herniated viscera are covered by the peritoneal sac. Both defects require emergent care in the delivery room. The extra-abdominal organs should be delicately wrapped with warm saline-soaked gauze and then covered in plastic. Care should be taken to position the bowel centrally over the defect with the infant supine or lying on his or her right side to prevent compromising blood flow to the intestines by kinking mesenteric blood vessels. A nasogastric tube should be placed to prevent distention of the bowel with air. Patients will have increased heat and insensible fluid losses, and intravenous fluid should be started promptly at times normal maintenance requirements to prevent dehydration and hypernatremia. Electrolytes and fluid status must be monitored closely. A surgical consultation should occur prenatally if the defect is diagnosed in utero. An urgent surgical evaluation should be obtained upon admission of the newborn to the NICU.

PATHOLOGY AND CARE OF THE PRETERM INFANT

In 2003, 12.3% of all births in the United States were preterm, a 16% increase since 1990. Advances in obstetric and neonatal care have markedly increased the survival of premature infants and improved outcomes. However, prematurity continues to account for a significant percent of neonatal and infant mortality in the United States. In fact, 2003 saw a slight increase in infant mortality in the United States from the previous year, a trend that has occurred in more than 40 years and is attributable to an increased number of babies with birth weights < 750 g. As fewer and less mature infants survive, we face new ethical and medical challenges to continue improving the long-term and societal impact of the care provided in the NICU.

Respiratory Distress Syndrome

In 1959 Mary Ellen Avery and Jere Mead reported data showing that the severe respiratory disease seen in preterm infants, then known as hyaline membrane disease, was due in part to a deficiency of surfactant. Surfactant, a complex of phospholipids and protein secreted by type II pneumocytes, reduces surface tension in the alveoli of the lung. Its absence, or deficiency, results in diffuse microatelectasis and decreased functional residual capacity leading to the presentation of a "ground-glass" pattern and poor expansion of the lungs on chest radiograph (CXR). The disease of the preterm infant, now known as respiratory distress syndrome (RDS), also is a consequence of the immature architecture of the lung at the time of birth.

RDS presents as tachypnea and increased work of breathing that develops shortly after birth. Both oxygenation and ventilation are impaired, and blood gas analysis typically reveals hypoxia and a respiratory acidosis. Although most commonly seen in premature infants, RDS is associated with other conditions as well. Infants of diabetic mothers are at risk, even at term, because high levels of insulin in the fetus suppress lung maturation, including surfactant production. Without intervention, RDS typically worsens over the first few days of postnatal life. Historically, improvement was often heralded by a marked increase in urine output ("diuretic phase" of RDS).

The likelihood of RDS is inversely proportional to gestational age. It now is standard to give corticosteroids to mothers at risk of delivery before 32–34 weeks' gestation to hasten maturation of fetal organs, including the lungs, and to decrease the incidence and severity of RDS. Some larger preterm infants may require supplemental oxygen via nasal cannula or no respiratory assistance whatsoever. Babies with significant RDS typically require assisted ventilation. Ventilatory support can be given with continuous positive airway pressure (CPAP), a pressure- or volume-limited ventilator, or a high-frequency ventilator. A recent analysis concluded the data are not sufficient to

recommend any mode of mechanical ventilation over the other as standard therapy for RDS. Provision of positive end-expiratory pressure (PEEP) (either as CPAP or PEEP) quickly after delivery is vital in order to prevent collapse of the lungs. If the lungs are allowed to collapse, oxygenation and ventilation will be compromised further and high pressures will be required to reinflate the lungs, causing avoidable barotrauma and volutrauma to the lungs.

Exogenous surfactant administration has significantly reduced morbidity and mortality from RDS since its routine began in the early 1990s. Prophylactic administration of surfactant to the preterm infant (ie, before 15 minutes of age) has been shown to reduce neonatal morbidity (pneumothorax and pulmonary interstitial edema) and mortality compared to rescue therapy (ie, waiting until after the diagnosis of RDS is made). Proposed explanations of this finding include a more homogeneous distribution of surfactant in the fluid-filled lung and the delivery of surfactant after a minimal period of PPV minimizing barotrauma and volutrauma to the lung. However, it is very important to ensure correct placement of the ETT prior to surfactant administration in the delivery room. If the ETT position cannot be determined, it may be better to delay surfactant until CXR has confirmed placement. If the degree of RDS is significant, an additional 2–4 doses of surfactant can be given every 6–12 hours depending on the surfactant preparation used. The newborn should be monitored closely after receiving surfactant because rapid changes in respiratory status usually occur, necessitating aggressive weaning of the ventilator settings. If the ventilator support is not weaned appropriately, the improving lung compliance will result in high tidal volume ventilation leading to volutrauma and hypocapnia. Complications such as obstruction of the ETT, pneumothorax, or pulmonary hemorrhage may occur with surfactant. Pulmonary hemorrhagic edema likely is due to the surfactant administration-associated rapid decrease in pulmonary vascular resistance and the resulting pulmonary overcirculation through ductus arteriosus. Blood gases should be checked frequently to prevent hypocapnia, which is associated with an increased incidence of periventricular leukomalacia (PVL) in the preterm neonate.

Despite the advances attributable to prenatal steroids, surfactant, and newer modes of ventilation, RDS continues to carry significant morbidity, including the risk of chronic lung disease, which is defined as the need for supplemental oxygen or ventilatory support at 36 weeks' postmenstrual age. New strategies have evolved over recent years to improve outcomes of newborns with RDS. Given the toxicities of oxygen, as discussed earlier, efforts are being made to limit exposure of preterm infants to hyperoxia. Many centers now aim to keep the oxygen saturation percent in the 80s or low 90s for preterm babies to prevent periods of hyperoxygenation and free-radical production. Although data are scant and not well controlled, no current evidence suggests adverse neurologic effects of the lower saturations. However, it is recommended that saturations be kept in the high 90s once an infant's corrected gestational age reaches near-term. Future studies must be designed to investigate the potential side effects of low saturations, including the development of pulmonary hypertension and subsequent cor pulmonale during infancy and early childhood.

Another recent change in neonatal practice has been the adoption of permissive hypercapnia. Permissive hypercapnia involves allowing CO₂ levels in the blood to rise above the normal value of 40 mm Hg in order to minimize the pressures required for ventilation and thereby reduce the lung injury caused by ventilator-induced barotrauma and volutrauma. This practice allows for infants to remain extubated who might have been reintubated in the past because of CO₂ retention. Although the procedure differs, CO₂ levels of 45–55 mm Hg are generally accepted, with some centers allowing higher CO₂ levels without a change in ventilatory management. The side effects of this approach are unknown, but hypercapnia may decrease the autoregulatory capacity of cerebral vessels, resulting in more-or-less pressure-passive cerebral circulation. Therefore, the potential long-term neurodevelopmental effects of hypercapnia-associated pressure-passive cerebral circulation require investigation.

Encouraged by data from nonrandomized studies at Columbia University, many neonatologists are now trying to avoid intubation and/or mechanical ventilation, even in the tiniest babies. Using CPAP with nasal prongs for newborns with respiratory distress soon after birth (regardless of gestational age or birth weight) and a strategy of permissive hypercapnia, physicians at Columbia University reported a low incidence of bronchopulmonary dysplasia (BPD)

compared to other tertiary care centers, without any significant increase in mortality. Because these findings need confirmation in appropriately designed randomized clinical trials, some centers have chosen an intermediate approach: VLBW infants are intubated for surfactant administration, but the ETT is removed shortly after and the period of mechanical ventilation is brief. Although approaches differ, early extubation is now a widely shared goal among neonatologists.

Dexamethasone was a key part of efforts to prevent and/or treat BPD for many years. However, a number of studies have shown a worse neurodevelopmental outcome in preterm infants who received dexamethasone treatment compared to controls with a similar degree of illness in the neonatal period. Many studies are still in progress, and data on long-term outcomes are not yet available, but the routine use of dexamethasone is no longer recommended. Dexamethasone is now reserved for those patients with the most severe lung disease although, in general, no data support a better pulmonary outcome with its use. The available data suggest that there may be a window for dexamethasone use at 7–14 postnatal days, categorized as "moderately early" treatment, which has not been shown to cause any adverse outcomes. However, as mentioned earlier, a significant direct benefit associated with the use of dexamethasone is not available. Steroids also are now usually given in lower doses and shorter courses than in the past. The AAP currently recommends that neonatologists counsel parents about the risks and benefits of dexamethasone prior to initiating treatment. Future studies are needed to evaluate the effect, if any, of the new treatment regimens on neurodevelopment outcome.

Nutrition

Providing optimal nutrition is an essential and challenging part of the care of the premature baby. Preterm infants are born with minimal nutrient stores and high metabolic demands, and growth failure is a frequent complication of prematurity. Supplying adequate nutrition for growth and development is complicated by the fact that many preterm newborns are too unstable to receive enteral nutrition in the first few days of postnatal life. There may be clear contraindications to enteral feeding, such as hypotension and vasopressor requirements, or factors can arise that raise concerns about early initiation of enteral feeds, such as cocaine exposure in utero, indomethacin administration, the presence of a patent ductus arteriosus (PDA), or respiratory instability. Parenteral hyperalimentation is used to meet the newborn's initial fluid and nutritional requirements, but the ultimate goal is to meet those needs with enteral feedings given as early as safely possible.

An IV infusion of 10% glucose typically is started soon after birth to maintain glucose homeostasis. Extremely-low birth-weight (ELBW) babies (birth weight < 1000 g) may require lower concentrations of dextrose because of high total fluid requirements. Calcium supplementation in the dextrose infusion is standard for VLBW babies because transfer of calcium from mother to fetus primarily occurs during the third trimester, so VLBW babies are born with inadequate stores. The infusion rate of fluids typically is begun at 80–120 cc/kg/d depending on the immaturity and severity of illness of the neonate. Excessive fluids should be avoided because they have been associated with an increased risk for RDS, PDA, intraventricular hemorrhage (IVH), and necrotizing enterocolitis (NEC). Electrolyte and fluid status must be closely monitored over the first few days of life to determine appropriate fluid management. Depending on the level of immaturity, prenatal steroid exposure, and ambient humidity, ELBW infants may have enormous insensible losses and may develop hypernatremia if fluid needs are not met.

Protein breakdown can begin within the first postnatal days in preterm infants receiving only dextrose-containing fluids as nutrition. As a result, protein supplementation should be started as soon as possible to prevent a catabolic state. Parenteral hyperalimentation containing amino acids can be safely initiated immediately after delivery with development of acidosis, hyperammonemia, or uremia. The amino acid infusion should be started at 1.5–2 g/kg/d and advanced over several days to a goal of 3–4 g/kg/d.

Preterm newborns typically require a glucose infusion rate (GIR) of 6–8 mg/kg/min. The GIR is advanced in small increments to provide additional calories. Carbohydrate should account for approximately 40% of the 90–120 kcal/kg/d provided to the neonatal patient receiving parenteral nutrition. (Caloric requirements are higher with

enteral feeding, typically 120–150 kcal/kg/d.) The need for GIR in excess of 15–18 mg/kg/min for adequate cal support is rare. Glucose levels should be monitored and the dextrose infusion adjusted to maintain normoglycer (ie, plasma glucose concentration 60–160 mg/dL). An insulin infusion can be started in the unusual event that hyperglycemia persists despite restricting the GIR to 4–6 mg/kg/min to continue to provide adequate calories fo growth.

Intralipids provide the essential fatty acids required for multiple physiologic processes. Ideally, 40–50% of the d caloric intake for a preterm infant receiving parenteral nutrition should come from fat. Usually a continuous 20% infusion at 0.5–1 g/kg/d is started on the first or second day of life, with the ultimate goal of providing 3 g/kg/d Triglyceride and cholesterol levels must be monitored closely; elevated levels may require lower levels of lipid supplementation. Lipid infusion of 0.5–1 g/kg/d is required to prevent essential fatty acid deficiency.

In addition to providing protein, glucose, and fats, parenteral hyperalimentation provides electrolytes, vitamins, minerals for the preterm infant unable to tolerate enteral feeds. Electrolyte levels must be monitored periodically ensure appropriate levels. Particular attention must be paid to providing maximal amounts of calcium and phosphorous to VLBW infants who are at risk for developing osteopenia of prematurity.

It is important to begin enteral feeds as soon as possible in preterm infants. Delayed enteral feeding has advers effects on the gut, such as mucosal atrophy, decreased digestive enzyme activity, and altered intestinal motility. addition, long-term parenteral nutrition can cause cholestasis and presents an increased risk of infection becaus the prolonged need for central venous access. Regimens for initiation of enteral feeding in VLBW infants vary bu usually involve starting volumes of 10–20 cc/kg/d. Feeds are given via an orogastric or nasogastric tube for all b the most mature infants. The infant is monitored carefully for signs of feeding intolerance, such as abdominal distention, emesis, or large-volume gastric residuals while the feed volume is increased daily by 10–20 cc/kg. Sc centers continue small-volume feeds for 5–10 days before advancing the volume toward the ultimate goal of 140–160 cc/kg/d.

Mothers of preterm infants should be encouraged to breastfeed. Although preterm infants almost always are un to feed from the breast and perhaps are not able to receive any breast milk at all during the first postnatal days preterm infants still ultimately will benefit by receiving breast milk. The advantages of breastfeeding on everythi from the appropriate function of the immune system to developmental outcomes and IQ are well documented. T caloric value of human milk clearly has proved to be superior to formula, and it is the most easily digested form infant nutrition. Many NICUs now use pasteurized human breast milk banks to provide these benefits to infants whose mothers are unable to breastfeed. Human milk fortifiers are used to increase the protein, calories, calciur phosphorous, vitamins, and minerals of mature human milk in order to meet the needs of the growing prematur infant. Breastfed infants should receive iron supplements once they reach the goal volume of enteral feeds.

Special formulas have been designed to better meet the nutritional needs of preterm infants receiving formula. Premature infant formulas contain 24 kcal/oz and provide higher amounts of protein, medium-chain triglycerides vitamins, and minerals (eg, calcium and phosphorous) than standard formulas. If needed for adequate growth, t caloric content of preterm formula can be increased with any of a number of commercially available supplement: majority of which provide additional calories as carbohydrate or fat. Although term infants gain an average of 3C 15–20 g/d is considered sufficient growth in the preterm infant.

Necrotizing Enterocolitis

NEC is a significant cause of morbidity and mortality in neonates. Although gastrointestinal in origin, NEC may le septic shock, respiratory failure, and death. Only 10% of cases occur in term newborns. The most premature an smallest infants are disproportionately affected; NEC occurs in 5–10% of all VLBW infants.

The presentation of NEC is highly variable. Signs and symptoms often are specific to the gastrointestinal tract, s as abdominal distention and/or erythema, emesis, bilious gastric residuals, and bloody stools; however, they ma

nonspecific, such as apnea, temperature instability, and lethargy. Findings may be subtle initially, or the onset may be fulminant. Acidosis and thrombocytopenia are worrisome findings that may indicate necrotic bowel. Hyponatremia due to upregulated sodium transport into the gut, and edema, due to increased capillary leak, often develop. Respiratory distress develops from abdominal distention due to inflammation and distention. The pathognomonic feature of NEC is the presence of intestinal pneumatosis on abdominal x-ray. Pneumatosis results from the production of hydrogen from bacteria in the bowel wall. Serial x-rays are obtained to follow disease progression. Air in the portal venous system or free air in the abdominal cavity indicates intestinal perforation, warranting surgical intervention for either an exploratory laparotomy to resect the necrotic bowel or placement of a right lower quadrant drain to decompress the abdomen if the patient is very small or unstable. Whether or not perforation has occurred, treatment of NEC includes at least 14 days of broad-spectrum antibiotics and discontinuation of enteral feeds, usually for 14 days. Many infants require fluid resuscitation and vasopressor/inotrope support. Seventy-five percent of infants with NEC survive, but half sustain long-term complications such as intestinal strictures and short gut syndrome.

Prematurity and enteral feeds have been clearly linked to NEC, but the pathogenesis of NEC is not well defined and is widely considered to be multifactorial. An infectious component is suggested by the association of certain organisms with outbreaks of NEC and the immature immune function of the preterm gastrointestinal tract. Mucosal injury as a result of altered intestinal and/or mucosal blood flow, either during periods of ischemia from hypotension or vasoconstriction or during reperfusion and free-radical production, is believed to make the infant vulnerable. The presence of bacteria, ischemia and reperfusion, formula, and other unknown factors may all work together to trigger the inflammatory cascade responsible for the pathologic findings of NEC.

Risk factors for NEC include ELBW, polycythemia, umbilical catheters, enteral feeding, formula feeding, low Apgar scores, cyanotic heart disease, in utero cocaine exposure, and the presence of a PDA. Data on whether or not the rate of advancement of enteral feeds contributes to the development of NEC are conflicting. However, a recent study showed a decreased incidence of NEC in VLBW neonates who received small-volume feeds for 10 days before advancement compared to those who received daily 20 cc/kg advancement of feeds. The incidence of NEC has also been shown to decrease when standardized feeding regimens are instituted within a unit. The effect may be due to heightened awareness of signs and symptoms of feeding intolerance rather than to the actual specific regimen, but the effect has been reproduced and is dramatic.

NEC occurs less frequently in infants who receive breast milk. The protective effect of breast milk is speculated to result from the transfer of components of breast milk such as cytokines, immunoglobulins, growth factors, and probiotics to the infant. Recent studies have shown a decreased incidence and severity of NEC in VLBW neonates who received supplementation with probiotic bacteria such as *Lactobacillus acidophilus*, *Bifidobacterium* spp., and *Streptococcus thermophilus*. However, further studies are needed to examine the safety of probiotics given recent reports of sepsis due to supplemented probiotic organisms. Antenatal steroids also have a protective effect against NEC, likely due to a demonstrated effect on gastrointestinal maturation and PDA closure.

Patent Ductus Arteriosus

During fetal life, close to 90% of the blood that leaves the right ventricle flows from the pulmonary artery to the aorta through the ductus arteriosus. After birth the pulmonary pressure falls, blood flow to the lungs increases, and the ductus arteriosus, primarily as a response to the increased oxygen tension in the blood and decreased circulating levels of prostaglandin E₂ (PGE₂), begins to close. Functional closure of the ductus arteriosus occurs within the first 1–2 days of postnatal life in the vast majority of term neonates, and definitive anatomic closure of the ductus arteriosus is complete by the end of the first postnatal week. However, in neonates born prematurely this process takes longer and may not always occur. In preterm neonates, failure of the ductus arteriosus to close is the result of several factors, including persistent hypoxia as a result of RDS and the continued presence of PGE₂. A PDA may be asymptomatic initially, but as the pulmonary pressure continues to fall, the left-to-right shunt of blood through the

ductus arteriosus increases. Increasing left-to-right shunt produces pulmonary overcirculation (often with > 50% of the left ventricular output shunting back into the lungs), worsening respiratory distress and gas exchange, an increasing oxygen requirement, and systemic hypotension. The presence of a PDA is suggested on physical examination by a hyperdynamic precordium (left ventricular overload), bounding palmar and brachial pulses, and a holosystolic precordial murmur. The pulse pressure usually is wide, and CXR typically demonstrates cardiomegaly and pulmonary congestion. Unless contraindications such as renal insufficiency, active bleeding, or thrombocytopenia are present, indomethacin, a nonselective inhibitor of the cyclooxygenase enzyme, is the first-line treatment of PDA because indomethacin effectively decreases prostaglandin synthesis. Indomethacin also has certain actions not directly related to inhibition of prostaglandin synthesis, such as a drug-induced decrease in global cerebral blood flow. This action may contribute to the indomethacin-induced decrease in severe IVH observed in ELBW neonates given indomethacin shortly after birth. However, there appears to be no significant long-term neurodevelopmental benefit of prophylactic indomethacin administration. In neonates with a PDA, fluids should be restricted to prevent worsening of pulmonary edema. Indomethacin may fail to achieve closure of the ductus, particularly in those who were born most prematurely or who received therapy later in postnatal life (beyond 10–14 days). Persistent patency of the ductus typically requires a repeat course of indomethacin followed by surgical ligation of the ductus, depending on the patient's age and clinical status.

Intraventricular Hemorrhage

IVH is one of the most feared complications of prematurity; severe IVH is a major risk for adverse long-term neurodevelopmental outcome. The incidence of IVH (approximately 20% in VLBW infants) is inversely proportional to gestational age. A number of factors combine to put the preterm neonate at risk. The blood vessels in the periventricular germinal matrix are abundant, immature, and fragile. These vessels may bleed when exposed to changes in blood flow. Sick newborns often experience periods of hypotension and hypertension, and they lack effective autoregulatory mechanisms to protect the brain during these variations in perfusion pressure. Changes in carbon dioxide levels in the blood also play an important role in regulating cerebral blood flow, and VLBW newborns may swing from hypocarbia to hypercarbia and back, particularly during the first few hours of life. In addition, bleeding may be aggravated by abnormal coagulation, particularly in the septic newborn.

Most IVH occurs during the first postnatal day; a few cases occur after 5 days of life. Recent findings suggest that, at least in the VLBW neonate, IVH during the transitional period is caused by an ischemia–reperfusion cycle. Although IVH usually occurs without any clear outward signs that the process is occurring, a large bleed may cause a sudden change in mental status, a drop in hematocrit (Hct) level, and a full fontanelle. IVH is characterized as grade I when the hemorrhage is confined to the region of the germinal matrix. Grade II IVH involves both the germinal matrix and the ventricles but does not fill or distend the ventricles. IVH grades I and II usually are not associated with a poor neurologic outcome and generally resolve. Grade III IVH fills greater than 50% of the ventricles with blood and causes distention of the ventricles. Grade III IVH carries a significantly increased risk of mortality and adverse neurologic outcome because it more frequently evolves into ex vacuo or obstructive (fibrosis obstructs the ventricular system) hydrocephalus. IVH is classified as grade IV when the hemorrhage involves the brain parenchyma. This hemorrhage historically was considered to be an extension of IVH into the parenchyma but may more accurately represent a distinct process of venous infarction or severe ischemia followed by reperfusion in the periventricular white matter. Irrespective of the etiology, intraparenchymal hemorrhage results in tissue destruction and is associated with neurodevelopmental deficits in a marked majority of affected patients.

Although numerous preventative therapies have been evaluated (indomethacin, phenobarbital, vitamin E, morphine), none is currently recommended for routine prophylactic use. Every effort is made to keep blood pressure and carbon dioxide levels stable and within the normal range and to avoid unnecessary interventions, such as suctioning, which may elevate intracranial pressure. Current guidelines recommend cranial ultrasound screening between postnatal day 7 and 14 days for infants less than 30 weeks' gestation and again when the infant reaches a corrected gestational age between 36 and 40 weeks. However, detection of IVH mandates repeated studies to follow the bleed for progres

and the ventricles for further dilation. Performing an ultrasound study earlier in life for newborns who are particularly unstable often is useful; the presence of a significant intraparenchymal bleed may help with decisions about direction of care for those whose viability is in question. Many centers advocate brain MRI prior to discharge to evaluate for white matter injury that may go undetected on cranial ultrasound and has been shown to be predictive of significant neurologic sequelae.

Retinopathy of Prematurity

Retinopathy of prematurity (ROP) is a disorder of retinal vascular proliferation that primarily affects premature infants. It is the second most common cause of blindness in children in the United States. Under normal conditions the retina is completely vascularized by 36–40 weeks of gestation. The earlier in gestation delivery occurs, the larger the avascular region of the retina and the greater the risk for ROP. The pathogenesis of ROP is not completely clear but seems to involve a period of vessel damage (from acidosis, hyperoxia, infection) and cessation of vessel development followed by abnormal proliferation. Hyperoxia and/or fluctuations in P_{aO_2} have been clearly shown to have an adverse effect on retinal development.

VLBW neonates, especially those who are critically ill and were born before 28 weeks' completed gestation, are at the highest risk for ROP. ROP tends to develop at 33 to 36 weeks' corrected gestation irrespective of the gestational age at birth. It may resolve spontaneously, as occurs in over 80–90% of cases, or it may progress to complete retinal detachment. Screening ophthalmologic examinations are recommended for infants born at less than 28 weeks' gestation or weighing less than 1500 g, or weighing 1500–2000 g but with an unstable course, to monitor the progression of retinal vascularization. The initial examination should be performed at 4–6 weeks of life or 31–33 weeks' corrected gestational age, whichever comes later. The frequency of repeat examinations is dictated by the findings, with the goal being early detection of ROP that meets criteria for surgical intervention.

PATHOLOGY AND CARE OF THE HIGH-RISK TERM NEONATE

Persistent Pulmonary Hypertension

During fetal life, oxygenated blood is delivered to the fetus from the placenta. Pulmonary vascular resistance is elevated in utero; consequently minimal blood flow goes to the lungs. Instead, as noted in PDA, close to 90% of output from the right ventricle passes from the pulmonary artery to the aorta through the ductus arteriosus. However, successful transition from fetal to extrauterine life requires a drop in pulmonary vascular resistance. The fall in pulmonary pressures results from a series of events that begins before birth but accelerates when a baby is born, the baby cries (filling the lungs with air), and the umbilical cord is cut. A number of processes can interrupt this process, either by mechanically blocking the airways, thus preventing essential lung expansion and increase in the partial pressure of oxygen, or by preventing relaxation of the pulmonary vascular bed. Meconium aspiration syndrome, asphyxia, sepsis, pneumonia, and CDH are among the most common causes of persistently elevated pulmonary vascular resistance, termed *persistent pulmonary hypertension of the newborn* (PPHN).

PPHN results in severe hypoxia in the newborn. Blood continues to shunt away from the pulmonary circulation through the foramen ovale, ductus arteriosus, or both, bringing poorly saturated blood to the body. Treatment consists of interventions aimed at lowering the pulmonary vascular resistance. Acidosis and hypoxemia are potent pulmonary vasoconstrictors and are avoided. When possible, P_{aO_2} is maintained in the normal range (80–100 mm Hg). Supplemental oxygen is weaned cautiously because even relatively small changes can cause an acute decompensation. Every effort should be made to maintain left ventricular output and blood pressure (thus systemic perfusion) in the normal range and to keep the blood pH in the 7.3–7.4 range. Acidosis is to be avoided, but aggressive use of bicarbonate or Thamb may not be beneficial. Although hyperventilation was used in the past to maintain an alkaline pH, concerns about ventilator-induced lung damage and the effect of hypocarbia on cerebral blood flow have altered this practice. In addition, studies have shown that it is the normalized pH, not the decrease in CO_2 , that improves pulmonary vasoconstriction. Most physicians adjust the ventilator support to target a P_{aCO_2}

40–50. High-frequency ventilators are often used, allowing for higher mean airway pressures without increasing barotrauma and volutrauma to the lungs. Vasopressors, typically dopamine, are used to maintain systemic blood pressure. If there is evidence of myocardial dysfunction, an inotrope such as dobutamine typically is used, and vasopressor support is adjusted to prevent undesirable increases in systemic vascular resistance. Patients with PPHN are extremely sensitive to noise and tactile stimulation, so infusions of sedatives and analgesia are routinely used to minimize agitation. However, use of neuromuscular blockade is to be avoided because it does not appear to impact clinical outcome and is associated with significant side effects, including sensorineural hearing loss.

Nitric oxide is a selective pulmonary vasodilator. Inhaled nitric oxide (iNO) reduces the need for extracorporeal membrane oxygenation (ECMO) in term infants with PPHN. iNO is routinely started at 20 ppm, although lower doses may be as effective. iNO is weaned as the patient stabilizes and the supplemental oxygen requirement falls. Despite the dramatic improvement in outcomes since the availability of iNO, a number of patients with PPHN still will require ECMO. Historically the criterion for ECMO has been a greater than 80% estimated risk of mortality with continued conventional medical management. General guidelines for the criteria for ECMO include an oxygenation index greater than 35–60 for between 0.5 and 6 hours, an alveolar–arterial oxygen difference greater than 605–620 (at sea level) for 4–12 hours, or a preductal P_{aO_2} less than 40 for more than 2 hours. ECMO is contraindicated in neonates less than 34 weeks' gestational age because of technical issues regarding catheter placement as well as the increase of intracranial bleeding in the preterm neonate. A preexisting grade II or higher IVH, signs of severe irreversible brain damage, lethal congenital anomalies, and nonreversible pulmonary disease are other contraindications to ECMO. Survival of patients with PPHN treated with ECMO varies depending on the underlying cause of PPHN. The survival rate of patients with meconium aspiration syndrome is 85–90%, but the survival rate of patients with PPHN is only 50%.

Congenital Diaphragmatic Hernia

CDH is a defect that results from incomplete development and closure of the diaphragm, usually at the foramen Bochdalek at 8–10 weeks' gestation. The defect in the diaphragm allows the contents of the abdominal cavity to migrate into the chest, resulting in compression of the lungs and, in more severe cases, the heart. The compression leads to pulmonary hypoplasia, abnormal lung development, and potentially underdevelopment of one or both ventricles. Ninety percent of CDH involves the left hemidiaphragm. CDH usually is prenatally diagnosed, but a number of cases still go undiagnosed, even with good prenatal care.

A number of features should raise suspicion about the possibility of CDH in the newborn with cyanosis and respiratory distress. Breath sounds may be absent on the left side of the chest and the heart sounds shifted to the right. The abdomen tends to be scaphoid, as some of the abdominal organs have shifted into the thorax. It may be difficult to effectively ventilate and resuscitate the patient. If a CDH is suspected, mask and bag ventilation must be avoided. The patient should be intubated and a nasogastric tube placed as soon as possible to prevent filling the stomach and bowel with air and thus compromising ventilation further. Many centers use sedation and sometimes paralysis to minimize activity, reduce the risk of pneumothorax, and prevent competition from swallowed air. CXR observation of bowel loops in the chest confirms the diagnosis.

Surgical repair of the defect usually is delayed for several days to allow time for the patient's condition to stabilize and pulmonary hypertension to improve. Efforts are made to use the lowest ventilator settings tolerated to minimize ventilator-induced lung injury. Surfactant, iNO, high-frequency ventilation, and, if necessary, ECMO are often used to manage patients with CDH. However, surfactant administration has been shown to be of no benefit, and some studies suggest that it may be associated with an increased need for ECMO, so its routine use cannot be recommended. To date, the evidence also has not shown a clear benefit of iNO for patients with CDH. Additional studies are needed to evaluate the role of each of these interventions in the care of the patient with CDH.

Reported survival rates vary from approximately 35–80%, perhaps reflecting differences between centers and/or related to referral patterns. The prognosis depends on the severity of the pulmonary hypertension and underlying

pulmonary hypoplasia as well as the presence of other anomalies or a chromosomal abnormality. Development of pneumothorax has been shown to predict a poor outcome. Failure to achieve a preductal P_{aO_2} greater than 100 Hg or a P_{aCO_2} lower than 60 in the first 24 hours of life generally indicates a poor prognosis as well. Some physicians argue that infants in whom the P_{aCO_2} level never falls below 60 or who never achieve a preductal oxygen saturation of at least 85% for at least 1 hour have severe pulmonary hypoplasia and are not appropriate candidates for ECMO. However, the outcome of the individual patient is hard to predict, and every measure must be made to provide mechanical ventilation and accept higher P_{aCO_2} and lower P_{aO_2} levels as long as systemic oxygen delivery is appropriate.

Transient Tachypnea of the Newborn

The differential diagnosis for the newborn with tachypnea in the first postnatal hours ranges from RDS to sepsis to CHD. One of the most common, and benign, causes of tachypnea in the newborn is transient tachypnea of the newborn (TTN). TTN results when fetal lung fluid production fails to cease with the onset of labor. The newborn presents with tachypnea, increased work of breathing, and cyanosis. Moderate supplemental oxygen may be required. CXR reveals interstitial and alveolar edema; fluid is characteristically seen in the right middle lobe fissure. Symptoms of TTN typically resolve over the first 24 hours without intervention (fetal lung fluid production ceases in response to stress), and CXR clears by the second or third day of life. However, TTN is a diagnosis of exclusion, other causes of tachypnea and respiratory distress must be ruled out. An evaluation for sepsis (including initiating antibiotic therapy pending culture results) as well as other causes of tachypnea is generally warranted.

Congenital Heart Disease

CHD occurs in approximately 1 in 100 live births, and approximately 3 in 1000 have CHD that requires surgical repair or results in death within the first year of life. CHD rarely presents in the delivery room. In fact, the majority of infants with prenatally diagnosed CHD initially appear well. Nevertheless, the newborn with cyanosis that fails to respond to oxygen should be evaluated for structural heart disease. Complex CHD typically presents as cyanosis, congestive heart failure and circulatory shock and only rarely as an asymptomatic murmur in a newborn. Signs such as tachypnea, weak peripheral pulses, or cool extremities may develop quickly with closure of the ductus arteriosus if the lesion has ductal-dependent pulmonary or systemic flow. Right-sided obstructive lesions (eg, pulmonic atresia), which are dependent on the ductus for pulmonary blood flow, tend to present with cyanosis due to diminished or absent pulmonary blood flow. Left-sided obstructive lesions (eg, coarctation of the aorta and hypoplastic left heart syndrome) typically present as shock and often are initially misdiagnosed as sepsis. However, statistically the term neonate who develops signs of shock after the first 24–48 hours of life is approximately 5 times more likely to have ductal-dependent CHD than bacterial sepsis.

The initial steps in evaluating a stable patient for suspected CHD include 4-extremity blood pressure measurement, measurement of preductal and post-ductal saturations, electrocardiogram, CXR, and hyperoxia test. If the P_{aO_2} fails to increase above 100 after exposure to 100% F_{iO_2} for 15 minutes, cyanotic CHD is likely; if the P_{aO_2} level increases above 250, CHD is unlikely. CXR may reveal black lungs that signify diminished pulmonary blood flow (as occurs in right-sided obstructive lesions) or congestion (as occurs with obstructed pulmonary venous return). The diagnosis of CHD usually is established by echocardiogram, although cardiac catheterization is sometimes necessary to clarify the specifics of the abnormal anatomy in complex cases. Low-dose PGE infusion should be started when critical CHD is suspected in order to maintain or reestablish ductal patency. Once the diagnosis of cyanotic heart disease has been made, supplemental oxygen should be used sparingly but as necessary to keep oxygen saturation around 75–85% until surgical repair occurs. This supplementation should provide adequate oxygen delivery to prevent the development of metabolic acidosis without decreasing pulmonary vascular resistance and causing pulmonary overcirculation.

Esophageal Atresia/Tracheoesophageal Fistula

Esophageal atresia occurs when there is an interruption in the separation of the foregut into the trachea and esophagus during the fourth week of gestation. In its most common form, there is a proximal esophageal pouch

a fistula between the trachea and the distal segment of the esophagus. The newborn with esophageal atresia typically presents in the first few hours after birth with copious secretions and coughing or gagging with the first feed. Respiratory distress may develop if secretions or feeds are aspirated. The prenatal history often is remarkable for polyhydramnios due to the inability of the fetus to regulate amniotic fluid levels by swallowing. The diagnosis usually is apparent when a CXR reveals a nasogastric tube coiled in the proximal esophageal pouch. Absence of a gastric bubble on x-ray usually suggests that a distal fistula is not present. Emergent gastrostomy may be necessary to decompress the stomach. The feasibility of primary repair depends on the distance between the proximal and distal portions of the esophagus. If primary repair is not possible, initial surgery involves ligation of the fistula. Patients typically then undergo serial dilations of the proximal pouch and delayed anastomosis or may require colonic interposition if the gap remains too wide to close. Postoperative complications include leaking or stenosis at the anastomosis site, poor esophageal motility, and gastroesophageal reflux.

Polycythemia

Polycythemia, defined as a central venous Hct greater than 65%, results from either increased in utero erythropoiesis or from maternofetal or twin-twin transfusion. Increased in utero erythropoiesis occurs most often as a response to fetal hypoxia, usually from placental insufficiency. Erythropoiesis in the fetus is also increased with maternal diabetes, chromosomal abnormalities, and endocrine disorders such as congenital adrenal hyperplasia, thyroid disease, and Beckwith-Wiedemann syndrome. Maternofetal hemorrhage most commonly results from delayed cord clamping.

Polycythemia may cause congestive heart failure from volume overload, as in the case of the recipient twin in twin transfusion syndrome. More commonly, the complications attributed to polycythemia arise from hyperviscosity rather than increased blood volume. Blood viscosity increases as the Hct level rises, placing the polycythemic infant at risk for complications from impaired blood flow and oxygen delivery. Polycythemia may present as hypoglycemia, poor feeding, respiratory distress, pulmonary hypertension, lethargy, jitteriness, or seizures. Infants are at increased risk for NEC, and thrombotic strokes may occur.

Although IV hydration may be useful, a symptomatic neonate with Hct level greater than 65% or an asymptomatic neonate with Hct level greater than 70% should undergo a partial exchange transfusion performed to decrease blood viscosity and ameliorate any symptoms. The volume of blood that should be removed and then replaced with isotonic saline (to lower the viscosity without causing hypovolemia) is determined by the following formula:

$$\text{Exchange volume} = \frac{(\text{Observed Hct} - \text{Goal Hct}) \times \text{Blood volume (cc/kg)} \times \text{Weight (kg)}}{\text{Observed Hct}}$$

Blood volume usually is estimated at 100 cc/kg. The goal Hct usually is 55%. The hope is that partial exchange transfusion will prevent symptoms from worsening and further complications from developing, but long-term follow-up studies have failed to show any benefit.

Hyperbilirubinemia

Hyperbilirubinemia is a common problem in the neonatal period, affecting 60–70% of all infants born in the United States to some degree. In most instances, the level of the unconjugated form of bilirubin is elevated. Although the course usually is benign and an increase in serum bilirubin level occurs in all newborns during the first postnatal week, severe unconjugated hyperbilirubinemia can cause kernicterus and long-term neurologic damage.

Bilirubin is produced when heme-containing compounds such as hemoglobin are broken down. The initial unconjugated product is fat soluble but water insoluble, a form that can cross the blood–brain barrier and cause central nervous system toxicity but cannot be excreted. The blood carries bilirubin to the liver, where it is conjugated to a water-soluble and excretable form by the enzyme glucuronyl transferase. The immature hepatic enzyme fur

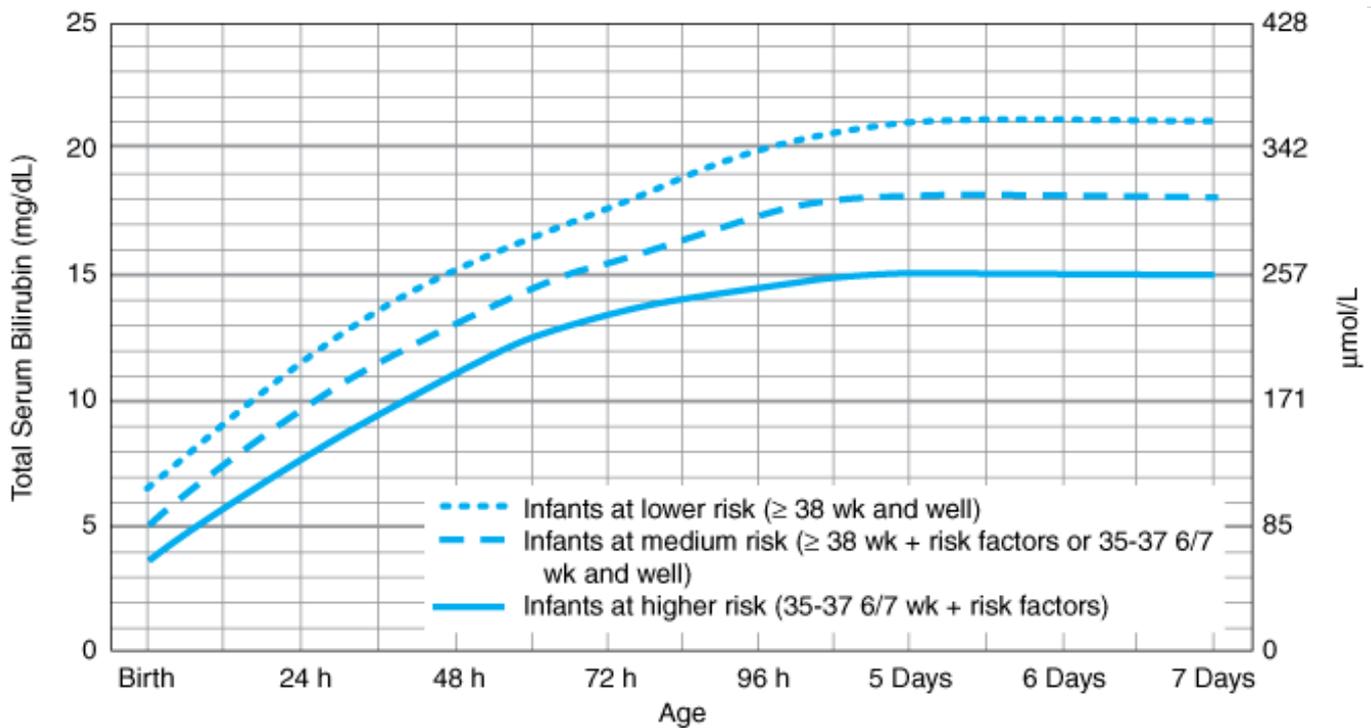

in the newborn impairs bilirubin conjugation and thus excretion. The shorter life span of red blood cells and increased red cell mass in neonates further predispose the newborn to elevated plasma concentrations of bilirubin, as does increased reabsorption of bilirubin that occurs in the sterile newborn intestinal tract.

Hyperbilirubinemia may be severe when other coexisting factors increase hemolysis, decrease the rate of bilirubin conjugation, or impede excretion. Hemolysis is increased by abnormal red cell enzyme function (glucose-6-phosphate dehydrogenase [G6PD] deficiency, less frequently pyruvate kinase deficiency) or morphology (spherocytosis, elliptocytosis) and isoimmunization due to ABO, minor antigen, or Rh incompatibility. Sepsis can increase hemolysis. A number of inborn errors of metabolism and enzyme defects can impair conjugation. Conjugation is impaired when there is delayed maturation of the conjugating enzymes, as is thought to occur in cases of congenital hypothyroidism. Obstructed biliary flow, as in biliary atresia, and gastrointestinal obstruction cause decreased excretion. Many disorders are associated with hyperbilirubinemia.

Hyperbilirubinemia presents clinically as jaundice, a yellow–green discoloration of the skin and mucous membranes. Serum bilirubin level should be checked in all jaundiced newborns. It is standard policy in some nurseries to check total serum bilirubin (TSB) level in all newborns prior to discharge. Most centers check a level within 24–48 hours of life in all VLBW infants as risk for sequelae from hyperbilirubinemia is believed to exist at lower serum bilirubin concentrations in preterm neonates. The etiology of the hyperbilirubinemia must be sought. A blood type, Coombs test, Hct level, and reticulocyte count will provide important information, as will the parent's ethnicity, maternal blood type, and history of jaundice in siblings. It is important to determine whether it is the level of conjugated or unconjugated fraction of bilirubin that is elevated. The differential diagnosis, evaluation, and treatment are markedly different depending on whether or not the elevated portion is conjugated. A conjugated bilirubin level greater than 10% of the total value should prompt an investigation for biliary obstruction or causes of hepatocellular damage such as TORCH (toxoplasmosis, other agents, rubella, cytomegalovirus, herpes simplex) infection, galactosemia and congenital antitrypsin deficiency. A complete sepsis work-up is indicated in the ill-appearing patient.

The American Academy of Pediatrics (AAP) has established practice parameters to help direct the use of phototherapy and exchange transfusion for hyperbilirubinemia in infants of greater than 35 weeks' gestation. Phototherapy causes the photoisomerization of unconjugated bilirubin to a water-soluble form that can be excreted by the kidneys and the gastrointestinal tract. Phototherapy is contraindicated for conjugated hyperbilirubinemia; it is not effective and can cause a bronze staining of the skin. Figure 32–6 shows the current AAP recommendations for initiation of phototherapy. A patient should receive phototherapy if the TSB level lies above the line for the appropriate risk group for the patient. A newborn is considered to have risk factors if any of the following are present: isoimmune hemolytic disease, G6PD deficiency, asphyxia, significant lethargy, temperature instability, sepsis, acidosis, or albumin level less than 3.0 g/dL.

Figure 32–6.

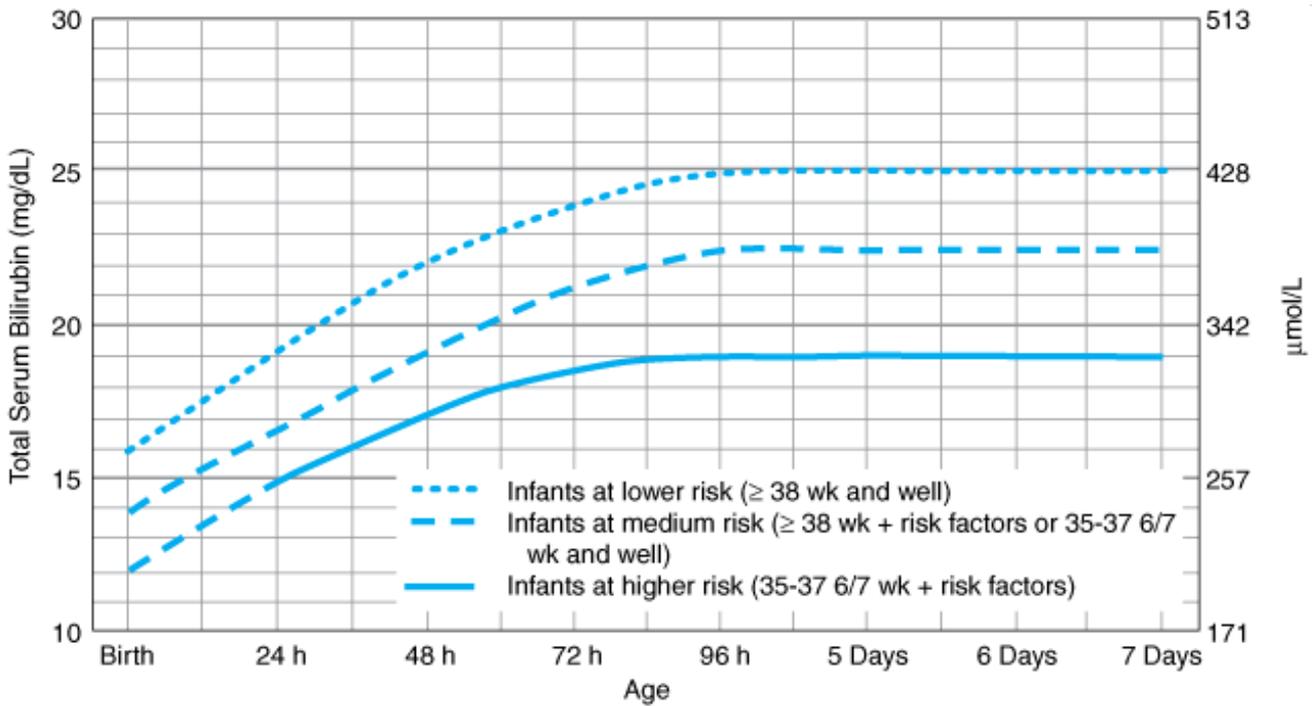

- Use total bilirubin. Do not subtract direct reacting or conjugated bilirubin.
- Risk factors = isoimmune hemolytic disease, G6PD deficiency, asphyxia, significant lethargy, temperature instability, sepsis, acidosis, or albumin < 3.0g/dL (if measured).
- For well infants 35–37 6/7 wk can adjust TSB levels for intervention around the medium risk line. It is an option to intervene at lower TSB levels for infants closer to 35 wks and at higher TSB levels for those closer to 37 6/7 wk.
- It is an option to provide conventional phototherapy in hospital or at home at TSB levels 2-3 mg/dL (35-50 mmol/L) below those shown but home phototherapy should not be used in any infant with risk factors.

Guidelines for phototherapy in hospitalized infants of 35 or more weeks' gestation.

Insensible losses increase under phototherapy, and liberal intravenous fluids should be given in anticipation of increased daily fluid needs. Infants who appear well, are tolerating enteral feeds, and not likely to require an exchange transfusion should continue feeding. Enteral nutrition will increase stooling and facilitate bilirubin excretion. Intravenous fluid should be given in addition if oral intake is insufficient or if needed for adequate hydration.

Figure 32–7 shows the AAP guidelines for exchange transfusion. Exchange transfusion effectively removes bilirubin as well as anti-red cell antibodies circulating in the blood. Twice the blood volume (estimated at 85–100 cc/kg) is removed from the patient in aliquots of 5–10 cc, with each aliquot followed by transfusion of an equal volume of fresh type O negative blood. The guidelines shown in Figure 32–7 are intended to apply to the newborn who has continuous rise in TSB level despite intensive phototherapy or to a neonate readmitted to the hospital after discharge who continues to have a TSB above the exchange level for 6 hours after initiation of phototherapy. Immediate exchange is recommended if the TSB is more than 5 mg/dL greater than the exchange threshold or if the patient has abnormal findings on neurologic examination that suggest acute bilirubin encephalopathy. Complications of exchange transfusion include hypocalcemia, hypoglycemia, hypothermia, coagulation abnormalities, apnea, and bradycardia. Many centers delay resuming oral feeds until 24–48 hours post exchange because of the increased risk of NEC after an exchange.

Figure 32–7.

- The dashed lines for the first 24 hours indicate uncertainty due to a wide range of clinical circumstances and a range of responses to phototherapy.
- Immediate exchange transfusion is recommended if infant shows signs of acute bilirubin encephalopathy (hypertonia, arching, retrocolitis, opisthotonos, fever, high pitched cry) or if TSB is ≥ 5 mg/dL (85 $\mu\text{mol/L}$) above these lines.
- Risk factors—isoimmune hemolytic disease, G6PD deficiency, asphyxia, significant lethargy, temperature instability, sepsis, acidosis.
- Measure serum albumin and calculate B/A ratio.
- Use total bilirubin. Do not subtract direct reacting or conjugated bilirubin.
- If infant is well and 35-37 6/7 wk (median risk) can individualize TSB levels for exchange based on actual gestational age.

Guidelines for exchange transfusion in infants 35 or more weeks' gestation.

Indications for phototherapy and exchange transfusion in preterm infants are not well established. A reasonable guideline is to begin phototherapy when the bilirubin concentration is equal to 0.5% of the birth weight (in gram and to consider an exchange transfusion when the concentration reaches 1% of the birth weight. These numbers represent a very general guideline, however, and it is important that treatment decisions take into account the etiology of the jaundice and the patient's overall clinical status (Table 32–2). The presence of significant bruising, hemolysis, sepsis, or acidosis should lower the physician's threshold for initiating treatment.

Infection

Infection is a significant cause of morbidity and mortality in the newborn. The immature newborn immune system places the neonate at increased risk for infection. The preterm infant, whose immune system is markedly immature and who has diminished levels of immunoglobulin compared to the term newborn, is at particularly high risk.

Typically infection is acquired when organisms ascend into the uterine cavity and come into contact with the fetus but infection can be acquired hematogenously, from the mother's blood, or at the time of delivery when the newborn passes through the vaginal canal.

SEPSIS

Neonatal sepsis occurs in 1 in 1000 term infants and 1 in 4 preterm infants. Risk factors for neonatal sepsis include premature delivery, multiple pregnancy, prolonged rupture of amniotic membranes (> 18 hours), maternal fever, maternal group B streptococcus (GBS) colonization, and chorioamnionitis. The most common causes of early-onset (within the first week of life) sepsis are GBS and *Escherichia coli*. *Listeria monocytogenes*, enterococci, and several different gram-negative rod species are other identified causes of early-onset neonatal sepsis. Late-onset infection in hospitalized infants is more often due to *Staphylococcus* spp.

Signs and symptoms of sepsis in the newborn can be very subtle and nonspecific, such as temperature instability, hypoglycemia or hyperglycemia, apnea, poor feeding, or tachypnea. In contrast, some neonates present in fulminant shock. A complete blood count and blood culture should be sent if sepsis is suspected and antibiotics should be started. A decreased or elevated white blood cell count, a predominance of immature white blood cell forms, and thrombocytopenia are suggestive of infection. Although nonspecific, an elevated C-reactive protein (CRP) level indicates the presence of an inflammatory or infectious process, and data support the value of the CRP level in the evaluation for sepsis in the neonate. In addition, CXR is indicated to evaluate for pneumonia. Often differentiating infiltrate from atelectasis, RDS, or retained lung fluid is difficult, but serial films may be useful in differentiating these various processes. There is debate about whether a culture of cerebrospinal fluid (CSF) is necessary in the newborn evaluated for early-onset sepsis. (A CSF culture is clearly warranted in suspected late-onset sepsis because the incidence of coexisting meningitis with late-onset bacteremia is very high.) Unless signs of meningitis (eg, seizure activity or altered mental status) or a documented positive blood culture is present, meningitis is unlikely in the immediate newborn period. However, studies have reported positive CSF cultures with concurrent negative blood cultures in asymptomatic neonates. The issue has been further complicated by the current widespread use of maternal intrapartum antibiotics. Consequently, given the ramifications of failure to diagnose or only partially treat a case of meningitis, CSF culture is a routine part of the newborn sepsis evaluation in many institutions. Urine culture, a routine part of the sepsis evaluation for late-onset disease, is rarely useful in the first few days of life.

life.

Antibiotics that provide broad-spectrum coverage, typically ampicillin and gentamicin in the first few days of life, should be continued for 48–72 hours pending the results of all cultures that were sent analysis. Vancomycin and gentamicin are often used for nosocomial infections. If bacteremia is documented by a positive blood culture or highly suspected based on clinical status or laboratory findings, antibiotics should be continued for 7–10 days. Intravenous antibiotics usually are continued for a minimum of 2 weeks for gram-positive meningitis and 3 weeks for gram-negative meningitis.

The Centers for Disease Control and Prevention (CDC) developed guidelines in 1996 that recommended screening for GBS colonization at 35–37 weeks' gestation. It was recommended that colonized women and those with other risk factors receive intrapartum antibiotic therapy beginning at least 4 hours prior to delivery. The incidence of early-onset GBS sepsis has been reduced by 65% in communities that have adopted the CDC GBS prevention guidelines. Currently no evidence suggests an increased incidence of non-GBS early-onset sepsis with adoption of the guidelines as had been feared.

CONJUNCTIVITIS

Infection of the conjunctiva may occur within the first few weeks of life. Prophylaxis with erythromycin 0.5% ophthalmic ointment immediately after delivery is now a standard part of newborn care. Conjunctivitis usually presents with injection of the conjunctiva and discharge from the eye, usually bilaterally, in the first week of life. Erythema of the conjunctiva helps differentiate conjunctivitis from lacrimal duct obstruction, a common cause of discharge in the neonate.

Chlamydia trachomatis and *Neisseria gonorrhoeae* are the most notable causes of neonatal conjunctivitis. Maternal treatment of either infection during pregnancy reduces the risk of infection in the neonate. Gonococcal conjunctivitis produces a purulent discharge and may cause serious complications, including blindness. A Gram stain and culture of the discharge should be performed if there is any suspicion of infection to determine appropriate therapy. It is important to recognize that the infant with *Chlamydia* conjunctivitis may have or may develop *Chlamydia* pneumonia. *Chlamydia* pneumonia commonly presents in the first 6 weeks of life with tachypnea and cough. The infant with gonococcal conjunctivitis should receive 7 days of IV or IM treatment with a third-generation cephalosporin such as ceftriaxone. *Chlamydia* conjunctivitis is treated with oral erythromycin for 14 days.

VIRAL INFECTION

A number of viral infections can cause disease in the newborn. The infection may be acquired in utero or at the time of delivery. Antibody titers and cultures should be sent when congenital viral infection is suspected. A number of viruses, including cytomegalovirus (CMV), varicella, parvovirus, and toxoplasmosis, are associated with congenital infection, and the presentation varies significantly depending on the virus. Herpesvirus and enterovirus infections present acutely with respiratory failure and/or shock. Hepatitis and coagulopathy are often seen in neonates with viral sepsis, even early in the disease process before end-organ damage is even suspected, and should raise suspicion about the possibility of a viral process. There is no maternal history of herpes simplex virus (HSV) in the majority of neonates diagnosed with HSV sepsis or encephalitis. Cultures for HSV should be sent from the asymptomatic infant born to a mother with active HSV lesions at the time of vaginal delivery. Although no clear evidence supports the practice, some experts advocate empiric therapy if the lesions are due to a primary infection. Acyclovir is used to treat herpes viruses such as HSV and varicella.

Transmission from mother to infant at birth is one of the most efficient modes of hepatitis B virus (HBV) transmission. From 80–90% of children born to mothers who are both hepatitis B surface antigen (HBsAg) and hepatitis B e antigen (HBeAg) positive will become infected, and 90% of those infants will become chronic HBV carriers. Transmission falls to less than 25% if HBeAg is negative and to 12% if anti-HBe is present. Babies born to HBsAg-positive mothers should receive hepatitis B immune globulin (HBIG) and the hepatitis B vaccine within 12 hours of delivery. If the mother's status is unknown at the time of delivery, the newborn should receive the vaccine.

within 12 hours of life. If the newborn weighs more than 2 kg, HBIg can be deferred for up to 7 days to allow determination of the mother's status according to the most recent AAP *Red Book* guidelines. However, given the reliable immune response to vaccine in the preterm host, HBIg should not be deferred in patients weighing less than 2 kg. Appropriate postexposure prophylaxis in the newborn has been shown to prevent transmission in 95% of exposures.

Perinatal infection with human immunodeficiency virus (HIV) now accounts for almost all new infections in preadolescents in the United States. The risk of perinatal transmission if a HIV-positive mother does not receive antiretroviral therapy during pregnancy is 13–39%. A trial of zidovudine during pregnancy and delivery, with continued treatment for the newborn for 6 weeks after delivery, showed a greater than 60% reduction in transmission. It is currently recommended that HIV-positive women receive zidovudine prophylaxis in addition to standard current recommendations for antiretroviral therapy for all HIV-positive patients. Zidovudine prophylaxis/treatment of the newborn should be started and analysis for HIV DNA polymerase chain reaction serology when in utero exposure to HIV is recognized before 7 days of life.

Infant of the Diabetic Mother

From 50,000–100,000 infants are born to diabetic mothers every year in the United States. The infant of a diabetic mother (IDM) is at increased risk for congenital malformations, macrosomia, birth injury, and a number of postnatal complications, such as RDS, polycythemia, and hypoglycemia. With improved obstetric monitoring and neonatal care, perinatal mortality has decreased significantly over the past few decades. With decreased losses from stillbirths, perinatal asphyxia, and RDS, congenital malformations now represent the single most important cause of perinatal mortality and severe morbidity in IDMs.

Studies have shown that IDMs have a 2- to 8-fold higher risk of a structural malformation compared to infants born to nondiabetic mothers. The most common malformations in IDMs are neural tube defects, CHD, renal anomalies, and abnormalities of the genitourinary tract. The exact pathogenesis of the malformations is unclear, but various mechanisms, including altered levels of arachidonic acid and/or myoinositol, free-radical damage, and altered gene expression, have been proposed. The risk of structural malformations has been clearly shown to correlate with poor glycemic control in the first trimester. Consequently, tight control of glucose levels must begin prior to conception in order to decrease the risk of structural malformations.

Metabolic alterations seen in IDMs are more closely associated with glycemic control later in pregnancy. Elevated maternal glucose levels result in elevated fetal glucose levels that produce hyperinsulinism in the fetus. Insulin is a growth factor, and abnormal exposure to insulin results in fetal macrosomia. After delivery, the hyperinsulinemic state persists, but there is no longer an ongoing supply of glucose coming across the placenta and the newborn is at high risk for hypoglycemia. IDMs should be closely monitored after birth to ensure that glucose requirements are met. Severe and prolonged hypoglycemia can cause significant injury to the developing brain. Poor glucose control during the second and third trimesters is associated with an increased risk for macrosomia and neonatal hypoglycemia. Other metabolic derangements frequently seen in IDMs are hypocalcemia and hypomagnesemia.

IDMs are at increased risk for RDS. Surfactant production occurs later than normal in diabetic pregnancies. Polycythemia also occurs at a higher rate. The greater red cell volume, in turn, increases the risk of hyperbilirubinemia. Hyperglycemia and the resulting hyperinsulinemia in the fetus generate a catabolic state, causing increased oxygen consumption. Erythropoiesis is believed to occur as a response to fetal hypoxia.

Hypertrophic cardiomyopathy is a frequent finding in IDMs. The cardiomyopathy may be asymptomatic, appearing only as cardiomegaly on CXR, or it may be clinically significant, usually as a result of left ventricular outflow tract obstruction and/or poor ventricular filling and cardiac output related to hypertrophy of the ventricular septum. The hypertrophy of the cardiac muscle resolves over time, and the only indicated treatment is supportive care.

Intrauterine Growth Restriction

Intrauterine growth restriction (IUGR) describes a pattern of aberrant and reduced fetal growth that is identified prenatal ultrasound examinations. The growth restriction is classified as asymmetric if the head circumference, used as a marker for brain growth, is spared. IUGR refers to growth in utero, and IUGR newborns may or may not be small for gestational age (SGA). (The definition of SGA varies, but historically it has been defined as less than the 10th percentile on the growth curve.) IUGR can result from a range of processes that may originate with the fetus (chromosomal abnormalities, fetal gender, genetic inheritance, TORCH infection), the placenta (abnormal implantation or insertion of the cord, preeclampsia, placental insufficiency), or the mother (chronic disease such as diabetes, systemic lupus erythematosus, or cyanotic heart disease, smoking, abnormal uterine anatomy, low pregnancy weight gain). The etiology of IUGR in approximately 40% of patients is never determined. CMV and toxoplasmosis studies are sometimes sent for affected newborns to determine an infectious cause. However, given the number of idiopathic cases of IUGR, some have questioned the utility of sending these cultures for infants with physical examination or imaging study findings suggestive of congenital infection. Prenatal management of the IUGR fetus is impacted by the increased risk of intrauterine demise and perinatal asphyxia with IUGR, but also requires consideration of the fact that gestational age at birth is still a major determinant of outcome in the premature growth-restricted infant. There is currently great interest in the connection between low birth weight and the development of type 2 diabetes, hypertension, and coronary artery disease in adulthood.

The Dysmorphic Infant

It is estimated that 2% of all newborns have a serious congenital malformation. Advances in prenatal care now allow for early diagnosis of many congenital birth defects or diseases, but many are still difficult or impossible to detect in utero. Dysmorphic features and structural abnormalities may be immediately apparent, or they may be subtle and identified only upon close inspection. Every newborn should undergo a thorough examination to identify features suggestive of underlying pathology, genetic abnormalities, or specific syndromes or disorders.

Transfer of the newborn to a referral center where an evaluation by a clinical geneticist or dysmorphologist can be conducted may be warranted if abnormalities are present. The remarkable progress in our understanding of human genetics over the past decade has dramatically increased our ability to identify the genetic defects responsible for countless diseases and syndromes. In addition, each year more is understood about numerous multifactorial disorders, improving the odds that affected patients will be correctly diagnosed. A geneticist can help identify pertinent elements of the family, exposure, and prenatal history and direct a thorough but targeted radiologic and cytogenetic work-up for the newborn. It is preferable to avoid making conclusions about the diagnosis (ie, a particular syndrome or sequence) until a complete evaluation has been performed. The emotional impact of an unsuspected defect or syndrome on the new parents should not be ignored, and misinformation can only hinder the process of acceptance (Table 32–3).

Current OB/GYN >Chapter 33. Gynecologic History, Examination, & Diagnostic Procedures>

GYNECOLOGIC HISTORY, EXAMINATION, & DIAGNOSTIC PROCEDURES: INTRODUCTION

The gynecologist needs to approach each patient not just as a person requiring medical intervention for a specific presenting problem, but also as one who may have a variety of factors possibly affecting her health. The initial approach to the gynecologic patient and the general diagnostic procedures available for the investigation of gynecologic complaints are presented here. Although other aspects of the general medical examination are left to other texts, concern for the patient's total health and well-being is mandatory.

THE PERIODIC HEALTH SCREENING EXAMINATION

It is now a generally accepted part of the physician's responsibility to advise patients to have periodic medical evaluations. The frequency of visits varies according to the patient's problem.

The periodic health screening examination helps detect the following ailments of women that are especially amenable to early diagnosis and treatment: diabetes mellitus; urinary tract infection or tumor; hypertension; malnutrition or obesity; thyroid dysfunction or tumor; and breast, abdominal, or pelvic tumor. These conditions can be detected by a review of systems, with specific questions regarding recent abnormalities or any variation in function. Determination of weight, blood pressure, and urinalysis may reveal variations from the previous examination. An examination of the thyroid gland, breasts, abdomen, and pelvis, including a Papanicolaou (Pap) smear, should then be performed. A rectal examination also is advisable, and a conveniently packaged test for occult blood (Hemoccult) is recommended for patients older than 40 years. Patients of an advanced age (> 50 years) may undergo blood test for lipid profile, bone density scan, pelvic ultrasound examination, and mammogram.

The physician should be concerned about conditions other than purely somatic ones. Unless a patient's problems require the services of a psychiatrist or some other specialist, the doctor should be prepared to act as a counselor and work with the patient during a mutually agreeable time when it is possible to listen to her problems without being hurried and to give support, counsel, and other kinds of help as required.

HISTORY

To adequately evaluate the gynecologic patient, it is important to establish a rapport during the history taking. The patient needs to tell her story to an interested listener who does not allow body language or facial expressions to imply disinterest or boredom. One should avoid cutting off the patient's story, because doing so may obscure important clues or other problems that may have contributed to the reasons for the visit.

The following outline varies from the routine medical history because, in evaluating the gynecologic patient, the problem often can be clarified if the history is obtained in the following order.

Identifying Information

AGE

Knowledge of the patient's age sets the tone for the complaint and the approach to the patient. Obviously, the problems and the approach to them vary at different stages in a woman's life (pubescence, adolescence, childbearing years, and premenopausal and postmenopausal years).

LAST NORMAL MENSTRUAL PERIOD

The date of onset of the last normal menstrual period (LNMP) is important to define. A missed period, irregularity of periods, erratic bleeding, or other abnormalities may all imply certain events that are more easily diagnosed when the date of onset of the LNMP is established.

GRAVIDITY AND PARITY

The process of taking the patient's obstetric history is detailed in Chapter 9, but the reproductive history should be recorded as part of the gynecologic evaluation. A convenient symbol for recording the reproductive history is a 4 digit code denoting the number of term pregnancies, premature deliveries, abortions, and living children (TPAL), eg, 2-1-1-3 means 2 term pregnancies, 1 premature delivery, 1 abortion, and 3 living children.

Chief Complaint

The chief complaint usually is best elicited by asking "What kind of problem are you having?" or "How can I help you?" It is important to listen carefully to the way the patient responds to this question and to allow her to fully explain her complaint. The patient should be interrupted only to clarify certain points that may be unclear.

Present Illness

Each of the problems the patient describes must be obtained in detail by questioning regarding what exactly the problem is, where exactly the problem is occurring, the date and time of onset, whether the symptoms are abating or getting worse, the duration of the symptoms when they do occur, and how these symptoms are related to or influence other events in her life. For example, the site, duration, and intensity of pain must be accurately described. Getting a sense of how the pain affects her life often is helpful in evaluating the intensity of pain: "Does the pain prevent you from standing or walking?"

It is important to maintain eye contact with the patient and to listen to every word. Do not rely on a patient's sophistication as a measure of her knowledge of anatomy and medical terminology. It is important for the physician to judiciously adjust the level of terminology according to the patient's knowledge and vocabulary. Communicating with the patient in this manner may help the physician obtain an accurate history and establish rapport.

In addition to physiologic events and the life cycle, symptoms described could be related to starting a new job, the beginning of a new relationship or difficulties in the current relationship, an exercise regimen, new medication, or any emotional changes in the patient's life.

Past History

After the physician is satisfied that all possible information concerning the present illness and the important corollaries has been obtained, the past history should be elicited.

CONTRACEPTION

Continuing with the history, it is important to elicit whether the patient is using or needs some form of contraception. If she is using contraception, her level of satisfaction with her chosen method should be determined. In patients taking oral contraceptives, the history should reflect the agent and dose, whether there is a great variation in the time of day she takes her pill, and any impact of the pill on other physiologic functions. Other forms of hormonal contraceptives, including vaginal rings, dermal patches, and injectable contraceptives, have become available and have their own unique issues. It is extremely important to ask questions during the remainder of the history and to key the physical examination to ascertain whether there are any contraindications to the patient's current form of contraception.

MEDICATIONS AND HABITS

Any medications, prescribed or otherwise, that are being taken or that were being taken when symptoms first occurred should be described. Particular attention must be directed to use of hormones, steroids, and other compounds likely to influence the reproductive tract. Herbal preparations may not be viewed by the patient as medications, so this question should be specifically asked. In addition to medications, the patient should be questioned concerning her use of street drugs. It must be ascertained whether the patient smokes and, if so, how much and for how long. It is important to ascertain the amount of alcohol ingested, if any. This questioning provides an ideal time to indicate the health risks of various habits.

MEDICAL

It is important to discover any history of serious medical and psychiatric illnesses and whether hospitalization was required. Particularly important are illnesses in the major organ systems. It is important to know whether there is a major endocrinopathy in the patient's history. Notable weight gain or loss prior to the onset of the patient's current symptoms should be detailed. Other important details include when she had her last physical examination including pelvic examination and Pap smear.

SURGICAL

The surgical history includes all operations, the dates performed, and associated postoperative or anesthetic complications.

ALLERGIES

Questioning should continue relating any possible allergic reactions to drugs or specific foods. The reaction produced (eg, rash, gastrointestinal upset) must be elicited and the approximate time when it occurred ascertained. Any testing to confirm or deny the observation must be noted. Latex allergy has become more common and severe and should be considered prior to most medical procedures, such as drawing blood samples, pelvic examination, and taking blood pressures.

BLEEDING AND THROMBOTIC DIATHESSES

Determining whether or not the patient bleeds excessively in relation to prior surgery or minor trauma is important. A history of easy bruising or of bleeding from the gums while brushing teeth may be useful in this judgment. The patient should be asked whether she or one of her close relatives experienced venous thromboembolism (VTE). A history of VTE may guide the physician as to which treatment to offer. Suspicion of a bleeding or clotting problem indicates the need for further laboratory evaluation.

OBSTETRICS

The obstetric history includes each of the patient's pregnancies listed in chronologic order. The date of birth; sex and weight of the offspring; duration of pregnancy; length of labor; type of delivery; type of anesthesia; and any complications should be included.

GYNECOLOGIC

The first item in the gynecologic past history is the menstrual history: age at menarche, interval between periods, duration of flow, amount and character of flow, degree of discomfort, and age at menopause. The menstrual history often is an important clue in the diagnosis.

A prior history of sexually transmitted disease (STD) needs to be detailed. Although in the past it was more common to note only gonorrhea and syphilis, it is important to also document exposure to human immunodeficiency virus (HIV), hepatitis, herpesvirus, chlamydia, and papillomavirus. Any treatment or admission to the hospital for treatment of salpingitis, endometritis, or tubo-ovarian abscess must be carefully documented. Attempts to assess the impact of these processes in relation to ectopic pregnancy, infertility, and type of contraception must be elicited.

Although its significance is less than that of the prior stated diseases, the occurrence of episodes of vaginitis

should not be dismissed. Their frequency and the medications used to treat them should be discussed. In the case of such infections, it is important to detail whether or not the episode was pathologic or merely a misinterpreted physiologic circumstance.

SEXUAL

The sexual history should be an integral part of any general gynecologic history. In taking a sexual history, the physician must be nonjudgmental and not embarrassed or critical.

Questions that may be covered include the following. Is she currently sexually active? Is the relationship satisfactory to her and, if not, why not? A question regarding whether the patient is heterosexual or lesbian is important but often difficult to ask because the question may be offensive to some patients. It is important, however, not to assume that a relationship is heterosexual because a lesbian woman will lose all rapport with the physician when the physician is insensitive to such issues.

SOCIAL

A social history can be an extension of earlier questions pertaining to the marital and sexual history. Knowing the type of work the patient does, the type of educational background, and her community activities may assist in ascertaining the patient's relationship to her entire environment.

The patient's involvement with her own health care should be carefully elicited, including her attention and knowledge concerning diet, health screening examinations, recreation, and the degree of regular physical exercise.

Family History

The patient's family history must include the state of health of immediate relatives (parents, siblings, grandparents, and offspring). In addition to listing these relatives, it is useful in cases where genetic illnesses may be apparent to record a 3-generation pedigree.

The incidence of familial heart disease, hypertensive renal or vascular disease, diabetes mellitus (insulin-dependent or non-insulin-dependent), vascular accidents, and hematologic abnormalities should be ascertained. If the patient has a problem with hirsutism or if she perceives excessive hair growth, it is important to elicit whether anyone in her family has the same distribution of hair growth. Familial history of breast, ovarian, and colon cancers is important to elicit because a close familial history may require additional testing and close follow-up. It is important to relate the time of menopause in the mother or grandmother and to ascertain a history of osteoporosis.

PHYSICAL EXAMINATION

The physical examination is most useful if it is conducted in an environment that is aesthetically pleasing to the patient. Adequate gowning and draping assist in preventing embarrassment. Often a physician's assistant conducts the patient to the dressing area and gives explicit instructions about what to take off and how to put on her gown and then may assist in draping the patient.

A physician may have a female assistant remain in the examining room to assist when necessary, but whether or not she remains solely as a chaperone depends on local custom and the preference of the patient and the physician. A chaperone is not legally required, but the physician, male or female, must use good judgment, especially during the breast and pelvic examinations. If the patient wants her partner, relative, or a friend to be present, the request should be honored unless, in the physician's judgment, such an arrangement would interfere with the examination or with obtaining an accurate history. It is highly recommended that the physician explain the steps and acts that will be taken, especially during the pelvic examination when the patient might lack a direct eye contact with the physician.

General Examination

If the gynecologist is the primary care physician for the patient, a general physical examination should be performed annually or whenever the situation warrants. A complete examination obviously provides more information, demonstrates the physician's thoroughness, and establishes rapport with the patient.

General Evaluation

VITAL SIGNS

As part of every examination—whether for a specific problem, routine annual examination, or a return visit for a previously diagnosed problem—the patient should be weighed and her blood pressure taken. Postmenopausal patients should have their height measured to document any loss of height from osteoporosis and vertebral fractures. Before the patient empties her bladder for the examination, determination should be made as to whether the urine will need to be sent for urinalysis, culture, or pregnancy testing.

The examination of the chest should include visual assessment for any skin lesions and symmetry of movement. Auscultation and percussion of the lungs are important for excluding primary pulmonary problems such as asthma and pneumonia. The examination of the heart includes percussion for size and auscultation for arrhythmias and significant murmurs.

Breast Examination

(See also Chapter 63.)

Breast examination should be a routine part of the physical examination. Breast cancer will occur in 1 in 8 women in the United States during her lifetime. Physicians who treat women should educate patients on the technique of self-examination, because the well-prepared patient is one of the most accurate screening methods for breast disease.

The physical examination provides an ideal time to ascertain the frequency and methodology of breast self-examination. It also is an ideal time to teach the patient how to perform breast self-examination. The patient should be advised to examine herself in the mirror, looking for skin changes or dimpling, and then carefully palpate all quadrants of the breast. Most women prefer to do this with soapy hands while showering or bathing. The examination should be repeated at the same time each month, preferably 1 week after the initiation of the menses, when the breasts are least nodular; postmenopausal women should perform self-examination on the same day each month.

The frequency of mammography or the earlier use of mammography depends on both the individual woman and her family history. Patients with a positive family history of breast cancer should have a mammogram at an early age, particularly those whose mother, aunt, or sister developed premenopausal breast cancer. In general, a mammogram should be obtained every 1–2 years from ages 40 to 50 years and annually thereafter.

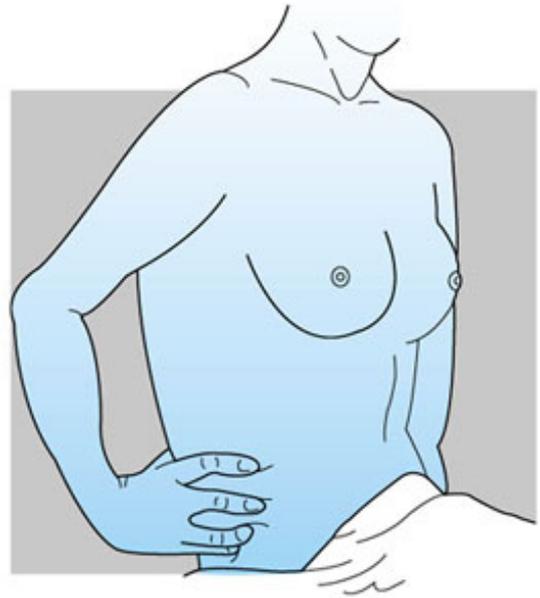

Ultrasonography now can reliably differentiate solid from cystic lesions; this technique complements but does not supplant mammography. Breast self-examination, physician examination, mammography, and ultrasonography are complementary, and all should be used for the early detection of breast cancer.

The correct technique for breast examination is shown in Figure 33–1. If abnormalities are encountered, a decision should be reached concerning the need for mammography (or other imaging methods) or direct referral to a breast surgeon unless the gynecologist is trained in performing breast biopsies. Skin lesions, particularly eczematous lesions in the area of the nipple, should be closely observed; if they are not easily cured by simple measures, they should be biopsied. An eczematous lesion on the nipple or areola may represent Paget's carcinoma.

E

F

G

H

Breast examination by the physician. A: Patient is sitting, arms at sides. Perform visual inspection in good light, looking for lumps or for dimpling or wrinkling of skin. B: Patient is sitting, hands pressing on hips so that pectoral muscles are tensed. Repeat visual inspection. C: Patient is sitting, arms above head. Repeat visual inspection of breasts and perform visual inspection of axillae. D: Patient is sitting and leaning forward, hands on examiner's shoulders, the stirrups, or her own knees. Perform bimanual palpation, paying particular attention to the base of the glandular portion of the breast. E: Patient is sitting, arms extended 60–90 degrees. Palpate axillae. F: Patient is supine, arms relaxed at sides. Perform bimanual palpation of each portion of breast (usually each quadrant, but smaller sections for unusually large breasts). Repeat examinations C, E, and F with patient supine, arms above head. G: Patient is supine, arms relaxed at sides. Palpate under the areola and nipple with the thumb and forefinger to detect a mass or test for expression of fluid from the nipple. H: Patient is either sitting or supine. Palpate supraclavicular areas.

Abdominal Examination

The patient should be lying completely supine and relaxed; the knees may be slightly flexed and supported as an aid to relaxation of the abdominal muscles. Inspection should detect irregularity of contour or color. Auscultation should follow inspection but precede palpation because the latter may change the character of intestinal activity. Palpation of the entire abdomen—gently at first, then more firmly as indicated—should detect rigidity, voluntary guarding, masses, and tenderness. If the patient complains of abdominal pain or if unexpected tenderness is elicited, the examiner should ask her to indicate the point of maximal pain or tenderness with 1 finger. Suprapubic palpation is designed to detect uterine, ovarian, or urinary bladder enlargements. A painful area should be left until last for deep palpation; otherwise, the entire abdomen can be guarded voluntarily. As a final part of the abdominal examination, the physician should carefully check for any abnormality of the abdominal organs: liver, gallbladder, spleen, kidneys, and intestines. In some instances, the demonstration of an abnormality of the abdominal muscle reflexes may be diagnostically helpful. Percussion of the abdomen should be performed to identify organ enlargement, tumor, or ascites.

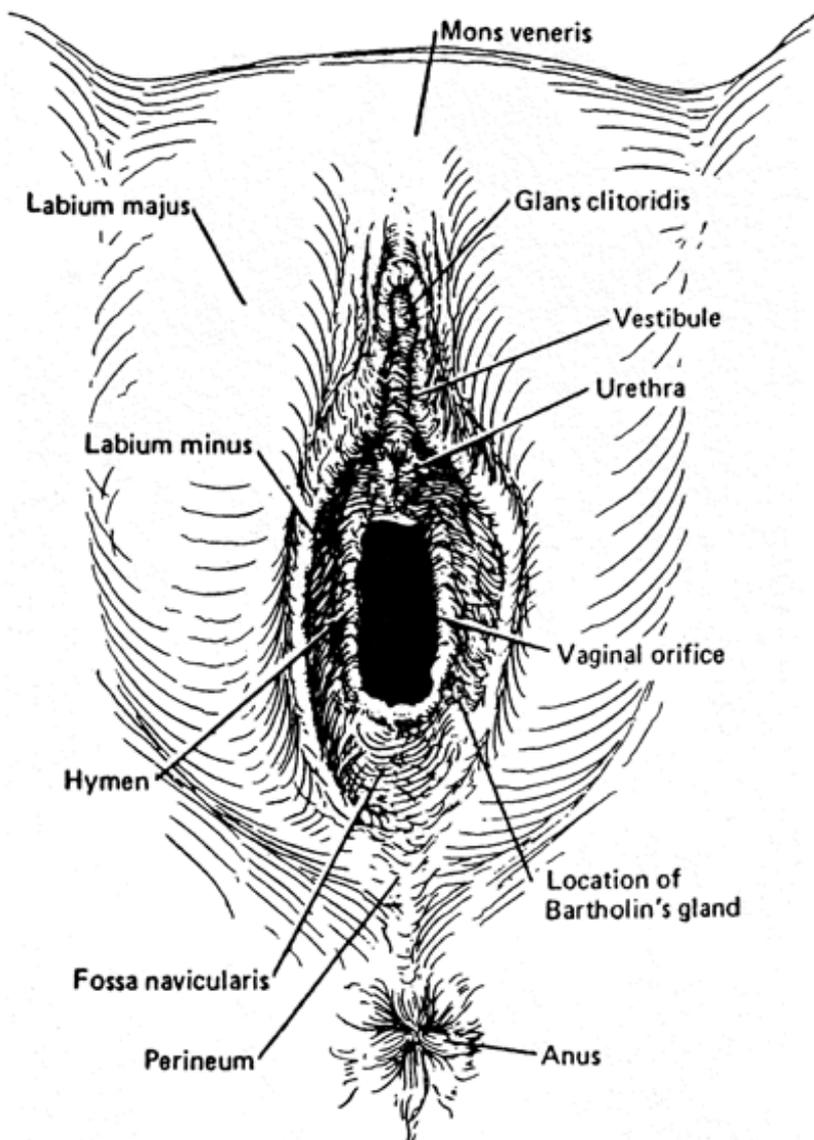

Pelvic Examination

The pelvic examination is a procedure feared by many women, so it must be conducted in such a way as to allay her anxieties. A patient's first pelvic examination may be especially disturbing, so it is important for the physician to attempt to allay fear and to inspire confidence and cooperation. The empathic physician usually finds that by the time the history has been obtained and a painless and nonembarrassing general examination performed, a satisfactory gynecologic examination is not a problem. Relaxing surroundings; a nurse or attendant chaperone if indicated; warm instruments; and a gentle, unhurried manner with continued explanation and reassurance are helpful in securing patient relaxation and cooperation. This is especially true with the woman who has never before undergone a pelvic examination. In these patients, a 1-finger examination and a narrow speculum often are necessary. In some cases, vaginal examination is not possible; palpation of the pelvic structures by rectal examination is then the only recourse. Occasionally an ultrasound examination may be helpful in ascertaining whether the pelvic organs are normal in size and configuration in patients who cannot adequately relax the abdominal muscles. If a more definitive pelvic examination is essential, it can be performed with the patient anesthetized.

EXTERNAL GENITALIA

(Fig 33–2) The pubic hair should be inspected for its pattern (masculine or feminine), for the nits of pubic lice, for infected hair follicles, and for any other abnormalities. The skin of the vulva, mons pubis, and perineal area should be examined for evidence of dermatitis or discoloration. The glans clitoridis can be exposed by gently retracting the surrounding skin folds. The clitoris is at the ventral confluence of the 2 labia; it should be no more than 2.5 cm in length, most of which is subcutaneous. The major and minor labia usually are the same size on both sides, but moderate difference in size is not abnormal. Small protuberances or subcutaneous nodules may be either sebaceous cysts or tumors. External condylomata are often found in this area. The urethra, just below the clitoris, should be the same color as the surrounding tissue and without protuberances. Normally, vestibular (Bartholin's) glands can be neither seen nor felt, so enlargement may indicate an abnormality of this gland system. The area of the vestibular glands should be palpated by placing the index finger in the vagina and the thumb outside and gently feeling for enlargement or tenderness (Fig 33–3). The perineal skin may be reddened as a result of vulvar or vaginal infection. Scars may indicate obstetric lacerations or surgery. The anus should be inspected at this time for the presence of hemorrhoids, fissures, irritation, or perianal infections (eg, condylomata or herpesvirus lesions).

HYMEN

An unruptured hymen may present in many forms, but only a completely imperforate, cribriform, or septate hymen is pathologic. After rupture, the hymen may be seen in various forms (Fig 33–4). After the birth of several children, the hymen may disappear almost completely.

Figure 33–4.

Ruptured hymen (parous introitus).

PERINEAL SUPPORT

To determine the presence of pelvic relaxation, the physician spreads the labia with 2 fingers and tells the patient

to "bear down." This will demonstrate urethrocele, cystocele, rectocele, or uterine prolapse, although sometimes an upright position may be necessary to demonstrate significant prolapse (see Chapter 44).

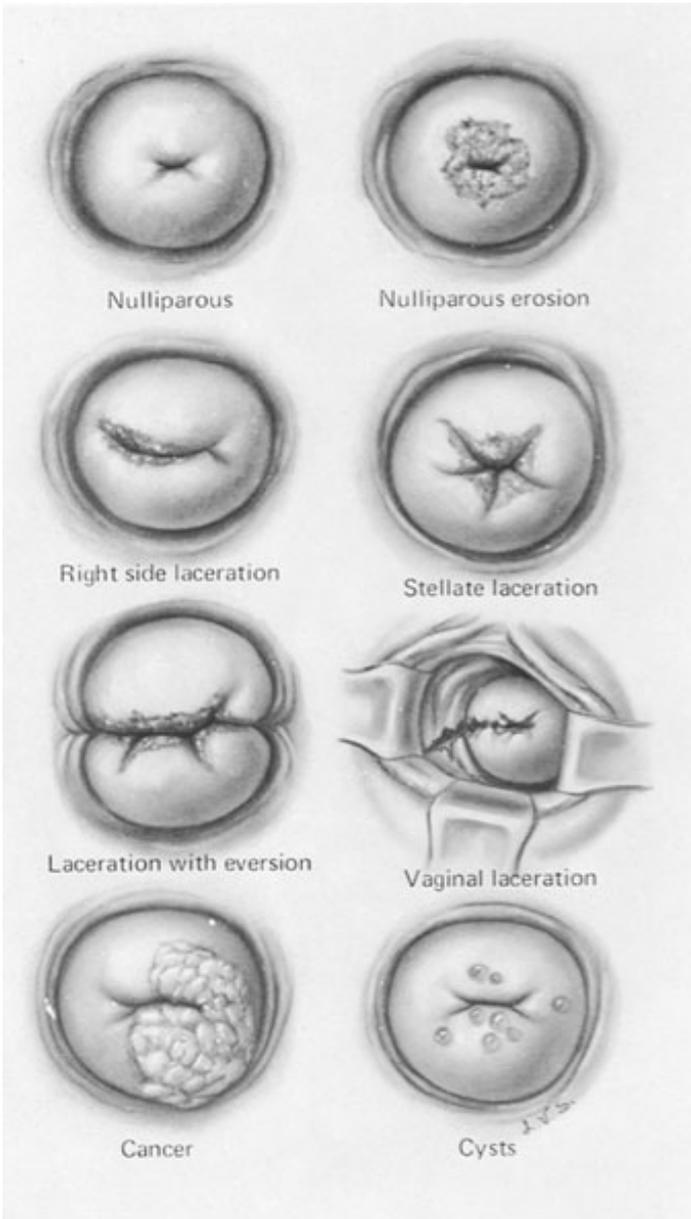

URETHRA

Redness of the urethra may indicate infection or a urethral caruncle or carcinoma. The paraurethral glands are situated below the urethra and empty into the urethra just inside the meatus. With the labia spread adequately for better vision, the urethra may be "stripped" (ie, pressure exerted by the examining finger as it is moved from the proximal to the distal urethra) to express discharge from the urethra or paraurethral glands.

Vaginal Examination

The vagina should first be inspected with the speculum for abnormalities and to obtain a Pap smear before further examination. A speculum dampened with warm water but not lubricated is gently inserted into the vagina so that the cervix and fornices can be thoroughly visualized (Fig 33–5). The cervix should be inspected for discharge, color, erosion, and other lesions. At that time, any discharge can be obtained for test of microbiology, virology, or microscopy and a Pap smear performed. After the Pap smear is prepared, the vaginal wall is again carefully inspected as the speculum is withdrawn (Fig 33–6). The type of speculum used depends on the preference of the physician, but the most satisfactory instrument for the sexually active patient is the Pederson speculum, although the wider Graves' speculum may be necessary to afford adequate visualization (Fig 33–7). For the patient with a small introitus, the narrow-bladed Pederson speculum is preferable. When more than the usual exposure is necessary, an extra large Graves' speculum is available. To visualize a child's vagina, a Huffman or nasal speculum, a large otoscope, or a Kelly air cystoscope is invaluable.

Uterine cervix: normal and pathologic appearance.

Figure 33-6

Materials Needed

- One cervical spatula, cut tongue depressor, cotton swab, or small brush made especially for obtaining endocervical cells.
- One glass slide (one end frosted). Identify by writing the patient's name on the frosted end with a lead pencil.
- One speculum (without lubricant).
- One bottle of fixative (75% ethyl alcohol) or spray-on fixative, eg, Aqua-Net or Cyto-Spray.

Preparation of a Papanicolaou (Pap) smear A: Obtain cervical scraping from complete squamocolumnar junction rotating 360 degrees around the external os. B: Place the material 1 inch from the end of the slide and smear along the slide to obtain a thin preparation. Place a saline-soaked cotton swab or small endocervical brush into the endocervical canal and rotate 360 degrees. Place this specimen onto the same slide and quickly fix with fixative.

Next, the vagina is palpated; unless the patient's introitus is too small, the index and middle fingers of either hand are inserted gently and the tissues palpated. The vaginal walls should be smooth, elastic, and nontender.

Bimanual Examination

The uterus and adnexal structures should be outlined between the 2 fingers of the hand in the vagina and the fingers of the opposite hand, which is placed upon the lower abdominal wall (Fig 33–8). Gentle palpation and manipulation of the structures will delineate position, size, shape, mobility, consistency, and tenderness of the pelvic structures—except in the obese or uncooperative patient or in a patient whose abdominal muscles are taut as a result of fear or tenderness. Tenderness can be elicited either on direct palpation or on movement or stretching the pelvic structures.

Bimanual pelvic examination.

CERVIX

The cervix is a firm structure traditionally described as having the consistency of the tip of the nose. Normally it is round and approximately 3–4 cm in diameter. Various appearances of the cervix are shown in Figure 33–5. The external os is round and virtually closed. Multiparous women may have an os that has been lacerated. An irregularity in shape or nodularity may be due to 1 or more nabothian cysts. If the cervix is extremely firm, it may contain a tumor, even cancer. The cervix (along with the body of the uterus) normally is moderately mobile, so it can be moved 2–4 cm in any direction without causing undue discomfort. (When examining a patient, it is helpful to warn her that she will feel the movement of her uterus but that ordinarily this maneuver is not painful.)

Restricted mobility of the cervix or corpus often follows inflammation, neoplasia, or surgery.

CORPUS OF THE UTERUS

The corpus of the uterus is approximately half the size of the patient's fist and weighs approximately 70–90 g. It is regular in outline and not tender to pressure or moderate motion. In most women, the uterus is anteverted; in approximately one-third of women, it is retroverted (see Chapter 44). A retroverted uterus usually is not a pathologic finding. In certain cases of endometriosis or previous salpingitis, the "tipped" uterus may be the result of adhesions caused by the disease process. The uterus usually is described in terms of its size, shape, position, consistency, and mobility.

ADNEXA

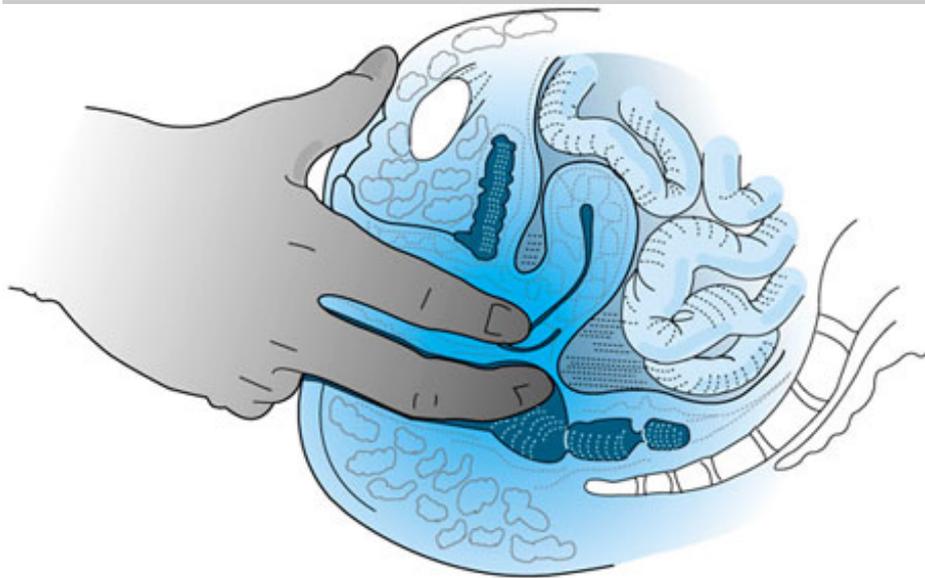

Adnexal structures (fallopian tubes and ovaries) cannot be palpated in many overweight women because the normal tube is only approximately 7 mm in diameter and the ovary no more than 3 cm in its greatest dimension. In very slender women, however, the ovaries nearly always are palpable and, in some instances, the oviducts are

as well. Usually no adnexal structures can be palpated in the postmenopausal woman. Unusual tenderness or enlargement of any adnexal structure indicates the need for further diagnostic procedures; an adnexal mass in a woman is an indication for investigation.

Rectovaginal Examination

At the completion of the bimanual pelvic examination, a rectovaginal examination should always be performed, especially after age 40 years. The well-lubricated middle finger of the examining hand should be inserted gently into the rectum to feel for tenderness, masses, or irregularities. When the examining finger has been inserted a short distance, the index finger can then be inserted into the vagina until the depth of the vagina is reached (Fig 33–9). It is much easier to examine some aspects of the posterior portion of the pelvis by rectovaginal examination than by vaginal examination alone. The index finger can now raise the cervix toward the anterior abdominal wall, which stretches the uterosacral ligaments. Usually this process is not painful; if it causes pain—and especially if the finger in the rectum can palpate tender nodules along the uterosacral ligaments—endometriosis may be present.

Figure 33–9

Rectovaginal examination.

Occult Bleeding Due to Gastrointestinal Cancer

Cancer of the gastrointestinal tract is the third most common cancer in women, after cancer of the breast and lung. The physician should check for occult bleeding from the gastrointestinal tract by performing a guaiac test on feces adhering to the examination glove following the rectovaginal examination. Several commercial test kits are available.

An early gastrointestinal tract lesion may not bleed continuously and may be associated with a false-negative result. Therefore, testing should be done at each routine health screening visit. If the patient has recently eaten a large amount of meat, a false-positive reaction may result. Therefore, patients with a positive guaiac test should be placed on a meat-free diet for 3 days and the test repeated. Alternatively, patients can be given a test kit to take home and mail back to the physician.

DIAGNOSTIC OFFICE PROCEDURES

Certain diagnostic procedures can be performed in the office because complicated equipment and general anesthesia are not required. Other office diagnostic procedures useful in specific situations (eg, tests used in infertility evaluation) can be found in appropriate chapters elsewhere in this book.

Tests for Vaginal Infection

If abnormal vaginal discharge is present, a sample of vaginal discharge should be scrutinized. A culture is obtained by applying a sterile cotton-tipped applicator to the suspect area and then transferring the suspect material to an appropriate culture medium. Because this procedure is inconvenient to perform in the physician's office, most laboratories supply a prepackaged kit that allows the physician to put the cotton-tipped applicator into a sterile container, which is then sent to the laboratory. The vaginal discharge can also be tested for the vaginal pH. An acidic pH of 4–5 is consistent with fungal infection, whereas an alkaline pH of 5.5–7 suggests infections such as bacterial vaginosis and *Trichomonas*. Often an endocervical infection may be perceived as a vaginal infection. Obtaining a swab for gonorrhea and chlamydia testing from the endocervix is warranted.

SALINE (PLAIN SLIDE)

To demonstrate *Trichomonas vaginalis* organisms, the physician mixes on a slide 1 drop of vaginal discharge with 1 drop of normal saline warmed to approximately body temperature. The slide should have a coverslip. If the smear is examined while it is still warm, actively motile trichomonads usually can be seen.

The saline slide can also be used to look for the mycelia of the fungus *Candida albicans*, which appear as segmented and branching filaments. The slide can be useful in looking for bacterial vaginosis by looking for "clue cells," epithelial cells covered from edge to edge by short coccobacilli-type bacteria.

POTASSIUM HYDROXIDE

One drop of an aqueous 10% potassium hydroxide solution is mixed with 1 drop of vaginal discharge on a clean slide and a coverslip applied. The potassium hydroxide dissolves epithelial cells and debris and facilitates visualization of the mycelia of a fungus causing vaginal infection. The slide can be brought near the nose to determine if the discharge has a "fishy" odor. This odor is strongly suggestive of bacterial vaginosis, a common vaginal infection associated with a mixed anaerobic bacterial flora. In addition, this same slide with a coverslip can be magnified with a microscope to visualize mycelia that may have been hidden by debris with just the saline smear.

BACTERIAL INFECTION

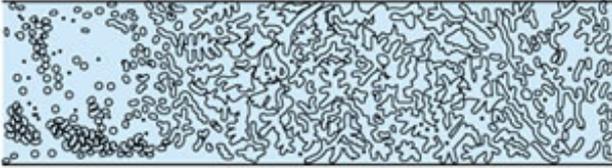

Bacterial infection may be present, especially if there is an ischemic lesion such as occurs after radiation therapy for cervical carcinoma, or if a patient is suspected of having bacterial vaginosis, gonorrhea, or a *Chlamydia trachomatis* infection. Material from the cervix, urethra, or vaginal lesion can be smeared, stained, and examined microscopically, or the material can be cultured.

Fern Test for Ovulation

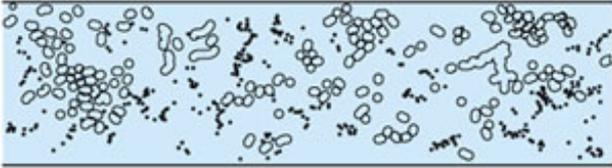

The fern test can determine the presence or absence of ovulation or the time of ovulation. When cervical mucus spread upon a clean, dry slide and allowed to dry in air, it may or may not assume a frondlike pattern when viewed under the microscope (sometimes it can be seen grossly). The fern frond pattern indicates an estrogenic effect on the mucus without the influence of progesterone; thus, a non-frondlike pattern can be interpreted as showing that ovulation has occurred (Fig 33–10).

Figure 33–10.

Patterns formed when cervical mucus is smeared on a slide, permitted to dry, and examined under a microscope. Progesterone makes the mucus thick and cellular. In the smear from a patient who failed to ovulate (bottom), there is no progesterone to inhibit the estrogen-induced fern pattern.

(Reproduced, with permission, from Ganong WF: *Review of Medical Physiology*, 20th ed. McGraw-Hill, 2003.)

Schiller Test for Neoplasia

Although colposcopy is more accurate, the Schiller test can be performed when cancer or precancerous changes of the cervix or vaginal mucosa are suspected. The suspect area is painted with Lugol's (strong iodine) solution, which interacts and marks the glycogen-rich epithelial cells of the cervix. Any portion of the epithelium that does not accept the dye is abnormal because of the presence of scar tissue, neoplasia and precursors, and columnar epithelium. Biopsy of samples taken from this area should be performed if there is any suspicion of cancer.

Biopsy

VULVA AND VAGINA

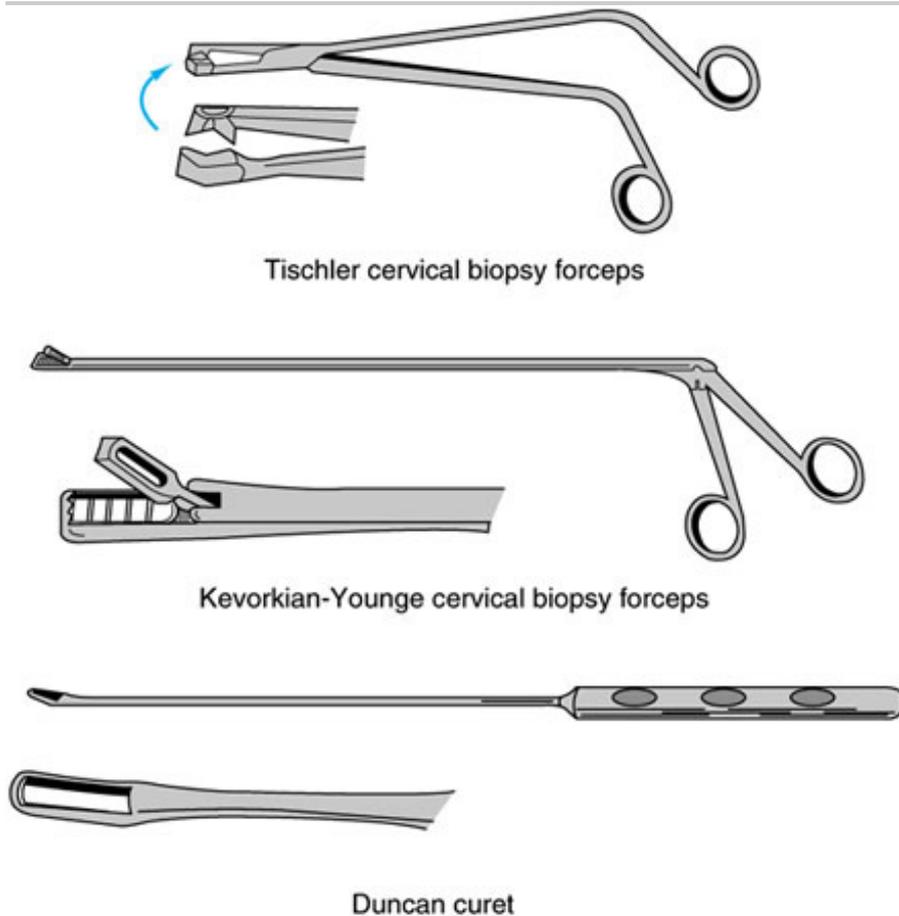

For biopsy of the vulva or vagina, a 1–2% aqueous solution of a standard local anesthetic solution can be injected around a small suspicious area and a sample obtained with a skin punch or sharp scalpel. Bleeding usually can be controlled by pressure or by Monsel's solution, but occasionally suturing is necessary.

CERVIX

Colposcopically directed biopsy is the method of choice for the diagnosis of cervical lesions, either suspected on visualization or indicated after an abnormal Pap smear. Colposcopy should reveal the full columnar–squamous "transformation zone" (TZ) at the juncture of the exocervix and endocervix. In addition, it may be advisable to sample the endocervix by curettage. Specific instruments have been devised for cervical biopsy and endocervical curettage (Fig 33–11). The cervix is less sensitive to cutting procedures than is the vagina, so 1 or more small biopsy samples of the cervix can be taken with little discomfort to the patient. Bleeding usually is minimal and controlled with light pressure for a few minutes or by use of Monsel's solution. A "4-quadrant" biopsy sample of

squamocolumnar junction can be taken at 12, 3, 6, and 9 o'clock positions if colposcopy is not available. A Schill test often may more quickly direct the physician to the area that should be biopsied.

Figure 33–11.

Biopsy instruments.

ENDOMETRIUM

Endometrial biopsy can be helpful in the diagnosis of ovarian dysfunction (eg, infertility) or irregular uterine bleeding and as a test for carcinoma of the uterine corpus. Endometrial biopsy can be performed with flexible disposable cannulas, such as the Pipelle, which have replaced most metal curettes previously used (Fig 33–12). In fact, endometrial biopsies have dramatically reduced the need for formal dilatation and curettage (D&C) because the accuracy of biopsy is nearly the same. Because the procedure causes cramping, the patient should be warned and advised to take a pain medication such as ibuprofen 1 hour prior to the procedure.

DIAGNOSTIC LABORATORY PROCEDURES

Routine procedures that are not discussed here but should be considered with periodic primary care visits include complete blood count (including differential white cell count), glucose screening, lipid profile, and thyroid function tests. The frequency with which these tests are performed should be at the discretion of the physician, based on risk factors and presenting complaints.

Urinalysis

Urinalysis should be obtained in symptomatic patients and should include both gross and microscopic examinations. A microscopic examination may reveal crystals or bacteria, but unless the specimen is collected in a manner that will exclude vaginal discharge, the presence of bacteria is meaningless (see below).

Urine Culture

Studies have demonstrated that a significant number of women (approximately 3% of nonpregnant women and 7% of pregnant women) have asymptomatic urinary tract infections. Culture and antibiotic sensitivity testing are required for the diagnosis and as a guide to treatment of urinary tract infections.

Reliable specimens of urine for culture often can be obtained by the "clean-catch" method: the patient is instructed

to cleanse the urethral meatus carefully with soap and water, to urinate for a few seconds to dispose of urethral contaminants, and then to catch a "midstream" portion of the urine. It is essential that the urine not dribble over the labia, but this may be difficult for some patients to accomplish.

A more reliable method of collecting urine for culture is by sterile catheterization performed by the physician or nurse. However, care must be exercised in catheterization to minimize the risk of introducing an infection.

Other Cultures

URETHRAL

Urethral cultures are indicated if an STD is suspected.

VAGINAL

A culture usually is unnecessary for the diagnosis of vaginal infections, as visual inspection or microscopic examination usually will enable the physician to make a diagnosis, eg, curdlike vaginal material that reveals mycelia (candidiasis). However, a culture should be obtained in questionable cases.

CERVICAL

As in the case of the urethra, the usual indication for a culture of cervical discharge is the suspected presence of an STD.

Specific Tests

HERPESVIRUS HOMINIS

Herpesvirus hominis (herpes genitalis, both types 1 and 2) is a frequently seen vulvar lesion (see Chapter 41). It can be diagnosed by the cytopathologist, who finds typical cellular changes. The most accurate method is culturing.

HUMAN PAPI LLOMAVIRUS

Human papillomavirus (HPV) infection is associated with the development of genital warts and the occurrence of vaginal and cervical intraepithelial lesions. Some of these lesions are precancerous or cancerous in origin. Different HPV subtypes are linked to either benign or more aggressive epithelial changes. The different subtypes can be identified by the specific fingerprints obtained from the polymerase chain reaction (PCR) products.

CHLAMYDIA AND GONORRHEAL INFECTIONS

These sexually transmitted infections are the two most prevalent infections, with chlamydia being the most common. They are found more often in women who have multiple sexual partners and those who do not use barrier methods of contraception. Nucleic acid amplification testing is the most commonly used method of diagnosis, with a sensitivity greater than 90%.

HUMAN IMMUNODEFICIENCY VIRUS

Acquired immunodeficiency syndrome (AIDS) has become one of the most difficult issues confronting all kinds of clinicians. The need to screen for HIV in the general population has become more pressing given that the largest increase in incidence is seen in young heterosexually active females with no other risk factors. An accurate blood test is available for diagnosis. Prior to drawing the blood, the physician must discuss with the patient the accuracy of the blood test for diagnosing the presence of HIV. The patient must be made aware that there are infrequent false-positive tests and a "window" during which the test may be falsely negative prior to the development of antibodies. At present, a written consent must be signed by the patient prior to drawing the blood.

Other Specific Tests

Specific diagnostic laboratory procedures may be indicated for some of the less common venereal diseases, eg, lymphogranuloma venereum and hepatitis B and C. A screening test for streptococcus B carrier is advocated at 35–37 weeks' gestation. A 1-step culture swab from the lower vagina, followed by the anus, is recommended. These tests are discussed with the specific diseases in other chapters of this book.

Pregnancy Testing

Pregnancy testing is discussed in Chapter 9.

Papanicolaou Smear of Cervix

The Pap smear is an important part of the gynecologic examination. The frequency of the need for this test has been recently revised. Epidemiologic statistics have led the US Preventive Services Task Force to recommend that for the average woman who has had 3 normal Pap smears, a Pap test every 2 or 3 years is adequate. This recommendation is based on the observation that most cervical cancers are slow growing. The American College of Obstetricians and Gynecologists recommends annual Pap smear screenings from 3 years after the start of sexual intercourse but no later than age 21 years. After age 30 years, a woman who has had 3 consecutive negative Pap smears can be screened every 2–3 years. Patients at risk, including women with multiple sexual partners, a history of STD, genital condylomata, prior abnormal Pap smears, or receiving immune suppression therapy, should undergo annual smear tests. Aside from premalignant and malignant changes, other local conditions often can be suspected by the cytologist. Viral infections, such as herpes simplex, HPV, and condylomata acuminata, can be seen as mucosal changes. Actinomycosis and *Trichomonas* infections can be detected by a Pap smear.

The Pap smear is a screening test only. Positive tests are an indication for further diagnostic procedures, such as colposcopy, endocervical curettage, cervical biopsy or conization, endometrial biopsy, or D&C. The properly collected Pap smear can accurately lead to the diagnosis of carcinoma of the cervix in approximately 95% of cases. The Pap smear also is helpful in the detection of endometrial abnormalities such as endometrial polyps, hyperplasia, and cancers, but it detects fewer than 50% of cases.

The techniques of collection of a Pap smear may vary, but the following is a common procedure.

The patient should not have douched for at least 24 hours before the examination and should not be menstruating. The speculum is placed in the vagina after it has been lubricated with water only. With the cervix exposed, a specially designed plastic or wooden spatula is applied to the cervix and rotated 360 degrees to abrade the surface slightly and to pick up cells from the squamocolumnar area of the cervical os. Next, a cotton-tipped applicator or small brush is inserted into the endocervix and rotated 360 degrees. These 2 specimens can be mixed or placed on the slide separately according to the preference of the examiner. A preservative is applied immediately to prevent air drying, which would compromise the interpretation. The slide is sent to the laboratory with an identification sheet containing pertinent history and findings (see Fig 33–6). Another method called ThinPrep automates the preparation of the Pap smear slide so that the variability introduced by the clinician preparing the slide itself is no longer a factor. With this method, the specimen is placed in a liquid-based medium and sent to the laboratory. In addition, the ThinPrep technique decreases the rate of smears showing atypical squamous cells-undetermined significance (ASCUS), thereby decreasing the need for colposcopic evaluations. For these reasons, in many parts of the country the ThinPrep technique has replaced the conventional Pap smear.

The liquid-based medium allows for testing for high-risk HPV, the most common being subtypes 16, 18, 31, 33, and 35. Testing for high-risk HPV has been proposed by the American Society for Colposcopy and Cervical Pathology as a method of evaluating and sorting out patients with ASCUS Pap smear results. If no high-risk HPV is present in the ASCUS Pap smear, then these individuals can be followed-up with a repeat Pap smear in 1 year, similar to those who have a negative Pap smear. Patients known to have a high-risk HPV subtype would undergo colposcopic evaluation.

The laboratory reports the Pap smear using the Bethesda System, which has advocated a standardized reporting system for cytologic reports. Chapter 50 discusses the recently updated nomenclature.

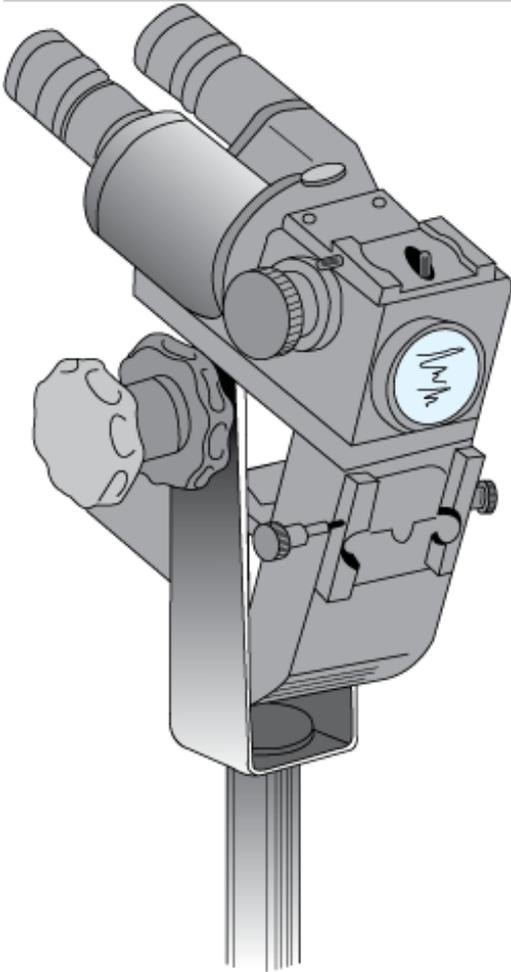

Alternatives to the traditional Pap smear are being evaluated in an attempt to decrease the false-negative and false-positive Pap smear results. Evidence indicates that computerized screening of Pap smears can decrease the

likelihood of missing significant pathologies. Various methods of computerized screening have been developed to aid the human eye in picking up abnormalities, although no system has yet achieved widespread acceptance.

Colposcopy

The colposcope is a binocular microscope used for direct visualization of the cervix (Fig 33–13). Magnification as high as 60x is available, but the most popular instrument in clinical use has 13.5x magnification, which effectively bridges the gap between what can be seen by the naked eye and by the microscope. Some colposcopes are equipped with a camera for single or serial photographic recording of pathologic conditions.

Figure 33–13.

Zeiss colposcope.

Colposcopy does not replace other methods of diagnosing abnormalities of the cervix; rather, it is an additional and important tool. The 2 most important groups of patients who can benefit by its use are (1) patients with an abnormal Pap smear and (2) diethylstilbestrol (DES)-exposed daughters, who may have dysplasia of the vagina cervix (see Chapter 38).

The colposcopist is able to see areas of cellular dysplasia and vascular or tissue abnormalities not visible otherwise which makes possible the selection of areas most propitious for biopsy. Stains and other chemical agents are also used to improve visualization. The colposcope has reduced the need to perform blind cervical biopsies for which the rate of finding abnormalities is low. In addition, the necessity for a cone biopsy, a procedure with a high

morbidity rate, has been greatly reduced. Thus the experienced colposcopist is able to find focal cervical lesions, obtain directed biopsy at the most appropriate sites, and make decisions about the most appropriate therapy largely based on what is seen through the colposcope.

Hysteroscopy

Hysteroscopy is the visual examination of the uterine cavity through a fiberoptic instrument, the hysteroscope. In order to inspect the interior of the uterus with the hysteroscope, the uterine cavity is inflated with a solution such as saline, glycine, or dextran, or by carbon dioxide insufflation. Intravenous sedation and paracervical block often are adequate for hysteroscopy so long as prolonged manipulation is not required.

Hysteroscopic applications include evaluation for abnormal uterine bleeding, resection of uterine synechiae and septa, removal of polyps and intrauterine devices (IUDs), resection of submucous myomas, and endometrial ablation. Most of these therapeutic maneuvers require extensive manipulation, so regional or general anesthesia is required.

Hysteroscopy should be performed only by physicians with proper training. The tip of the instrument should be inserted just beyond the internal cervical os and then advanced slowly, with adequate distention under direct vision.

Hysteroscopy is often used in conjunction with another operative procedure, such as curettage and laparoscopy.

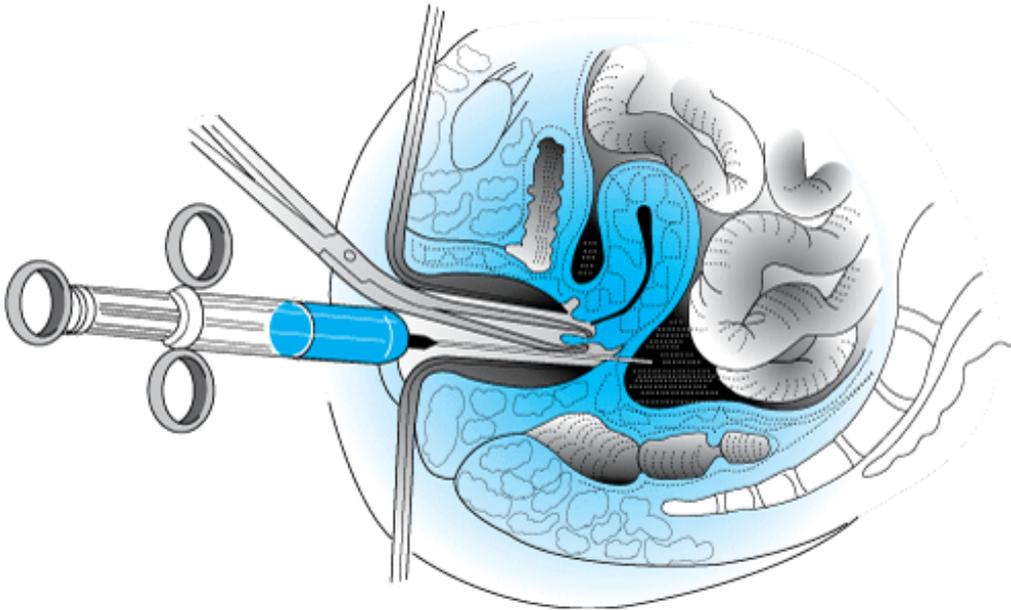

Failure of hysteroscopy may be the result of cervical stenosis, inadequate distention of the uterine cavity, bleeding, or excessive mucus secretion. The most common complications include perforation, bleeding, and infection.

Perforation of the uterus usually occurs at the fundus. Unless a viscus is damaged or internal bleeding develops, surgical repair may not be required. Bleeding generally subsides, but fulguration following attempts to remove polyps or myomas may be required to stop bleeding in some cases. Parametritis or salpingitis, rarely noted, usually necessitates antibiotic therapy. Intravascular extravasation of fluid or gas from hysteroscopy often does not become clinically significant but has been associated with severe consequences such as hyponatremia, air embolism, cerebral edema, and even death.

Culdocentesis

The passage of a needle into the cul-de-sac—culdocentesis—in order to obtain fluid from the pouch of Douglas is a diagnostic procedure that can be performed in the office or in a hospital treatment room (Fig 33–14). The type of fluid obtained indicates the type of intraperitoneal lesion, eg, bloody with a ruptured ectopic pregnancy, pus with acute salpingitis, or ascitic fluid with malignant cells in cancer. With refinements in ultrasound technology enabling more definitive evaluation of pelvic pathology, culdocentesis is performed less frequently today.

Figure 33–14.

Culdocentesis.

Radiographic Diagnostic Procedures

Many common radiologic procedures may be helpful in the diagnosis of pelvic conditions. The "flat film" shows calcified lesions, teeth, or a ring of a dermoid cyst and indicates other pelvic masses by shadows or displaced intestinal loops. Use of contrast media frequently is indicated to help delineate pelvic masses or to rule out metastatic lesions. Barium enema, upper gastrointestinal series, intravenous urogram, and cystogram may be helpful.

HysteroGRAPHY & SonohysteroGRAPHY

The uterine cavity and the lumens of the oviducts can be outlined by instillation of contrast medium through the cervix, followed by fluoroscopic observations or film. The technique was first widely used for the diagnosis of tubal disease as part of the investigation of infertile women. Its use now is being extended to the investigation of uterine disease.

To diagnose tubal patency or occlusion, the medium is instilled through a cervical cannula. Filling of the uterine cavity and spreading of the medium through the tubes are watched via a fluoroscope, with the radiologist taking spot films at intervals for subsequent, more definitive, scrutiny. If no occlusion is present, the medium will reach the fimbriated end of the tube and spill into the pelvis—evidence of tubal patency. This procedure can reveal an abnormality of the uterus, eg, congenital malformation, submucous myomas, or endometrial polyps.

Another technique that is gaining acceptance is sonohysteroGRAPHY, in which the uterine cavity is filled with fluid while ultrasound is used to delineate the architecture of the endometrial cavity and detect a spillage through the fallopian tubes. Thus it becomes easier to diagnose intrauterine abnormalities, such as polyps or fibroids, and tubal patency.

Angiography

Angiography is the use of radiographic contrast medium to visualize the blood vascular system. By demonstrating the vascular pattern of an area, tumors or other abnormalities can be delineated. Angiography also is used to delineate continued bleeding from pelvic vessels postoperatively, to visualize bleeding from infiltration by cancer patients, or to embolize the uterine arteries in order to decrease acute bleeding and/or reduce the size of

uterine myomas. These vessels then can be embolized with synthetic fabrics to stop the bleeding or indicate therapy that can prevent the need for a major abdominal operation in a highly compromised patient.

Computed Tomography

Computed tomography (CT) scan is a diagnostic imaging technique that provides high-resolution 2-dimensional images. The CT scan takes cross-sectional images through the body at very close intervals so that multiple "slices" of the body are obtained. The beam transmission is measured and calculated through an array of sensors that are approximately 100 times more sensitive than conventional x-rays. The computer is able to translate the densities of different types of tissues into gray-scale pictures that can be read on an x-ray film or a television monitor.

Contrast media can be given orally, intravenously, or rectally. They are used to outline the gastrointestinal and urinary systems, thus helping to differentiate these organ systems from the pelvic reproductive organs. In gynecology, the CT scan is most useful in accurately diagnosing retroperitoneal lymphadenopathy associated with malignancies. It also has been used to determine the depth of myometrial invasion in endometrial carcinoma as well as extrauterine spread. It is an accurate tool for locating pelvic abscesses that cannot be located by ultrasonography. Often a needle can be placed into an abscess pocket to both drain the abscess and determine what organism may be involved. Pelvic thrombophlebitis often can be diagnosed by CT scan as an adjunct to clinical suspicion. Common abnormalities such as ovarian cysts and myomas are easily diagnosed (Fig 33–15).

(Picture courtesy of Dr. Barbara Carter, New England Medical Center, Boston.)

Magnetic Resonance Imaging

Magnetic resonance imaging (MRI) is a diagnostic imaging technique that creates a high-resolution, cross-sectional image of the body like a CT scan. The technique is based on the body absorbing radio waves from the machine. A small amount of this energy is absorbed by the nuclei in the various tissues. These nuclei act like small bar magnets and are influenced by the magnetic field created by the machine. These nuclei then emit some of the radio waves back out of the body. The waves are picked up by sensitive and sophisticated receivers, and these signals are translated into images by computer technology.

The advantages of MRI include the fact that it uses nonionized radiation that has no adverse or harmful effects on the body. MRI is superior to CT in its ability to differentiate among various types of tissue, including inflammatory masses, cancers, and abnormal tissue metabolism. Its disadvantages are mainly its high cost and its poor demonstration of calcifications. Its main use in gynecology appears to be staging and follow-up of pelvic cancers. MRI in obstetrics is limited to its use as an adjunct to prenatal diagnosis of fetal anomalies. It allows for multiple image cuts that can help decipher complex anomalies. Other potential uses of MRI include evaluation of placental blood flow and accurate performance of pelvimetry.

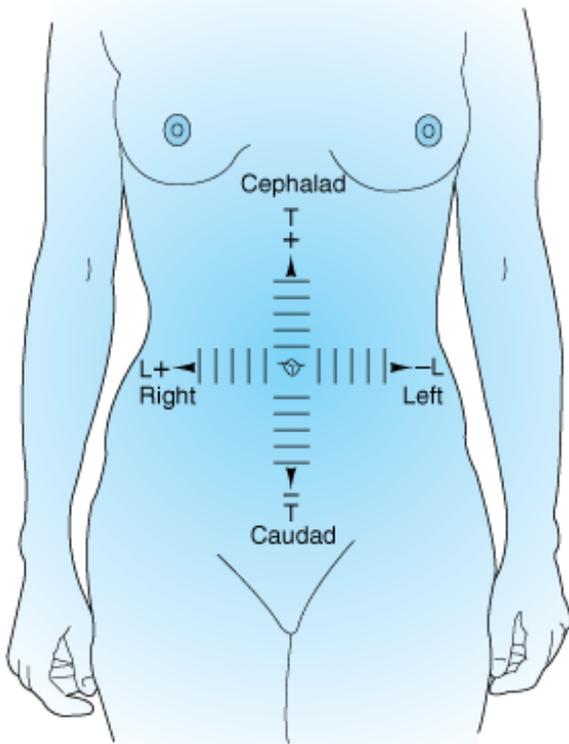

Ultrasonography

Ultrasonography records high-frequency sound waves as they are reflected from anatomic structures. As the sound waves pass through tissues, they encounter variable acoustic densities. Each of the tissues returns a different echo, depending on the amount of energy reflected. This echo signal can be measured and converted into a 2-dimensional image of the area under examination, with the relative densities shown as differing shades of gray.

Ultrasonography is a simple and painless procedure that has the added advantage of freedom from any radiation hazard. It is especially helpful in patients in whom an adequate pelvic examination may be difficult, such as in children, virginal women, and uncooperative patients.

The pelvis and lower abdomen are scanned and recorded at regular intervals of distance, using a sector scanner that provides a better 2-dimensional picture than does the linear array scanner (Fig 33–16). Generally, the abdominal scan is performed with the bladder full; this condition elevates the uterus out of the pelvis, displaces air-filled loops of bowel, and provides the operator with an index of density—a sonographic "window" differentiating the pelvic organs.

Figure 33–16.

Planes of ultrasonograms.

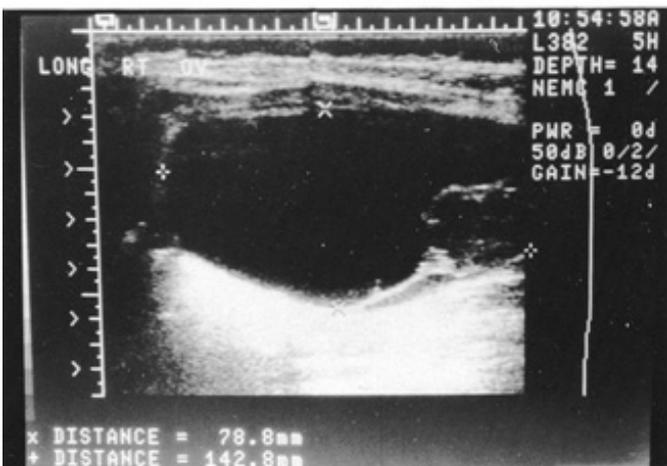

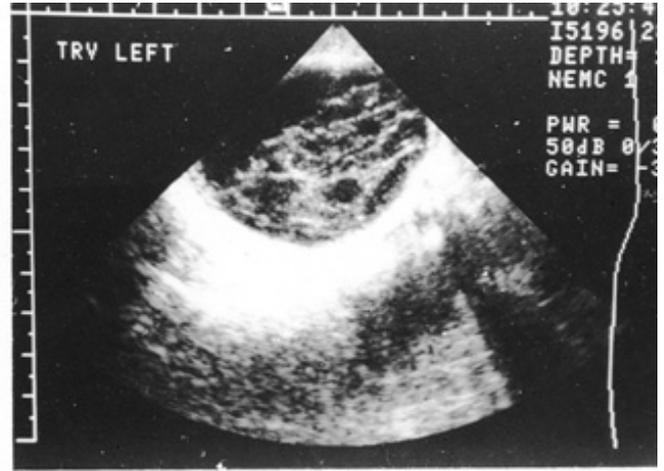

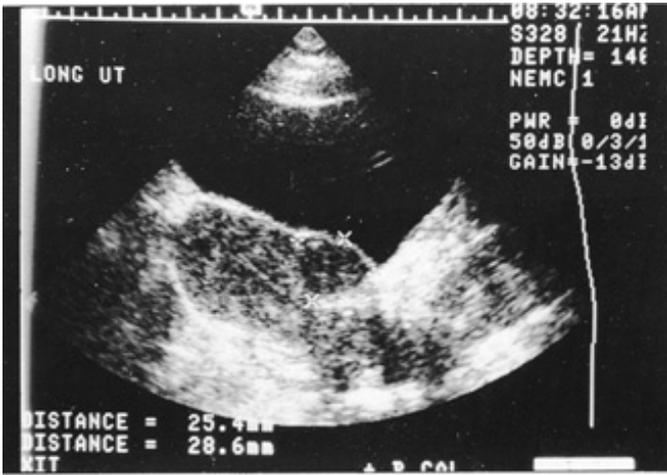

Ultrasonography can be helpful in the diagnosis of almost any pelvic abnormality, as all structures, normal and abnormal, usually can be demonstrated. In most instances, a clinical picture has been developed—by history, physical examination, or both—before ultrasonograms are obtained. Thus, the scan often corroborates the clinic impression, but it also may uncover an unexpected condition of which the clinician should be aware.

There are many indications for ultrasonography. Normal early pregnancy can be diagnosed, as can pathologic pregnancies such as incomplete and missed abortions and hydatidiform moles. Ultrasonography can be extremely helpful in avoiding the placenta and fetus during midtrimester amniocentesis. The uses for ultrasound examination in obstetrics are discussed elsewhere in this book.

Ultrasonography may be used to locate a lost IUD or a foreign body in the vagina of a child. Congenital malformations such as a bicornuate uterus or vaginal agenesis are sometimes, but not always, detected. Ultrasound examination is useful in the placement of uterine tandems for radiation therapy for endometrial cancer and for guidance during second-trimester abortion procedures.

One of the more common uses for ultrasonography is the diagnosis of pelvic masses. Often because of their location, attachment, and density, myomas can be diagnosed without too much difficulty (Fig 33–17A).

Figure 33–17.

(Pictures courtesy of Dr. Frederick Doherty, New England Medical Center, Boston.)

Adnexal masses can be found with relative ease by ultrasonography, although an accurate diagnosis is more difficult because of the various types of adnexal masses that can be found (Fig 33–17B and C).

Ovarian cysts can be described as unilocular or multilocular, totally fluid-filled, or partially solid. A common adnexal mass, the dermoid cyst, can have characteristic ultrasound findings because of fat tissue and bone densities seen in these cysts (Fig 33–17D). Pelvic abscesses can be diagnosed by ultrasonography, especially if a well-encapsulated large abscess pocket is present.

In addition to the traditional abdominal scan, the vaginal probe scan has become a useful modality. The vaginal probe is used for determining early gestations and can diagnose a pregnancy as early as 5 weeks from the LNMV. Although vaginal ultrasonography can sometimes visualize ectopic pregnancies, it is more useful for excluding an intrauterine gestation when there is suspicion of an ectopic pregnancy.

Ultrasonography is commonly used to diagnose ovarian cysts, especially in obese patients in whom abdominal

scans are of limited use. The vaginal scan is used often to determine follicular size with in vitro fertilization and to predict the best time for ovum retrieval.

Innovations in ultrasound probes and computerizing processes of the obtained images enable the development of 3-dimensional ultrasound machines. The 3-dimensional images help to accurately evaluate normal and abnormal findings, such as uterine shape and cavity, pelvic masses, and fetal malformations.

Carbon Dioxide Laser

Controlled tissue vaporization by laser is a modality for treatment of cervical, vaginal, or perineal condylomata and dysplasia. It also can be used for conization of the cervix for diagnosis of dysplasia or carcinoma within the cervical canal.

The vaporization procedure is not difficult, but training is essential, especially in the physics of laser light and the potential risks of laser therapy not only to the patient but to the operator and others in the immediate vicinity. Antiseptic preparation of the vagina should be gentle to avoid trauma to the tissue that is to be examined histologically. Local anesthesia, with or without preliminary intravenous sedation, usually is adequate.

Advantages of the laser method of cervical conization include little or no pain; a low incidence of infection because the beam sterilizes the tissues; decreased blood loss, because the laser instrument—at a decreased energy level—is a hemostatic agent; less tissue necrosis than occurs with electrocautery (but probably the same as with excision by a sharp knife); and a decreased incidence of postoperative cervical stenosis.

Loop Electrosurgical Excision Procedure

Loop electrosurgical excision procedure (LEEP) is another modality of therapy for vulvar and cervical lesions. LEEP uses a low-voltage, high-frequency alternating current that limits thermal damage but at the same time has good hemostatic properties. It is most commonly used for excision of vulvar condylomata and cervical dysplasias and cone biopsies of the cervix. It has displaced sharp knife and laser cone biopsies for treatment of most cervical dysplasias.

The technique requires the use of local anesthesia followed by the use of a wire loop cautery unit that cauterizes and cuts the desired tissue. Loops of various sizes are used for specimens of different size. The major advantages of LEEP are its usefulness in an office setting with lower equipment cost, minimal damage to the surrounding tissue, and low morbidity.

[Current OB/GYN >](#) [Chapter 34. Pediatric & Adolescent Gynecology >](#)

PEDIATRIC & ADOLESCENT GYNECOLOGY: INTRODUCTION

The field of pediatric and adolescent gynecology has expanded greatly over the past century, as increased attention has been directed to the complex roles of children and adolescents in society. Today, pediatric and adolescent gynecology has evolved from reviews of developmental physiology and case reports of aberrations to discussions that include not only these topics but also address issues related to adolescent reproductive health.

Gynecologic care begins in the delivery room, with inspection of the external genitalia during routine newborn examination. Evaluation of the external genitalia continues through routine well-child examinations, permitting early detection of infections, labial adhesions, congenital anomalies, and even genital tumors. A complete gynecologic examination is indicated when a child has symptoms or signs of a genital disorder. The American College of Obstetricians and Gynecologists recommends that adolescents should have their first visit to an obstetrician/gynecologist for health guidance, general physical screening, and the provision of preventive health care services at age 13–15 years. A pelvic examination should be performed on adolescents who are sexually active, older than 18 years, or when indicated by medical history. Specially designed equipment must be used (eg, vaginoscope, virginal vaginal speculum) to prevent undue discomfort and consequent anxiety about future examinations.

ANATOMIC & PHYSIOLOGIC CONSIDERATIONS

Newborn Infants

During the first few weeks of life, residual maternal sex hormones may produce physiologic effects on the newborn. Breast budding occurs in nearly all female infants born at term. In some cases, breast enlargement is marked, and there may be fluid discharge from the nipples. No treatment is indicated. The labia majora are bulbous, and the labia minora are thick and protruding (Fig 34–1). The clitoris is relatively large, with a normal index of 0.6 cm² or less.* The hymen initially is turgid, covering the external urethral orifice. Vaginal discharge is common, composed mainly of cervical mucus and exfoliated vaginal cells.

Figure 34–1.

External genitalia of a newborn female. Note the hypertrophy and turgor of the vulvar tissues. A small catheter is inserted into the vagina to demonstrate patency.

(Reproduced, with permission, from Huffman JW: *The Gynecology of Childhood and Adolescence*. WB Saunders, 1968.)

The vagina is approximately 4 cm long at birth. The uterus is enlarged (4 cm in length) and without axial flexion; the ratio between the cervix and the corpus is 3:1. Columnar epithelium protrudes through the external cervical os, creating a reddened zone of physiologic eversion. The ovaries remain abdominal organs in early childhood and should not be palpable on pelvic or rectal examination. Vaginal bleeding may occur as estrogen levels decline following birth and the stimulated endometrial lining is shed. Such bleeding usually stops within 7–10 days.

* Clitoral index (cm^2) = Length (cm) \times width (cm). For example, a clitoris 1 cm long and 0.5 cm wide = 0.5 cm^2 .

Young Children

In early childhood, the female genital organs receive little estrogen stimulation. The labia majora flatten and the labia minora and hymen become thin (Fig 34–2). The clitoris remains relatively small, although the clitoral index is unchanged. The vagina, lined with atrophic mucosa with relatively few rugae, offers very little resistance to trauma and infection. The vaginal barrel contains neutral or slightly alkaline secretions and mixed bacterial flora. Because vaginal fornices do not develop until puberty, the cervix in childhood is flush with the vaginal vault, and its opening appears as a small slit. The uterus regresses in size and does not regain the size present at birth until approximately age 6 years. As the child matures, the ovaries begin to enlarge and descend into the true pelvis. The number and size of ovarian follicles increase. They may attain significant size and then regress.

Figure 34–2.

Copyright ©2006 by The McGraw-Hill Companies, Inc.
All rights reserved.

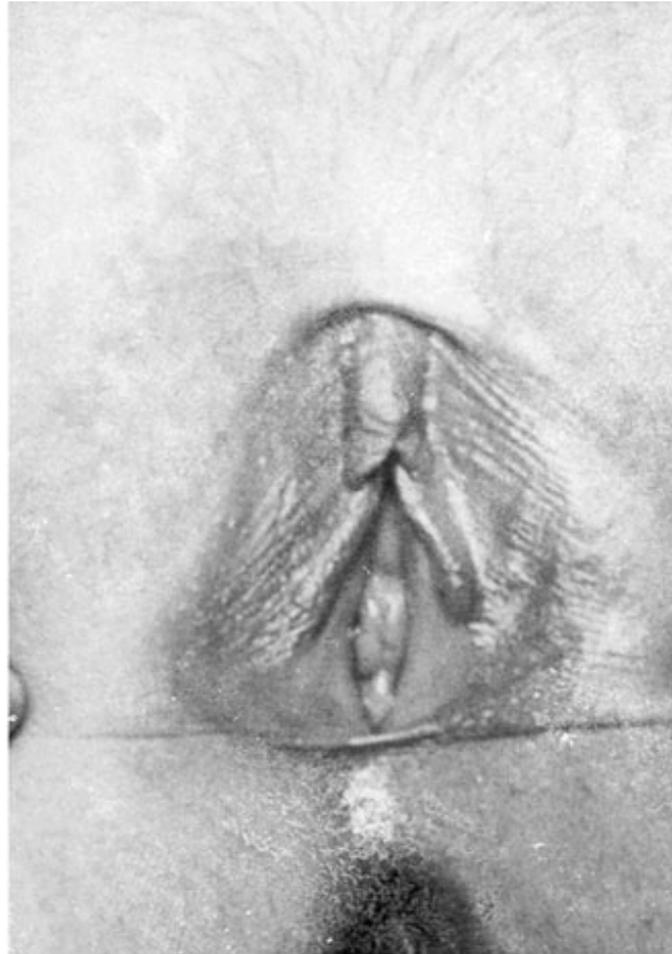

External genitalia of a child 3 years of age.

At laparotomy, the uterus may appear as merely a strip of dense tissue in the anteromedial area of the broad ligaments. Palpation may aid in delineating the uterine outline. The ovaries may appear cystic secondary to follicular development. Biopsy is not warranted.

Older Children

During late childhood (age 7–10 years), the external genitalia again show signs of estrogen stimulation: the mons pubis thickens, the labia majora fill out, and the labia minora become rounded. The hymen thickens (Fig 34–3), losing its thin, transparent character. The vagina elongates to 8 cm, the mucosa becomes thicker, the corpus uteri enlarges, and the ratio of cervix to corpus becomes 1:1. The cervix remains flush with the vault. A maturation index determination at this time will show not only basal cells but also a greater proportion of parabasal cells and superficial cells, in a typical ratio of 75:25:0 or 70:25:5.

Figure 34–3.

Copyright ©2006 by The McGraw-Hill Companies, Inc.
All rights reserved.

External genitalia of a child 11 years of age. Early estrogen response is evidenced by the fuller labia, wrinkling of the vulvar mucosa, and thickening of the hymen.

By the time a girl reaches age 9–10 years, uterine growth begins, with alteration in uterine shape resulting primarily from myometrial proliferation. Rapid endometrial proliferation occurs as menarche is imminent. Prior to this time, the endometrium gradually thickens, with modest increases in the depth and complexity of the endometrial glands. As the ovaries enlarge and descend into the pelvis, the number of ovarian follicles increases. Although these follicles are in various stages of development, ovulation generally does not occur.

Young Adolescents

During early puberty (age 10–13 years), the external genitalia take on adult appearance. The major vestibular glands (Bartholin's glands) begin to produce mucus just prior to menarche. The vagina reaches adult length (10–12 cm) and becomes more distensible, the mucosa thickens, vaginal secretions grow more acidic, and lactobacilli reappear. With the development of vaginal fornices, the cervix becomes separated from the vaginal vault, and the differential growth of the corpus and cervix becomes more pronounced. The corpus grows twice as large as the cervix. The ovaries descend into the true pelvis.

Secondary sexual characteristics develop, often rapidly, during the late premenarcheal period. Body

habitus becomes more rounded, especially the shoulders and hips. Accelerated somatic growth velocity (the adolescent growth spurt) occurs. At the same time, estrogen increases adipose tissue deposition and initiates stromal and ductal growth in the breasts. Physiologic leukorrhea often is noted.

Pubic hair growth appears to be under the control of adrenal androgens. Sparse, long, slightly curly, pigmented hair over the pubic area gives way to coarse, pigmented curly hair. The pubic hair pattern assumes the characteristic triangle with the base above the mons pubis. Hair growth in the axilla appears later, also as a result of adrenocorticosteroid stimulation. The development of secondary sexual features described by Marshall and Tanner is summarized in Table 34–1 (see Fig 6–3).

Table 34–1. Tanner Classification of Female Adolescent Development.

Stage	Breast Development	Pubic Hair Development
I	Papillae elevated (preadolescent), no breast buds	None
II	Breast buds and papillae slightly elevated	Sparse, long, slightly pigmented
III	Breasts and areolae confluent, elevated	Darker, coarser, curly
IV	Areolae and papillae project above breast	Adult-type pubis only
V	Papillae projected, mature	Lateral distribution

GYNECOLOGIC EXAMINATION OF INFANTS, CHILDREN, & YOUNG ADOLESCENTS

Examination of the Newborn Infant

Newborns should be examined immediately upon delivery or in the nursery. When an infant is born with ambiguous genitalia, immediate actions should be to counsel the parents and to prevent dehydration, as congenital adrenal hyperplasia accounts for greater than 90% of cases of ambiguous genitalia, and salt-wasting forms may lead to rapid dehydration and fluid imbalances. In most cases, an internal examination is unnecessary, as most gynecologic abnormalities that should be recognized at this stage are limited to the external genitalia.

GENERAL EXAMINATION

As in adults, the first step in a genital evaluation of the newborn is a careful general examination, which may reveal abnormalities suggesting genital anomaly (eg, webbed neck, abdominal mass, edema of the hands and legs, coarctation of the aorta).

CLITORIS

Clitoral enlargement in the newborn almost always is associated with congenital adrenal hyperplasia. Other causes, such as hermaphroditism and neoplasms, also must be considered.

VULVA AND VAGINA

The vaginal orifice should be evident when the labia are separated or retracted. If the vaginal orifice cannot be located, the infant most likely has an imperforate hymen or vaginal agenesis. Inguinal hernias are uncommon in females, and the presence of inguinal masses suggests the possibility that the child is a genetic male.

RECTOABDOMINAL EXAMINATION

Usually, the uterus and adnexa in the newborn cannot be palpated on rectal examination. Occasionally, a small central mass representing the uterine cervix can be felt on examination. An ovary that is palpable denotes enlargement, and the possibility of an ovarian tumor should be investigated, even though pelvic

masses in newborns likely represent a Wilms' tumor. In addition, a rectal examination can confirm patency of the anorectal canal, which is most important in newborns who have not yet passed meconium.

Examination of the Premenarcheal Child

The examination of the premenarcheal and peripubertal child should focus on the main symptoms identified in this population: pruritus, dysuria, skin color changes, and discharge.

Parents can be helpful during the examination of a young child because they provide a sense of security and they can distract the patient. Placing a child up to age 5 years on her parent's lap affords a better opportunity to perform an adequate examination (Fig 34–4). Older children can be placed on the examination table, but the use of stirrups is not generally necessary. The examiner may have adequate exposure of the genitalia when the patient is asked to flex her knees and abduct her legs. I often ask the young patient to assist in the examination, as this may distract the child as well as provide her with a sense of control. In some patients, the knee–chest position may be useful in visualizing the upper vagina and cervix.

Figure 34–4.

All rights reserved.

Child is positioned on mother's lap and feels secure in mother's arms. The mother can assist by supporting the child's legs, providing an excellent view of the genital area.

(Photo courtesy of Dr. T. Anglin.)

Studies indicate that young patients and adolescents tend to prefer physicians who wear white coats. As a uniform, the white coat identifies the physician in his or her role, which may involve inspection and

occasional palpation of private areas. This is even more important today when many children have been instructed in personal safety programs.

In older girls, explaining procedures, demonstrating the various instruments, and providing health information during the examination may decrease apprehension and help establish a good patient–physician relationship.

PHYSICAL EXAMINATION

General Inspection

The examination begins with an evaluation of the patient's general appearance, nutritional status, body habitus, and any gross congenital anomalies.

Breasts

Breast budding usually begins at approximately age 8–9 years. Prominence of the nipple and breast development at an earlier age may be early signs of sexual precocity. Appropriate monitoring may include assessment of bone age, as well following height and breast development at 3-month intervals.

Abdomen

Inspection and palpation of the abdomen should precede examination of the genitalia. If the child is ticklish, having her place one hand on or under the examiner's hand usually will overcome the problem.

The ovary of a premenarcheal child is situated high in the pelvis. This location and the small size of the pelvic cavity tend to force ovarian tumors above the true pelvic brim. Thus, large neoplasms of the ovary are likely to be mistaken for other abdominal masses (eg, polycystic kidney). Although inguinal hernias are less common in females than in males (approximately 1:10), they may occur, usually without discomfort. An excellent method of demonstrating an inguinal hernia is to have the child stand up and increase the intra-abdominal pressure by blowing up a balloon.

Genitalia

The vulva and vestibule can be exposed by light lateral and downward pressure on each side of the perineum, a technique referred to as *labial separation*. When exposure of the vaginal walls is necessary, the labia can be grasped between the examiner's thumb and forefinger and pulled forward, downward, and sideways, a technique called *labial traction*. Particular attention should be paid to the adequacy of perineal hygiene, because poor hygiene may predispose a child to local inflammation. The examiner should look for skin lesions, perineal excoriations, ulcers, and tumors. Signs of hormonal stimulation in early childhood and absence of such signs later in childhood are important signs of endocrine disorders associated with precocious or delayed puberty. Enlargement of the clitoris is of diagnostic significance, especially during early pubertal development, because it alerts the clinician to the presence of an endocrinopathy.

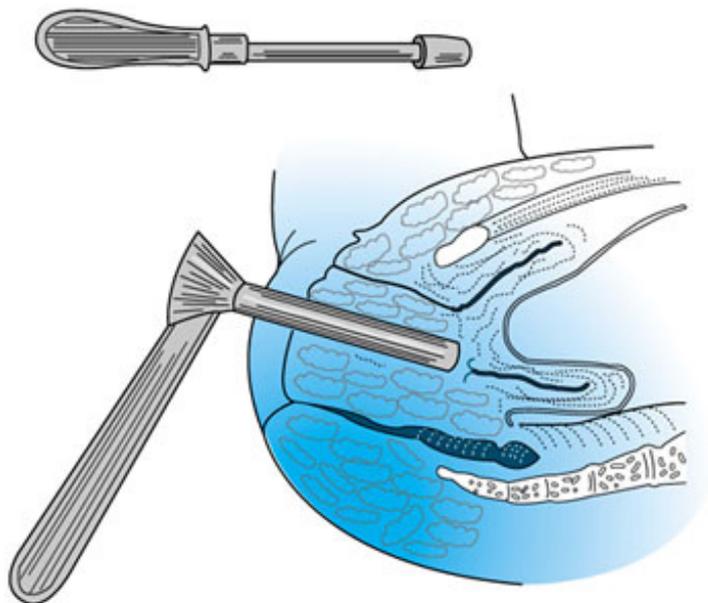

Special attention should be paid to vulvar inflammation and vulvar and vaginal discharge. In some patients the vestibule or the vaginal orifice may not be visible because of labial adhesions or congenital anomalies. The former condition is frequently mistaken for vaginal agenesis or imperforate hymen.

It is extremely difficult to perform a digital vaginal examination in a child whose vagina is of normal size for her age. The hymeneal orifice is small, and the tissue is thin, friable, and extremely sensitive. Gentle rectal digital examination can be accomplished, but the small size of the uterus and ovaries and the resistance most children offer to the examination render accurate intrapelvic evaluation difficult. If the uterus and ovaries are not palpable, the child likely does not have a genital tumor. If the presence of a pelvic tumor is suspected and the neoplasm cannot be palpated on rectal examination, other diagnostic procedures (eg, sonography, laparoscopy) should be performed.

VAGINOSCOPY

Instrumentation is required when it is necessary to carefully visualize the upper third of the vagina for a source of abnormal vaginal bleeding, to confirm patency of the genital tract, to detect and remove foreign bodies, or to exclude penetrating injuries. In the latter case, the examination is often performed under general anesthesia. Figure 34–5 shows the office vaginoscope in use. I prefer to use a water cystoscope, which distends the vagina and permits visualization of the vaginal mucosa, while washing away secretions, blood, and debris (Fig 34–6). Alternatively, a urethroscope or laparoscope can be used.

Performing vaginoscopy under anesthesia using a water cystoscope.

In infancy and childhood, the hymenal orifice normally will admit a 0.5-cm vaginoscope. An instrument 0.8 cm in diameter can be used to examine older premenarcheal girls. Topical lidocaine gel can be used to anesthetize the vulva and provide lubrication. If the aperture is too small to allow instrument passage without patient discomfort, vaginoscopy should not be further attempted without general anesthesia.

Examination of the Adolescent

The adolescent's first trip to the gynecologist is often laden with fear and apprehension. Time spent putting the patient at ease and winning her confidence will save time and frustration in the examining room. The physician should make it clear that the adolescent is the patient. She, the patient, rather than an accompanying adult if present, is asked for information that will go on the medical record. Questions about high-risk behaviors, including sexual behavior and sexually transmitted diseases (STDs), should be asked privately.

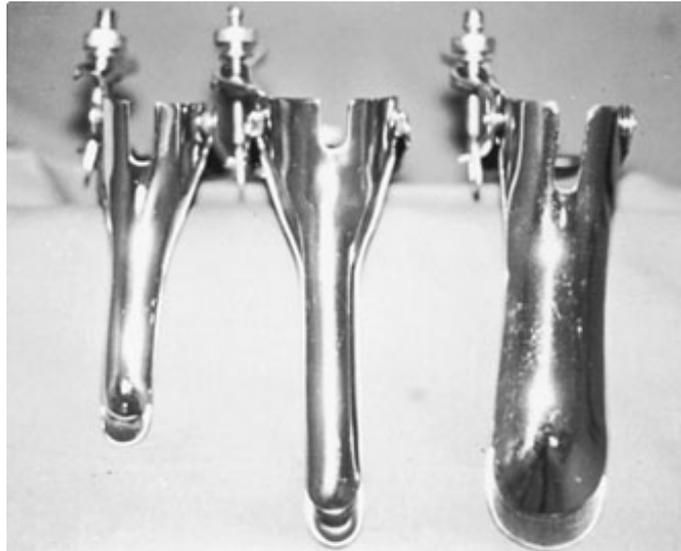

After the history is taken, the patient should be given a brief description of what the examination entails. She should be assured that the examination will not be painful. The examination is performed in the presence of a female chaperone.

A breast examination is an integral part of the physical examination of every female patient. Controversy exists over whether self-examination techniques should be taught to adolescents at this time, as the risks of a mass being cancerous in this age group are extremely low and evaluation at the time of routine examination most likely is sufficient.

The examination is also used to provide the patient with health maintenance instructions and explanations about her body and its various functions. Many adolescents are not familiar with the appearance of their own genitalia. Some physicians use mirrors during the examination to show normal anatomic details, to demonstrate abnormalities, to explain treatment plans, and to provide explanations regarding health maintenance. Others use a colposcope attached to a video monitor for the genital examination of young children. This provides an enlarged image seen simultaneously by the examiner and the patient and permits direct communication, particularly in difficult cases.

Following inspection of the genitalia, a speculum is inserted into the vagina. The introitus of most virginal adolescents is approximately 1 cm in diameter and will admit a narrow speculum. The Huffman-Graves and Pedersen specula both are designed to allow for easy inspection of the cervix in adolescents, in whom the vagina is 10–12 cm long (Fig 34–7). The larger Graves speculum, although useful in parous women, is generally not appropriate for most younger patients. In a patient with a large hymenal opening, bimanual examination is performed by inserting a finger into the vagina. If the hymenal orifice is too small for digital examination, rectal examination can be performed.

Figure 34–7.

The Huffman-Graves speculum (middle) is as long as the adult Graves speculum (right) and as narrow as the short pediatric Graves speculum (left).

Following the examination, the patient is given an opportunity to speak alone with the examiner. Confidentiality is essential to the physician–patient relationship, and problems can be discussed with the patient's guardians only with the patient's consent. Physical or sexual abuse, however, is a legal issue, which may require breach of confidentiality.

The gynecologic visit serves as an excellent opportunity to review basic health care maintenance. For example, current recommendations advise universal vaccination for hepatitis B for all adolescents at ages 11–12 years, with immunization for older adolescents based on risk status. Tetanus and measles-mumps-rubella (MMR) vaccinations also should be updated. In addition, screening for eating disorders, depression, and behavioral risks including sexual activity and tobacco, alcohol, and substance abuse should be done routinely. To assist providers of adolescent health care, the American Medical Association has issued recommendations based on annual health guidance, screening, and immunization schedules.

Examination of the Young Victim of Sexual Abuse

Studies show that approximately 38% of girls are sexually victimized before age 18 years. Among adolescent girls in grades 9–12, 26% report experiencing physical or sexual abuse. Therefore, all adolescents should be asked about history of abuse. Many children who are possible victims of sexual abuse are brought to a hospital emergency room or to their physician's office for a comprehensive medical evaluation. Statutes vary from state to state as to the need for legal consent from a parent or guardian to perform a genital examination and collect evidence in cases of suspected abuse.

HISTORY

In some facilities, a designated individual conducts an investigative interview, to minimize repetitive questioning of the child. When asking young children about abuse, line drawings, dolls, or other aids are generally used only by professionals trained in interviewing young children. However, this does not preclude the physician from asking relevant questions to obtain a detailed history, a review of systems, and basic information about the assault. An account of the incident is extremely valuable, as it can later

be used in court as evidence, or it may reveal an unusual area of injury and thus uncommon sites for collection of evidence. It is important to know how and from whom the patient sustained the injury and whether the child is in a safe environment.

It is imperative that the clinician use questions that are not leading, avoid showing strong emotions such as shock or disbelief, and maintain a "tell me more" or "and then what happened" approach. The courts have allowed physicians to testify regarding specific details of the child's statements obtained in the course of taking a medical history to provide a diagnosis and treatment. The American Academy of Child and Adolescent Psychiatry and the American Professional Society on the Abuse of Children have published guidelines for interviewing sexually abused children.

The examiner should note the patient's composure, behavior, and mental state, as well as how she interacts with her parents and other persons. Victims of physical or sexual abuse must be removed immediately from an unsafe environment.

The information should be recorded carefully, using the patient's own words. Written notes in the medical record or audiotape or videotape should be used to document the questions asked and the child's responses. Although a detailed history is desirable, the victim should not be made to repeatedly recount the incident. When obtaining a history from a very young child is not possible, the physician should obtain accounts of the incident from other sources.

PHYSICAL EXAMINATION

The physical examination has 2 purposes: to detect and treat injuries and to collect samples that later can be used as evidence.

Detection of Injuries

Nonspecific findings are relatively common in young children. Vulvar irritation is often seen in small children as a result of poor local hygiene, maceration of the skin because of wetness from diapers, or excoriations caused by local infection. Such nonspecific findings should not be regarded as diagnostic of sexual abuse. It is important to remember that the examination is often normal in most children who were sexually abused. In one study of 2384 children who were seen in a tertiary referral center, less than 5% had genital findings suggesting abuse. The examination was deemed normal in 96.3% of children referred for the evaluation. Even so, interviews of the children indicated that 68% of the girls reported penetration of vagina or anus.

The physician should be able to recognize hymenal trauma. A lacerated hymen usually is discontinuous from 3 to 9 o'clock. In postpubertal girls, penetration and stretch trauma can result in hymeneal remnants.

Collection of Evidence

During the general inspection, all foreign material (eg, sand and grass) should be removed and placed in clearly labeled envelopes. Scrapings from underneath the fingernails and loose hairs on the skin are collected. Semen can be detected on the skin many hours after the assault. A Wood's lamp can be used to detect the presence of seminal fluid on the patient's body, as the ultraviolet light causes semen to fluoresce. The stain can be lifted off the skin with moistened cotton swabs for further analysis.

If vaginal penetration is suspected, vaginal fluid is collected and sent for sexual disease evaluation, wet-mount preparation, cytology, acid phosphatase determination, and enzyme p30. To avoid additional psychological trauma in a prepubescent child, these specimens can be collected without the insertion of a pediatric speculum, via vaginal aspiration using a feeding tube or Angiocath. An immediate wet-mount preparation done by the examining physician may detect motile sperm.

Culture swabs are obtained from the rectum, vagina, urethra, and pharynx. Current data indicate that a prepubertal child with gonorrhea or trichomonas most likely had genital–genital contact. The mode of transmission of other STDs is controversial. Testing for STDs, including human immunodeficiency virus (HIV), should be offered.

All specimens must be clearly labeled and the containers and envelopes sealed and signed by the examiner. All persons handling the materials must sign for them. Such a system is necessary to maintain the chain of evidence; otherwise, these specimens may not be admissible in court. Some hospitals provide preassembled "rape kits" that guide the examiner in documenting and collecting specimens in a manner suitable for legal uses.

If an STD or other signs of abuse are found, all states require that the findings be reported to child protective service agencies for investigation of sexual abuse. Furthermore, it is important to keep in mind that a normal physical examination does not exclude the possibility of sexual abuse.

CONGENITAL ANOMALIES OF THE FEMALE GENITAL TRACT: INTRODUCTION

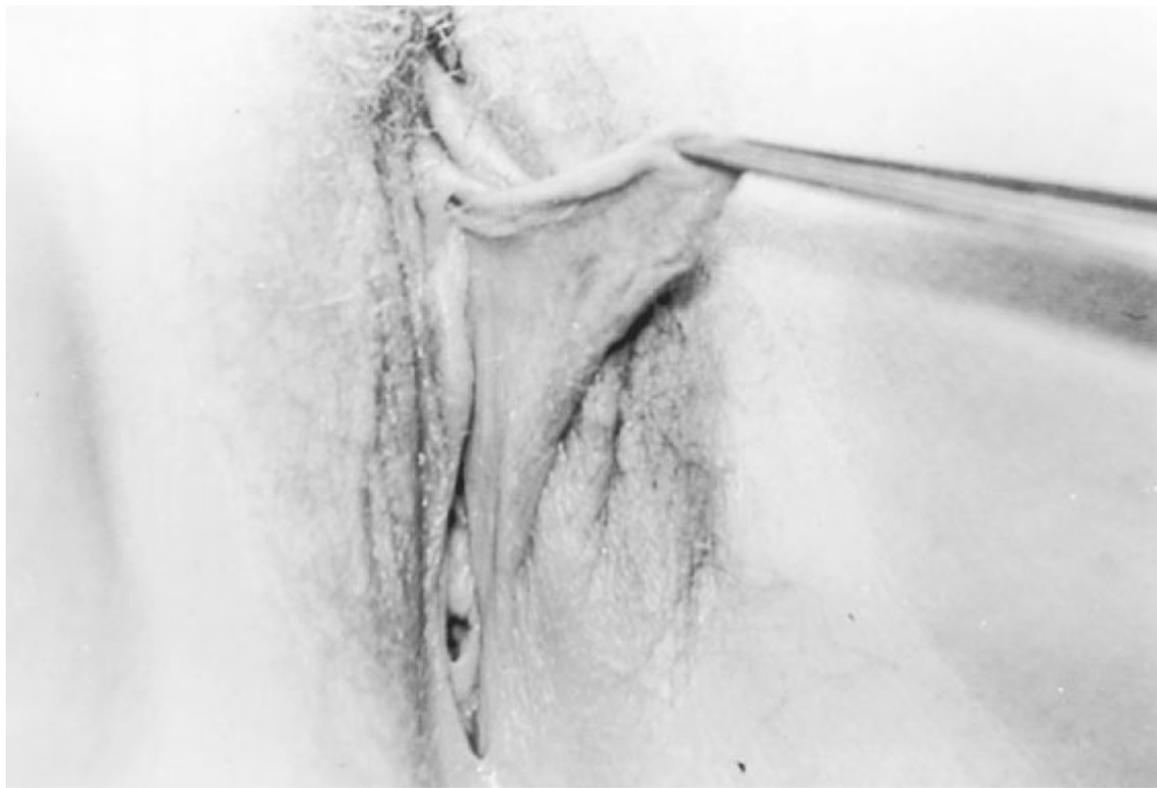

Congenital anomalies of the genitalia can be divided into those that suggest sexual ambiguity (intersex problems) and those that do not. Intersex individuals have significant ambiguity of the external genitalia such that the true gender cannot be immediately determined. Detailed discussion on intersex conditions is beyond the scope of this chapter.

ANOMALIES OF THE VULVA & LABIA

Minor differences in the contour or size of vulvar structures are not unusual. Often there is considerable variation in the distance between the posterior fourchette and the anus or between the urethra and the clitoris. Rare anomalies of the vulva include bifid clitoris, which occurs in conjunction with bladder exstrophy; a caudal appendage resembling a tail; congenital prolapse of the vagina; and variations in the insertion of the bulbocavernosus muscle, which may alter the appearance of the labia majora and at times obliterate the fossa navicularis. Duplication of the vulva is an extremely rare anomaly, which may be associated with duplication of the urinary or intestinal tracts.

There is considerable variation in the size and shape of the labia minora. One of the labia may be considerably larger than the other, or both labia may be unusually large. These variations usually require no treatment (Fig 34–8). If asymmetry is significant or if large labia are pulled into the vagina during intercourse, the hypertrophied labia can be trimmed surgically to provide a more symmetric appearance or to relieve dyspareunia. Surgical reduction can be accomplished by amputating the protuberant segment, excising a wedge of protuberant labial tissue, or simply removing the central portion.

Figure 34–8.

Labial asymmetry resulting from enlargement of the left labium minor.

ANOMALIES OF THE CLITORIS

Clitoral enlargement almost invariably suggests exposure to elevated levels of androgens. Such enlargement is often associated with fusion of the labioscrotal folds. Recklinghausen's neurofibromatosis, lymphangiomas, and fibromas may also involve the clitoris and cause enlargement. When an isolated neoplasm causes enlargement of the clitoris, therapy consists of excision of the neoplasm with reduction of the clitoris to normal size.

Clitoral splitting is caused by a midline fusion defect. Bifid clitoris usually occurs in conjunction with bladder exstrophy, epispadias, and absence or cleavage of the symphysis pubis. The labia majora are widely separated, and the labia minora are separated anteriorly but can be traced posteriorly around the vaginal orifice. The uterus often shows a fusion deformity, and the vaginal orifice is narrow. The vagina is shortened and rotated anteriorly. The pelvic floor is incomplete, and uterine prolapse is often observed in these patients. Other congenital anomalies may be present. Clitoral agenesis is extremely rare.

Finally, children with clitoral enlargement must be fully evaluated to exclude the presence of an intersex condition. Clitoral reduction is often performed as part of therapy once the diagnosis is made and a female gender is assigned. Many techniques have been described. Although the surgery is often performed in early childhood, the long-term effects on sexual function are unknown. A recent study of 39 adults who had intersex conditions with ambiguous genitalia and who were living as females showed that those who had undergone clitoral surgery had higher rates of nonsensuality and of inability to achieve orgasm. The authors concluded that sexual function of adult females could be compromised by clitoral

surgery.

ANOMALIES OF THE HYMEN

Hymenal anomalies result from incomplete degeneration of the central portion of the hymen. Variations include imperforate, microperforate, septate, and cribriform hymens. Although most of these variants are not clinically significant, hymenal anomalies require surgical correction if they block vaginal secretions or menstrual fluid, interfere with intercourse, or prevent treatment of a vaginal disorder.

Imperforate Hymen

Imperforate hymen represents a persistent portion of the urogenital membrane. It occurs when the mesoderm of the primitive streak abnormally invades the urogenital portion of the cloacal membrane. It is one of the most common obstructive lesions of the female genital tract. When mucocolpos develops from accumulation of vaginal secretions behind the hymen, the membrane is seen as a shiny, thin bulge (Fig 34–9). The distended vagina forms a large mass that may interfere with urination and at times may be mistaken for an abdominal tumor. The diagnosis is quite easy, and the condition can be treated in the nursery. Topical anesthetic is used to prevent discomfort to the newborn, and the central portion of the obstructing membrane is excised. When imperforate hymen is corrected in infants, the central portion of the membrane is excised; sutures usually are not necessary (Fig 34–10).

Newborn infant following excision of an imperforate hymen. Forward traction on the labia majora provides an unimpaired view of the hymenal ring. Note the large opening created. No bleeding was noted, and no sutures were required.

If missed during the newborn period, imperforate hymen often is not diagnosed until an adolescent presents with complaints of primary amenorrhea and cyclic pelvic pain. It may present as back pain or difficulty with defecation or urination secondary to mass effect from vaginal distention. Inspection of the vulva may reveal a purplish-red hymenal membrane bulging outward as a result of accumulation of blood above it (hematocolpos). Blood may fill the uterus (hematometra) and spill through the fallopian tubes into the peritoneal cavity. Endometriosis and vaginal adenosis are known but not inevitable complications.

Repair of imperforate hymen is facilitated if the tissue has undergone estrogen stimulation and the membrane is distended. When the procedure is performed in an adolescent, a large central portion of the membrane should be removed because the edges of a small incision may coalesce, allowing the obstructing membrane to reform.

ANOMALIES OF THE VAGINA

Transverse Vaginal Septum

Transverse vaginal septa result from faulty fusion or canalization of the urogenital sinus and müllerian ducts. The incidence is approximately 1 in 30,000 to 1 in 80,000 women. Approximately 46% occur in the upper vagina, 40% in the midportion, and 14% in the lower vagina. When the septum is located in the upper vagina, it is likely to be patent, whereas those located in the lower part of the vagina are more often complete.

A complete septum results in signs and symptoms similar to those of an imperforate hymen. An undiscovered imperforate transverse septum may lead to the formation of a large mucocolpos in infancy.

Diagnosis is often delayed until after menarche, when menstrual blood is trapped behind an obstructing membrane. An incomplete septum usually is asymptomatic, as the central aperture allows for vaginal secretions and menstrual flow to egress from the vagina. Excision is indicated in the sexually active patient with dyspareunia.

Treatment

If the diagnosis of a complete septum is established prior to menarche, it should be incised, creating an aperture to allow drainage. Incision of a complete septum is most easily accomplished when the upper vagina is distended and the membrane is bulging, reducing the risk of injury to adjacent structures. Because of the technical difficulties in performing intravaginal surgery on immature structures, it is best to limit the procedure only to allow the establishment of vaginal drainage.

Surgical correction of vaginal narrowing should be performed only when the patient is contemplating initiation of sexual activity. The membrane should be excised with its surrounding ring of subepithelial connective tissue at the level of partition. End-to-end reanastomosis of the upper and lower vaginal mucosa, which may be accomplished with the aid of a Lucite bridge, is then undertaken.

Longitudinal Vaginal Septum

Duplication of the vagina is an extremely rare condition, often associated with duplication of the vulva, bladder, and uterus. More commonly, a longitudinal vaginal septum forms when the distal ends of the müllerian ducts fail to fuse properly. Both parts of the vagina are encircled by one muscular layer, and a fibrous septum lined with epithelium divides the vagina. The uterus may be bicornuate, with 1 or 2 cervixes (Fig 34–11).

Figure 34–11.

Longitudinal septum dividing the vagina.

Asymptomatic longitudinal septa require no treatment. Division of the septum is indicated when dyspareunia is present, when obstruction of drainage from half of the vagina is noted, or when it appears that the septum will interfere with vaginal delivery.

Vaginal Agenesis

The incidence of vaginal agenesis is approximately 1 in 5000. The external genitalia of patients with

vaginal agenesis (Mayer-Rokitansky-Kuster-Hauser [MRKH] syndrome) are normal, with a ruffled ridge of tissue representing the hymen (Fig 34–12). Variable levels of uterine development are present, with most cases accompanied by cervical and uterine agenesis. Other developmental defects are often present, affecting the urinary tract (45–50%), the spine (10%), and, less frequently, the middle ear and other mesodermal structures. Evaluation of the urinary tract and spine, as well as a hearing test, should be performed after diagnosis.

Figure 34–12.

All rights reserved.

Vaginal agenesis in a girl 16 years of age.

Persons with vaginal agenesis typically have normal female karyotypes with normal ovaries and ovarian function; thus, they develop normal secondary sexual attributes. Patients often present with primary amenorrhea or, in women with functioning uteri, with cyclic pelvic pain. Serum testosterone level and karyotyping may identify the rare instances in which müllerian agenesis represents the effects of testicular activity, indicating male pseudohermaphroditism.

Treatment

Creation of a satisfactory vagina is the objective of treatment of vaginal agenesis. Treatment should be deferred until the patient is contemplating sexual activity. Nonoperative creation of a vagina using serial vaginal dilators, in a method described by Frank and later modified by Ingram, is relatively risk-free but

requires patient motivation and cooperation. The procedure takes a few months to complete. Repetitive coitus can also be used to create a functioning vagina.

The McIndoe procedure involves the creation of a cavity by surgical dissection between the urethra and bladder anteriorly and the perineal body and rectum posteriorly. The cavity is lined by a split-thickness skin graft overlying a plastic or soft silicone mold. The labia minora are secured around the mold for 7 days prior to removal. Postoperatively the patient must continue to use dilators for several months to maintain vaginal patency. Patient satisfaction rates greater than 80% have been reported. Complications include graft failure, hematoma, fistula formation, and rectal perforation.

The Williams vulvovaginoplasty utilizes the labia majora to construct a coital pouch. Placing the labia under tension, a U-shaped incision is carried from the level of the urethra along the margins of the labia majora to the midpoint between the posterior fourchette and the anus. The vulvar skin is dissected from the subcutaneous fat to allow approximation without tension. The vagina is closed in 3 layers. This procedure is not performed as often as the McIndoe procedure because the vaginal pouch created is only 4–5 cm in length and positioned at an unusual angle for intercourse.

Alternative procedures, such as sigmoid vaginoplasty and laparoscopic approaches using the Vecchietti procedure and the Davydov procedure, have been described. Limited data on success and complications rates are available.

Few studies address the long-term success of both vaginal dilatation and surgical correction in patients with vaginal agenesis. Unfortunately, each medical center has only limited experience with such patients. Morgan and Quint identified 14 patients with vaginal agenesis, but only 7 could be contacted. In this small series, the authors noted that sexual functioning was variable and patients had unique psychosocial and psychosexual concerns. In another series, Crouch et al. sent questionnaire to 43 women who underwent vaginal dilatation. The authors reported that 23% of the patients never used the dilators they were given, compliance was poor, and only 50% of users were satisfied with their dilators. Sexual difficulties were common irrespective of dilator use or vaginal length.

Partial Vaginal Agenesis

Partial vaginal agenesis occurs when a large portion of the vaginal plate, usually the distal part, fails to canalize. The affected vaginal segment of the vagina is replaced by a soft mass of tissue. The cause of this uncommon anomaly is unknown. Absence of the distal vagina may be identified when the infant is examined at birth, and sonographic visualization of the upper vagina, cervix, and uterus serves to distinguish the condition from Rokitansky syndrome.

If the uterus has developed normally, the upper part of the vagina fills with blood when menstruation begins. The symptoms are similar to those associated with imperforate hymen after the menarche. Vulvar inspection reveals findings identical with those of vaginal agenesis, but rectoabdominal palpation reveals a large, boggy pelvic mass. Diagnostic imaging using sonography, computed tomography, or magnetic resonance imaging will confirm the diagnosis.

Treatment

Surgery is indicated because obstruction to menstrual flow may occur. In some patients, drainage of the uterus can be achieved through a reconstructed vagina. In others, particularly when the uterus is rudimentary, consideration may be given to performing a hysterectomy.

ANOMALIES OF THE UTERUS

Uterine anomalies result from agenesis of the müllerian duct or a defect in fusion or canalization. These anomalies include bicornuate uterus (37%), arcuate uterus (15%), incomplete septum (13%), uterine

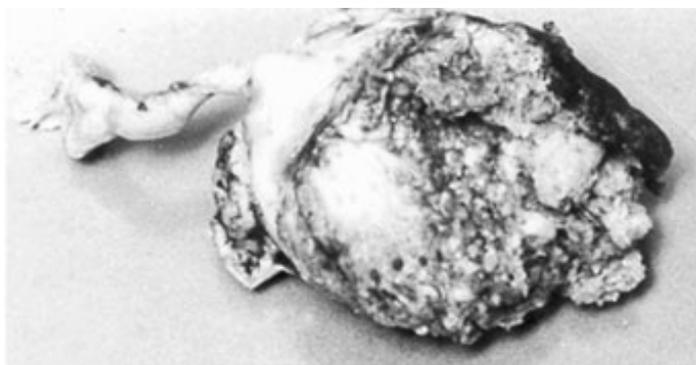

didelphys (11%), complete septum (9%), and unicornuate uterus (4%).

Most uterine anomalies are asymptomatic and therefore are not detected during childhood or early adolescence. Symptoms during adolescence are primarily caused by retention of menstrual flow. Asymptomatic abnormalities often escape detection until they interfere with reproduction.

Unicornuate Uterus and Rudimentary Uterine Horn

A unicornuate uterus is a single-horned uterus with its corresponding fallopian tube and round ligament. It results from agenesis of one müllerian duct, with absence of structures on that side. When the other hemiuterus is present, it often creates a small rudimentary uterine horn. If this rudimentary horn does not communicate with the other uterine cavity or the vagina, menstrual blood cannot escape, resulting in severe dysmenorrhea, hematometra, or pyometra. A pregnancy that occurs in a rudimentary horn may result in rupture, a complication that is potentially fatal for both mother and fetus (Fig 34–13). Women with unicornuate uteri are at higher risk for preterm labor, infertility, endometriosis, and malpresentation.

Figure 34–13.

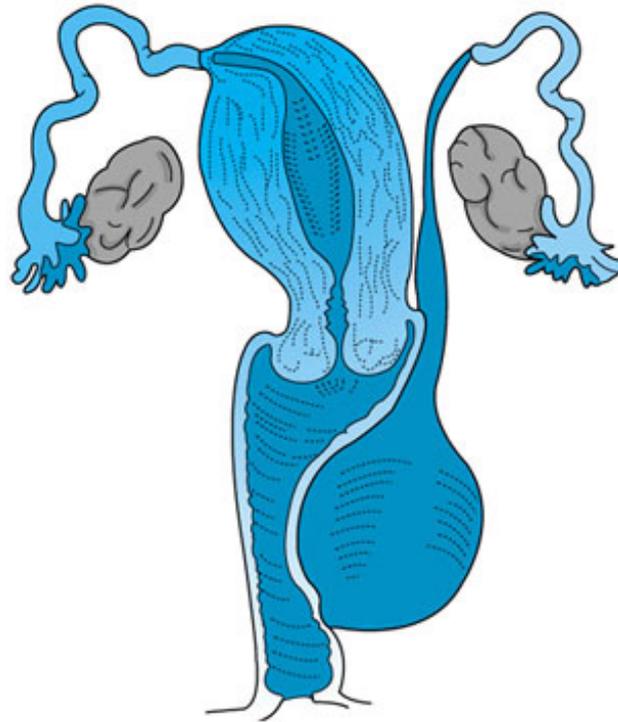

Copyright ©2006 by The McGraw-Hill Companies, Inc.
All rights reserved.

Pregnancy in a noncommunicating rudimentary uterine horn that has resulted in rupture.

Ideally, a rudimentary horn should be resected before conception. The tube and ovary on the affected side can be preserved, provided that the blood supply is not impaired. If the endometrial cavity of the remaining horn is entered during the operation, cesarean section is a reasonable mode of delivery for any subsequent pregnancies.

A unicornuate uterus occasionally is accompanied by an anomaly of the opposite paramesonephric duct, creating a lateral vaginal wall cyst with an endometrial lining. As a result, the cyst fills with blood following menarche and produces a vaginal mass (Fig 34–14). Excision of a small segment of the wall between the cyst and the vagina often provides adequate drainage. Attempts to remove the cyst may involve extensive dissection, with potential damage to the urethra, bladder, or ureter.

Figure 34–14.

Copyright ©2006 by The McGraw-Hill Companies, Inc.
All rights reserved.

Unicornuate uterus with paramesonephric vaginal cyst. The endometrium lining the upper part of the cyst bleeds at menarche, and the blood filling the lower part of the cyst forms a mass that protrudes into the vagina.

Uterine Didelphys

Failure of fusion of the müllerian duct may result in 2 separate uterine bodies. The fusion defect usually is limited to the uterine body and cervix. Duplication of the bladder, urethra, vagina, anus, and vulva may also occur.

Women with uterine didelphys generally have good reproductive outcomes. Vaginal septae may require resection if they cause difficulty with sexual intercourse or vaginal delivery or if pain results from obstructed menstrual flow.

Bicornuate Uterus and Septate Uterus

Bicornuate uterus results from partial fusion of the müllerian ducts, leading to varying degrees of separation of the uterine horns. Uterine septa result from failures of canalization or resorption of the midline septum between the 2 müllerian ducts. Although reproductive function is good overall in bicornuate uterus, the risk for miscarriage is higher with increasing length of septa. Hysteroscopic resection of septa or metroplasty may be considered for infertility.

ANOMALIES OF THE OVARIES

At approximately week 5 of gestation, the midportion of the urogenital ridge, close to the mesonephric duct, thickens to form the gonadal ridge. Located along the urogenital ridge, an additional ovary is infrequently found, separated from the normal ovaries (supernumerary ovary). Similarly, excess ovarian tissue may be observed near a normally placed ovary and connected to it (accessory ovary).

During development, the testes are drawn into the scrotum by the gubernaculum testis. Similarly, an ovary may be drawn by the round ligament into the inguinal canal or the labium major. A firm inguinal mass should alert the examiner to the possible presence of an aberrant gonad, possibly containing testicular elements, even in the presence of female external genitalia. A karyotype should be obtained. At the time of hernia repair, the gonad should be biopsied. If it proves to be an ovary, it should be returned to the peritoneal cavity and the hernia repaired. If a testis is identified, the gonad should be removed.

Patients with gonadal dysgenesis may demonstrate typical physical manifestations. These include cutis laxa and edema of the dorsal surfaces of the hands and feet in infants, height and weight below the third percentile, broad chest and small nipples, webbed neck, coarctation of the aorta, prominent epicanthal folds, nevi, and other somatic anomalies (eg, short fourth metacarpal). In most adults with gonadal dysgenesis, the normal gonad is replaced by a white fibrous streak, 2–3 cm long and approximately 0.5 cm wide, located in the gonadal ridge. Histologically, the streak gonad is characterized by interlacing waves of dense fibrous stroma, indistinguishable from normal ovarian stroma.

Although oocytes are present in children, they usually are absent in 45,X adults. Increased atresia and failure of germ cell formation deplete oocyte supply, but when atresia is incomplete, pubertal changes, spontaneous menstruation, and even pregnancies have been reported.

ANOMALIES OF THE URETHRA & ANUS

Failure of a newborn infant to pass meconium or urine demands investigation. Passage of feces or urine through the vagina suggests a fistulous communication, and usually either the urethra or the anus is imperforate.

Anal and rectal anomalies are classified according to Ladd and Gross (Table 34–2). In general, anomalies are divided into 2 major groups: those that form complete obstruction of the intestinal tract and those that are associated with some type of abnormal opening or fistula.

Table 34–2. Malformations of the Anus and Rectum.

	Female	Male
Anal stenosis		
Imperforate anal membrane		
Anal agenesis	With fistula	With fistula
	Anoperineal (ectopic perineal anus, anovulvar)	Anoperineal (ectopic perineal anus, anocutaneous [covered anus]), or anourethral (bulbar or membranous)
	Without fistula	Without fistula

	Female	Male
Rectal agenesis	With fistula	With fistula
	Rectovestibular, rectovaginal, rectocloacal (urogenital sinus)	Rectourethral, rectovesical
	Without fistula	Without fistula
Rectal atresia		

Reproduced, with permission, from Ladd WE, Gross RE: Congenital malformations of the anus and rectum: Report of 162 cases. *Am J Surg* 1934;23:167.

Because findings are so diverse, only broad generalizations on the management of urogenital anomalies of this type can be offered. The following principles may serve as guidelines. (1) Obstruction of the intestinal tract must be corrected. (2) Obstruction of the urinary tract must be relieved (this may require an initial ureterostomy or cystostomy). (3) If the urogenital sinus cannot be used later as a urethra, a permanent diversion (eg, ileal conduit) must be created. (4) Fecal contamination of the urinary tract, if present, must be corrected, usually with a temporary colostomy.

Epispadias & Bladder Exstrophy

Epispadias denotes the failure of normal fusion of the anterior wall of the urogenital sinus, resulting in a urethra that opens cephalad to a bifid clitoris under the symphysis pubis (Fig 34–15). Occasionally, the defect is more extensive, involving the bladder and the anterior abdominal wall, causing exstrophy of the bladder. Both conditions may be associated with defects involving the anterior pelvic girdle, resulting in diminished pelvic support. Uterine and vaginal vault prolapse as well as anterior displacement of the vagina are common gynecologic complications. Rarely, vaginal and uterine prolapse occur in the absence of other malformations. Major urologic reconstruction is required promptly, although gynecologic defects can be repaired later, usually during adolescence.

Figure 34–15.

Adolescent girl following repair of bladder exstrophy. Note the bifid clitoris and anterior displacement of the vagina.

VULVOVAGINITIS

Pruritus vulvae and vulvovaginitis are common gynecologic disorders in children. Pruritus vulvae refers to itching of the external female genitalia. Vulvovaginitis, although inconsistently delineated in the literature, generally involves prominent vaginal discharge. The child is susceptible to both these conditions for several reasons: the prepubertal vulva is thin without labial fat pads and pubic hair, as well as anatomically in close proximity to the anus and its contaminants; the unestrogenized vagina is atrophic with pH ranges excellent for bacterial growth; and perineal hygiene often is suboptimal as supervision declines with age. Table 34–3 lists classification of vulvovaginitis according to cause.

Table 34–3. Classification of Vulvovaginitis According to Cause.

Nonspecific vulvovaginitis

Polymicrobial infection associated with disturbed homeostasis: secondary to poor perineal hygiene or a foreign body

Vulvovaginitis due to secondary inoculation

Infection resulting from inoculation of the vagina with pathogens affecting other areas of the body by contact or bloodborne transmission: secondary to upper respiratory tract infection or urinary tract infection

Specific vulvovaginitis

Specific primary infection, most commonly sexually transmitted: *Neisseria gonorrhoeae*, *Gardnerella vaginalis*, herpesvirus, *Treponema pallidum*, others

Clinical Findings

Acute vulvovaginitis may denude the thin vulvar or vaginal mucosa; however, bleeding usually is minimal. Mucopurulent or purulent discharge usually is present. Vaginal discharge may vary from minimal to copious, and at times it is bloodstained. Symptoms vary from minor discomfort to relatively intense perineal pruritus. The child often complains of a burning sensation accompanied by a foul-smelling discharge. The irritating discharge inflames the vulva and often causes the child to scratch the area to the point of bleeding. Inspection of the vagina reveals an area of redness and soreness that may be minimal or may extend laterally to the thighs and backward to the anus. Many patients experience a burning sensation when urine flows over the inflamed tissues, and vulvovaginitis should be excluded in children prior to treatment for urinary tract infection.

Diagnosis is suspected by the typical appearance of the inflamed tissue. A wet-mount preparation reveals numerous leukocytes and occasional red blood cells. Culture of vaginal secretions sometimes identifies the offending organism.

Evaluation of the vaginal secretions may include smears for Gram's stain, bacterial cultures, cultures for mycotic organisms, wet prep, *Trichomonas*, and parasitic ova.

Improvement of perineal hygiene is important to relieve the symptoms and to prevent recurrences. Most cases of nonspecific pruritus vulvae resolve with improvements in hygiene and avoidance of irritants, including soaps.

Amoxicillin (20–40 mg/kg/d in 3 divided doses) is effective against a variety of potentially pathogenic organisms in nonspecific vulvovaginitis. When the infection is severe and extensive mucosal damage is seen, a short course of topical estrogen cream is given to promote healing of vulval and vaginal tissues. When irritation is intense, hydrocortisone cream may be necessary to alleviate the itch. In recurrent

infections refractory to treatment or associated with a foul-smelling, bloody discharge, vaginoscopy is necessary to exclude a foreign body or tumor.

FOREIGN BODIES

Vaginal foreign bodies induce an intense inflammatory reaction and result in blood-stained, foul-smelling discharge. Usually, the child does not recall inserting the foreign object or will not admit to it.

Radiographs are not reliable for revealing a foreign body because many objects are not radiopaque.

Foreign bodies in the lower third of the vagina can be flushed out with warm saline irrigation. If the vagina cannot be adequately inspected in the office even after removal of the foreign body, vaginoscopy is indicated to confirm that no other foreign bodies are present in the upper vagina.

URETHRAL PROLAPSE

Occasionally, vulvar bleeding is the result of urethral prolapse. The urethral mucosa protrudes through the meatus and forms a hemorrhagic, sensitive vulvar mass. Urethral prolapse can be definitively diagnosed without laboratory or radiographic evaluation by demonstrating that the edematous tissue surrounds the meatus circumferentially and is separated from the vagina. When the lesion is small and urination is unimpaired, treatment consists of parental reassurance, observation, warm soaks, and a short course of therapy using estrogen cream. When urinary retention is present, if the lesion is large and necrotic, if medical therapy fails, or if the child is being examined under anesthesia, resection of the prolapsed tissue should be performed and an indwelling catheter inserted for 24 hours.

LICHEN SCLEROSUS

Lichen sclerosus of the vulva is a hypotrophic dystrophy. More common in postmenopausal women, it is occasionally seen in children. Histologically, the findings in both age groups are similar, with flattening of the rete pegs, hyalinization of the subdermal tissues, and keratinization. In children, the lesion has no known malignant potential if only hypoplastic dystrophy is present.

The clinical presentation includes flat papules that may coalesce into plaques or, in extreme cases, involve the entire vulva (Fig 34–16). Usually, the lesion does not extend beyond the middle of the labia majora laterally or into the vagina medially. The clitoris, posterior fourchette, and anorectal areas are frequently involved. Occasionally, lesions affect extragenital areas. Although most lesions are predominantly white, some have pronounced vascular markings. They tend to bruise easily, forming bloody blisters, and they are susceptible to secondary infections. Symptoms consist of vulvar irritation, dysuria, and pruritus. Scratching is common and occasionally provokes bleeding or leads to secondary infection.

Figure 34–16.

Lichen sclerosus of the vulva in a 6-year-old child.

Histologic confirmation is necessary in postmenopausal women but is not always mandatory in children. Treatment usually consists of improved local hygiene, reduction of trauma, and short-term use of hydrocortisone cream to alleviate the pruritus. Topical testosterone or newer androgen-containing skin patches have also been used, but longer-term exposure may induce androgen-dependent secondary sex characteristics. Over half of children improve significantly or recover during puberty.

LABIAL ADHESION

Labial adhesion is common in prepubertal children. The cause is not known but probably is related to low estrogen levels. The skin covering the labia is extremely thin, and local irritation may induce scratching, which may denude the labia. The labia then adhere in the midline, and reepithelialization occurs on both sides (Fig 34–17). It is important to differentiate this condition from congenital absence of the vagina.

Figure 34–17.

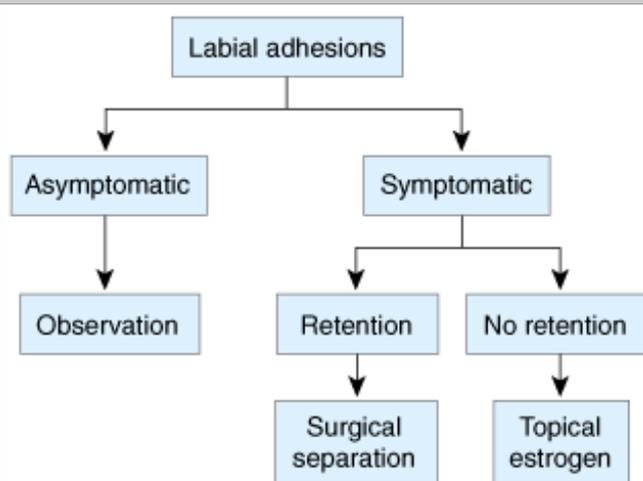

Labial adhesion in a young girl. Note the translucent vertical line in the center where the labia are fused together.

Most children with small areas of labial adhesions are asymptomatic. When symptoms occur, they usually relate to interference with urination or accumulation of urine behind the adhesion. Dysuria and recurrent vulvar and vaginal infections are cardinal symptoms. Rarely, urinary retention may occur.

Asymptomatic minimal to moderate labial fusion does not require treatment. Symptomatic fusion may be treated with a short course of estrogen cream applied twice daily for 7–10 days; this may separate the labia. Some girls may require manual separation once they have been treated with topical estrogen. When medical treatment fails or if severe urinary symptoms exist, surgical separation of the labia is indicated. This can be performed in the operating room under anesthesia, or as an office procedure using 1–2% topical lidocaine (Xylocaine) gel. A schematic approach to the management of labial adhesions is shown in Fig 34–18.

Figure 34–18.

Management of labial adhesions.

Because of low estrogen levels, recurrences of labial adhesion are common until puberty. Following puberty, the condition resolves spontaneously. Improved perineal hygiene and removal of vulvar irritants may help prevent recurrences.

GENITAL INJURIES

Most injuries to the genitalia during childhood are accidental. Many are of minor significance, but a few are life-threatening and require surgical intervention. The physician must determine how the child sustained the injury, bearing in mind that the child requires protection if she is the victim of physical or sexual abuse.

Vulvar Injuries

Contusion of the vulva usually does not require treatment. A hematoma manifests as a round, tense, ecchymotic, tender mass (Fig 34–19). A small vulvar hematoma usually can be controlled by pressure with an ice pack. The vulva should be kept clean and dry. A hematoma that is large or continues to increase in size may require incision, with removal of clotted blood and ligation of bleeding points. If the source of bleeding cannot be found, the cavity should be packed with gauze and a firm pressure dressing applied. The pack is removed in 24 hours. Prophylactic broad-spectrum antibiotics may be advisable.

Figure 34–19.

All rights reserved.

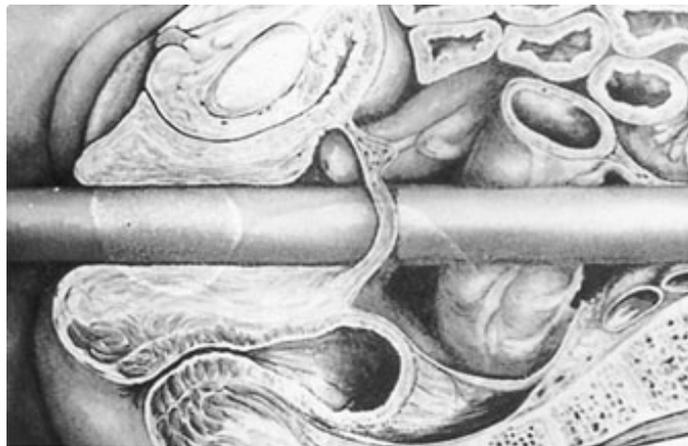

Large vulvar hematoma secondary to bicycle injury.

When a large hematoma obstructs the urethra, insertion of a catheter is necessary, usually by a suprapubic approach. Radiography of the pelvis may be necessary to rule out pelvic fracture.

Vaginal Injuries

Usually, only a small amount of bleeding results from a hymenal injury. However, when the hymen is lacerated or other evidence indicates an object has entered the vagina or penetrated the perineum, a detailed examination is necessary to exclude injuries to the upper vagina or intrapelvic viscera (Fig 34–20).

Figure 34–20.

Copyright ©2006 by The McGraw-Hill Companies, Inc.
All rights reserved.

Transvaginal perforation of cul-de-sac and penetration of peritoneal cavity by a fall on a mop handle. Scanty bleeding from a hymenal tear was the only symptom on admission.

Most vaginal injuries involve the lateral walls. Generally, there is relatively little blood loss, and the child

does not have much pain if only the mucosa is damaged. If the laceration extends beyond the vaginal vault, exploration of the pelvic cavity is necessary to rule out extension into the broad ligament or peritoneal cavity. Bladder and bowel integrity must be confirmed by catheterization and rectal palpation. Because of the small caliber of the organs involved, special instruments, as well as proper exposure and assistance, may be required for repair of vaginal injuries in young girls. Many vaginal lacerations are limited to the mucosal and submucosal tissues and are repaired with fine suture material after complete hemostasis is secured.

A vaginal wall hematoma from a small vessel may stop bleeding spontaneously. Larger vessels may form large, tense hematomas that distend the vagina and require evacuation and ligation of the bleeding vessel. When a vessel is torn above the pelvic floor, a retroperitoneal hematoma may develop. If the hematoma is enlarging, laparotomy must be performed, the clot removed, and the bleeding vessel ligated. Alternatively, the bleeding may be controlled by angiographic embolization of the bleeding vessel.

Anogenital Injuries Caused by Abuse

Many children who are victims of sexual abuse do not sustain physical injuries, and an examination is not expected to detect signs of abuse. Even when injured, many of these children may not be seen for weeks, months, or even years after the incident. The delay allows for semen and debris to wash away and for most, if not all, injuries to heal.

Injuries to the vulva may be caused by manipulation of the vulva or introitus, without vaginal penetration, or by friction of the penis against the child's vulva ("dry intercourse"). Erythema, swelling, skin bruising, and excoriations are found on the labia and vestibule. These injuries are superficial and often limited to the vulvar skin; they should resolve within a few days and require no special treatment.

Meticulous perineal hygiene is important in the prevention of secondary infections. Sitz baths should be used to remove secretions and contaminants. In some patients with extensive skin abrasions, broad-spectrum antibiotics should be given as prophylaxis. Large vulvar tears require suturing, which is best performed under general anesthesia, using fine absorbable sutures. Bite wounds on the genitalia should be irrigated copiously and necrotic tissue cautiously debrided. A noninfected fresh wound often can be closed primarily, but most bite wounds should be left open. Closure is completed when granulation tissue is formed. After 3–5 days, secondary debridement may be required to remove necrotic tissues. Antitetanus immunization should be given if the child is not already immunized. Broad-spectrum antibiotics should be used for therapy rather than prophylaxis.

Most vaginal injuries occur when an object penetrates the vagina through the hymenal opening. Such penetration may result in a laceration or a tear of the hymenal ring as well as associated vaginal injuries. A detailed examination is necessary to exclude injuries to the upper vagina.

Examination of the anus and rectum is easier than is examination of the vagina, and most children tolerate it well. Because the anal sphincter and anal canal allow for some dilatation, a tear of the anal mucosa or sphincter rarely occurs following a digital assault. However, penetration by a larger object almost always results in some degree of injury, which varies from swelling of the anal verge to gross tearing of the sphincter. In the period immediately following penetration, the main findings are sphincter laxity and swelling and small tears of the anal verge. If the sphincter is not severed, it may be in spasm and will not permit a digital examination. Within days, the swelling subsides and the mucosal tears heal, occasionally forming skin tags. If not severed, the anal sphincter regains function. Repeated anal penetration over a prolonged period may cause the anal sphincter to become loose, forming an enlarged opening. The anal mucosa thickens and loses its normal folds. Although some investigators suggest that

many of the children who experienced anal assault exhibit perianal scars and tags, longitudinal studies showed that anal injuries heal completely in most children.

Occasionally, child victims of abuse contract an STD. The risk of a prepubertal child contracting an STD after sexual assault is relatively low, estimated to range from 2–5%. Treatment of gonorrhea, chlamydia, and syphilis may be deferred until the results of tests become available. If vulvovaginitis is clinically suspected on the initial visit, appropriate antibiotic therapy is given. If the infection is severe, a short course of topical estrogen cream is given to promote healing of vulval and vaginal tissues. When irritation is intense, hydrocortisone cream may be necessary to alleviate itching. A repeat VDRL (Venereal Disease Research Laboratory) test to detect seroconversion is required 6 weeks later. Prophylaxis for hepatitis B with hepatitis B vaccination is recommended following sexual assault. For nonimmune victims with a high-risk exposure, practitioners may also consider adding hepatitis B immune globulin to the regimen.

The Sexually Transmitted Diseases Treatment Guidelines from 2002 do not recommend the routine screening for HIV for all child victims of sexual abuse. In view of recent data, the CDC issued a revised policy (2005) which recommends that people exposed to AIDS virus from rapes, accidents, occasional drug use, or unsafe sex receive drug cocktails that can keep them from becoming infected. Clinicians should try to identify children who are at high risk for HIV exposure and consider offering them counseling and prophylactic therapy.

Protective Services & Counseling

It is imperative to ensure that the child will be discharged to a safe environment. Sometimes it is advisable to admit the child to the hospital or to utilize temporary placement. All patients who are suspected of being victims of child sexual abuse must be referred to child protective services for further evaluation.

In the period immediately following sexual assault or disclosure of sexual abuse, the child and her family often require intensive day-to-day emotional support, counseling, and guidance. Child victims often show signs of depression and have feelings of guilt, fear, and low self-esteem. Appropriate referral for counseling is imperative. The major emphasis of emotional support involves strengthening the child's ego, improving her self-image, and helping her to learn to trust others and feel secure again. To begin the strengthening process, the child needs to realize that she was a victim. She must be encouraged to express her feelings of anger and hurt so that these feelings can be later expressed without experiencing further guilt. Often, the child has both positive and negative feelings toward the perpetrator and may need help in sorting out these feelings. Sometimes the child blames her parents for not protecting her. The child's relationships with her parents and other family members are critical and may need restructuring. Following this crisis intervention phase, a treatment program using individual and peer-group therapy is initiated. The patient and her family should be offered treatment.

GENITAL NEOPLASMS

Genital tumors are uncommon but must be considered when a girl is found to have a chronic genital ulcer, nontraumatic swelling of the external genitalia, tissue protruding from the vagina, a fetid or bloody discharge, abdominal pain or enlargement, or premature sexual maturation. Virtually every type of genital neoplasm reported in adults has also been found in girls younger than 14 years. Approximately 50% of the genital tumors in children are premalignant or malignant.

Benign Tumors of the Vulva & Vagina

Teratomas, hemangiomas, simple cysts of the hymen, retention cysts of the paraurethral ducts, benign granulomas of the perineum, and condylomata acuminata are some of the benign vulvar neoplasms observed in children and adolescents.

Obstruction of a paraurethral duct may form a relatively large cyst that distorts the urethral orifice. The recommended treatment is incision and drainage, marsupialization, or excision.

Teratomas usually present as cystic masses arising from the midline of the perineum. Although a teratoma in this area may be benign, local recurrence is likely. To prevent recurrences, a generous margin of healthy tissue is excised about the periphery of the mass.

Capillary hemangiomas usually disappear as the child grows older and thus require no therapy except reassurance. Cavernous hemangiomas, in contrast, are composed of vessels of considerable size, and injury to them may cause serious hemorrhage. They are best treated surgically.

Most benign tumors of the vagina in children are unilocular cystic remnants of the mesonephric duct (Fig 34–21). Small cysts of the mesonephric duct (Gartner's duct) do not require surgery when they are asymptomatic. Large cysts (eg, those that block the vagina) must be treated surgically. The technical difficulties associated with excision of a large mesonephric cyst from the wall of the vagina in an infant may be considerable. Removal of a large portion of the cyst wall and marsupialization of the edges, which prevents reaccumulation of fluid, usually are sufficient.

Malignant Tumors of the Vagina & Cervix

Embryonal Carcinoma of the Vagina (Botryoid Sarcoma)

Embryonal vaginal carcinomas are most commonly seen in very young girls (< 3 years old). The tumor usually involves the vagina, but the cervix may be affected as well, particularly in an older child. The tumors arise in the submucosal tissues and spread rapidly beneath an intact vaginal epithelium. The vaginal mucosa then bulges into a series of polypoid growths (thus the term botryoid sarcoma; Fig 34–22). The diagnosis is made on the basis of histologic evaluation of a biopsy specimen, but routine microscopic evaluation may lead to an erroneous diagnosis of these lesions as benign. Striated muscle fibers are not always seen, and most of the tumor demonstrates myxomatous changes. Electron microscopy may be required to confirm the diagnosis of embryonal rhabdomyosarcoma.

Figure 34–22.

Botryoid sarcoma presenting as a hemorrhagic growth extruding from the vagina.

Combination chemotherapy regimens—often, vincristine, dactinomycin (actinomycin D), and cyclophosphamide—have been used with success. Following a course of chemotherapy lasting for at least 6 months, the tumor is reexamined and rebiopsied. If following chemotherapy no residual tumor is found, surgical extirpation may not be required. If a tumor is present and is amenable to surgical removal, radical hysterectomy and vaginectomy may be performed. The ovaries are preserved, and exenteration is not recommended. If the tumor is unresectable, radiation therapy is used to further shrink and control tumor growth. Following surgery, chemotherapy should be continued for another 6–12 months.

Other Malignant Tumors of the Vagina

Three types of vaginal carcinoma may appear during childhood and the early teens. Endodermal carcinoma occurs most often in young children. Carcinoma arising in a remnant of a mesonephric duct (mesonephric carcinoma) occurs more often in girls 3 years of age or older. Clear cell adenocarcinoma of müllerian origin, often associated with a history of antenatal exposure to diethylstilbestrol (DES), is encountered most frequently in postmenarcheal teenage girls. The clinical features and treatment of malignant lesions of the vagina and cervix are similar to those in adult women.

Ovarian Tumors

With the increasing use of antenatal imaging modalities, greater numbers of fetal ovarian cysts are being diagnosed. Although many of these cysts are small, some may pose a risk of acute and long-term complications, such as torsion or rupture. Because many of the cysts regress after birth, many clinicians prefer to observe such cysts and intervene only infrequently. The decision to intervene is based on cyst size, ultrasound characteristics, and clinical symptoms. Treatment options include antenatal or neonatal cyst aspiration, laparoscopic cystectomy, and laparotomy.

Even though ovarian tumors are the most common genital neoplasm encountered in children and adolescents, they represent only 1% of all neoplasms in premenarcheal children. Ovarian tumors of all varieties (except Brenner's tumors) have been reported in premenarcheal children, with benign cystic teratomas accounting for at least 30%. Seventy percent of ovarian cancers in youth are of germ cell

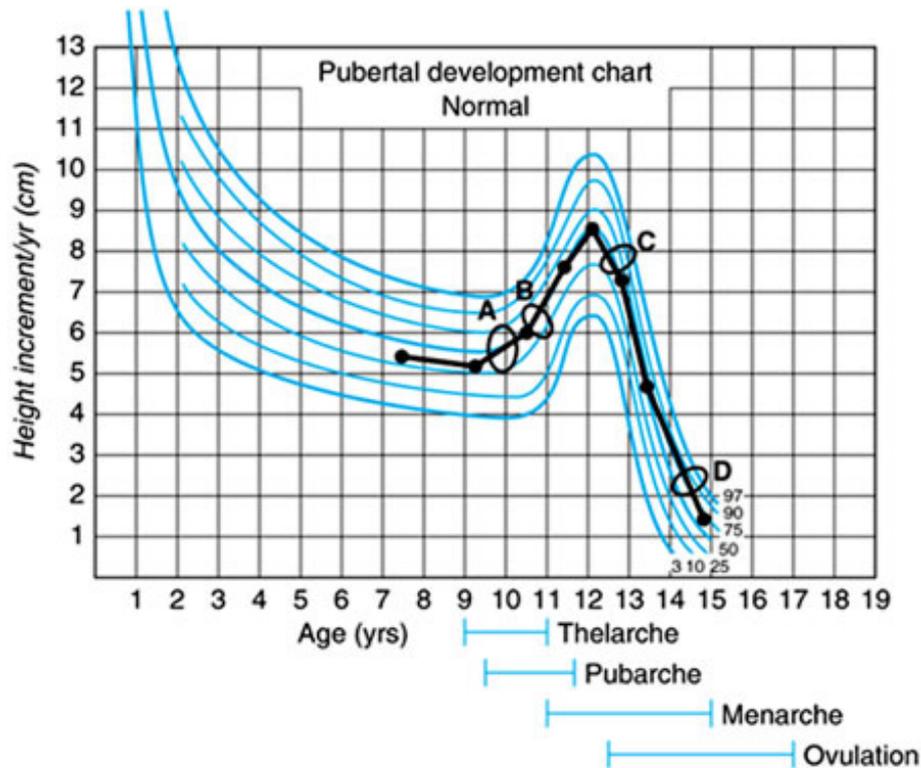

origin. The most common symptoms of ovarian tumors are abdominal pain and an abdominal mass. The small pelvic cavity of a child causes most ovarian tumors to rise above the pelvic inlet and present abdominally. Acute symptoms of severe pain, peritoneal irritation, or intra-abdominal hemorrhage resulting from a tumor accident (torsion, rupture, or perforation) may lead to an erroneous diagnosis of appendicitis, intussusception, or volvulus. At least 25% of all childhood ovarian tumors elude diagnosis until exploratory laparotomy is performed. Tumors of the ovary should be considered in the differential diagnosis of most disorders causing abdominal pain or mass in a child. Pelvic (rectal) examination may be helpful if the tumor is in the pelvis but will not detect most abdominal tumors. Imaging is a critical step in the evaluation of the adolescent or child with an adnexal mass. The use of serum markers, such as inhibin or α -fetoprotein, may be helpful in children with ovarian enlargement.

The management of ovarian neoplasms in premenarcheal children varies from that in older patients because continued ovarian function is necessary to complete sexual and somatic maturation in children. Although laparoscopy is an acceptable option if an adnexal mass is thought to be benign, suspicion of malignancy should prompt laparotomy. Conservative surgery (unilateral salpingo-oophorectomy) is justified for most premenarcheal patients with stage I cancer of the ovary, provided the tumor can be shown to be limited to the ovary. If a tumor has extended beyond the ovary, more radical surgery (bilateral salpingo-oophorectomy with hysterectomy) is indicated, regardless of age. Germ cell tumors are highly responsive to chemotherapy, with the exception of dysgerminomas, which respond well to radiation.

ACCELERATED SEXUAL MATURATION

Puberty is the process by which sexually immature persons become capable of reproduction. These changes occur largely as the result of maturation of the hypothalamic-pituitary-gonadal axis. As a rule, breast development, cornification of the vaginal mucosa, and growth of genital hair precede uterine bleeding by approximately 2 years. The normal sequence of events in sexual development is outlined in Fig 34–23. Accelerated growth and early estrogen effects of the genitalia occur first, but the most obvious sign of early puberty usually is breast enlargement, which initially may be unilateral. Pubic and axillary hair may appear before, at about the same time, or well after the appearance of breast tissue. The vaginal mucosa, which in prepubertal girls is a deep red color, takes on a moist pastel-pink appearance as estrogen exposure increases. Menses are a late event, usually not occurring until 2–3 years after onset of breast enlargement.

Figure 34–23.

Pubertal development chart for a normally developing female adolescent. Growth data are converted to growth velocity and plotted. The growth velocity curve shows initial acceleration in growth, followed by the growth spurt and subsequent deceleration. Superimposed on this curve are the following pubertal events: A, thelarche; B, pubarche; C, menarche; D, onset of ovulation.

(Reproduced, with permission, from Reindollar RH, McDonough PG: Delayed sexual development: Common causes and basic clinical approach. *Pediatr Ann* 1981;10:178.)

In young Northern American girls, breast budding occurs between ages 7 and 11 years and is followed by pubarche and a marked increase in growth rate, often referred to as the *adolescent growth spurt*. Secondary sexual features often occur earlier in African-American girls. The first menstrual period occurs at an average age of 12.8 years in girls in the United States. Regular ovulatory cycles, 20 months later, mark the end of the pubertal changes.

Sexual precocity is the onset of sexual maturation at any age that is 2.5 SD earlier than the normal age for that population. It may be classified as gonadotropin-releasing hormone (GnRH)-dependent precocious puberty (true precocious puberty) or GnRH-independent precocious puberty (pseudoprecocious puberty).

GnRH-Dependent Precocious Puberty

GnRH-dependent precocious puberty is normal pubertal development that occurs at an early age. Premature activation of the hypothalamic-pituitary axis is followed by gonadotropin secretion, which in turn stimulates the gonads to produce steroid hormones and, subsequently, pubertal changes. GnRH-dependent precocious puberty is seen more frequently in girls than in boys. The cause of such early development often remains unclear and has been labeled central precocious puberty (CPP). Most girls suspected of having CPP are otherwise healthy children whose pubertal maturation begins at the early end of the normal distribution curve. In general, the older the child, the less the chance of finding an

organic etiology for CPP. Central nervous system (CNS) imaging studies of these otherwise healthy 6- to 8-year-old girls usually reveal no structural abnormalities.

Occasionally, precocious puberty is associated with CNS abnormalities, including hypothalamic hamartomas, optic gliomas, and neurofibromas, as well as other CNS neoplasms. Cranial irradiation and CNS injuries may also be associated with precocious puberty. Prolonged excessive therapy with exogenous sex steroids may accelerate hypothalamic-pituitary axis maturation, resulting in precocious puberty.

The diagnosis is made with the help of a careful history and physical examination in conjunction with radiologic and laboratory evaluations.

GnRH-Independent Precocious Puberty

GnRH-independent precocious puberty is the appearance of pubertal development, but the presence of sex steroids is independent of pituitary gonadotropin release. Causes of precocious pseudopuberty include congenital adrenal hyperplasia, tumors that secrete human chorionic gonadotropin, tumors of the adrenal gland or gonads, McCune-Albright syndrome (MAS), and exposure to exogenous sex steroid hormones.

ENDOGENOUS ESTROGENS

The ovary in the newborn female contains 1–2 million primordial follicles, most of which undergo atresia during childhood without producing significant quantities of estrogen. However, large follicular cysts capable of estrogen production occur occasionally and may cause early feminization. Benign tumors of the ovary (eg, teratoma, cystadenoma) may produce estrogen or may induce surrounding ovarian tissue to produce steroids. Circulating sex steroids cause secondary sexual development. The sex steroids (estrogen or testosterone) come from either the adrenal gland or the gonad, independent of the hypothalamic-pituitary portion of the pubertal axis. Sex steroids also may be ingested or absorbed from exogenous sources.

Granulosa cell tumors capable of estrogen production are a rare cause of prepubertal feminization. Other rare tumors of extragonadal origin, including adrenal adenomas and hepatomas, may produce estrogens as well. In rare instances, the neoplasm secretes GnRH, which in turn stimulates the gonad to produce sex hormones.

EXOGENOUS ESTROGENS

Ingestion of estrogens or prolonged use of creams containing estrogens is a possible, but uncommon, cause of early feminization. Prompt discontinuation is indicated.

MCCUNE-ALBRIGHT SYNDROME

McCune-Albright syndrome (MAS) in its classic form consists of at least 2 features of the triad of polyostotic fibrous dysplasia, café-au-lait skin pigmentation, and autonomous endocrine hyperfunction, the most common form of which is GnRH secretion and subsequent precocious puberty. Although changes in ovary, bone, and skin tissue are most common, other endocrine and nonendocrine tissues also may be affected, including the adrenal, thyroid, pituitary, liver, and heart.

The fibrous dysplasia seen in children, MAS most commonly affects the long bones, ribs, and skull. The lesions range in size from small asymptomatic areas to markedly disfiguring lesions that can result in pathologic fractures.

The café-au-lait spots in children with MAS are large melanotic macules with irregular outline, described as "coast of Maine" (Fig 34–24).

Figure 34–24.

Four-year-old child with idiopathic precocious puberty.

MAS is caused by a postzygotic somatic mutation in the gene coding for the α subunit of the stimulatory G protein, which is involved in transmitting hormone signals. In patients with MAS, the signaling cascades are activated in the absence of hormone stimulation.

Affected children usually present at a younger age than those with idiopathic precocious puberty. Vaginal bleeding occurs early and in most is the first sign of puberty. The diagnosis is made on the basis of skin pigmentation and demonstration of bone lesions or pathologic fractures. The exact cause is unknown, but a primary ovarian abnormality with premature estrogen production has been suggested.

The prognosis for children with MAS is unfavorable. Adult height is significantly reduced, not only because of early epiphyseal closure but also because of pathologic bone fractures. Multiple endocrinopathies often exist as well. As in adults, most patients have menstrual abnormalities and many are infertile.

INCOMPLETE FORMS OF PUBERTAL DEVELOPMENT

Occasionally, for reasons that remain unclear, only 1 sign of pubertal development is present (breast development, pubic hair, or menstruation). Premature thelarche and premature pubarche, which are more common conditions than true precocious puberty, are 2 benign normal variant conditions that can

look like precocious puberty but are nonprogressive or very slowly progressive. It possibly results from transient elevations of the levels of circulating steroid hormones or from extreme sensitivity of the end organ (eg, breast tissue) to the low, prepubertal levels of sex hormones. Such isolated development, however, may represent the initial sign of precocious puberty, and these patients should be reevaluated at regular intervals.

PREMATURE THELARCHE

Premature thelarche is the isolated development of breast tissue prior to age 8 years, most commonly occurring between 1 and 3 years of age. It may affect 1 or both breasts (Fig 34–25). A thorough history, physical examination, and growth curve review can help distinguish this normal variant from true sexual precocity. On examination, the somatic growth pattern is not accelerated, bone age is not advanced, and smear of vaginal secretions fails to show estrogen effect. The diagnosis is made by exclusion of other disorders. Surgical biopsy of the breast is not indicated, as extensive excision of tissue may cause permanent damage to the breast. Occasionally, premature thelarche occurs when the child is exposed to exogenous estrogens. In Puerto Rico, an epidemic of premature thelarche in the 1970s was suspected to have been caused by exposure to estrogens in the food chain.

Figure 34–25.

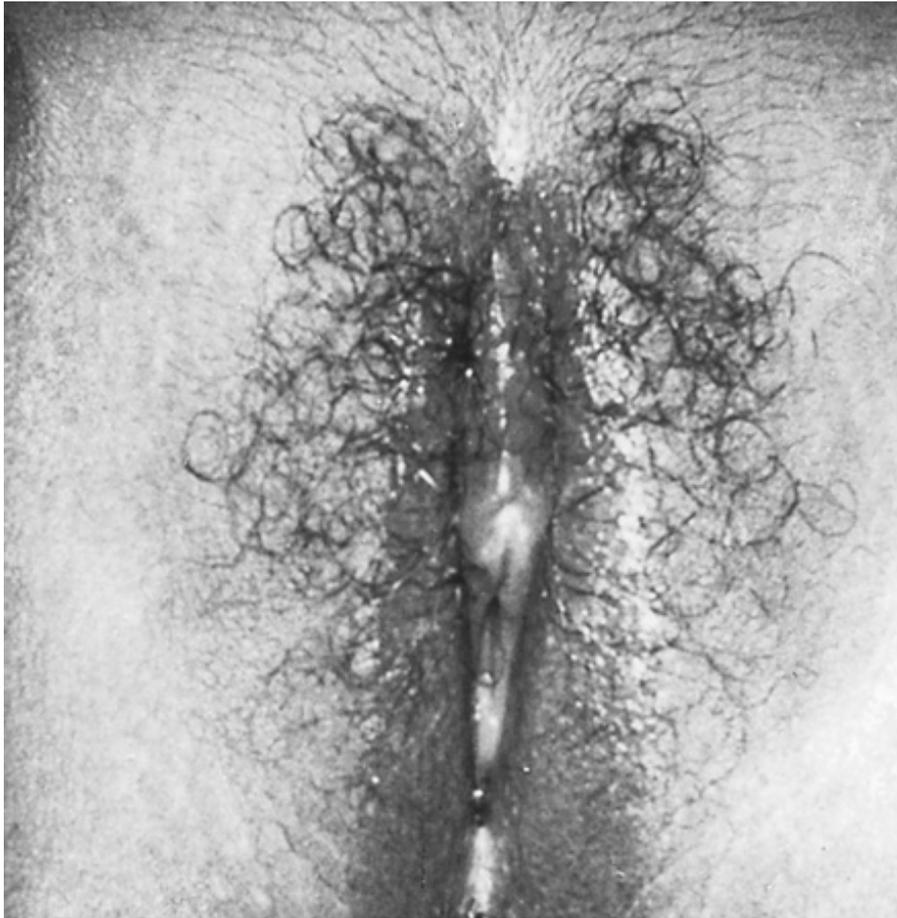

Copyright ©2006 by The McGraw-Hill Companies, Inc.
All rights reserved.

Premature thelarche in a child 5 years of age.

PREMATURE PUBARCHE

Premature pubarche previously was defined as the appearance of pubic or axillary hair prior to age 8 years, without other signs of precocious puberty (Fig 34–26). However, new guidelines suggest that this presentation should not be considered precocious unless noted before age 7 years in white girls and before age 6 years in black girls. Such hair growth may be idiopathic and of no clinical significance.

Figure 34–26.

Premature pubarche in a child 4 years of age.

Premature pubarche probably results from an earlier-than-usual increase in the secretion of androgens by the adrenal glands. Regulation of adrenal androgen secretion is distinct from that of gonadal steroids; therefore, early appearance of pubic hair may not correlate with true precocious puberty and generally is not a cause for concern. Thorough evaluation of adrenal and gonadal function and assessment of androgen production are necessary to exclude such abnormalities. The diagnosis of idiopathic premature pubarche is made only after such an evaluation fails to detect an abnormality.

Signs of severe androgen excess (eg, clitoral enlargement, growth acceleration, acne) should prompt further investigation for a rare virilizing tumor (Leydig cell tumor), or a variant form of congenital adrenal hyperplasia.

PREMATURE MENARCHE

Premature menarche denotes the appearance of cyclic vaginal bleeding in children in the absence of other signs of secondary sexual development. The cause is unknown but may be related to increased end-organ sensitivity of the endometrium to low prepubertal levels of estrogens. Alternatively, bleeding may be related to transient elevation of estrogens due to premature follicular development. These patients have estradiol levels in the prepubertal range, and cytologic smears of vaginal secretions indicate lack of estrogenic stimulation. When patients are given GnRH, the response of the pituitary gland is similar to that seen in prepubertal children.

The diagnosis of premature menarche is formulated by exclusion following investigation of other causes of vaginal bleeding and is confirmed when the cyclic nature of the bleeding becomes apparent. The prognosis is excellent. Adult height is uncompromised, the menstrual pattern is normal, and fertility potential remains unimpaired.

Evaluation of the Patient with Precocious Puberty

When evaluating the patient with sexual precocity, the age at onset, duration, and progression of signs and symptoms constitute important historical information. Family history and review of systems may add important facts.

GENERAL CHANGES

Enhancement of general growth is coincident with the onset of estrogen-stimulated change. The child often exhibits accelerated growth velocity, tall stature for age, and advanced skeletal maturation.

SKIN

Additional androgen-dependent findings include acne and adult-type body odor.

BREAST DEVELOPMENT

Breast development is at least at Tanner stage II, with the areolae having a broadened, darkened appearance.

GENITALIA

Genital changes reflect estrogen-induced thickening of the genital tissues. Increased vaginal secretions may result in leukorrhea. Dark, coarse pubic hair may be present.

Diagnosis

The diagnosis of GnRH-dependent precocity requires demonstration of pubertal gonadotropin secretion. The diagnostic evaluation required to document early pubertal development and differentiate central from peripheral causes includes the determination of serum luteinizing hormone (LH), follicle-stimulating hormone (FSH), and estradiol levels, and a GnRH stimulation test. In patients with GnRH-dependent precocious puberty, the results of these tests will be in the normal pubertal range. In addition, these patients will require diagnostic imaging to document skeletal age and the absence of gonadal or CNS lesions.

With the improvement in imaging technology, clinicians often order such studies to help establish the diagnosis. Sonography may aid in the evaluation of the ovaries and adrenal glands. Uterine size is estrogen dependent and is a good bioassay to determine the length of time and magnitude of estrogen exposure. Ovarian cysts and tumors are also visible. Sonography of the adrenal glands is less sensitive than abdominal computed tomography (CT) and magnetic resonance imaging (MRI). A skeletal survey and bone scan may identify areas of fibrous dysplasia in patients with MAS. Brain MRI is indicated in patients with sexual precocity or with neurologic signs.

Treatment of GnRH-Dependent Precocious Puberty

The treatment of choice for GnRH-dependent precocious puberty is GnRH analogues. Analogues of GnRH are modifications of the native hormone, which have greater resistance to degradation and increased affinity for the pituitary GnRH receptors. They induce downregulation of receptor function, resulting in temporary, reversible inhibition of the hypothalamic-pituitary-ovarian axis, as reflected by minimal or no response to GnRH stimulation and regression of the manifestations of puberty.

Treatment with GnRH analogues decreases gonadotropins and sex steroids to prepubertal levels, which is followed by regression of secondary sexual features. Treatment also causes a deceleration in the skeletal maturation rate, preserving or even improving predicted height, unless bone age is so advanced that

further growth is precluded. All published evidence indicates a gain of adult height over height predicted before treatment or over untreated historical controls. However, ascertaining the exact height increment is difficult because of the inaccuracy of height prediction methods. Use of GnRH agonists in girls who begin pubertal development only 1 or 2 years earlier than normal is of limited or no benefit. Treatment is continued until puberty is appropriate based on age, emotional maturity, height, and height potential. Resumption of puberty occurs promptly after discontinuation of GnRH analogue therapy.

DELAYED SEXUAL MATURATION

Delayed sexual development has been defined as the absence of normal pubertal events at an age 2.5 SD later than the mean. The absence of thelarche by age 13 years or the absence of menarche by age 15 years is an indication for investigation. Some degree of sexual maturation occurs in more than 30% of patients with gonadal dysgenesis; therefore, a patient who presents following thelarche with a delay in the orderly progression of pubertal development should undergo investigation. Delayed sexual development can be classified according to gonadal function (Table 34–4).

Table 34–4. Classification of Patients with Delayed Sexual Maturation.

Delayed Menarche with Adequate Secondary Sexual Development

- Anatomic genital abnormalities

- Inappropriate positive feedback

- Androgen insensitivity syndromes (complete forms)

Delayed Puberty with Inadequate or Absent Secondary Sexual Development

- Hypothalamic-pituitary dysfunction (low FSH)

- Reversible: Constitutional delay, weight loss due to extreme dieting, protein deficiency, fat loss without muscle loss, drug abuse

- Irreversible: Kallmann's syndrome, pituitary destruction

- Gonadal failure (high FSH)

- Abnormal chromosomal complement (eg, Turner's syndrome)

- Normal chromosomal complement: chemotherapy, irradiation, infection, infiltrative or autoimmune disease, resistant ovary syndrome

Delayed Puberty with Heterosexual Secondary Sexual Development (Virilization)

- Enzyme deficiency (eg, 21 α -hydroxylase deficiency), neoplasm, male pseudohermaphroditism

FSH, follicle-stimulating hormone.

Delayed Menarche with Adequate Secondary Sexual Development

Patients with functioning gonads and delayed sexual maturation usually consult a physician while they are in their mid-teens because of amenorrhea. Most have well-formed female configuration with adequately developed breasts. Many of these patients suffer from an inappropriate hypothalamic-pituitary-ovarian feedback mechanism leading to anovulation and androgen excess. Primary amenorrhea may persist until a progestin challenge is given. Patients should be monitored for continued menstrual

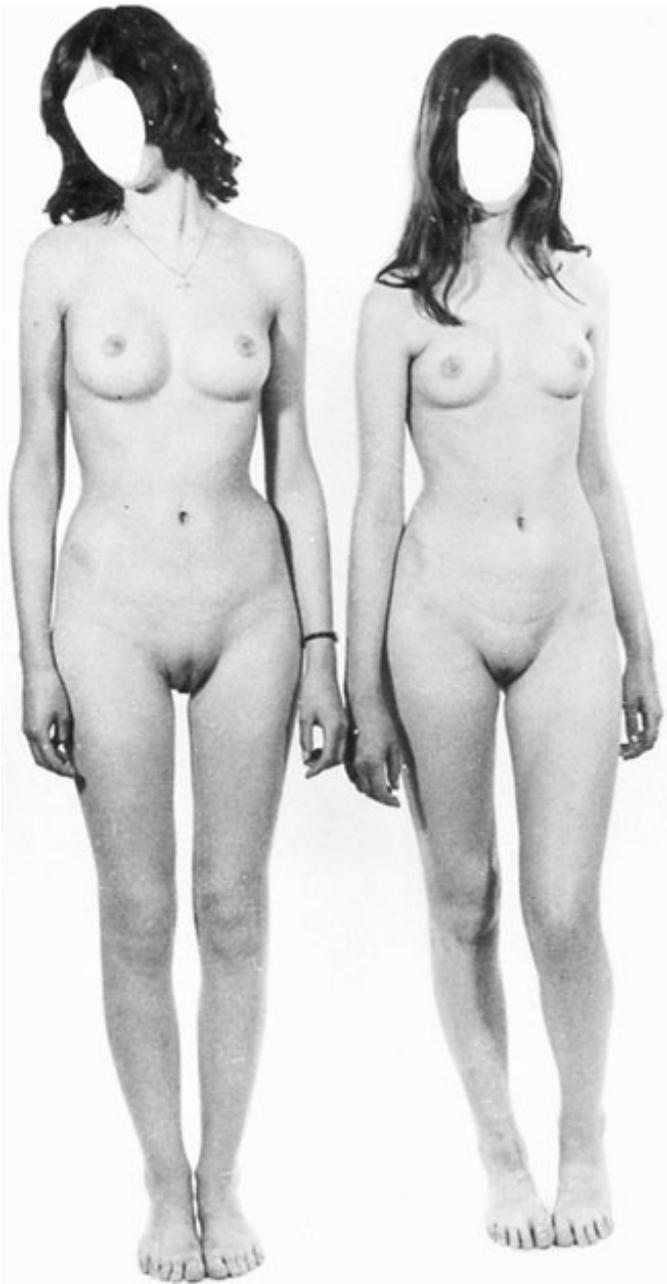

shedding. Persistent amenorrhea is treated with progestins administered every other month to prevent endometrial hyperplasia. A sexually active girl should be given oral contraceptives rather than cyclic progestins. Further evaluation is required in patients with persistent menstrual abnormalities, because similar clinical manifestations are encountered in adolescents with adult-onset congenital adrenal hyperplasia and those with polycystic ovarian disease.

The possibility of pregnancy in an adolescent who has not begun to menstruate is highly unlikely but must be borne in mind when considering causes of delayed menarche in patients with normal pubertal development.

Most patients with congenital anomalies of the paramesonephric (müllerian) structures complain of primary amenorrhea. The most common defect is congenital absence of the uterus and vagina. Other causes are obstructive abnormalities, such as imperforate hymen, transverse vaginal septa, and agenesis of the cervix. Gynecologic examination supplemented by pelvic sonogram or MRI establishes the diagnosis of these congenital anomalies.

The complete forms of androgen insensitivity (Fig 34–27) are also associated with amenorrhea and normal breast development. Affected persons have normal testicular function but are not responsive to male concentrations of testosterone, and the development of breasts is secondary to the small amounts of unopposed estrogens produced by the testis. Pubic and axillary hair is scant or often absent. A short blind vaginal pouch is present. Once pubertal development has been completed, surgical extirpation of the gonads and reconstruction of the vagina are necessary. Recent data suggest that regardless of the technique used, sexual function may be impaired in some of these young women. A study of 66 women with complete forms of androgen insensitivity showed that 90% had sexual difficulties, most commonly sexual infrequency and vaginal penetration difficulty. Furthermore, most women perceived the newly created vagina to be too small, even though the vagina was of adequate size in many of the women.

Delayed Puberty with Inadequate or Absent Secondary Sexual Development

Hypothalamic-Pituitary Dysfunction

Both reversible and irreversible causes of delayed puberty secondary to lack of maturation or function of the hypothalamus and pituitary have been described.

The onset of puberty depends on an ill-defined stage of maturity that is reflected in skeletal age. Maturation is partly genetically determined but also depends on multiple environmental factors; thus the

chronologic age of puberty varies considerably. Statistical limits of normal variation in a defined population group indicate that, by definition, 2.5% of all normal adolescents will develop later than the age defined as "normal." This group has been labeled "late bloomers" or as having a constitutional growth delay (CGD). These girls often have retarded linear growth within the first 3 years of life, and then their growth resumes at a normal rate. As a result, these girls grow either along the lower growth percentiles or beneath the curve but parallel to it for the remainder of the prepubertal years.

At the expected time of puberty, the height of children with CGD begins to drift further from the growth curve because of delayed onset of the pubertal growth spurt. Catch-up growth, onset of puberty, and pubertal growth spurt occur later than average, resulting in normal adult stature and sexual development. Although CGD is a variant of normal growth rather than a disorder, absence of signs of puberty (including the growth spurt) often concerns the patient when her adolescent friends have developed secondary sexual features and gained the characteristic increase in height.

The diagnosis of hypothalamic-pituitary dysfunction is made by exclusion of other causes of delayed sexual maturation. Growth charts, bone age, and the GnRH challenge test differentiate constitutional delay from similar conditions associated with GnRH deficiency. Reassurance is the only treatment necessary, but the patient must be kept under observation until regular menstrual cycles are established. Occasionally, an adolescent requires hormonal replacement therapy because of emotional distress over her condition.

Kallmann's syndrome is a genetic condition characterized by hypogonadotropic hypogonadism and anosmia. It affects approximately 1 in 40,000 females, with most presentations of the "sporadic" type. Various forms of Kallmann's syndrome are inherited, and the gene responsible for the X-linked form has been identified.

The clinical features include deficiency of GnRH associated with anosmia. Because GnRH neurones originate extracranially within the olfactory system, both can be simultaneously affected, and the defects are believed to be secondary to abnormalities of neuronal migration during development. Patients with Kallmann's syndrome fail to develop secondary sexual features, and blood levels of gonadotropins are very low.

Patients with Kallmann's syndrome have a diminished gonadotropin response to the GnRH stimulation test. Pulsatile administration of GnRH for 1 week usually restores subsequent pituitary responsiveness to GnRH. All postpubertal-age patients with Kallmann's syndrome are candidates for gonadal steroid replacement therapy in the absence of specific contraindications. Estrogen replacement therapy is used to initiate and sustain sexual development. Induction of ovulation with human menopausal gonadotropins or GnRH is necessary when pregnancy is desired.

A pituitary or parasellar tumor, particularly craniopharyngioma or pituitary adenoma, must be considered in the evaluation of a patient with delayed sexual maturation. Craniopharyngiomas are rapidly growing tumors that often develop in late childhood. Pituitary adenomas are slow growing, may become symptomatic during puberty, and may interfere with sexual maturation. An occult pituitary prolactinoma in adolescents with unexplained delayed sexual maturation must be ruled out. Serum prolactin levels should be measured yearly in patients with unexplained delayed sexual maturation.

Weight loss due to extreme dieting, marked protein deficiency, and fat loss without notable loss of muscle (often seen in athletes) may delay or suppress hypothalamic-pituitary maturation. Heroin addiction may cause amenorrhea, but its effects on sexual maturation have not been documented.

Gonadal Failure

Most patients with gonadal dysgenesis present during adolescence with delayed puberty and primary amenorrhea. For young women with gonadal failure the most common cause is Turner's syndrome, which occurs with an incidence of 1 in 2500 to 1 in 10,000 live births. If untreated, estrogen and androgen levels are decreased and FSH and LH levels are increased. Estrogen-dependent organs show the predictable effects of hormonal deficiency. Breasts contain little parenchymal tissue, and the areolar tissue is only slightly darker than the surrounding skin. The well-differentiated external genitalia, vagina, and müllerian derivatives remain small. Pubic and axillary hair fail to develop in normal quantity.

However, normal pubertal development, menstruation, and even pregnancies have been reported in adults with gonadal dysgenesis. It is possible that a few of these persons maintain some germ cells into adulthood. Spontaneous development is more commonly observed in patients with mosaicism with a 46,XX line. The rare offspring of these women probably do not have an increased risk for chromosomal abnormalities.

Some patients may have ovarian failure even though they have a normal chromosome complement and two intact sex chromosomes (46,XX). An autosomal recessive form of ovarian failure has been demonstrated in some families. Other causes of follicular depletion include chemotherapy, irradiation, infections (eg, mumps), infiltrative disease processes of the ovary (eg, tuberculosis), autoimmune diseases, and unknown environmental agents.

A karyotype is necessary to rule out the presence of Y chromosome material. DNA probes and assays for the minor histocompatibility antigen H-Y have also been used to identify Y chromosome material. A high incidence of neoplastic changes in the gonadal ridge has been reported in the presence of a Y chromosome (Fig 34–28), so prophylactic gonadectomy is recommended. Replacement hormonal therapy is then given in a cyclic manner.

Figure 34–28.

Gonadoblastoma developing in a gonadal ridge in a patient with gonadal dysgenesis and 45,XO/46,XY karyotype.

Some patients have similar features, yet follicles are present but unresponsive, a condition called the *resistant ovary syndrome*. It is characterized by delayed menarche or primary amenorrhea, a 46,XX chromosome complement, high FSH levels, and ovaries with apparently normal follicular apparatus that do not respond to endogenous gonadotropins. Absence of follicular receptors for gonadotropins is

assumed to be responsible for ovarian dysfunction in these patients. These individuals may have normally developed secondary sexual characteristics. Estrogen replacement therapy is required to prevent long-term complications of estrogen deficiency (eg, vaginal dryness, osteoporosis). Pregnancies have been reported in some patients treated with menotropins or following discontinuation of estrogen therapy.

Delayed Puberty with Heterosexual Secondary Sexual Development

Virilization refers to the concomitant presentation of hirsutism with various signs of androgen excess, including acne, frontotemporal balding, deepening of the voice, decrease in breast size, clitoral hypertrophy, increase in muscle mass, and amenorrhea. Virilization at puberty is the result of elevated levels of androgens from adrenal or gonadal sources. These may be the result of an enzyme deficiency (eg, late-onset congenital adrenal hyperplasia) or a neoplasm (eg, Leydig cell tumor).

A small group of patients are male pseudohermaphrodites. These adolescents are being reared as girls and have female external genitalia, intra-abdominal or ectopic malfunctioning testes, and a normal 46,XY chromosomal complement. The diagnosis and treatment of intersex disorders are discussed in Chapter 5.

Evaluation of the Patient with Delayed Sexual Development

Determination of gonadal function can be accomplished by obtaining a medical history and performing a detailed physical examination, supplemented by selected laboratory studies. Historical information should center around previous growth and pubertal development. Linear and velocity growth charts as well as a pubertal development chart clarify previous growth patterns and are useful in subsequent follow-up. Knowledge of previous medical disorders may immediately identify the cause of aberrant puberty.

Physical examination must include height and weight assessments and a careful search for somatic anomalies. Staging of pubertal development by Tanner criteria is most important in the determination of gonadal function. Presence of breast development signifies prior gonadal function. A vaginal smear for cytochemical evaluation can determine whether the gonad is continuing to produce estrogen. Pelvic and rectal examination will identify patients with an obstructed outflow tract, as well as patients with congenital absence of the vagina and uterus. Further confirmation of patients with Rokitansky sequence is dependent on a karyotype to identify normal 46,XX complement and a pelvic sonogram to confirm uterine absence and ovarian presence.

Absence of pubic hair is suggestive of the androgen insensitivity syndrome. Karyotype will identify the 46,XY cell line in patients with testicular feminization syndrome (Fig. 34–27). Patients with complete pubertal development, evidence of continued estrogen production, and normal müllerian systems probably have inappropriate positive feedback and thus chronic anovulation. Progesterone challenge in such patients is helpful. A withdrawal bleed signifies a normal müllerian system and continued estrogen production.

When breast development is minimal, the usual diagnosis is lack of gonadal function. Serum gonadotropin assays are performed for further elucidation. Elevated FSH levels suggest gonadal failure. Other endocrine profiles should be obtained if hypothyroidism, congenital adrenal hyperplasia, or Cushing's syndrome is suspected. Karyotype is necessary in all patients with gonadal failure and will identify both normal and abnormal chromosome complements. The presence of a Y chromosome in either group dictates gonadal removal.

Low FSH levels suggest interference with hypothalamic-pituitary maturation and gonadotropin release. Skull films and prolactin assays must be obtained for all patients to rule out the presence of pituitary or hypothalamic tumors. Appropriate endocrine evaluation identifies the occasional patient with

hypothyroidism or congenital adrenal hyperplasia and the rare patient with Cushing's syndrome.

Diagnosis of Kallmann's syndrome is suspected in hypogonadotropic patients who have an associated anosmia, and the diagnosis is confirmed by GnRH challenge tests. The presumed diagnosis of constitutional delay is made by exclusion of all other causes and by the typical GnRH release patterns after GnRH challenge.

Evaluation of the Patient with Vaginal Bleeding

VAGINAL BLEEDING IN CHILDREN

When vaginal bleeding occurs in children, 2 sources generally should be suspected: (1) the endometrium (bleeding usually is a manifestation of precocious puberty) and (2) a local vulvar or vaginal lesion (eg, vulvovaginitis, foreign bodies, urethral prolapse, trauma, botryoid sarcoma, adenocarcinoma of the cervix or vagina, and vulvar skin disorders).

Vaginal bleeding during childhood should always alert the physician to the possibility of a genital tumor. Vaginoscopy and examination under anesthesia are the mainstays of evaluation to exclude the presence of tumors, foreign bodies, and other local lesions. Benign tumors of the vulva and vagina are rare in childhood, and those that do occur seldom cause bleeding. Malignant neoplasms usually bleed from necrotic or ulcerative areas that appear early in their development. Suspicious lesions require biopsy for diagnosis.

BLEEDING DISORDERS IN ADOLESCENTS

One of the most common gynecologic complaints of adolescents is a problem with the menstrual period. In most cases, there is no true medical disorder, especially in the first 2 years after menarche, when 50–80% of periods are anovulatory. Evaluation of abnormal bleeding is indicated if the menstrual interval is less than 22 days or more than 44 days, lasts longer than 1 week, menses is so heavy that anemia develops, or if the cycle interval is still unstable 2 years after menarche. Dysfunctional uterine bleeding accounts for 95% of abnormal vaginal bleeding in teenagers. Screening for inherited coagulation disorders, such as von Willebrand's disease, may be indicated, as 18% of adolescents hospitalized for menorrhagia have an underlying bleeding disorder. When menstrual irregularity is accompanied by symptoms such as acne, hirsutism, and obesity, polycystic ovarian syndrome should be suspected, and treatment may need to address some of these symptoms as well.

Pregnancy should always be considered in a young woman with abnormal bleeding or amenorrhea until proven otherwise. Nonmenstrual causes of bleeding, such as hypothyroidism, cervicitis, condylomas, polyps, cervical cancer, estrogen-producing ovarian tumors, and vaginitis, also should be considered.

Management of anovulatory bleeding is directed toward controlling symptoms and preventing anemia. Oral contraceptive pill tapers, cyclic oral contraceptives, and medroxyprogesterone acetate have been used to control bleeding. In severe cases, hospitalization and intravenous conjugated equine estrogen in doses of 25 mg every 4–6 hours until bleeding stops for 24 hours have been used successfully. If oral contraceptives are given for secondary amenorrhea, they should be continued for at least 9–12 months before attempting to stop. If menses do not resume within 8 weeks, oral contraceptive pills should be resumed for another 9–12 months.

PRECOCIOUS (JUVENILE) PREGNANCY

Precocious, or juvenile, pregnancy is rare. The youngest known patient was a Peruvian girl aged 5 years 8 months, who in 1939 delivered at term by cesarean section a healthy male infant weighing 2950 g (6 lb 8 oz). Both mother and infant survived. In every reported instance, the underage mothers were sexually precocious, and most had menstruated for several years before becoming pregnant. Juvenile pregnancy per se does not increase the chance of congenital anomalies in the offspring. However, in many cases the mother is a victim of sexual abuse, and if the pregnancy is the result of incest, there is a greater likelihood of genetic malformations carried by recessive genes.

Most precocious mothers and their babies have not done well, with increased incidences of spontaneous abortion, pregnancy-induced hypertension, and premature labor and delivery. In patients younger than 9 years, less than 50% have normal labor, with a 35% likelihood of neonatal loss.

The underage mother and her family may need psychiatric counseling, both during pregnancy and following delivery. Lessening the emotional, social, and medical trauma associated with such a gestation is an important task for all who assist in the care of the pregnant child.

SEXUALLY TRANSMITTED DISEASES

STDs are the most common infectious diseases in adolescents today. Approximately 25% of all sexually active adolescents aged 13–19 years become infected each year. By age 15 years, 1 in 4 girls in the United States has sexual relations. The younger the age of first intercourse, the higher the risk for STDs. Chlamydia is the most prevalent of the bacterial STDs, with almost 30% of inner-city female adolescents aged 12–19 showing positive cultures in a longitudinal 2-year study of family planning, school-based, and STD clinics. Sequelae of chlamydial infections include pelvic inflammatory disease (PID), ectopic pregnancy, and infertility. This age group accounts for 8% of cases of HIV in females, with the majority of these women asymptomatic at the time of positive testing. In the United States, 15- to 24-year-olds accounted for approximately 60% of gonorrhea cases, 25% of syphilis cases, and 17% of hepatitis B cases in 1996. By the time they reach college age, 43% of women are infected with human papillomavirus (HPV).

Nearly 70% of patients with PID are younger than 25 years. The estimated incidence of PID in sexually active females is approximately 1 in 8 for 15-year-olds and 1 in 10 for 16-year-olds. PID in adolescents should be treated with hospitalization and intravenous antibiotics. Tubo-ovarian abscess has been found in 2–4% of adolescents with adnexal masses. Treatment includes broad-spectrum antibiotics and possible surgical drainage. Patients who have had PID or tubo-ovarian abscess are at high risk for pelvic pain, pelvic adhesive disease, infertility, and ectopic pregnancy.

CERVICAL CANCER SCREENING IN ADOLESCENTS

Because infection with certain strains of HPV is the most important risk factor for the development of cervical cancer and HPV infection in women usually is acquired via heterosexual transmission, cervical cancer screening with a Papanicolaou (Pap) test should be initiated soon after the onset of sexual activity. Pap smear screening is underutilized in sexually active adolescents. Although measures that include teen clinics have increased the rate of surveillance, efforts at both prevention by encouraging condom use and increased availability of services are still needed.

If a Pap smear is abnormal, colposcopic evaluation may be indicated. STD screening should be incorporated as part of the evaluation. Low-grade lesions usually can be followed with serial Pap smears. Ablative or excisional procedures are indicated for moderate- to high-grade lesions, regardless of age. Cryotherapy offers a 92–95% cure rate for cervical intraepithelial neoplasia (CIN) 2–3 in young women. Loop electrosurgical excisional procedure (LEEP) offers similar cure rates and does not appear to impact cervical competence in future pregnancies with depths of excision of 1.5 cm or less. Teens with abnormal Pap smears should be advised regarding smoking cessation and follow-up.

CONTRACEPTION IN ADOLESCENTS

More than 95% of adolescent pregnancies are unintended. By age 18 years, 1 in 4 experiences a pregnancy. Half of adolescent pregnancies occur in the first 6 months after initiation of sexual activity. Despite a decline in teenage pregnancy rates during the 1990s, teenage pregnancy rates remain higher in the United States than in other Western countries. In addition, teenagers in the United States use contraceptives less frequently and use less effective methods of contraception than do their European counterparts. Although great inroads in adolescent access to health care have been made over the last decade, problems of cost and fears of lack of confidentiality still appear to inhibit young women from obtaining contraceptives, ultimately resulting in high teenage pregnancy rates.

Contraception is the voluntary prevention of impregnation. As such, postponing sexual activity is an appropriate option to suggest. If this is not realistic, counseling regarding various methods of contraception requires consideration not only of the side effects and efficacy of the various methods but also of the personal requirements of each teenager. For example, a teenager who has difficulty remembering to take pills or who must hide pill packs may be better served by medroxyprogesterone acetate injections. Health benefits of adolescents taking oral contraceptive pills include decreased menstrual pain; increased menstrual regularity; decreased risk of PID, anemia, and fibrocystic breast disease; improved long-term fertility; and treatment of acne and hirsutism. The importance of both contraception and STD prevention should be reviewed, and the use of barrier methods should be encouraged. Adolescents with chronic medical illnesses represent an especially high-risk group, as issues of both fertility and contraceptive risks and efficacy may be affected by these illnesses.

Emergency contraception regimens with progestin-only regimens or combined estrogens and progestins are highly effective means of preventing pregnancy after intercourse if taken at the appropriate interval. Improving access through education or prescribing pills in advance or over the telephone may give a young woman a second chance at preventing unintended pregnancy.

PREGNANCY TERMINATION

The rate of teenage abortion remains higher in the United States than in other Western countries for which data are available. The U.S. Supreme Court initially ruled in favor of a minor's right to have an abortion in 1976. Although this ruling has been amended to allow states to require parental notification before abortion, a system of judicial bypass for minors who do not want parental involvement is required in these states.

ADOLESCENT PREGNANCY

For years it has been accepted that adolescent pregnancy is a high-risk pregnancy. Many pregnant adolescents come from low socioeconomic backgrounds and have poor education and perhaps poor general health due to inadequate nutrition, cigarette smoking, drug abuse, or STDs. Nutrition is an important problem. Bone mineral content, iron stores, and caloric intake often are reduced among adolescent girls, and iron deficiency anemia is frequently found. Proper education and dietary counseling may improve nutritional status and prevent anemia.

Optimal care should be given to teenage mothers. not only to improve the pregnancy outcome but also to enhance their social, educational, and emotional adjustment. Complications of labor and delivery are highly dependent on the quality of prenatal care. Preeclampsia–eclampsia, which is more common in a first pregnancy, occurs more frequently among adolescents than among adult women. Prematurity and small-for-dates infants are a major problem in adolescent pregnancies. Predisposing factors are high-risk factors such as low prepregnancy weight, poor weight gain, adverse socioeconomic conditions, cigarette smoking, anemia, first pregnancy, and deficient prenatal care, all of which occur more commonly in adolescents. To minimize prenatal complications and to improve maternal and fetal outcome, the young patient should be enrolled in an aggressive prenatal care program that addresses the unique problems of the adolescent patient.

Current OB/GYN > Chapter 35. Complications of Menstruation; Abnormal Uterine Bleeding >

PREMENSTRUAL SYNDROME

Essentials of Diagnosis

- Symptoms include mood symptoms (irritability, mood swings, depression, anxiety), physical symptoms (bloating, breast tenderness, insomnia, fatigue, hot flushes, appetite changes), and cognitive changes (confusion and poor concentration).
- Symptoms must occur in the second half of the menstrual cycle (luteal phase).
- There must be a symptom-free period of at least 7 days in the first half of the cycle.
- Symptoms must occur in at least two consecutive cycles.
- Symptoms must be severe enough to require medical advice or treatment.

General Considerations

Premenstrual syndrome (PMS) is a psychoneuroendocrine disorder with biologic, psychologic, and social parameters. It is both difficult to define adequately and quite controversial. One major difficulty in detailing whether PMS is a disease or a description of physiologic changes is its extraordinary prevalence. Up to 75% of women experience some recurrent PMS symptoms; 20–40% are mentally or physically incapacitated to some degree, and 5% experience severe distress. The highest incidence occurs in women in their late 20s to early 30s. PMS is rarely encountered in adolescents and resolves after menopause. Evidence suggests that women who have suffered with PMS and premenstrual dysphoric disorder are more likely to suffer from perimenopausal symptoms.

The symptoms of PMS may include headache, breast tenderness, pelvic pain, bloating, and premenstrual tension. More severe symptoms include irritability, dysphoria, and mood lability. When these symptoms disrupt daily functioning, they are clustered under the name *premenstrual dysphoric disorder* (PMDD).

Other symptoms commonly included in PMS are abdominal discomfort, clumsiness, lack of energy, sleep changes, and mood swings. Behavioral changes include social withdrawal, altered daily activities, marked change in appetite, increased crying, and changes in sexual desire. In all, more than 150 symptoms have been related to PMS. Thus the symptom complex of PMS has not been clearly defined.

Pathogenesis

The etiology of the symptom complex of PMS is not known, although several theories have been proposed, including estrogen–progesterone imbalance, excess aldosterone, hypoglycemia, hyperprolactinemia, and psychogenic factors. A hormonal imbalance previously was thought to be related to the clinical manifestations of PMS/PMDD, but in the most recent consensus, physiologic ovarian function is believed to be the trigger. This is supported by the efficacy of ovarian cyclicity suppression, either medically or surgically, in eliminating premenstrual complaints.

Further research has shown that serotonin (5-hydroxytryptamine [5-HT]), a neurotransmitter, is important in the pathogenesis of PMS/PMDD. Both estrogen and progesterone have been shown to

influence the activity of serotonin centrally. Many of the symptoms of other mood disorders resembling the features of PMS/PMDD have been associated with serotonergic dysfunction.

Diagnosis

No objective screening or diagnostic tests for PMS and PMDD are available; thus special attention must be paid to the patient's medical history. Certain medical conditions (eg, thyroid disease and anemia) with symptoms that can mimic those of PMS/PMDD must be ruled out.

The patient is instructed to chart her symptoms for at least 2 symptomatic cycles. The classic criteria for PMS require that the patient have symptoms in the luteal phase and a symptom-free period of at least 7 days in the first half of the cycle for a minimum of 2 consecutive symptomatic cycles. To meet the criteria for PMDD, in addition to the criteria for PMS, she must have a chief complaint of at least 1 of the following: irritability, tension, dysphoria, or mood lability; and 5 of 11 of the following: depressed mood, anxiety, affective lability, irritability, decreased interest in daily activities, concentration difficulties, lack of energy, change in appetite or food cravings, sleep disturbances, feeling overwhelmed, or physical symptoms (eg, breast tenderness, bloating).

Clinical Findings

A careful history and physical examination are most important to exclude organic causes of PMS localized to the reproductive, urinary, or gastrointestinal tracts. Most patients readily describe their symptoms, but careful questioning may be needed with some patients who may be reluctant to do so. Although it is important not to lead a patient to exaggerate her concerns, it is equally important not to minimize them.

Symptoms of PMS may be specific, well localized, and recurrent. They may be exacerbated by emotional stress. Migrainelike headaches may occur, often preceded by visual scotomas and vomiting.

Symptomatology varies among patients but often is consistent in the same patient.

A psychiatric history should be obtained, with special attention paid to a personal history of psychiatric problems or a family history of affective disorders. A mental status evaluation of affect, thinking, and behavior should be performed and recorded. A prospective diary correlating symptoms, daily activities, and menstrual flow can be useful to document changes and to encourage patient participation in her care.

If underlying psychiatric illness is suspected, a psychiatric evaluation is indicated. The most common associated psychiatric illness is depression, which generally responds to antidepressant drugs and psychotherapy. Recall that psychiatric illnesses have premenstrual exacerbations, so medications should be altered accordingly.

Treatment

Treatment of PMS/PMDD depends on the severity of the symptoms. For some women, changes in eating habits—limiting caffeine, alcohol, tobacco, and chocolate intake, and eating small, frequent meals high in complex carbohydrates—may be sufficient. Decreasing sodium intake may alleviate edema. Stress management, cognitive behavioral therapy, and aerobic exercise have all been shown to improve symptoms.

Low-risk pharmacologic interventions that may be effective include calcium carbonate (1000–1200 mg/d) for bloating, food cravings, and pain; magnesium (200–360 mg/day) for water retention; vitamin B₆ (note that prolonged use of 200 mg/d may cause peripheral neurotoxicity) and vitamin E; nonsteroidal anti-inflammatory drugs (NSAIDs); spironolactone for cyclic edema; and bromocriptine for mastalgia. Herbal preparations have been proposed. St. John's wort has potential given its selective serotonin reuptake inhibitor (SSRI)-like effects but should be used with caution given its enzyme-inducing property

on cytochrome P450. Chaste berry fruit (*Vitex agnus-castus*) 20 mg/day has been shown to be more effective than placebo and has minimal side effects but is not as effective as fluoxetine.

For symptoms of severe PMS and PMDD, further pharmacologic intervention may be necessary. Psychotropic medications that are effective include SSRIs, desipramine, and L-tryptophan. SSRIs have minimal side effects and provide symptom improvement in more than 60% of patients studied. Treatment should be given 14 days prior to the onset of menstruation and continued through the end of the cycle. Anxiolytics such as alprazolam and buspirone also have been shown to be efficacious, but their side effects and potential for dependence must be seriously considered.

Hormonal interventions have been shown to be effective. Use of gonadotropin-releasing hormone (GnRH) agonists leads to a temporary "medical menopause" and an improvement in symptoms. Their limitations lie in a hypoestrogenic state and a risk for osteoporosis, although "add-back" therapy with estrogen and progesterone may obviate these problems. Danazol may improve mastalgia. Finally, bilateral oophorectomy is a definitive surgical treatment option; again, estrogen replacement would be recommended.

Use of oral contraceptives has been suggested because they suppress ovulation. However, studies have found little difference between women taking a low-dose birth control pill and women who do not take pills, and oral contraceptives currently are not recommended for treatment of PMS/PMDD.

MASTODYNIA

Pain, and usually swelling, of the breasts caused by edema and engorgement of the vascular and ductal systems is termed *mastodynia*, or mastalgia. A positive correlation between degree of ductal dilatation and degree of breast pain has been documented. Mastodynia specifically refers to a cyclical occurrence of severe breast pain, usually in the luteal phase of the menstrual cycle. It is common in women with PMS/PMDD, and it may be the primary symptom of this syndrome in some. It has been shown to be related to high gonadotropin levels. Estrogen stimulates the ductal elements, whereas progesterone stimulates the stroma. An augmented response to prolactin has also been suggested. Examination is always necessary to rule out neoplasm, although most malignant tumors are painless. In postpartum patients, mastitis must be considered.

The presence of solitary or multiple cystic areas suggests fibrocystic change. The diagnosis usually can be confirmed by aspiration, but excisional biopsy occasionally is necessary. Serial mammograms or ultrasound examinations can be used to help monitor these patients (see Chapter 64).

Treatment

Management of painful breasts due to fibrocystic changes consists of support of the breasts, avoidance of methylxanthines (coffee, tea, chocolate, cola drinks), avoidance of nicotine, and occasional use of a mild diuretic. Patients with mastodynia have improved with topical NSAIDs, tamoxifen, danazol, bromocriptine, oral contraceptives, and vitamins, but with limited success. Recent data suggest goserelin (Zoladex) is an effective short-term treatment; however, the side-effect profile indicates continued treatment with alternative therapies.

DYSMENORRHEA

Dysmenorrhea, or painful menstruation, is one of the most common complaints of gynecologic patients. Many women experience mild discomfort during menstruation, but the term *dysmenorrhea* is reserved for women whose pain prevents normal activity and requires medication, whether an over-the-counter or a prescription drug.

There are 3 types of dysmenorrhea: (1) primary (no organic cause), (2) secondary (pathologic cause),

and (3) membranous (cast of endometrial cavity shed as a single entity). This discussion focuses mainly on primary dysmenorrhea. Secondary dysmenorrhea is discussed elsewhere in this book in association with specific diseases and disorders (eg, endometriosis, adenomyosis, pelvic inflammatory disease, cervical stenosis, fibroids, and endometrial polyps). Membranous dysmenorrhea is rare; it causes intense cramping pain due to passage of a cast of the endometrium through an undilated cervix. Another cause of dysmenorrhea that should be considered is cramping due to the presence of an intrauterine device (IUD).

Pathogenesis

Pain during menstruation has long been known to be associated with ovulatory cycles. The mechanism of pain has been attributed to prostaglandin activity. Prostaglandins are present in much higher concentrations in women with dysmenorrhea than in those with mild or no pain.

Other studies have confirmed increased leukotriene levels as a contributing factor. Vasopressin was thought to be an aggravating agent, but atosiban, a vasopressin antagonist, has shown no effect on menstrual pain.

Psychologic factors may be involved, including attitudes passed from mother to daughter. Girls should receive accurate information about menstruation before menarche; this can be provided by parents, teachers, physicians, or counselors. Emotional anxiety due to academic or social demands may be a cofactor.

Clinical Findings

Reactions to pain are subjective, and questioning by the physician should not lead the patient to exaggerate or minimize her discomfort. History taking is most important and should include the following questions: When does the pain occur? What does the patient do about the pain? Are there other symptoms? Do oral contraceptives relieve or intensify the pain? Does the pain become more severe over time?

Because dysmenorrhea almost always is associated with ovulatory cycles, it does not usually occur at menarche but rather later in adolescence. As many as 14–26% of adolescents miss school or work as a result of pain. Typically, pain occurs on the first day of the menses, usually about the time the flow begins, but it may not be present until the second day. Nausea and vomiting, diarrhea, and headache may occur. The specific symptoms associated with endometriosis are not present.

The physical examination does not reveal any significant pelvic disease. When the patient is symptomatic, she has generalized pelvic tenderness, perhaps more so in the area of the uterus than in the adnexa. Occasionally, ultrasonography or laparoscopy is necessary to rule out pelvic abnormalities such as endometriosis, pelvic inflammatory disease, or an accident in an ovarian cyst.

Differential Diagnosis

The most common misdiagnosis of primary dysmenorrhea is secondary dysmenorrhea due to endometriosis. With endometriosis, the pain usually begins 1–2 weeks before the menses, reaches a peak 1–2 days before, and is relieved at the onset of flow or shortly thereafter. Severe pain during sexual intercourse or findings of adnexal tenderness or mass or cul-de-sac nodularity, particularly in the premenstrual interval, help to confirm the diagnosis (see Chapter 43). A similar pain pattern occurs with adenomyosis, although in an older age group and in the absence of extrauterine clinical findings.

Treatment

NSAIDs or acetaminophen may relieve mild discomfort. Addition of continuous heat to the abdomen in addition to NSAIDs decreases pain significantly. For severe pain, codeine or other stronger analgesics

may be needed, and bed rest may be desirable. Occasionally, emergency treatment with parenteral medication is necessary. Analgesics may cause drowsiness at the dosages required.

ANTI-PROSTAGLANDINS

Anti-prostaglandins are now used for treatment of dysmenorrhea. The newer, stronger, faster-acting drugs appear to be more useful than aspirin. Ibuprofen, an NSAID that is available over the counter and in prescription strength, has been extremely effective in reducing menstrual prostaglandin and relieving dysmenorrhea. Less frequently dosed naproxen (550 mg/day) also is effective. Cyclooxygenase-2 (COX-2) inhibitors such as valdecoxib (20–40 mg/day) is equally effective and has fewer gastrointestinal side effects, but it is more costly. The drug must be used at the earliest onset of symptoms, usually at the onset of, and sometimes 1–2 days prior to, bleeding or cramping.

Anti-prostaglandins work by blocking prostaglandin synthesis and metabolism. Once the pain has been established, anti-prostaglandins are not nearly as effective as with early use.

ORAL CONTRACEPTIVES

Cyclic administration of oral contraceptives, usually in the lowest dosage but occasionally with increased estrogen, prevents pain in most patients who do not obtain relief from anti-prostaglandins or cannot tolerate them. The mechanism of pain relief may be related to absence of ovulation or to altered endometrium resulting in decreased prostaglandin production. In women who do not require contraception, oral contraceptives are given for 6–12 months. Many women continue to be free of pain after treatment has been discontinued. NSAIDs act synergistically with oral contraceptive pills to improve dysmenorrhea.

SURGICAL TREATMENT

In a few women, no medication controls dysmenorrhea. Cervical dilatation is of little use. Laparoscopic uterosacral ligament division and presacral neurectomy are infrequently performed, although some physicians consider these procedures to be important adjuncts to conservative operation for endometriosis.

Adenomyosis, endometriosis, or residual pelvic infection unresponsive to medical therapy or conservative surgical therapy eventually may require hysterectomy with or without ovarian removal in extreme cases. Rarely a patient with no organic source of pain eventually requires hysterectomy to relieve symptoms.

ADJUVANT TREATMENTS

Continuous low-level topical heat therapy has been shown to be as effective as ibuprofen in treating dysmenorrhea, although its practicality in daily life may be questionable. Many studies have indicated that exercise decreases the prevalence and/or improves the symptomatology of dysmenorrhea, although solid evidence is lacking.

Diets low in fat and meat products have been shown to decrease serum sex-binding globulin and decrease the duration and intensity of dysmenorrhea.

ABNORMAL UTERINE BLEEDING

Abnormal uterine bleeding includes abnormal menstrual bleeding and bleeding due to other causes such as pregnancy, systemic disease, or cancer. The diagnosis and management of abnormal uterine bleeding present some of the most difficult problems in gynecology. Patients may not be able to localize the source of the bleeding from the vagina, urethra, or rectum. In childbearing women, a complication of pregnancy must always be considered, and one must always remember that more than 1 entity may be present, such as uterine myomas and cervical cancer.

Patterns of Abnormal Uterine Bleeding

The standard classification for patterns of abnormal bleeding recognizes 7 different patterns.

- (1) Menorrhagia (hypermenorrhea) is heavy or prolonged menstrual flow. The presence of clots may not be abnormal but may signify excessive bleeding. "Gushing" or "open-faucet" bleeding is always abnormal. Submucous myomas, complications of pregnancy, adenomyosis, IUDs, endometrial hyperplasias, malignant tumors, and dysfunctional bleeding are causes of menorrhagia.
- (2) Hypomenorrhea (cryptomenorrhea) is unusually light menstrual flow, sometimes only spotting. An obstruction such as hymenal or cervical stenosis may be the cause. Uterine synechiae (Asherman's syndrome) can be causative and are diagnosed by a hysteroqram or hysteroscopy. Patients receiving oral contraceptives occasionally complain of light flow and can be reassured that this is not significant.
- (3) Metrorrhagia (intermenstrual bleeding) is bleeding that occurs at any time between menstrual periods. Ovulatory bleeding occurs midcycle as spotting and can be documented with basal body temperatures. Endometrial polyps and endometrial and cervical carcinomas are pathologic causes. In recent years, exogenous estrogen administration has become a common cause of this type of bleeding.
- (4) Polymenorrhea describes periods that occur too frequently. This usually is associated with anovulation and rarely with a shortened luteal phase in the menstrual cycle.
- (5) Menometrorrhagia is bleeding that occurs at irregular intervals. The amount and duration of bleeding also vary. Any condition that causes intermenstrual bleeding can eventually lead to menometrorrhagia. Sudden onset of irregular bleeding episodes may be an indication of malignant tumors or complications of pregnancy.
- (6) Oligomenorrhea describes menstrual periods that occur more than 35 days apart. Amenorrhea is diagnosed if no menstrual period occurs for more than 6 months. Bleeding usually is decreased in amount and associated with anovulation, either from endocrine causes (eg, pregnancy, pituitary-hypothalamic causes, menopause) or systemic causes (eg, excessive weight loss). Estrogen-secreting tumors produce oligomenorrhea prior to other patterns of abnormal bleeding.
- (7) Contact bleeding (postcoital bleeding) is self-explanatory but must be considered a sign of cervical cancer until proved otherwise. Other causes of contact bleeding are much more common, including cervical eversion, cervical polyps, cervical or vaginal infection (eg, *Trichomonas*), or atrophic vaginitis. A negative cytologic smear does not rule out invasive cervical cancer, and colposcopy, biopsy, or both may be necessary.

EVALUATION OF ABNORMAL UTERINE BLEEDING

Detailed history, physical examination, cytologic examination, pelvic ultrasound, and blood tests are the first steps in the evaluation of abnormal uterine bleeding. The main aim of the blood tests is to exclude a systemic disease, pregnancy, or a trophoblastic disease. The blood tests usually include complete blood count, assay of the β subunit of human chorionic gonadotropin (hCG), and thyroid stimulating hormone

(TSH).

HISTORY

Many causes of bleeding are strongly suggested by the history alone. Note the amount of menstrual flow, the length of the menstrual cycle and menstrual period, the length and amount of episodes of intermenstrual bleeding, and any episodes of contact bleeding. Note also the last menstrual period, the last normal menstrual period, age at menarche and menopause, and any changes in general health. The patient must keep a record of bleeding patterns to determine whether bleeding is abnormal or only a variation of normal. However, most women have an occasional menstrual cycle that is not in their usual pattern. Depending on the patient's age and the pattern of the bleeding, observation may be all that is necessary.

PHYSICAL EXAMINATION

Abdominal masses and an enlarged, irregular uterus suggest myoma. A symmetrically enlarged uterus is more typical of adenomyosis or endometrial carcinoma. Atrophic and inflammatory vulvar and vaginal lesions can be visualized, and cervical polyps and invasive lesions of cervical carcinoma can be seen. Rectovaginal examination is especially important to identify lateral and posterior spread or the presence of a barrel-shaped cervix. In pregnancy, a decidual reaction of the cervix may be the source of bleeding. The appearance is a velvety, friable erythematous lesion on the ectocervix.

CYTOLOGIC EXAMINATION

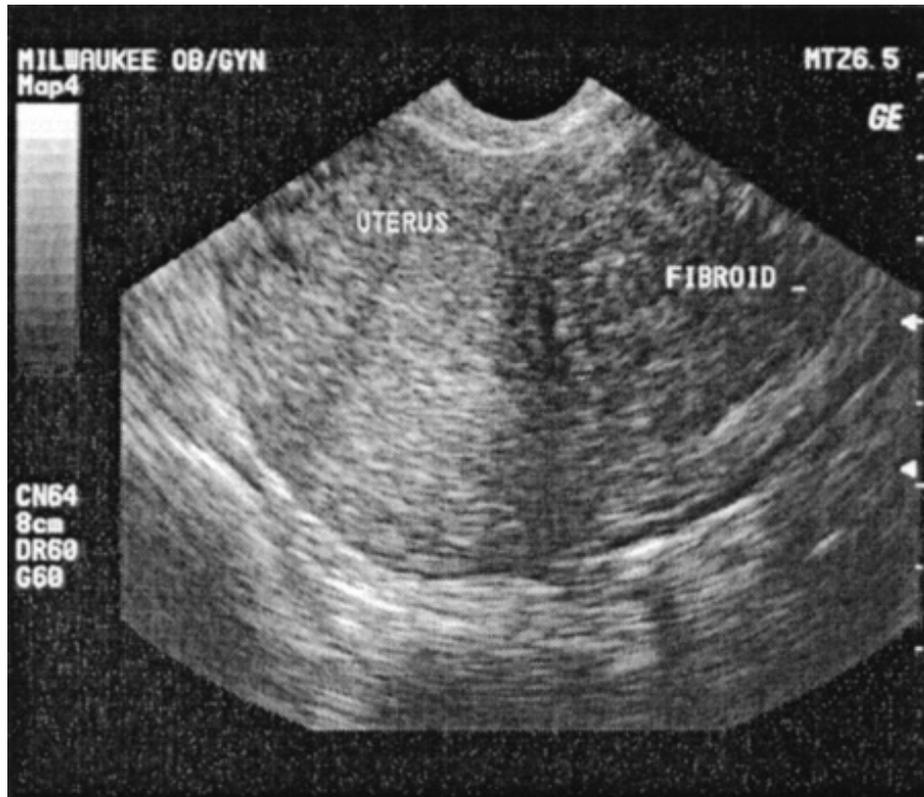

Although most useful in diagnosing asymptomatic intraepithelial lesions of the cervix, cytologic smears can help screen for invasive cervical (particularly endocervical) lesions. Although cytology is not reliable for the diagnosis of endometrial abnormalities, the presence of endometrial cells in a postmenopausal woman is abnormal unless she is receiving exogenous estrogens. Likewise, women in the secretory phase of the menstrual cycle should not shed endometrial cells. Of course, a cytologic examination that is positive or suspicious for endometrial cancer demands further evaluation.

Tubal or ovarian cancer can be suspected based on a cervical smear. The technique of obtaining a smear is important, because a tumor may be present only in the endocervical canal and may not shed cells to the ectocervix or vagina. Laboratories should report the presence or absence of endocervical cells. The current use of a spatula and endocervical brush has significantly increased the adequacy of cytologic smears from the cervix. Any abnormal smear requires further evaluation (see Chapter 50).

PELVIC ULTRASOUND SCAN

Pelvic ultrasonography has become an integral part of the gynecological pelvic examination. The scan can be performed either transvaginally or transabdominally. The transvaginal examination is performed with an empty bladder and enables a closer look with greater details at the pelvic organs. The transabdominal examination is performed with a full bladder and enables a wider, but less discriminative, examination of the pelvis. The ultrasound scan can add many details to the physical examination, such as a description of the uterine lining and its width and regularity (Fig 35–1), and the presence of intramural or submucous fibroids (Fig 35–1), intrauterine polyps, and adnexal masses. Persistent thick and irregular endometrium is one of the preoperative predictors of endometrial pathology and demands further evaluation and tissue biopsy.

Figure 35–1.

Typical ultrasound scan of a uterine fibroid (top) and normal endometrial lining (bottom).

Sonohysterography is a modification of the pelvic ultrasound scan. The ultrasound is performed following injection of saline by a thin catheter into the uterus. This technique increases significantly the sensitivity of transvaginal ultrasonography and has been used to evaluate the endometrial cavity for polyps, fibroids, and other abnormalities.

ENDOMETRIAL BIOPSY

Methods of endometrial biopsy include use of the Novak suction curette, the Duncan curette, the Kevorkian curette, or the Pipelle. Cervical dilatation is not necessary with these instruments. Small areas of the endometrial lining are sampled.

If bleeding persists and no cause of bleeding can be found or if the tissue obtained is inadequate for diagnosis, hysteroscopy and, in some cases, formal dilatation and curettage (D&C) must be performed.

HYSTEROSCOPY

Placing an endoscopic camera through the cervix into the endometrial cavity allows direct visualization of the cavity. Because of its higher diagnostic accuracy and suitability for outpatient investigation, hysteroscopy is increasingly replacing D&C for the evaluation of abnormal uterine bleeding. Hysteroscopy currently is regarded as the gold standard evaluation of pathology in the uterine cavity. Resection attachments allow immediate capability to remove or biopsy lesions.

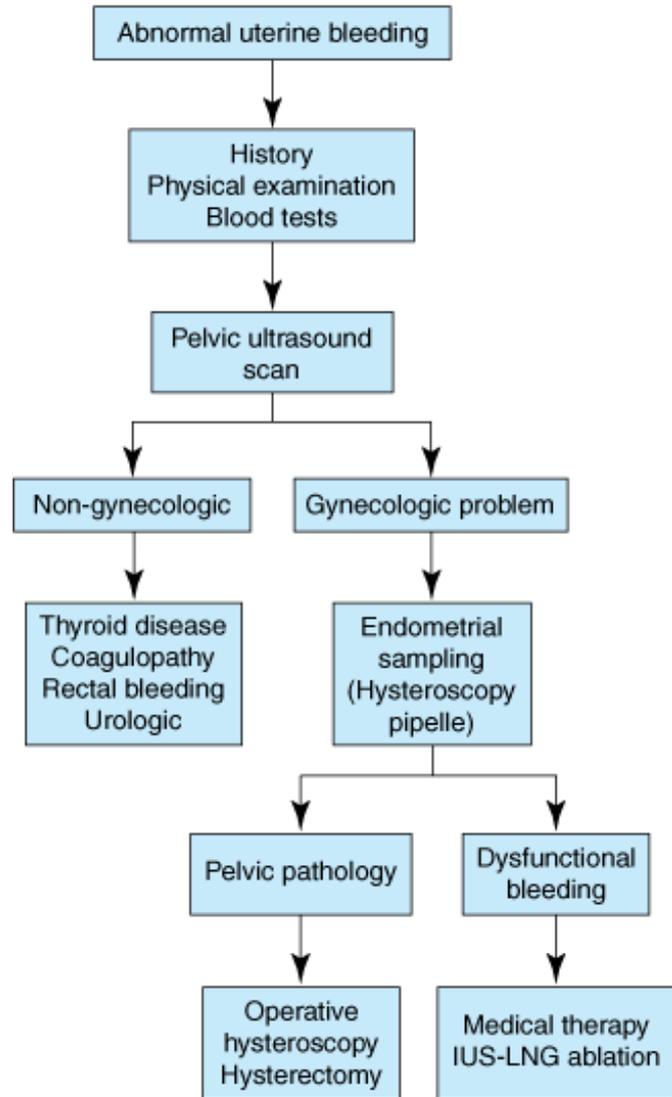

DILATATION AND CURETTAGE

For many years D&C has been regarded as the gold standard for the diagnosis of abnormal uterine bleeding. It can be performed with the patient under local or general anesthesia, almost always in an outpatient or ambulatory setting. With general anesthesia, relaxation of the abdominal musculature is greater, allowing for a more thorough pelvic examination, more precise evaluation of pelvic masses, and more complete curettage. Nevertheless, D&C is a blind procedure, and its accuracy, particularly when the cause of the abnormal uterine bleeding is a focal lesion such as a polyp, is debateable.

General Principles of Management

(Fig 35–2) In making the diagnosis, it is important not to assume the obvious. A careful history and pelvic examination are vital. The possibility of pregnancy must be considered, as well as use of oral contraceptives, IUDs, and hormones. Adequate sampling of the endometrium is essential for a definitive diagnosis.

General principles of management of abnormal uterine bleeding. IUS-LNG = intrauterine system-levonorgestrel releasing.

Improved diagnostic techniques and treatment have resulted in decreased use of hysterectomy to treat abnormal bleeding patterns. If pathologic causes (eg, submucous myomas, adenomyosis) can be excluded, if there is no significant risk for cancer development (as from atypical endometrial hyperplasia), and if there is no acute life-threatening hemorrhage, most patients can be treated with hormone preparations. Myomectomy can be suggested for treatment of myoma if the patient wishes to retain her childbearing potential. Endometrial ablation and endometrial resection may offer successful outpatient and in-office alternatives.

For menorrhagia, prostaglandin synthetase inhibitors have been shown to significantly decrease blood loss during menses, as has antifibrinolytic therapy. Long-acting intramuscular progestin administration (Depo-Provera) can be given but may result in erratic bleeding or even amenorrhea. Finally, levonorgestrel-releasing IUDs are as effective as endometrial resection in decreasing blood loss.

ABNORMAL UTERINE BLEEDING DURING PREGNANCY

See Chapter 20.

ABNORMAL BLEEDING DUE TO NONGYNECOLOGIC DISEASES & DISORDERS

In the differential diagnosis of abnormal bleeding, nongynecologic causes of bleeding (eg, rectal or urologic disorders) must be ruled out, because patients may have difficulty differentiating the source of bleeding. Gynecologic and nongynecologic causes of bleeding may coexist. Systemic disease may cause abnormal uterine bleeding. For example, myxedema usually causes amenorrhea, but less severe hypothyroidism is associated with increased uterine bleeding. Liver disease interferes with estrogen metabolism and may cause variable degrees of bleeding. Both of these conditions are usually clinically apparent before gynecologic symptoms appear. Blood dyscrasias and coagulation abnormalities can also produce gynecologic bleeding. Patients receiving anticoagulants or adrenal steroids may expect abnormalities. Extreme weight loss due to eating disorders, exercise, or dieting may be associated with anovulation and amenorrhea.

DYSFUNCTIONAL UTERINE BLEEDING

Exclusion of pathologic causes of abnormal bleeding establishes the diagnosis of dysfunctional uterine bleeding. Although a persistent corpus luteum cyst or short luteal phase can produce abnormal bleeding associated with ovulation, most patients are anovulatory. The exact cause of anovulation is not truly understood but probably represents dysfunction of the hypothalamic-pituitary-ovarian axis, resulting in continued estrogenic stimulation of the endometrium. The endometrium outgrows its blood supply, partially breaks down, and is sloughed in an irregular manner. Conversion from proliferative to secretory endometrium corrects most acute and chronic bleeding problems. Organic causes of anovulation must be excluded (eg, thyroid or adrenal abnormalities).

Dysfunctional bleeding occurs most commonly at the extremes of reproductive age (20% of cases occur in adolescents and 40% in patients over age 40 years). Management depends on the age of the patient (adolescent, young woman, or premenopausal woman). The diagnosis is made by history, absence of ovulatory temperature changes, low serum progesterone level, and results of endometrial sampling in the older woman.

Treatment

ADOLESCENTS

Because the first menstrual cycles frequently are anovulatory, the menses not unusually are irregular, and explanation of the reason is all the treatment that is necessary. Heavy bleeding—even hemorrhage—may occur. Invasive diagnostic procedures usually are not necessary in young patients, but physical (pelvic if possible) examination and ultrasonography must be performed to exclude pregnancy or pathologic conditions. Estrogens given orally should be adequate for all patients except those requiring curettage to control hemorrhage. Numerous regimens are available, including estrogens followed by progesterone, progesterone alone, or combination oral contraceptives. For acute hemorrhage, high-dose estrogen given intravenously (25 mg conjugated estrogen every 4 hours) gives rapid response. In hemodynamically stable patients, the oral dose of conjugated estrogens is 2.5 mg every 4–6 hours for 14–21 days. Once bleeding has stopped, medroxyprogesterone acetate 5 mg once or twice per day should be given for 7–10 days.

Oral contraceptives, 3–4 times the usual dose, are just as effective and may be simpler to use than sequential hormones. Again, the dose is lowered after a few days and the lower dose is continued for the

next few cycles, particularly to raise the hemoglobin levels in an anemic patient. Medroxyprogesterone acetate 10 mg/d for 10 days can be given to patients who have proliferative endometrium on biopsy. In patients receiving cyclic therapy, 3–6 monthly courses are usually administered, after which treatment is discontinued and further evaluation performed if necessary. In adolescents in whom the bleeding is not severe, oral contraceptives can be used as normally prescribed.

YOUNG WOMEN

In patients 20–30 years old, pathologic causes are similarly not very common and the appropriate diagnostic procedures should be considered following the initial evaluation by history, physical and cytologic examination, and pelvic ultrasound. Hormonal management is the same as for adolescents.

PREMENOPAUSAL WOMEN

In the later reproductive years, even more care must be given to excluding pathologic causes because of the possibility of endometrial cancer. The initial evaluation should be complemented by hysteroscopy and endometrial biopsy and should clearly establish anovulatory or dyssynchronous cycles as the cause before hormonal therapy is started. Recurrences of abnormal bleeding demand further evaluation.

SURGICAL MEASURES

For patients whose bleeding cannot be controlled with hormones, who are symptomatically anemic, and whose lifestyle is compromised by persistence of irregular bleeding, D&C may temporarily stop bleeding. If bleeding persists, levonorgestrel-releasing IUDs or a minimal invasive procedure such as endometrial ablation may be offered. Studies have shown that approximately 80% of patients scheduled for hysterectomy changed their minds following endometrial ablation. However, if these minimally invasive procedures fail or if the patient prefers a definitive solution, hysterectomy may be necessary. Definitive surgery may also be needed for coexistent endometriosis, myoma, and disorders of pelvic relaxation.

POSTMENOPAUSAL BLEEDING

Postmenopausal bleeding may be defined as bleeding that occurs after 12 months of amenorrhea in a middle-aged woman. When amenorrhea occurs in a younger person for 1 year and premature ovarian failure or menopause has been diagnosed, episodes of bleeding may be classified as postmenopausal, although resumption of ovulatory cycles can occur. Follicle-stimulating hormone (FSH) levels are particularly helpful in the differential diagnosis of menopausal versus hypothalamic amenorrhea. An FSH level greater than 30 mIU/mL is highly suggestive of menopause.

Postmenopausal bleeding is more likely to be caused by pathologic disease than is bleeding in younger women and must always be investigated. Nongynecologic causes must be excluded; these causes are more likely to result from pathologic disease in older women, and patients may be unable to determine the site of bleeding. The source of bleeding should not be assumed to be nongynecologic unless there is good evidence or proper evaluation has excluded gynecologic causes.

Neither normal ("functional") bleeding nor dysfunctional bleeding should occur after menopause. Although pathologic disorders are more likely, other causes may also occur. Atrophic or proliferative endometrium is not unusual. Secretory patterns should not occur unless the patient has resumed ovulation or has received progesterone therapy.

After nongynecologic causes of bleeding are excluded, gynecologic causes must be considered.

Exogenous Hormones

The most common cause of postmenopausal uterine bleeding is the use of exogenous hormones. In the past, face creams and cosmetics contained homeopathic amounts of estrogens, but today this cause is highly unlikely. Careful history taking becomes vital, because patients may not follow specific instructions

on the use of estrogen and progesterone therapy.

In light of the new caution placed on postmenopausal hormone replacement therapy (HRT) because of cardiovascular risks, long-term estrogen/progesterone administration for prevention of osteoporosis is no longer recommended. Women continue HRT for menopausal symptoms to improve their quality of life. Regular menstrual bleeding may resume if they take HRT agents cyclically. Not uncommonly, these patients present with vaginal bleeding as many as 6–12 months after initiation of HRT. If bleeding is still occurring by that time, further investigation is warranted to determine its etiology. If endometrial hyperplasia is found, specific attention must be paid to the presence of atypia and treatment started by increasing the progesterone component or by hysterectomy.

Vaginal Atrophy and Vaginal and Vulvar Lesions

Bleeding from the lower reproductive tract almost always is related to vaginal atrophy, with or without trauma. Examination reveals thin tissue with ecchymosis. Rarely, a tear at the introitus or deep in the vagina requires suturing. With vulvar dystrophies, a white area and cracking of the skin of the vulva may be present. Cytologic study of material obtained from the cervix and vagina will reveal immature epithelial cells with or without inflammation. After coexisting upper tract lesions are excluded, treatment can include local or systemic estrogen therapy for vaginal lesions. Vulvar lesions require further diagnostic evaluation to determine the proper treatment.

Tumors of the Reproductive Tract

The differential diagnosis of organic causes of postmenopausal uterine bleeding includes endometrial hyperplasias (simple, complex, and atypical), endometrial polyps, endometrial carcinoma or other more rare tumors such as cervical or endocervical carcinoma, uterine sarcomas (including mixed mesodermal and myosarcomas), and, even more rarely, uterine tube and ovarian cancer. Estrogen-secreting ovarian tumors also should be considered.

Uterine sampling must be done and tissue obtained. Endocervical curettage should be performed, along with any endometrial sampling technique. If a diagnosis cannot be established or is questionable with office procedures, D&C is necessary. Hysteroscopy performed in the office or operating room may prove helpful in locating endometrial polyps or fibroids that could be missed even by fractional curettage. Pelvic ultrasonography may be extremely helpful in the diagnosis of ovarian tumors and in evaluation of the thickness of the endometrium, as well as in discerning between uterine myomas and adnexal tumors. Recurring episodes of postmenopausal bleeding may rarely require hysterectomy, even when a diagnosis cannot be established by endometrial sampling.

Current OB/GYN >Chapter 36. Contraception & Family Planning>

CONTRACEPTION

Decision-making concerning fertility control is, for many people, a deeply personal and sensitive issue, often involving religious or philosophical convictions. Thus, it is important for the clinician to approach the subject with particular sensitivity, empathy, maturity, and nonjudgmental behavior.

Despite the introduction of modern contraceptives, unintended or unplanned pregnancies continue to be a major problem in the United States. According to the 1995 National Survey of Family Growth, there were a total of 6.3 million pregnancies in the United States, of which 49.2% were unintended. Among the unintended pregnancies, nearly half result in a pregnancy termination and over 10% in spontaneous abortion, a substantial degree of pregnancy wastage. Unintended and unplanned pregnancies have social and economic ramifications; they also have a significant impact on public health. Approximately 40% of unintended pregnancies occur among women who do not desire pregnancy yet do not use a method of contraception. Approximately 60% of unintended pregnancies occur among women using some form of birth control. Such data suggest that many women and couples are inadequately motivated to use contraception, that side effects may be problematic for some, that access may be an issue for others, or that some methods may be difficult for women to use correctly.

Individual Indications for Birth Control

Contraception is practiced by most couples for personal reasons. Many couples use contraception to space their children or to limit their family size. Others desire to avoid childbearing because of the effects of preexisting illness on the pregnancy, such as severe diabetes or heart disease. For all of these types of decisions, clinicians must provide accurate information about the benefits and risks of both pregnancy and contraception. However, medical conditions that may substantially increase the risk of using some form of contraception usually increase the risks associated with pregnancy to an even greater extent. As a matter of public policy, some countries, especially those that are less developed, promote contraception in an effort to curb undesired population growth.

Legal Aspects of Contraception

Contraceptives are prescribed, demonstrated, and sold throughout most of the United States without restriction.

Despite high rates of unprotected intercourse and unintended pregnancy, the pros and cons of providing contraceptive information and materials to teenagers have been vigorously debated. Most states either have legislation that permits access to contraception for persons under 18 years or have not addressed the issue legislatively. There is a general consensus among physicians that teenagers should be given contraceptive advice and prescriptions within the limits of the law. Physicians must be careful to avoid imposing their own religious or moral views on their patients.

Health care providers are obliged to provide all persons requesting contraception with detailed information about the method(s) and its benefits, risks, and side effects so that the patient can make an informed choice relative to a particular method. Not only is the provision of this information of ethical and legal importance, but such counseling is likely to increase the likelihood the method will be used appropriately with overall improved compliance.

Documentation of the discussion with the patient and her understanding of what has been said is important both clinically and legally. In particular, when using methods that require instrumentation or surgery and that also may require intervention by a health care professional for discontinuation (eg, intrauterine contraceptive device [IUD], injectable progestin, or sterilization), signed consent forms that outline the information discussed and the patient's understanding of it may reduce potential legal issues should a problem occur. If needed, the signed consent form serves as evidence that the patient was given counseling about use of a particular birth control method, that she appeared competent to understand what was said to her, and that she consented to receive contraceptive management in the manner specified.

METHODS OF CONTRACEPTION

The available methods of contraception can be classified in many ways. For this discussion, traditional or folk methods are coitus interruptus, postcoital douche, lactational amenorrhea, and periodic abstinence (rhythm or natural family planning). Barrier methods include condoms (male and female), diaphragm, cervical cap, vaginal sponge, and spermicides. Hormonal methods encompass oral contraceptives and injectable or implantable long-acting progestins. In addition, the IUD and sterilization (tubal ligation or vasectomy) are part of the contraceptive armamentarium. Sterilization is discussed in Chapter 48.

COITUS INTERRUPTUS

One of the oldest contraceptive methods is withdrawal of the penis before ejaculation. This process results in deposition of the semen outside the female genital tract. It has the disadvantage of demanding sufficient self-control by the man so that withdrawal precedes ejaculation. Although the failure rate probably is higher than the most methods, reliable statistics are not available. Failure may result from escape of semen before orgasm or the deposition of semen on the external female genitalia near the vagina.

POSTCOITAL DOUCHE

Plain water, vinegar, and a number of "feminine hygiene" products are widely used as postcoital douches. Theoretically, the douche flushes the semen out of the vagina, and the additives to the water may possess some spermicidal properties. Nevertheless, sperm have been found within the cervical mucus within 90 seconds after ejaculation. Hence, the method is ineffective and unreliable.

LACTATIONAL AMENORRHEA

The lactational amenorrhea method can be a highly efficient method for breastfeeding women to utilize physiology to space births. Suckling results in a reduction in the release of gonadotropin-releasing hormone, luteinizing hormone (LH), and follicle-stimulating hormone (FSH). β -Endorphins induced by suckling also induce a decline in secretion of dopamine, which normally suppresses the release of prolactin. This results in a condition of amenorrhea and anovulation. During the first 6 months, if breastfeeding is exclusive, menses are mostly anovulatory and prolactin remains low. A recent World Health Organization (WHO) study on lactational amenorrhea revealed that during the first 6 months of nursing, cumulative pregnancy rates ranged from 0.9–1.2%. However, at 12 months, pregnancy rates rose as high as 7.4%. When using lactation as a method of birth control, the mother must provide breastfeeding as the only form of infant nutrition. Supplemental feedings may alter both the pattern of lactation and the intensity of infant suckling, which secondarily may affect suppression of ovulation. Second, amenorrhea must be maintained. Finally, the method should be practiced as the only form of birth control for a maximum of 6 months after birth. If another pregnancy is undesired, most practitioners advise lactating women to use a reliable contraceptive method starting 3 months after delivery.

MALE CONDOM

The condom, or contraceptive sheath, serves as a cover for the penis during coitus and prevents the deposition of semen in the vagina. The most common material used for male condom manufacture is latex, although available

condoms are also made from polyurethane material and lamb ceca. The advantages of the condom are that it provides highly effective and inexpensive contraception as well as protection against sexually transmitted infections (STIs). Some condoms now contain a spermicide, which may offer further protection against failure, particularly if the condom breaks. Given the concern about STIs, including human immunodeficiency virus (HIV), condom use should be recommended for all couples except those in a mutually monogamous relationship.

The condom probably is the most widely used mechanical contraceptive in the world today. Condoms made of latex or polyurethane are impervious to both sperm and most bacterial and viral organisms that cause sexually transmitted diseases (STDs) or HIV infection. However, the less commonly used lamb's cecum condom is not impermeable to such organisms. The failure of all condoms results from imperfections of manufacture (approximately 3 in 1000); errors of technique, such as applying the condom after some semen has escaped into the vagina; and escape of semen from the condom as a result of failure to withdraw before detumescence. In typical use, failure rates with condoms range from 10–30% in the first year of use.

When greater contraceptive effectiveness is desired, a second method such as contraceptive vaginal jelly or foam should be used in conjunction with the condom. This combination significantly reduces the chances for condom failure due to mechanical or technical deficiencies. No association has been established between the use of vaginal contraceptives (spermicides) and the occurrence of congenital malformations if a pregnancy occurs.

FEMALE CONDOM

The female condom is made of thin polyurethane material with 2 flexible rings at each end. One ring fits into the depth of the vagina, and the other ring sits outside the vagina near the introitus. Female condoms have the advantage of being under the control of the female partner and of offering some protection against STDs. Significant disadvantages may be their cost and overall bulkiness. Comparisons of the female condom with other female barrier methods such as the diaphragm and cervical cap indicate that typical use failure rates are comparable. The 6-month probability of failure during perfect use of the condom is 2.6%, which is much lower than the initial prediction of 15%. Perfect use of the female condom may reduce the annual risk of acquiring HIV by more than 90%.

VAGINAL DIAPHRAGM

The diaphragm is a mechanical barrier between the vagina and the cervical canal. Diaphragms are circular rings ranging from 50–105 mm in diameter. They are designed to fit in the vaginal cul-de-sac and cover the cervix. Although the designs vary, the arcing spring version probably is the easiest for most women to use. A contraceptive jelly or cream should be placed on the cervical side of the diaphragm before insertion because the device is ineffective without it. This medication also serves as a lubricant for insertion of the device. Additional jelly should be introduced into the vagina on and around the diaphragm after it is securely in place. The diaphragm can be inserted up to 6 hours prior to intercourse and should be left in place for at least 6–24 hours after intercourse. When the diaphragm is of proper size (as determined by pelvic examination and trial with fitting rings) and is used according to directions, its failure rate is as low as 6 pregnancies per 100 women per year of exposure. With typical use, however, the pregnancy rate is 15–20 pregnancies per 100 woman-years. The diaphragm has the disadvantages of requiring fitting by a physician or a trained paramedical person and the necessity for anticipating the need for contraception. Weight alterations and deliveries might change the vaginal diameter. Therefore, the fit of the diaphragm to the user must be assessed yearly during the routine pelvic examination. Failures may result from improper fitting or placement and dislodgment of the diaphragm during intercourse. It cannot be used effectively by women with significant pelvic relaxation, a sharply retroverted or anteverted uterus, or a shortened vagina. As with condoms, diaphragms offer some protection against STDs. The only side effects are vaginal wall irritation, usually with initial use or if the device fits too tightly, and an increased risk of urinary tract infections due to pressure of the rim against the urethra and alterations in the composition of the vaginal flora.

CERVICAL CAP

Cervical caps are small cuplike diaphragms placed over the cervix that are held in place by suction. To provide a successful barrier against sperm, they must fit tightly over the cervix. Because of variability in cervical size, individualization is essential. Tailoring the cap to fit each cervix is difficult, greatly limiting the practical usefulness of the method. In addition, many women are unable to feel their own cervix and thus have great difficulty in placing the cap correctly over the cervix. Because of these problems, the cervical cap has few advantages over the traditional vaginal diaphragm. Although some advocates of the cervical cap recommend that it remain in place for 1 or 2 days at a time, a foul discharge often develops after approximately 1 day of use. With proper use, the efficacy of the cervical cap is similar to that of the diaphragm, with dislodgment being the most frequently cited cause of failure in most reports. The cap should be left in place for 8–48 hours after intercourse, and its proper placement over the cervix should be confirmed by digital self-examination after each sexual act.

SPERMICIDAL PREPARATIONS

Spermicidal vaginal jellies, creams, gels, suppositories, vaginal sponge, and foams, in addition to their toxic effect on sperm, act as a mechanical barrier to entry of sperm into the cervical canal. The only spermicide available in the United States contains nonoxynol 9, which is a long-chain surfactant that is toxic to spermatozoa. Spermicides can be used alone or in conjunction with a diaphragm or condom. Some foam tablets and suppositories require a few minutes for adequate dispersion throughout the vagina, and failures may result if dispersion is not allowed to occur. In general, when used alone, spermicides have a failure rate of approximately 15% per year with perfect use but double that rate with typical use. These chemical agents may irritate the vaginal mucosa and external genitalia. Recent evidence indicates that spermicides containing nonoxynol 9 are not effective in preventing cervical gonorrhea, chlamydia, or HIV infection. In addition, frequent use of spermicides containing nonoxynol 9 without barrier has been associated with genital lesions that may be linked to increased risk of HIV transmission.

PERIODIC ABSTINENCE

It has long been known that women are fertile for only a few days of the menstrual cycle. The periodic abstinence (rhythm or natural family planning) method of contraception requires that coitus be avoided during the time of the cycle when a fertilizable ovum and motile sperm could meet in the oviduct. Fertilization takes place within the tube and the ovum remains in the tube for approximately 1–3 days after ovulation; hence the fertile period is from the time of ovulation to 2–3 days thereafter.

Accurate prediction or indication of ovulation is essential to the success of the periodic abstinence method. Data from surveys in developed and developing countries performed during the past decade indicate the use of natural family planning methods varies from 0–11%. Pregnancy rates vary, but most reliable studies report 1-year life table pregnancy rates between 10 and 25 per 100 woman-years.

(1) The calendar method predicts the day of ovulation by means of a formula based on the menstrual pattern recorded over a period of several months. Ovulation ordinarily occurs 14 days before the first day of the next menstrual period. The fertile interval should be assumed to extend from at least 2 days before ovulation to no later than 2 days after ovulation. An overlap of 1–2 days of abstinence either way increases the likelihood of success. Successful use of this approach is based on the knowledge that the luteal phase of a menstrual cycle is relatively constant at 14 days for normal women. Furthermore, for this approach to be successful as the only form of contraception requires regular menstrual cycles so that the various timing schedules retain validity. Although this is the most commonly used method of periodic abstinence, it is also the least reliable, with failure rates as high as 35% in 1 year's use.

(2) A somewhat more efficacious approach to periodic abstinence is the temperature method, as more reliable evidence of ovulation can be obtained by recording the basal body temperature (BBT). The vaginal or rectal temperature must be recorded upon awakening in the morning before any physical activity is undertaken. Although it is often missed, a slight drop in temperature occurs 24–36 hours after ovulation. The temperature then rises

abruptly approximately 0.3–0.4 C (0.5–0.7 F) and remains at this plateau for the remainder of the cycle. The third day after the onset of elevated temperature is considered the end of the fertile period. For reliability, care must be taken by the woman to ensure that true basal temperatures are recorded, ie, that temperature elevations due to other causes such as fever do not provide misleading information. A distinct limitation of this technique is that prediction of timing of ovulation in any given cycle is retrospective, making it difficult to predict the onset of the fertile period.

(3) The combined temperature and calendar method uses features of the 2 methods to more accurately predict the time of ovulation. Failure rates of only 5 pregnancies per 100 couples per year have been reported in studies of well-motivated couples.

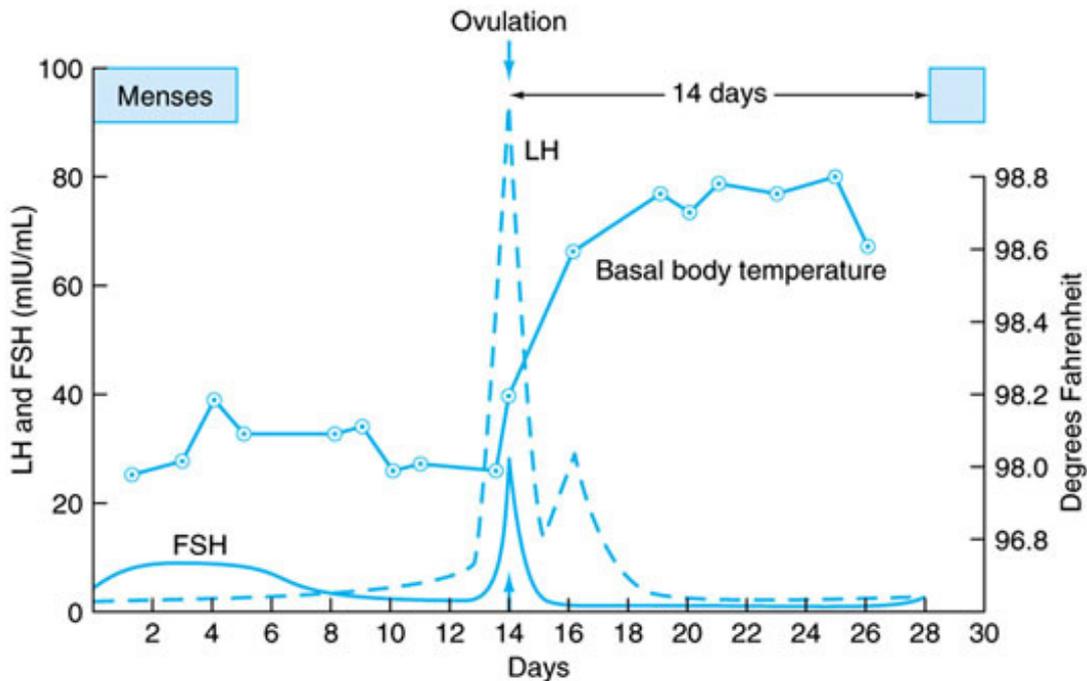

(4) The cervical mucus (Billings) method uses changes in cervical mucus secretions as affected by menstrual cycle hormonal alterations to predict ovulation. Starting several days before and until just after ovulation, the mucus becomes thin and watery, whereas at other times the mucus is thick and opaque. Women using this approach are trained to evaluate their mucus on a daily basis. Success rates are similar to those described for the combined temperature and calendar method. Advantages of this approach include relative simplicity and lack of a requirement for charting. Disadvantages include difficulty in evaluating mucus in the presence of vaginal infection and the reluctance of some women to evaluate such secretions.

(5) The symptothermal method, if used properly, probably is the most effective of all the periodic abstinence approaches. It combines features of both the cervical mucus and the temperature methods. In addition, symptoms that may occur just prior to ovulation, such as bloating and vulvar swelling, are used as adjuncts to predict the occurrence of ovulation.

The most accurate method of determining ovulation time is to demonstrate the LH peak in serum specimens. Because of the cost and the time required for serial measurements of LH level that are essential to indicate the abrupt rise, this method is impractical as a method of birth control. It is valuable in the treatment of infertility, however, when the optimal time for coitus or artificial insemination is of great importance.

Figure 36–1 shows the relationships among ovulation, BBT, serum levels of LH and FSH, and menses. At least 20% of fertile women have enough variation in their cycles that reliable prediction of the fertile period is impossible.

Figure 36–1.

Relationships among ovulation, basal body temperature, and luteinizing hormone (LH) and follicle-stimulating hormone (FSH) surges in the normal menstrual cycle.

Epidemiologic studies of women using periodic abstinence have suggested an increased incidence of congenital anomalies, such as anencephaly and Down syndrome, among children resulting from unplanned pregnancies. Animal experiments have shown delayed fertilization results in an increased incidence of aneuploidy and polyploidy in offspring, thus suggesting a possible explanation for similar human fetal anomalies. However, despite a theoretical explanation for the occurrence of such birth defects, it is important to recognize that much of the data are subject to bias, and concluding that such associations have been conclusively proved would be inappropriate.

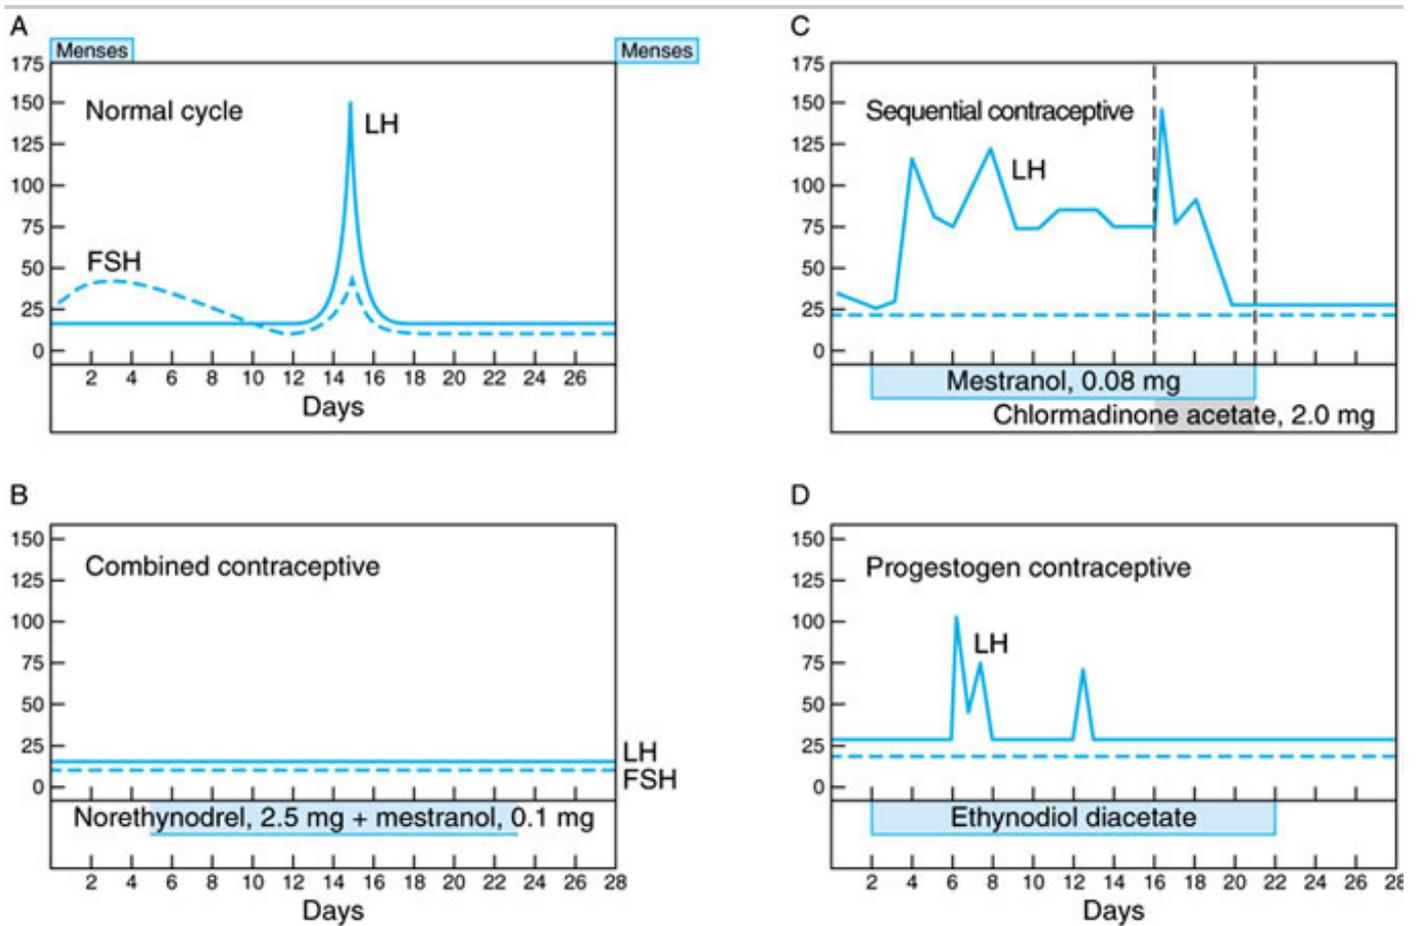

ORAL HORMONAL CONTRACEPTIVES

Oral contraceptives when placed in general use in 1960 heralded the modern era of contraception. Oral contraceptives provide an estrogen, ethinyl estradiol, and a progestin. The most commonly used progestins in the United States are the estranes: norethindrone and norethindrone acetate; the gonanes: levonorgestrel, desogestrel, and norgestimate; and the spironolactone analogue drospirenone. When first developed, the two principal regimens for oral contraception were combined and sequential. The sequential method has been abandoned in the United States because several studies showed a higher than normal incidence of endometrial cancer in women using this method of contraception. In the most commonly used combined method, pills containing both estrogen and progestin are taken each day for 21 days, followed by 7 days of placebo pills during which time most women experience withdrawal bleeding. Over the past several decades the estrogen content has been reduced by a factor of 3-fold to 4-fold, such that the current dose of ethinyl estradiol ranges between 20 and 35 µg. Similarly, the progestin content has been substantially reduced. In general use, the combined regimen is started either with the onset of the menstrual cycle or on the Sunday closest to the start of menses. Because most oral contraceptive preparations are packaged in 28-day regimens, the Sunday start approach may be easier to follow for some women. However, a good practice is to recommend use of an additional form of contraception during the first week of the cycle to maximize efficacy. Recently, some practitioners have initiated an approach in which birth control pills are started on the day of the office visit if pregnancy is unlikely. It appears this approach may reduce unwanted pregnancies. However, backup contraception is required for at least 7 days after initiation of the method. The newest approach

with combined oral contraceptives is to administer active pills for 84 days followed by 7 days (extended-use regimen) to allow for withdrawal bleeding to occur. Although this approach is designed to reduce the number of withdrawal bleeding episodes to 4 per year, a significant number of women experience irregular bleeding, especially during the first few cycles of use. With standard oral contraceptive preparations, withdrawal bleeding can be expected within 3–5 days after completion of the 21-day regimen of active pills.

The serum levels of FSH and LH throughout the normal menstrual cycle are shown in Figure 36–2A. During a typical cycle under the combined oral contraceptive regimen (Fig 36–2B), there is no rise during the first half of the cycle thus the growth of the dominant follicle and ovulation do not occur, and there are no midcycle alterations of FSH and LH levels. Oral contraceptives change the consistency of cervical mucus, resulting in less sperm penetration; make the endometrial lining less receptive to implantation; and alter tubal transport of both sperm and oocytes. During the sequential oral contraceptive regimen (Fig 36–2C), the estrogen stimulates LH secretion in an irregular manner. There is no concomitant early rise in FSH level when progestin is added, and another LH surge usually is produced. When a progestin-only regimen (Fig 36–2D) is followed (see Progestin-Only Pill), there are multiple LH surges but no significant changes in FSH levels.

Advantages

Benefits that are reasonably established include reduction in risk of ovarian and endometrial cancer, ectopic pregnancy, pelvic inflammatory disease (PID), menstrual disorders, benign breast disease, and acne. Emerging benefits include protection against bone mineral density loss, development of colorectal cancer, and progression of rheumatoid arthritis. Multiple observational studies have documented that combination oral contraceptives decrease the risk of ovarian cancer by 40–80% and endometrial cancer by approximately 50%. These effects take place after 1 year of use, and protection persists for a significant period after oral contraceptive use is discontinued. Oral contraceptives also reduce the risk of ectopic pregnancy by approximately 90% and the risk of acute salpingitis by as much as 50–80% in some studies, although other studies suggest the protection occurs to a lesser extent. However, birth control pills do not offer protection against lower tract infections such as gonorrhea or chlamydia. Oral contraceptives reduce menstrual blood loss as well as dysmenorrhea. There is a 30–50% overall decrease in benign fibrocystic conditions of the breast. Randomized placebo controlled trials have demonstrated a reduction in acne lesions with some oral contraceptive preparations. Evidence from several studies indicates that oral contraceptives maintain bone mineral density. Other recent studies suggest that oral contraceptive use offers protection against colorectal cancer and that they also prevent the progression of rheumatoid arthritis to more severe varieties.

Disadvantages & Side Effects

Much attention has been paid to a possible relationship between the use of oral contraceptives and the incidence of thromboembolic disease, including pulmonary embolism. Use of most current combination oral contraceptives roughly triples a user's risk of venous thromboembolism (VTE) from approximately 3 to 9 events per 100,000 users annually, although some studies of formulations containing desogestrel suggest that the risk could climb as high as 7-fold. However, it is important to recognize that even with the worst case scenarios, the attributable risk annually is approximately 18 additional events per 100,000 users compared with nonusers of combination oral contraceptives. VTE risk is enhanced by risk factors such as recent leg trauma, pelvic surgery, stasis (but not varicose veins), and the presence of the mutation known as factor V Leiden. Although the presence of this latter clotting abnormality markedly elevates a user's risk of VTE, the absolute risk is still low such that routine screening for the disorder among all potential oral contraceptive users would not be cost effective.

Myocardial infarction (MI) is a rare condition that occurs among combination oral contraceptive users only in the presence of risk factors such as hypertension, diabetes, severe dyslipidemia, and, in particular, cigarette smoking. Age above 35 years and smoking also act synergistically to increase risk; thus, prescribing combination oral contraceptives to women over 35 years who smoke is not recommended. However, even with a 20- to 30-fold relative risk of MI among smoking combination oral contraceptive users, this risk equates to only a maximum of 500–600 events per million woman-years. However, unlike VTE in which the case fatality rate in the reproductive age group is less than 1%, the case fatality rate for MI is approximately 50%.

Stroke is a rare condition among women in the reproductive age group, with hemorrhagic stroke somewhat more common than ischemic stroke. Among nonsmoking women, the rates range from 6–46 events per million woman-years; combination oral contraceptive use increases that risk only if risk factors such as age, cigarette smoking, migraine headaches (for ischemic but not hemorrhagic stroke), and especially hypertension are present. Overall relative risk of stroke varies between 2-fold and 10-fold, depending on the number of risk factors present.

Although cancer of the cervix among users of oral contraceptives has been a matter of concern, a major problem with many studies attempting to examine this relationship is confounding factors such as multiple sexual partners, age at first intercourse, and frequency of sexual activity and the concomitant use of barrier contraceptive methods. A recent meta-analysis determined that the risk of cervical cancer among oral contraceptive users compared to nonusers increased with duration of use, reaching a relative risk of approximately 4 after 10 years. For several

decades, concern has been expressed regarding the possible association between oral contraceptive use and breast cancer. In 1996, a collaborative project representing a reanalysis of 54 studies demonstrated that for current users of oral contraceptives, the relative risk of breast cancer for users compared with women who had never used oral contraceptives was 1.24. This small increase in risk persisted for approximately 10 years after discontinuation of contraceptive use, with the risk essentially disappearing after that time. In addition, there was no overall effect of oral contraceptive use by dosage, specific formulation, duration of use, age at first use, age at time of cancer diagnosis, or family history of breast cancer. The pattern of disappearance of risk after 10 years coupled with a tendency toward localized disease suggests that the overall effect may represent detection bias or perhaps a promotional effect. Another recent, large population-based case-control study showed that neither current nor past use of any type of oral contraceptive increased the risk of breast cancer compared to population-based controls. Further, the results did not vary according to potential risk factors such as estrogen dose, duration of use, family history of breast cancer, or age at initiation of use. Other infrequent problems occasionally noted with oral contraceptive use include hypertension, cholelithiasis, and benign liver tumors. However, none of these problems occurs frequently enough to be of significant concern to most users.

Because the current formulations are associated with significant reductions in risk of serious sequelae, side-effect control will be of greater importance to most users in the future. Furthermore, studies have shown that compliance is affected by occurrence of side effects and that such "minor" problems, particularly spotting and breakthrough bleeding, account for approximately 40% of the discontinuations. Approximately 10–20% of women experience intermenstrual bleeding, including breakthrough bleeding and spotting, in the first few months of use. With today's formulations, such problems stabilize after approximately 6 months and are seen in only approximately 5% of users. Missed menstrual periods or amenorrhea are relatively infrequent and of little clinical significance, except that these problems can raise concern as regarding contraceptive failure. Nausea may be seen in up to 10% of users; as with intermenstrual bleeding, this is a duration effect that declines rapidly after several months of use. Significant headaches and weight gain are far less frequent than reported with higher-dose preparations.

Contraindications for use of oral contraceptives include pregnancy; undiagnosed vaginal bleeding; prior history of VTE, MI, or stroke; women at increased risk for cardiovascular sequelae, such as active systemic lupus erythematosus, uncontrolled diabetes, or hypertension, and cigarette smokers over age 35 years; current or prior breast cancer; and active liver disease.

Because compliance and a clear understanding of how to take oral contraceptives are important to their successful use, health care providers should take the time at the initial visit to explain the packaging of the brand being prescribed, discuss the side effects, review how to start the first cycle, and discuss what to do when pills are missed. It should be emphasized that the patient package insert provides useful information on these topics. In addition, users should be encouraged to contact their provider or someone in the office or clinic who is familiar with oral contraceptive health care if problems occur. Finally, users should be advised to use alternate forms of contraception if oral contraceptive use is interrupted because of forgotten pills or the occurrence of side effects.

Table 36–1 lists the currently available oral contraceptives and their contents.

	Estrogen (mg)	Progestin (mg)

Some of the above oral contraceptives are available as generic formulations. *Active pills take 24 out of 28 days

Progestin-Only Pill (Minipill)

Several studies have demonstrated that a small daily quantity of a progestin alone, usually norethindrone or levonorgestrel, provides reasonably good protection against pregnancy without suppressing ovulation. The method has several advantages: the side effects attributable to the estrogen component of conventional oral contraceptives are eliminated because no estrogen is given, and no special sequence of pill-taking is necessary because the pill is taken every day. Although the mechanism of action of progestin-only pills is not known, it has been postulated that the cervical mucus becomes less permeable to sperm and that endometrial activity goes out of phase so that nidation is thwarted even if fertilization does occur. In clinical trials, progestin-only oral contraceptives result in a pregnancy rate of approximately 2–7 pregnancies per 100 woman-years. Unlike combined oral contraceptives, which permit a certain margin of patient error and forgetfulness, minipill progestin agents must be taken each day promptly. Even a delay of 2–3 hours diminishes the contraceptive effectiveness for the following 48 hours. Progestins given alone are associated with side effects, particularly irregular bleeding. Progestin-only contraceptives are ideal for women for whom estrogen is contraindicated. Ideal candidates include older women who smoke; women with sickle cell anemia, mental retardation, migraine headache, hypertension, or systemic lupus erythematosus; or women who are breastfeeding.

Emergency Contraception

Postcoital or emergency contraception is a therapy used to prevent unwanted pregnancy after unprotected intercourse or after a failure to use a contraceptive method appropriately. The major methods used for emergency contraception include combination oral contraceptives containing the progestin levonorgestrel (also known as the Yuzpe method), levonorgestrel tablets given alone, or the copper T 380A intrauterine contraceptive device. The hormonal methods prevent pregnancy by delaying or inhibiting ovulation or by disrupting the function of the corpus luteum. The usual combination hormonal formulation consists of 100 µg ethinyl estradiol and 500–600 µg levonorgestrel in several tablets administered twice, 12 hours apart. Under current recommendations, the first dose is administered within 72 hours of intercourse. The levonorgestrel-alone formulation requires administration of 750 µg of the progestin twice, also 12 hours apart. Many authorities currently recommend initial dosing within 72 hours although data suggest this approach may be effective as long as 5 days after intercourse. Furthermore, data suggest that a single dose of 1500 µg levonorgestrel may be as effective as the 2-dose regimen. The intrauterine device may inhibit implantation or possibly interfere with sperm function. The T 380A is inserted within 7 days from the time of unprotected intercourse.

Nausea occurs in approximately 50% and vomiting in 20% of the combination hormonal emergency contraceptive users. Administration of an antiemetic (eg, meclizine) 1 hour before may reduce this effect. The levonorgestrel-alone approach is associated with rates of nausea and vomiting that are 50% and 70% lower than the rates experienced by combination emergency contraception users, respectively.

HORMONAL CONTRACEPTION BY INJECTION

Depot medroxyprogesterone acetate (DMPA), an aqueous suspension of 17-acetoxy-6-methyl progesterone, has been used as a contraceptive in the United States for at least 4 decades. The usual dose is 150 mg administered intramuscularly into the gluteus maximus or deltoid every 3 months. The mechanisms of action include suppression of ovulation by suppressing the surge of gonadotropins, thickening cervical mucus to impede ascent of sperm, and thinning of the endometrium such that implantation of a blastocyst is less likely. Although labeled as effective for up to 13 weeks, the contraceptive activity actually persists for approximately 4 months after an injection, allowing some leeway for providers to schedule follow-up injections. During 1 year of use, the perfect use failure rate is 0.1 pregnancies per 100 woman-years, whereas the failure rate with typical use is 3 pregnancies per 100 woman-years.

Use of DMPA is associated with several health benefits. The risk of ectopic pregnancy is significantly lower among users compared to women who do not use contraception. The risk of endometrial cancer is reduced by as much

80%, an effect that is long term and increases with duration of use. Studies have shown as much as a 70% reduction in the frequency of sickle cell crises; the mechanism for this effect is not known. Some women with endometriosis have improvement of symptoms with use of DMPA.

Use of DMPA does not increase the risk for arterial or venous disease. The most significant potential risk associated with DMPA use is a reduction in bone mineral density. Overall, prospective studies of at least 1 year's duration have shown a maximum reduction of 1.5–2.3% in bone mineral density. No studies have shown any increase in fracture risk. Finally, retrospective studies have shown improvement in bone mineral density when DMPA was discontinued. Until further data become available, adequate calcium intake should be encouraged for DMPA users, particularly young patients and longer-term users. Irregular bleeding and prolonged menstrual flow are not uncommon during the first 6 months of use. However, with continued use, many women become amenorrheic, and up to 70% of users experience no menses after 1 year. Mood change and depression have been reported in association with DMPA use. However, most studies are uncontrolled. Although earlier studies suggested DMPA users gained an average of 5 kg after 1 year of use, a recent randomized clinical trial demonstrated that DMPA was not associated with significant weight gain or changes in variables that might lead to weight gain. Finally, when DMPA users stop injections in an effort to achieve pregnancy, the return to baseline fertility may take an average of 10 months.

Implants

Although no implantable contraceptives currently are available in the United States, clinical trials of a single rod implant 4 cm long and 2 mm in diameter have been completed. This system releases etonogestrel, the major metabolite of desogestrel, and maintains its efficacy for up to 3 years. The rod usually is inserted in the upper arm using a trocar. Removal is easier than with other implants because it is a single rod system. The likely mechanism of action is similar to that of DMPA. Overall efficacy is extremely high, with no reported pregnancies in more than 70,000 cycles of use. No major complications have been reported to date. Side effects include menstrual abnormalities and weight gain.

Vaginal Ring

The vaginal ring is approximately 5 cm in diameter and 4 mm thick. The ring is flexible. It releases ethinyl estradiol and etonogestrel at fairly constant rates. The ring is worn for 3 weeks per month, although the ring's reservoir contains enough contraceptive steroid for approximately 14 more days. The ring maintains its efficacy even if it is removed for up to 3 hours, although it is designed to be left in place even during intercourse. Users are instructed to insert the ring high into the vagina; fitting by a health professional is not required. The overall pregnancy rate over 1 year of use is 0.65 pregnancies per 100 woman-years.

No published data indicate the rates of major side effects or potential noncontraceptive benefits. However, because the vaginal ring contains steroids that are used in combination oral contraceptives, rates of serious side effects may be similar, and some of the noncontraceptive benefits may accrue to users of this method. Minor side effects are similar to those seen in users of combination oral contraceptives, although the frequency of breakthrough bleeding and spotting appears lower. Approximately 10–15% of users report vaginal-related symptoms, such as slight discomfort, a sensation of a foreign body, leukorrhea, vaginitis, or coital problems.

Transdermal Patch

The transdermal contraceptive patch is 20 cm², roughly the size of a small adhesive-back (Post-It) pad consisting of 3 layers. The transdermal contraceptive patch is designed to deliver norelgestromin, the active metabolite of norgestimate, and ethinyl estradiol daily for a 7-day period. After 7 days, the patch is removed and a new patch is applied to another skin site. Three consecutive 7-day patches are applied in a typical cycle, followed by a 7-day patch-free period to allow withdrawal bleeding. Application sites include the buttocks, lower abdomen, upper outer arm, and upper torso except for the breasts. Because this is a combination steroid preparation, the same contraindications noted for combination oral contraceptives use apply.

The transdermal contraceptive patch has a method use rate of 0.70 and a typical use rate of 0.88 pregnancies per 100 woman-years. These rates are comparable to pregnancy rates achieved with current oral contraceptives. However, a failure rate approaching the typical use failure rate seen with combination oral contraceptive users was noted for women weighing over 198 pounds who used the patch.

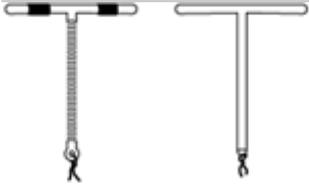

Although few reports have documented the rates of serious adverse events, one should assume that the events risks will be similar to those noted for combination oral contraceptives. To date, one published study has indicated that the risk of venous thromboembolism is similar to that of an oral contraceptive. Similarly, no data on noncontraceptive benefits are available. The frequency of side effects such as headache and nausea are similar to that seen among users of combination oral contraceptives, although contraceptive patch users have application site reactions, more breast symptoms (only during the first 2 cycles), and more dysmenorrhea than combination oral contraceptive users. The pattern of breakthrough bleeding and spotting with the transdermal contraceptive patch is similar to that seen with oral contraceptive users. No evidence indicates that use of the patch influences body weight. Among users, 1.8% of women required replacement for complete detachment and 2.9% became partially detached. Detachment rates were similar for women living in warm, humid climates and for women who were subjected to vigorous exercise, swimming, and sauna use compared to other users. When patches do become detached, users should attempt to reattach them if possible, without using ancillary adhesives or tape. If detachment has occurred for 24 hours or less, the cycle continues as usual, with the patch changed on the previously determined change day. If detachment has occurred for more than 24 hours, a new patch should be applied, backup contraception should be used for 1 week, and the day that the new patch is applied now becomes the patch change day.

INTRAUTERINE CONTRACEPTIVE DEVICES

Two types of IUDs are available in the United States: the copper T 380A device and a levonorgestrel-releasing device (Fig 36–3). The T 380A is a T-shaped device approximately 36 mm in length and 32 mm in diameter that contains 380 mm² of copper on its vertical and side arms. Two monofilament strings are attached to the vertical arm to ascertain placement in the uterus over the course of use. This IUD has a useful lifespan of at least 10 years. The exact mechanism of action is unknown, although current theories include spermicidal activity, interference with either normal development of ova or the fertilization of ova, and activity on the endometrium that may promote phagocytosis of sperm and which may impede sperm migration or capacitance. No data support this or other IUDs as abortifacients. The perfect use failure rate with the T 380A is 0.6 pregnancies per 100 woman-years and approximately 0.8 for typical use. In the past, IUDs were associated with an increased risk for PID around the time of insertion. However, by restricting use to mutually monogamous couples and couples currently at low risk of STIs, the absolute risk of PID in association with IUD use is almost negligible. PID appears to be associated primarily with the insertion of the device (Fig 36–4) and not with its duration of use. Currently, with appropriately selected use, the rate of PID is approximately 1 case per 1000 insertions. Women at risk for HIV infection or who are already infected are not believed to be candidates for use of this device. Other ideal candidates are women in whom combination hormonal contraception is contraindicated. The other major risks reported in association with use of this IUD include ectopic pregnancy, spontaneous abortion, uterine perforation, and expulsion. Although 5–8% of pregnancies that occur with use of this IUD are ectopic, overall, because of the high effectiveness of this device, absolute risk of ectopic pregnancy in users is substantially less than that experienced by nonusers of contraceptives. In addition, if a user becomes pregnant with the device in place, the risk of a spontaneous abortion is approximately 50%. Removing the device when the strings can be readily identified will reduce this risk by approximately 50%. If the pregnancy continues with the IUD in place, users should be apprised of an increased risk for premature rupture of the membranes and preterm delivery. Uterine perforation, which occurs at the time of insertion, has been reported at a rate of 1–2 events per 1000 insertions. This risk is minimized by performing a preinsertion pelvic examination to determine the position of the uterus and by using a tenaculum to straighten the uterine axis during insertion. Expulsions of the device are more common in the first few weeks of use, with rates of approximately 5

Minor side effects include abnormal bleeding and cramping. Use of nonsteroidal anti-inflammatory drugs often w reduce the overall amount of flow as well as reduce cramping.

Insertion of the ParaGard T 380A intrauterine copper contraceptive device.

The levonorgestrel-releasing intrauterine device (LNG-20 IUD) has a T-shaped frame with a reservoir on the vertical arm that releases the progestin levonorgestrel daily. Two monofilament strings are attached to the vertical arm. Blood levels of levonorgestrel among users are approximately 25% the levels seen among users of oral contraceptives containing this progestin. In contrast to the copper T 380A device, the LNG-20 IUD has a life span of 5 years in clinical trials. The primary mechanisms of action of the LNG-20 IUD are thickening the cervical mucus to impede ascent of sperm and altering the uterine fluid to also interfere with sperm migration. This IUD causes anovulation in approximately 10–15% of cycles and changes the characteristics of the endometrium to reduce the likelihood of implantation. Candidates for use of this IUD fit the same profile as those who would consider use of the T 380A. The perfect and typical use pregnancy rates are 0.1 pregnancies per 100 woman-years after 1 year of use and the cumulative pregnancy rate over 5 years is 0.7 pregnancies per 100 woman-years. Approximately 50% of the pregnancies that occur are ectopic. However, as with the T 380A device, the absolute risk of ectopic pregnancy still is substantially lower than that experienced by nonusers of contraception. Because the LNG-20 IUD releases potent progestin at the endometrial level, the bleeding pattern is substantially different from that seen with the T 380A. During the initial 3–4 months of use, some women experience irregular bleeding that may be heavy at times. However, after a few months of use, most women experience a significant decrease in menstrual flow by as much as 70%. In some studies, 20–25% of users become amenorrheic in the second year of use. In addition, dysmenorrhea tends to improve with use of this device. Because of the effectiveness of the LNG-20 IUD in reducing menstrual blood flow, it has been used for treatment of menorrhagia, a significant noncontraceptive benefit. Major risks with this IUD are similar to those noted for the copper T 380A, except that PID has not been associated with use of this device. The minor side effects of bleeding and cramping are less frequent with this device, except for irregular bleeding patterns during the first few months of use. Some women have reported headache, acne, or mastalgia, which could be related to the systemic effects of the progestin.

A not infrequent issue with IUD use is the management of missing strings. First, the patient should be encouraged to use a backup contraceptive method until she is evaluated. If the IUD strings cannot be seen even with gentle probing of the endocervical canal, one should perform a pregnancy test if indicated and consider ordering a transvaginal ultrasound to determine if the IUD is intrauterine, intraperitoneal, or likely has undergone expulsion. If the patient is pregnant, an ectopic pregnancy must be excluded. If the IUD is determined to be intraperitoneal in location, removal usually is indicated because of likely peritoneal irritation by the device.

INDUCED ABORTION

Induced abortion is the deliberate termination of pregnancy in a manner that ensures that the embryo or fetus will not survive. Societal attitudes toward elective abortion have changed markedly in the past few decades. In some situations the need for abortion is accepted by most people, but political and medical attitudes regarding induced abortion have continued to lag behind changing attitudes. Certain religious objections continue to prevail, resulting in personal, medical, and political conflicts.

Approximately one-third of the world's population lives in nations with nonrestrictive laws governing abortion. Another third live in countries with moderately restrictive abortion laws, ie, in countries where unwanted pregnancies may not be terminated as a matter of right or personal decision but only on broadly interpreted medical, psychologic, and sociologic indications. The remainder live in countries where abortion is illegal without qualification or is allowed only when the woman's life or health would be severely threatened if the pregnancy were allowed to continue.

An estimated 1 of every 4 pregnancies in the world is terminated by induced abortion, making it perhaps the most common method of reproduction limitation. In the United States, estimates of the number of criminal abortions performed prior to legalization of the procedure ranged from 0.25–1.25 million per year. The number of legal

abortions now being performed in the United States approximates 1 abortion per 4 live births. In 1997, there were 1.33 million induced abortions compared to 3.88 million live births.

The procedures being used in the United States for legally induced abortions during the first trimester are relatively safe. Table 36–2 shows that first-trimester legal abortions are consistently safer for the woman than if she used a birth control method and gave birth. Table 36–2 also shows that although the number of maternal deaths related to births steadily increased from 5.6 to 22.6 per 100,000 women as age increased, the age-related increase in the number of deaths per 100,000 women per year from legal abortions was insignificant.

Weeks of Gestation	Deaths per 100,000 Procedures
--------------------	-------------------------------

Adapted from Tyler CW Jr: In: *Abortion Surveillance, 1975*. Center for Disease Control, United States Department of Health, Education, and Welfare Annual Summary 1975, April 1977, p. 36.

Paracervical anesthesia has replaced general anesthesia in many health settings, resulting in fewer complications related to anesthesia. Midtrimester abortion techniques still are problematic and are associated with a higher mortality rate. Hysterectomy carries a far greater risk than does induction of labor by amnioinfusion or dilatation and evacuation.

Legal Aspects of Induced Abortion in the United States

The United States Supreme Court ruled in 1973 that the restrictive abortion laws in the United States were invalid largely because these laws invaded the individual's right to privacy, and that an abortion could not be denied to a woman in the first 3 months of pregnancy. The Court indicated that after 3 months a state may "regulate the abortion procedure in ways that are reasonably related to maternal health" and that after the fetus reaches the stage of viability (approximately 24 weeks) the states may refuse the right to terminate the pregnancy except when necessary for the preservation of the life or health of the mother. Still, much opposition is raised by various "right-to-life" groups and religious groups. In spite of this opposition, more than 1 million procedures are still performed annually in the United States, with approximately one-third performed on teenaged women. This dramatically emphasizes the inadequacy of sex education and the need for greater availability of adequate contraceptive methods in order to avoid such pregnancy wastage.

The patient must be informed regarding the nature of the procedure and its risks, including possible infertility or even continuation of pregnancy. The rights of the spouse, parents, or guardian also must be considered and permission obtained when indicated (until the individual woman's rights are clearly established). State laws must be obeyed with special reference to residence, duration of pregnancy, indications for abortion, consent, and consultations required.

Evaluation of Patients Requesting Induced Abortion

Patients give varied reasons for requesting abortion. Because in some cases the request is made at the urging of a woman's parents, in-laws, husband, or peers, every effort should be made to ascertain that the patient herself desires abortion for her own reasons. In addition, one should be certain that the patient knows she is free to choose from among other methods of solving the problem of unplanned pregnancy, such as adoption or single-parent rearing.

Although the majority of abortions are performed as elective procedures, ie, because of social or economic reasons as opposed to medical reasons, some women still request such services for medical or surgical indications. For example, continuation of pregnancy may pose a threat to the life of women with certain medical conditions, such as Eisenmenger's syndrome and cystic fibrosis. Other indications are pregnancy resulting from a rape or pregnancy with a fetus affected with a major disorder, such as trisomy 13. In any event, the ultimate decision rests with the pregnant woman. Help from social agencies should be made available as necessary. A complete social history, medical history, and physical examination are required. Particular attention must be given to uterine size and position; the importance of accurate calculation of the duration of pregnancy (within 2 weeks but preferably within 1 week) cannot be overstated. With uncertainty, pelvic sonography should be used liberally. Routine laboratory tests should include pregnancy tests, urinalysis, hematocrit level, Rh typing, serologic tests for syphilis, culture for gonorrhea, and Pap smear.

Methods of Induced Abortion

Numerous methods are used to induce an abortion: suction or surgical curettage; induction of labor by means of

intraovular or extraovular injection of a hypertonic solution or other oxytocic agent; dilatation and evacuation; extraovular placement of devices such as catheters, bougies, or bags; hysterotomy—abdominal or vaginal; hysterectomy—abdominal or vaginal; and menstrual regulation.

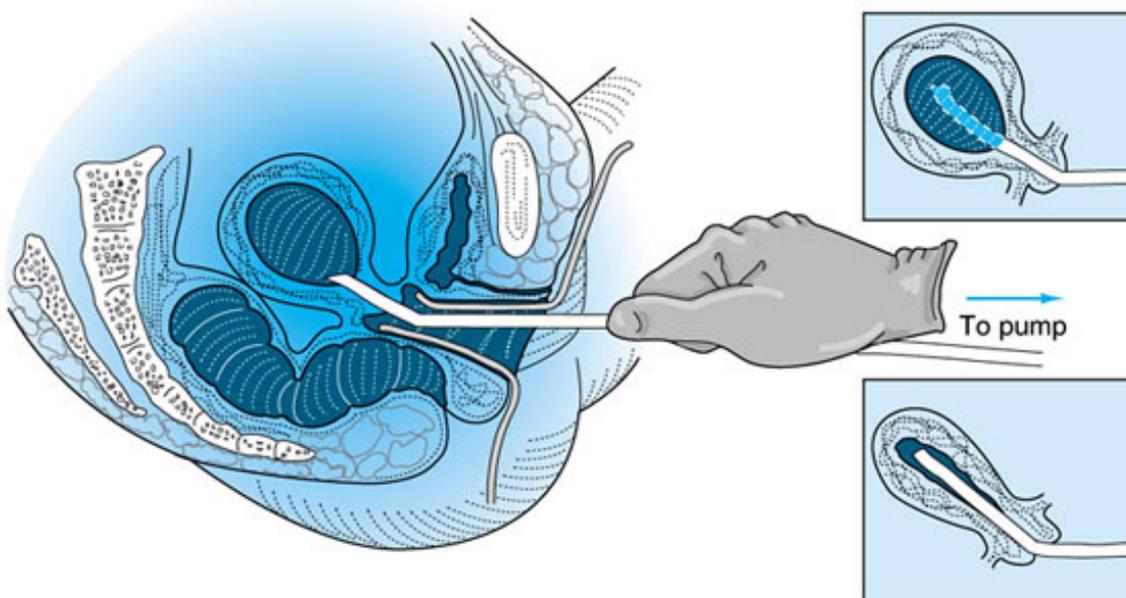

The method of abortion used is determined primarily by the duration of pregnancy, with consideration for the patient's health, the experience of the physician, and the available physical facilities.

Suction curettage on an outpatient basis performed under local or light general anesthesia can be accomplished a high degree of safety. The safety of outpatient abortion and the shortage of hospital beds have led to the development of single-function, "freestanding" abortion clinics. In addition to providing more efficient counseling and social services, these clinics have effectively reduced the cost of abortion. Many hospitals have "short-stay units," which match the efficiency of outpatient clinics but also offer the backup facilities of the general hospital.

SUCTION CURETTAGE

Suction curettage is the safest and most effective method for terminating pregnancies of 12 weeks' duration or less. This technique has gained rapid worldwide acceptance, and over 90% of induced abortions in the United States are now performed by this method. The procedure involves dilatation of the cervix by instruments or by hydrophilic *Laminaria* tent (see Induction of Labor by Intra-amniotic Instillation), followed by insertion of a suction cannula of the appropriate diameter into the uterine cavity (Fig 36–5). Most procedures are performed using a paracervical block with local anesthesia with or without additional medication for sedation. Standard negative pressures used range from 30–50 mm Hg. Many physicians follow aspiration with light instrumental curettage of the uterine cavity.

Figure 36–5.

Suction method for induced abortion.

The advantages of suction over surgical curettage are that suction curettage empties the uterus more rapidly, minimizes blood loss, and reduces the likelihood of perforation of the uterus. However, failure to recognize perforation of the uterus with a cannula may result in serious damage to other organs. Knowledge of the size and position of the uterus and the volume of the contents is mandatory for safe suction curettage. Moreover, extreme care and slow minimal dilatation of the cervix, with special consideration for the integrity of the internal os, should prevent injury to the cervix or uterus. Attention to the decrease in uterine size that occurs with rapid evacuation

helps to avoid uterine injury.

When performed in early pregnancy by properly trained physicians, suction curettage should be associated with very low failure rate. The complication rate should be less than 1% for infection, approximately 2% for excessive bleeding, and less than 1% for uterine perforation. The risk of major complications, such as persistent fever, hemorrhage requiring transfusion, and unintended major surgery, ranges between 0.2% and 0.6% and is proportional to pregnancy duration. The incidence of mortality for suction curettage is approximately 1 in 100,000 patients.

SURGICAL CURETTAGE

Surgical ("sharp") curettage has been used for first-trimester abortion in the absence of suction curettage equipment. This procedure is performed as a standard dilatation and curettage, such as for the diagnosis of abnormal uterine bleeding or for the removal of endometrial polyps. The blood loss, duration of surgery, and likelihood of damage to the cervix or uterus are greatly increased when surgical curettage is used. In addition, the risk of uterine synechiae or Asherman's syndrome is increased with this approach. Accordingly, suction curettage is generally preferred over sharp curettage for first-trimester termination procedures.

MEDICAL ABORTION WITH METHOTREXATE AND MISOPROSTOL

Women with first-trimester pregnancies less than 49 days from their first day of the last menstrual period may be eligible for medical abortion. An alternative method of medical abortion consists of the administration of an oral antiprogesterin (RU-486[mifepristone]) followed by oral misoprostol 48 hours later. The reported success rate of this method is greater than 90%, provided the protocol is started prior to 7 weeks from the last menstrual period. Complications include cramping, bleeding due to incomplete abortion, and failure to evacuate the uterus necessitating completion by suction curettage. With one of the more common protocols, 50 mg methotrexate is administered orally, followed by 800 mg misoprostol per vagina (by the patient at home) 3–7 days later using the same tablets as those used for oral dosing. The patient is seen at least 24 hours after the misoprostol administration; a vaginal ultrasound is performed to determine if there has been passage of the gestational sac. If abortion has not occurred, the misoprostol dose is repeated. The patient is then followed-up in 4 weeks; if abortion has not occurred by this time, a suction curettage is typically performed. If fetal cardiac activity is noted on ultrasound, office follow-up is more frequent. Efficacy with this method is up to 98% for pregnancies up to 49 days of gestation; complete abortion rates are inversely proportional to duration of gestation. Nausea is the most frequently reported side effect. Contraindications include active liver disease, active renal disease, severe anemia, acute inflammatory bowel disease and coagulopathy, or anticoagulant therapy.

INDUCTION OF LABOR BY INTRA-AMNIOTIC INSTILLATION

The Japanese developed this technique for induced abortion after the first trimester. Currently, the technique is used almost exclusively for initiating midtrimester abortion. The original procedure consisted of amniocentesis, aspiration of as much fluid as possible, and instillation into the amniotic sac of 200 mL hypertonic (20%) sodium chloride solution. In most (80–90%) cases, spontaneous labor and expulsion of the fetus and placenta occur within 48 hours. This technique has been modified, primarily to reduce the injection–abortion interval, and as a result of the development of other agents that initiate labor when instilled intra-amniotically.

Because of the problems associated with hypertonic sodium chloride, many clinicians have used intra-amniotic hyperosmolar (59.7%) urea, usually with oxytocin or prostaglandin or intra-amniotic prostaglandin alone. These approaches result in injection–abortion intervals of 16–17 hours for urea and 19–22 hours for prostaglandin. The urea is instilled in a fashion similar to that described for hypertonic sodium chloride. The prostaglandin, most frequently prostaglandin F_{2α} (PGF_{2α}), usually is instilled as a single dose of 40–50 mg or as 2 doses of 25 mg instilled 6 hours apart. When oxytocin is used to augment these agents, doses as high as 332 mU/min are required to produce uterine contractions because of the relative insensitivity of the myometrium to oxytocin at this stage of pregnancy. To avoid water intoxication, the oxytocin is made up in highly concentrated solutions and given at slow

rates.

It is advantageous to soften the unripe cervix with *Laminaria* tents placed in the cervix a few hours before amniocentesis is performed. Such an approach markedly reduces the risk of cervical injury.

Midtrimester abortion induced by this method must be accomplished with scrupulous aseptic surgical technique, the patient must be monitored until the fetus and placenta are delivered and postabortion bleeding is under control. The complication rate is high—up to 20% in some institutions—and the mortality rate is comparable to that of term parturition. Fortunately, because first-trimester abortion is now more readily available, more women are consulting their physicians early and thus availing themselves of the much safer suction curettage.

Several types of complications are associated with the use of instillation agents. Retained placenta is the most common problem; rates ranging from 13–46% have been reported. The placenta usually can be removed without difficulty using ring forceps and large curettes with the patient under local anesthesia. Hemorrhage may be caused by retained products or atony; coagulopathy is seen in up to 1% of patients in whom hypertonic sodium chloride is used. Infection can occur but is reduced significantly by use of prophylactic antibiotics in high-risk situations, e.g., patients with early ruptured membranes and during injection–abortion intervals greater than 24 hours. Cervical laceration can occur but is reduced by the use of *Laminaria* tents. Hyponatremia can occur with the use of hypertonic sodium chloride if the drug is absorbed rapidly by the placental bed or if it is given intravascularly by mistake.

Failure of labor to expel the products of conception necessitates either a repetition of the procedure if the membranes are still intact or oxytocin stimulation, usually by intravenous injection or use of the dilatation and evacuation technique.

Emotional stress is an important factor for many women because they are awake at the time of the expulsion of fetus and the fetus is well formed. (The emotional stress is also a factor for hospital personnel—a problem impossible to avoid.)

INDUCTION OF LABOR WITH VAGINAL PROSTAGLANDINS

Prostaglandin E₂ given intravaginally can be used to induce midtrimester abortion. Vaginal suppositories containing 20 mg are used every 3–4 hours until abortion occurs; the presence or absence of labor determines whether the prostaglandin E₂ should be stopped. Misoprostol, a synthetic prostaglandin E₁ analogue, is also used.

Treatment–abortion intervals, rates of incomplete abortion, and complications are similar to those described for instillation agents. The major disadvantages are significant gastrointestinal side effects, a higher incidence of live abortion, and a more frequent occurrence of fever.

DILATATION AND EVACUATION

This technique for inducing midtrimester abortion is essentially a modification of suction curettage. Because fetal parts are larger at this stage of pregnancy, most operators use serial placement of *Laminaria* tents to effect cervical dilatation with less likelihood of injury. Larger suction cannulas and specially designed forceps are used to extract tissue. In most instances, the operation can be performed in the outpatient setting using paracervical block anesthesia and intravenous sedation on patients with pregnancies up to 18 weeks' gestation. Complications include hemorrhage (usually due to atony or laceration), perforation, and rarely infection. Retained tissue is uncommon, especially when tissue is carefully inspected for completion at the end of each procedure. Compared with instillation techniques or vaginal prostaglandin, the overall incidence of complications (in pregnancies up to 18 weeks' gestation) is less with dilatation and evacuation. In addition, most patients prefer the technique because it is an outpatient procedure and the woman does not undergo labor.

HYSTEROTOMY AND HYSTERECTOMY

The use of hysterotomy and hysterectomy is currently reserved for special circumstances such as the failure to complete a midtrimester abortion due to cervical stenosis or the management of other complications. Both

approaches, compared with other techniques discussed, have unacceptably high rates of morbidity and mortality and neither should be used as a primary method.

MENSTRUAL REGULATION

Menstrual regulation consists of aspiration of the endometrium within 14 days after a missed menstrual cycle or within 42 days after the beginning of the last menstrual period by means of a small cannula attached to a source of low-pressure suction, such as a syringe or other suction machine. This is a simple and safe procedure that can be readily performed in the office or outpatient clinic, usually without any anesthetic, although paracervical block can be used if necessary. Menstrual regulation was used extensively in the 1970s and 1980s before reliable, inexpensive, and sensitive urine pregnancy tests became available. It offered a safe early approach to pregnancy termination; however, approximately 40% of women were not pregnant at the time of the procedure. With the advent of urine pregnancy tests that have the ability to document pregnancy even before a missed menstrual period, standard first-trimester suction curettage probably is more widely used. Complications are similar to those described for suction curettage except that persistent pregnancy is more common, particularly when very early menstrual regulation procedures are performed.

RU-486

RU-486 (mifepristone) is a synthetic drug, developed by French pharmacologists, that acts at least partially as an antiprogesterone agent. When given orally in conjunction with a prostaglandin such as misoprostol, it effects first-trimester abortion. Complications include failure to terminate a pregnancy, incomplete abortion, and significant uterine cramping.

Follow-Up of Patients after Induced Abortion

Follow-up care after all procedures must be ensured. After abortion by all methods, human Rho (D) immune globulin (RhoGAM) should be administered promptly if the patient is Rh-negative, unless the male partner is known to be Rh-negative. The patient should take her temperature several times daily and report fever or unusual bleeding at once. She should avoid intercourse or the use of tampons or douches for at least 2 weeks. The physician should discuss with the patient the possibility that emotional depression, similar to that following term pregnancy and delivery, may occur after induced abortion. Follow-up care should include pelvic examination to rule out endometritis and parametritis, salpingitis, failure of involution, or continued uterine growth. Finally, effective contraception should be made available according to the patient's needs and desires.

Long-Term Sequelae of Induced Abortion

Many studies during the past 2 decades have examined the possible long-term sequelae of elective induced abortion. Most of the attention has focused on subsequent reproductive function; unfortunately, many of the studies had inherent biases and serious methodologic flaws. Despite these problems, enough information is available to provide relative estimates of potential risks. Data from some studies suggest that midtrimester pregnancy loss is more common in women who have undergone 2 or more induced or spontaneous abortions. However, women who have undergone 1 procedure have essentially the same risk as women who have experienced a single term pregnancy. Regarding low birthweight, only women who have undergone a first-trimester procedure by sharp curettage under general anesthesia appear to have increased risks. The reason for this association might be related to the method of dilatation used. Finally, studies that have examined both ectopic pregnancy and infertility have failed to show any consistent association between these adverse events and prior induced abortion.

Current OB/GYN >Chapter 37. Benign Disorders of the Vulva & Vagina>

BENIGN DISORDERS OF THE VULVA & VAGINA: INTRODUCTION

Benign vulvar and vaginal disorders are common gynecologic conditions. These disorders may present with significant clinical symptoms or may be asymptomatic and noted only during routine examination. A thorough understanding of vulvar and vaginal pathophysiology is of clinical importance in diagnosing and treating these disorders. This chapter reviews the predisposing factors that contribute to the development of these disorders as well as the evaluation, diagnosis, and treatment of the different benign vulvovaginal disorders. The premalignant and invasive vulvar and vaginal disorders are discussed in Chapter 49.

ANATOMY & PHYSIOLOGY

The anatomy of the vagina and vulva is described in Chapter 2. The development of vulvar and vaginal disorders is influenced in part by the presence or absence of endogenous and exogenous estrogen. Estrogen thickens the vaginal epithelium and results in the presence of large quantities of glycogen in the epithelial cells. The collection of intraepithelial glycogen results in the production of lactic acid. This acid environment (pH 3.5–4.0) promotes the growth of normal vaginal flora, chiefly lactobacilli and acidogenic corynebacteria. *Candida* organisms may be present, but only in small quantities, because of the preponderance of the bacteria. The absence of endogenous estrogen in prepubertal girls results in a thin vaginal epithelium, which predisposes this age group most commonly to bacterial infections. In postmenopausal women, endogenous estrogen production declines, the cell of the vaginal epithelium and vulvar skin lose glycogen, and the vaginal acidity declines. The resulting atrophic vaginal and vulvar tissue is prone to trauma and infection, and the lactobacilli are replaced by a mixed flora consisting chiefly of pathogenic cocci. Vulvar irritation also occurs with urinary and fecal soiling, which can be an underlying factor in this age group.

EVALUATION

Evaluation of a patient with vulvar and/or vaginal symptoms requires a detailed history and physical examination including inspection of other mucosal and skin surfaces. Specific questions regarding symptoms of vulvar or vaginal pain, itching, discharge, and previous infections should be elicited. Sexual activity, the use of feminine hygiene products (douching, soaps, perfumes), and medications (oral contraceptive pills, antibiotics) can alter the normal vaginal flora. Any underlying medical conditions, such as diabetes, can impact the development of certain vulvovaginal disorders. Overlying garments made of synthetic fabrics that retain heat and moisture can exacerbate vulvovaginal symptoms.

The first symptom of vaginal irritation is often vulvar pruritus, which often results from contact with vaginal discharge. Any variance from the normal, physiologic milky vaginal discharge should be noted. Before menarche a scant vaginal discharge occurs that normally does not cause irritation and is not considered abnormal. Inspection in the adolescent girl may reveal a small amount of white mucoid material in the vaginal vault that is the result of normal desquamation and accumulation of vaginal epithelial cells. The most common cause of leukorrhea (vaginal discharge) is a vaginal infection. The presence or absence of odor, pruritus, and the color can help determine the etiology.

A vaginal discharge is considered abnormal by the patient if there is an increase in the volume (especially if there is soiling of the clothing), an objectionable odor, or a change in consistency or color. Specific characteristics depend on the cause (Table 37–1). Secondary irritation of the vulvar skin may be minimal or extensive, causing pruritus or dyspareunia. Ideally, evaluation should occur after the onset of symptoms if the patient is not menstruating. She should be instructed not to douche. After the clinical history is obtained, the vulva, vagina, and cervix should be thoroughly inspected (Table 37–2). The pH of the vaginal secretions in the speculum blade should be determined, and a small amount of secretion should be placed on each of 2 glass slides. One slide should be treated with 10% room-temperature potassium hydroxide (KOH) and the other diluted with room-temperature normal saline. A transient "fishy odor" after KOH application is characteristic of bacterial vaginosis, the "sniff test" or "whiff test." White blood cells and epithelial cells are digested by the KOH; therefore, the candidal pseudohyphae and spores are easier to detect (Figs 37–1 and 37–2). Motile trichomonads may be detected under low power on the saline-diluted slide (Fig 37–3). Bacterial vaginosis is diagnosed by the presence of "clue cells," which are epithelial cells that have bacteria attached to their cell membranes (Fig 37–4). The relative number of white blood cells and the maturity of the epithelial cells should be determined. Patients with vaginitis or cervicitis show many white blood cells, and the presence of intermediate or basal cells indicates inflammation of the vaginal epithelium. Selective cultures may be performed for trichomoniasis, bacterial infection, and candidiasis.

VAGINAL DISORDERS

Candidiasis

It is estimated that approximately 75% of women will experience an episode of vulvovaginal candidiasis. *Candida albicans* is the most common *Candida* species causing symptomatic candidiasis in approximately 90% of cases (Table 37–3). *C. albicans* frequently inhabits the mouth, throat, large intestine, and vagina normally. Clinical infection may be associated with a systemic disorder (diabetes mellitus, human immunodeficiency virus [HIV], obesity), pregnancy, medication (antibiotics, corticosteroids, oral contraceptives), and chronic debilitation.

Parasitic

Noninfectious

Atrophic vaginitis

Allergic vaginitis

Foreign body

Desquamative inflammatory vaginitis (steroid responsive)

Collagen vascular disease, Behet's syndrome, pemphigus syndromes

Vulvovaginal candidiasis presents with intense vulvar pruritus; a white curdlike, cheesy vaginal discharge; and vulvar erythema. A burning sensation may follow urination, particularly if there is excoriation of the skin from scratching. Widespread involvement of the skin adjacent to the labia may suggest an underlying systemic illness such as diabetes. The labia minora may be erythematous, excoriated, and edematous. The ubiquitous nature of the organism allows for repeated infections that may be interpreted as a recurrent vulvovaginal candidiasis. Diagnosis is based on demonstration of candidal mycelia and a normal vaginal pH \leq 4.5. Identification of *C. albicans* requires finding filamentous forms (pseudohyphae) of the organism (Fig 37–2) when vaginal secretions are mixed with 10% KOH solution. The gold standard for its diagnosis is a vaginal culture.

Treatment is reserved for symptomatic patients (Table 37–4). Underlying metabolic illnesses (diabetes) should be well controlled, and complicating medications (antibiotics) should be discontinued if possible. Nonabsorbent undergarments should be avoided, as should douching. Treatment of yeast infections consists of 3 echelons. (1) Chemicals and dyes— 1% Gentian violet is an aniline dye that when painted over vaginal surfaces once per week is effective against *C. albicans* and *Candida glabrata*. Boric acid compounded in a suppository form is also

effective therapy for all candida infections. (2) Polyenes— Nystatin is not absorbed from the gastrointestinal tract and may be used orally to reduce the intestinal colonization. As topical agents, they have been largely replaced by imidazoles. (3) Imidazoles— Include clotrimazole and oral agents such as ketoconazole. They are mostly used as topical agents and are effective against *C albicans*. However resistant strains of *C glabrata* and *Candida tropicalis* are found with increasing frequency. Inclusion of a topical steroid (Mycolog [triamcinolone acetonide, nystatin], Lotrisone [betamethasone dipropionate, clotrimazole]) also may be beneficial in the patient who remains symptomatic to help decrease inflammation and relieve itching externally. A single 150-mg oral dose of fluconazole has been shown to be effective in treating symptomatic candidiasis in nonpregnant patients. With severe cases of vaginal candidiasis, a 2-dose sequential regimen has been proposed.

Table 37–4. Medications Used in the Treatment of Vulvovaginal Candidiasis.

Butoconazole 2% cream, 1 applicator vaginally, for 3–5 days

Clotrimazole 1% cream, 1 applicator (5 g) vaginally, for 7 days (14 days if chronic)

Clotrimazole 100-mg tablet, vaginally, for 7 days

Clotrimazole 100-mg tablets, 2 tablets vaginally, for 3 days

Clotrimazole 500-mg tablet, vaginally, for 1 dose

Miconazole 2% cream, 1 applicator vaginally, for 7 days

Miconazole 100-mg suppository, vaginally, for 7 days

Miconazole 200-mg suppository, vaginally, for 3 days

Tioconazole 2% cream, 1 applicator vaginally, for 3 days

Tioconazole 6.5% cream, 1 applicator vaginally, for 1 dose

Terconazole 0.4% cream, 1 applicator vaginally, for 7 days

Terconazole 0.8% cream, 1 applicator vaginally, for 3 days

Terconazole 80-mg suppository, vaginally, for 3 days

Boric acid 600-mg gelatin capsule, vaginally at night, for 2 weeks or nightly for 1 week then 2 times per week for 3 weeks

Ketoconazole 200 mg, orally 2 times per day for 5 days

Itraconazole 200 mg, orally 2 times per day for 1 day

Fluconazole 150-mg tablet, orally, for 1 day

During pregnancy, vulvovaginal candidiasis may be more difficult to eradicate. The azoles have not been well studied for use during the first trimester; therefore, treatment should be avoided until the second trimester, or a tablet of nystatin 100,000 units may be administered vaginally at night for 2 weeks during the first trimester.

Chronic or recurrent infections (≥ 4 infections per year) may occur in 5% of the population. Recurrent disease may result from insufficient duration of therapy, recontamination, and/or resistant strains. In evaluating the patient with recurrent vulvovaginal candidiasis, underlying predisposing disease processes should be ruled out. Additionally, cultures of the vagina should be obtained to identify possible resistant strains. High-dose estrogen or oral contraceptive use may precipitate infections and therefore should be discontinued. Treatment includes prolonging antifungal therapy for at least 2 weeks but preferably for 3 weeks to cover the life cycle of yeast, self-medication for 3–5 days at the first evidence of symptoms, and prophylactic treatment for several days prior to menstruation or during antibiotic therapy. Ketoconazole 100 mg orally each day for 6 months, fluconazole 150 mg weekly for 6 months, or itraconazole 100 mg orally daily for 6 months may reduce the frequency of recurrence to 10% during maintenance therapy. Unfortunately, within 6 months of discontinuation of prophylaxis, close to 57% of patients develop recurrences. Liver function tests should be monitored during prolonged oral therapy. Treatment of the partner may be considered in cases of symptomatic balanitis. Chronic or recurrent infections are secondary to *C tropicalis* or *C glabrata* may be resistant to topical imidazoles. In this case, ketoconazole or fluconazole should be given. Acidification of the vagina may also help.

Bacterial Infections

In the premenarcheal and postmenopausal hypoestrogenic vagina, a mixed bacterial flora may be expected, particularly in the presence of trauma or a foreign body. Specific diagnosis can be made through stained smears and cultures, although culture reports can be misleading in the presence of mixed flora. Bacterial vaginosis, previously referred to as *Gardnerella* vaginitis or nonspecific vaginitis, is the most common cause of symptomatic bacterial infection in reproductive-age women. In bacterial vaginosis the normal vaginal flora is altered. The concentration of the hydrogen peroxide-producing lactobacilli is decreased, and there is overgrowth of *Gardnerella vaginalis*, *Mobiluncus* spp., anaerobic gram-negative rods (*Prevotella* spp., *Porphyromonas* spp., *Bacteroides* spp.), and *Peptostreptococcus* spp. Other significant causes of bacterial infections are *Neisseria gonorrhoeae*, *Chlamydia*, *Mycoplasma hominis*, and *Ureaplasma urealyticum*.

In the hypoestrogenic vagina, bacterial infection may present as discharge and spotting. Inspection of the vagina will rule out a foreign body. Microscopic examination of the vaginal secretions is necessary to detect the more common causes of vaginitis and will demonstrate intermediate and parabasal epithelial cells.

BACTERIAL VAGINOSIS

Bacterial vaginosis presents as a "fishy" vaginal discharge, which is more noticeable following unprotected intercourse. The patient complains of a malodorous, nonirritating discharge, and examination reveals homogeneous, gray-white secretions with a pH of 5.0–5.5. A transient "fishy" odor can be released on application of 10% KOH to the vaginal secretions on a glass slide. A wet mount of the vaginal secretions using normal saline under microscopy demonstrates the characteristic clue cells, decreased lactobacilli, and few white blood cells. Clue cells are identified as numerous stippled or granulated epithelial cells (Fig 37–4). This appearance is caused by the adherence of *G vaginalis* organisms to the edges of the vaginal epithelial cells. Gram stain reveals a large number of small gram-negative bacilli and a relative absence of lactobacilli. Gram stain provides a more sensitiv

(93%) and specific (70%) diagnosis than does wet mount. Whether bacterial vaginosis is a true sexually transmitted disease is controversial, although women who are not sexually active are rarely affected.

Treatment in symptomatic patients should be implemented and should be considered in asymptomatic patients. Treatment regimens in nonpregnant women include metronidazole 500 mg orally twice daily for 7 days, metronidazole gel 0.75% (1 full applicator, 5 g) intravaginally once or twice daily for 5 days, or clindamycin cream 2% (1 full applicator, 5 g) intravaginally at bedtime for 7 days. (Clindamycin is oil based, so patients should be told that condoms or diaphragms might be weakened during treatment.) Alternative regimens include metronidazole 2 g orally in a single dose, clindamycin 300 mg orally twice daily for 7 days, or clindamycin ovules 100 g intravaginally once at bedtime for 3 days. In pregnant women, the recommended treatment is metronidazole 250 mg orally 3 times daily for 7 days. Alternatively, clindamycin 300 mg orally twice daily for 7 days can be given. Existing data do not support the use of topical agents during pregnancy. Possible management strategies for recurrent vaginosis includes use of condoms, longer treatment periods, prophylactic maintenance therapy, oral or vaginal application of yogurt containing lactobacillus acidophilus, intravaginal planting of other exogenous lactobacilli, and hydrogen peroxide douches. Treatment of the male does not help in preventing recurrence in the female.

Bacterial vaginosis has been reported to increase the risk of preterm delivery, although not all studies have confirmed that metronidazole treatment of asymptomatic pregnant women reduces the occurrence of preterm delivery or adverse pregnancy outcomes. In nonpregnant women, bacterial vaginosis has been related to posthysterectomy vaginal cuff cellulitis, postabortion infection, and pelvic inflammatory disease.

NEISSERIA GONORRHOEAE

Symptoms of infection by *N gonorrhoeae* may be quite severe, but up to 85% of women are asymptomatic. The incidence of the disease is rising and depends on the patient population. Family planning clinics report a 10% prevalence; private practitioners report 2–3%. The glandular structures of the cervix, urethra, vulva, perineum, and anus are most commonly infected. In acute disease, patients present with a copious mucopurulent discharge and Gram's stain reveals gram-negative diplococci within leukocytes. However, diagnosis should be confirmed with a culture or with nucleic acid amplification. The specimen is collected from the endocervix. Cultures may also be taken from the urethra, rectum, and mouth. An estimated 15–20% of women with lower tract disease will develop upper tract disease presenting with salpingitis, tubo-ovarian abscess, and peritonitis. Ectopic pregnancy and infertility may result. If active infection is present during delivery, the newborn may develop conjunctivitis by contamination during vaginal delivery. Treatment of uncomplicated gonococcal infections of the cervix consists of ceftriaxone 125 mg IM in a single dose. Cefixime 400 mg orally in a single dose, ciprofloxacin 500 mg orally in a single dose, ofloxacin 400 mg orally in a single dose, or levofloxacin 250 mg orally in a single dose are other recommended regimens. Because of quinolone-resistant strains of *N gonorrhoeae* in parts of Asia and the Pacific, quinolones are no longer recommended for patients residing in, or who may have acquired infection while in, Asia and the Pacific (including Hawaii). The prevalence of quinolone resistance in California is increasing; therefore, the use of fluoroquinolones in California probably is inadvisable. Spectinomycin 2 g IM in a single dose can be given to patients sensitive to cephalosporins and quinolones. Treatment of *Chlamydia trachomatis* infection should be considered.

CHLAMYDIA TRACHOMATIS

C trachomatis infections can be asymptomatic, or they can present with a mucopurulent cervicitis, dysuria, and/or postcoital bleeding. Sexually active young women should be screened. *C trachomatis* can be identified by culture (50–90% sensitivity), a direct fluorescent antibody (50–80% sensitivity) and enzyme immunoassay (40–60% sensitivity), or most recently using nucleic acid amplification tests (polymerase chain reaction or ligase chain reaction, 60–100% sensitivity). All tests have a specificity > 99%. *Chlamydia* can also cause an ascending infection, salpingitis, in 20–40% of untreated patients. More than 50% of upper tract infections may be caused by

C trachomatis, leading to tubal occlusion, ectopic pregnancy, or infertility. *C trachomatis* also can cause neonata conjunctivitis if untreated and atypical cytologic findings on Papanicolaou smear. *C trachomatis* may present as lymphogranuloma venereum (LGV), which most commonly affects the vulvar tissues. Retroperitoneal lymphadenopathy may be present. The initial lesion in LGV presents as a transient, painless vesicular lesion or shallow ulcer at the inoculation site. More advanced disease is characterized by anal or genital fistulas, stricture, or rectal stenosis. The disease is uncommon in the United States but is endemic in Southeast Asia and Africa.

If *C trachomatis* is suspected or diagnosed, both the patient and partner should be treated. In addition, a concurrent gonococcal infection should be considered. Recommended therapy includes azithromycin 1 g orally in single dose or doxycycline 100 mg orally twice daily for 7 days. Erythromycin base 500 mg orally 4 times daily for 7 days, ofloxacin 300 mg orally twice daily, or levofloxacin 50 mg once daily for 7 days are alternative regimens. Doxycycline, levofloxacin, and ofloxacin should be avoided in pregnancy and during lactation. Patients should abstain from intercourse for 7 days. Test of cure is required in cases of possible reinfection or persistent symptoms and in pregnancy. Repeat testing can be considered 3 weeks after treatment with erythromycin. Women should be rescreened 3–4 months after treatment. For LGV, the recommended regimen is doxycycline 100 mg twice daily for 21 days.

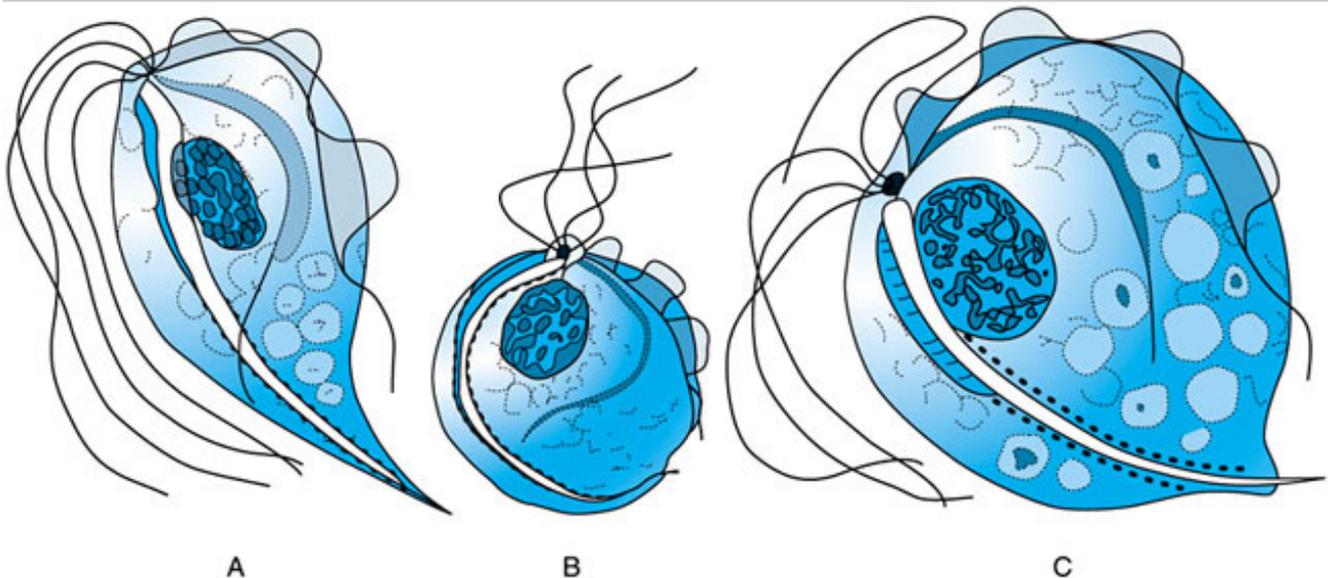

OTHER

M hominis and *U urealyticum* also cause genital disease. Identification using polymerase chain reaction can increase the sensitivity over culture. Mycoplasma infections may cause infertility, spontaneous abortion, postpartum fever, nongonococcal urethritis in men, and possibly salpingitis and pelvic abscess. The most effective treatment is doxycycline 100 mg orally twice daily for 10 days.

Trichomonas Vaginitis

Trichomonas vaginalis is a unicellular flagellate protozoan (Fig 37–5). *T vaginalis* organisms are larger than polymorphonuclear leukocytes but smaller than mature epithelial cells. *T vaginalis* infects the lower urinary tract in both women and men. It is the most prevalent nonviral sexually transmitted disease in the United States. Nonsexual transmission is infrequent because large numbers of organisms are required to produce symptoms.

Figure 37–5.

Trichomonas vaginalis as found in vaginal and prostatic secretions. A: Normal trophozoite. B: Round form after division. C: Common form seen in stained preparation. Cysts not found.

(Reproduced, with permission, from Brooks GF, Butel JS, Ornston LN: *Jawetz, Melnick, & Adelberg's Medical Microbiology*, 19th ed. Appleton & Lange, 1991.)

A persistent vaginal discharge is the principal symptom with or without secondary vulvar pruritus. The discharge is profuse, extremely frothy, greenish, and at times foul-smelling. The pH of the vagina usually exceeds 5.0. Involvement of the vulva may be limited to the vestibule and labia minora. The labia minora may become edematous and tender. Urinary symptoms may occur; however, burning with urination is most often associated with severe vulvitis. Examination of the vaginal epithelium and cervix shows generalized vaginal erythema with multiple small petechiae, the so-called strawberry spots, which may be confused with epithelial punctation. Wet mount with normal saline reveals an increase in polymorphonuclear cells and characteristic motile flagellates in 50–70% of culture-confirmed cases (Fig 37–3). Papanicolaou smears have a sensitivity of approximately 60% and may yield false-positive results. Culture is the gold standard, providing 95% sensitivity and 100% specificity. DNA probes and monoclonal antibodies may assist with accurate diagnosis.

Systemic therapy with metronidazole is the treatment of choice as trichomonads can be present in the urinary tract system. Partners should be treated simultaneously, with intercourse avoided or a condom used until treatment is completed. Metronidazole is the only Food and Drug Administration (FDA)-approved treatment in the United States, with cure rates of approximately 90–95%. A single-dose regimen of 2 g may assure compliance. Other regimens include a 500-mg tablet orally twice daily for 7 days. In resistant cases, which most likely are related to reinfection, oral metronidazole can be repeated after 4–6 weeks if the presence of trichomonads has been confirmed and the white blood cell count and differential are normal. Side effects of metronidazole include nausea or emesis with alcohol consumption. Contraindications include certain blood dyscrasias (neutropenia) and central nervous system diseases. An oncogenic effect has been demonstrated in animals but not in humans. Resistance to metronidazole therapy is rare but is rising and can be confirmed in vitro. A maximal dose of metronidazole 2–4 g daily should be given for 10 to 14 days if the patient tolerates it. If treatment fails, consultation with the Centers for Disease Control is recommended. Nonoxynol 9 and other spermicidal agents have been demonstrated to decrease the transmission of *Trichomonas*.

Trichomoniasis is associated with many perinatal complications and an increased incidence in the transmission of HIV. Women with trichomoniasis should be evaluated for other sexually transmitted diseases, including *N. gonorrhoeae*, *C. trachomatis*, syphilis, and HIV.

Viral Infections

The viruses that affect the vulva and vagina are the herpesvirus (herpes simplex, varicella-zoster, and cytomegalovirus), poxvirus (molluscum contagiosum), and papovavirus types.

HERPESVIRUS

The herpesvirus (HSV) may cause superficial ulcerations or an exophytic necrotic mass involving the cervix, which may cause a profuse vaginal discharge. The cervix may be tender to manipulation and bleed easily. The primary lesion lasts 2–6 weeks and heals without scarring. Recurrent infections may cause cervical lesions. The virus may be cultured from ulcers or ruptured vesicles. Cervical cytologic examination may reveal multinucleated giant cells with intranuclear inclusions. The herpesvirus hominis has 2 immunologic variants, type I and type II. In general, most genital lesions are secondary to the type II virus. The type I virus is responsible for only 10–15% of genital herpes infections. Approximately 83% of patients will develop antibodies to herpesvirus type II in a minimum of 21 days following a primary infection. HSV is responsible for recurrent and disabling symptomatic disease, venereal transmission, and infection to the neonate (ie, herpes encephalitis). Further discussion of HSV is reviewed later in the chapter.

HUMAN PAPILLOMAVIRUS

Human papillomavirus (HPV) is responsible for condyloma acuminata of the vagina, cervix, vulva, perineum, and

perianal areas as well as for dysplasia and cancer. The rate of HPV infection is high and is rising. Approximately 30–60% of people may have been infected with HPV at some point in their lives, but the gross clinical prevalence of HPV is less than 1%. The virus is small and contains all its genetic material on a single double-stranded molecule of DNA. More than 20 types of HPV have been identified using viral DNA probes that can infect the genital tract. Types 16, 18, 31, 33, and 35 appear to have the most oncogenic potential. Types 6 and 11 are associated with genital condyloma. Most types cause an asymptomatic infection. The viruses are sexually transmitted and infect both partners.

The typical lesion is an exophytic or papillomatous condyloma. Colposcopic examination permits identification of flat, spiked, and inverted condyloma (Fig 37–6). The florid, papillomatous condyloma shows a raised white lesion with fingerlike projections often containing capillaries. Although large lesions may be seen with the naked eye, the colposcope is necessary to identify smaller lesions. The flat condyloma appears as a white lesion with a somewhat granular surface. A mosaic pattern and punctation also may be present, suggesting vaginal intraepithelial neoplasia (VAIN), which must be excluded by biopsy. Spiked lesions present as a hyperkeratotic lesion, with surface projections and prominent capillary tips. An inverted condyloma grows into the glands of the cervix but has not been identified on the vaginal epithelium. Condylomatous vaginitis causes a rough vaginal surface, demonstrating white projections from the pink vaginal mucosa. Vaginal discharge and pruritus are the most common symptoms with florid condylomas. Postcoital bleeding may occur. No specific symptoms are related to the other types of condylomas. The entire lower tract usually is involved with subclinical or florid lesions when vulvar lesions are present. States of immunosuppression (pregnancy, HIV infection, diabetes, renal transplant) are associated with massive proliferation of condyloma and often are difficult to treat. Laryngeal papilloma and vulvar condylomas in infants delivered through an infected vaginal canal have been reported; however, unlike herpetic lesions, the presence of HPV lesions is not a contraindication to a vaginal delivery.

Figure 37–6.

Copyright ©2006 by The McGraw-Hill Companies, Inc.
All rights reserved.

Vaginal condylomata acuminata as seen with a colposcope (x 13).

HPV infection is associated with dysplasia. The presence of koilocytes is pathognomonic for HPV infection. Koilocytes are superficial or intermediate cells on biopsy characterized by a large perinuclear halo. Colposcopic-directed biopsies must be taken to exclude intraepithelial neoplasia. The chief histologic difference between dysplasia and condyloma is the progression of cellular atypia. In dysplasia, the dysplastic cells move toward the surface, whereas in condyloma the changes progress from the surface inward toward the basal membrane.

Prior to treatment, a colposcope can be used to inspect the lower genital tract. Lesions may extend to the anal canal or urethral meatus. The virus is present in normal cells as well as those with condylomatous changes; therefore, recurrence is common. Cure of clinically identifiable disease depends on the responsiveness of the patient's immune system. On gross examination, condylomas cannot always be distinguished from dysplastic warts. Therefore, biopsy should be considered, especially if the cervix is involved, if the condyloma has not responded to standard treatment, or if the lesion is pigmented, indurated, fixed, and/or ulcerated. Normal micropapillae of the inner labia minora (vestibular micropapillomatosis) may be confused with papillary HPV. True HPV disease is patchy and has koilocytes and more intense acetowhite changes.

Multiple therapies are available for treatment (Table 37–5); however, whether treatment actually affects the natural progression or eradicates HPV infection is unclear. Coexistent vulvovaginitis should be treated. Treatment should be based on patient preference and convenience. If treatment fails with an initial regimen, a different agent can be used. Patients should be informed that complications with treatment are rare but can result in

scarring and pigmentation changes.

Table 37–5. Treatment of Condyloma Acuminata.

Applied by Provider

Bichloroacetic acid (BCA) or trichloroacetic acid (TCA), 50–80% solution

A lower percentage solution is generally applied to the cervix and vagina, a higher percentage to the vulva. One should be careful to avoid excessive amounts, which may burn normal skin. Xylocaine 1% gel can be applied around the wart to prevent damage to adjacent skin. Repeat treatments are given weekly as necessary.

Podophyllin 10–25% in tincture of benzoin

Cryosurgery, electrosurgery, simple surgical excision, laser vaporization

Applied by Patient

Podofilox 0.5% solution or gel

Imiquimod 5% cream (topically active immune enhancer that stimulates production of interferon and other cytokines)

Prevention of recurrence is difficult in patients who are immunosuppressed or receiving lifelong corticosteroid therapy. Examination of sex partners is not necessary as most partners are likely to have subclinical infection. The use of condoms may help in reducing transmission to partners who are not already infected.

Condylomas may complicate pregnancy. In most cases if the lesions are small, therapy is not necessary. Treatment with trichloroacetic acid (TCA) may be applied in the last 4 weeks of pregnancy to avoid cesarean section with larger lesions. Electrocoagulation, cryotherapy, or laser therapy should be used prior to 32 weeks to avoid posttreatment necrosis, which may last as long as 4–6 weeks. Podophyllin, podofilox, and imiquimod should not be used during pregnancy.

Atrophic Vaginitis

Prepubertal, lactating, and postmenopausal women lack the vaginal effects of estrogen production. The pH of the vagina is abnormally high, and the normally acidogenic flora of the vagina may be replaced by mixed flora. The vaginal epithelium is thinned and more susceptible to infection and trauma. Although most patients are asymptomatic, many postmenopausal women report vaginal dryness, spotting, presence of a serosanguineous or watery discharge, and/or dyspareunia. Some of the symptoms of irritation are caused by a secondary infection. On examination, the vaginal mucosa is thin, with few or absent vaginal folds. The pH is 5.0–7.0. The wet mount shows small, rounded parabasal epithelial cells and an increased number of polymorphonuclear cells.

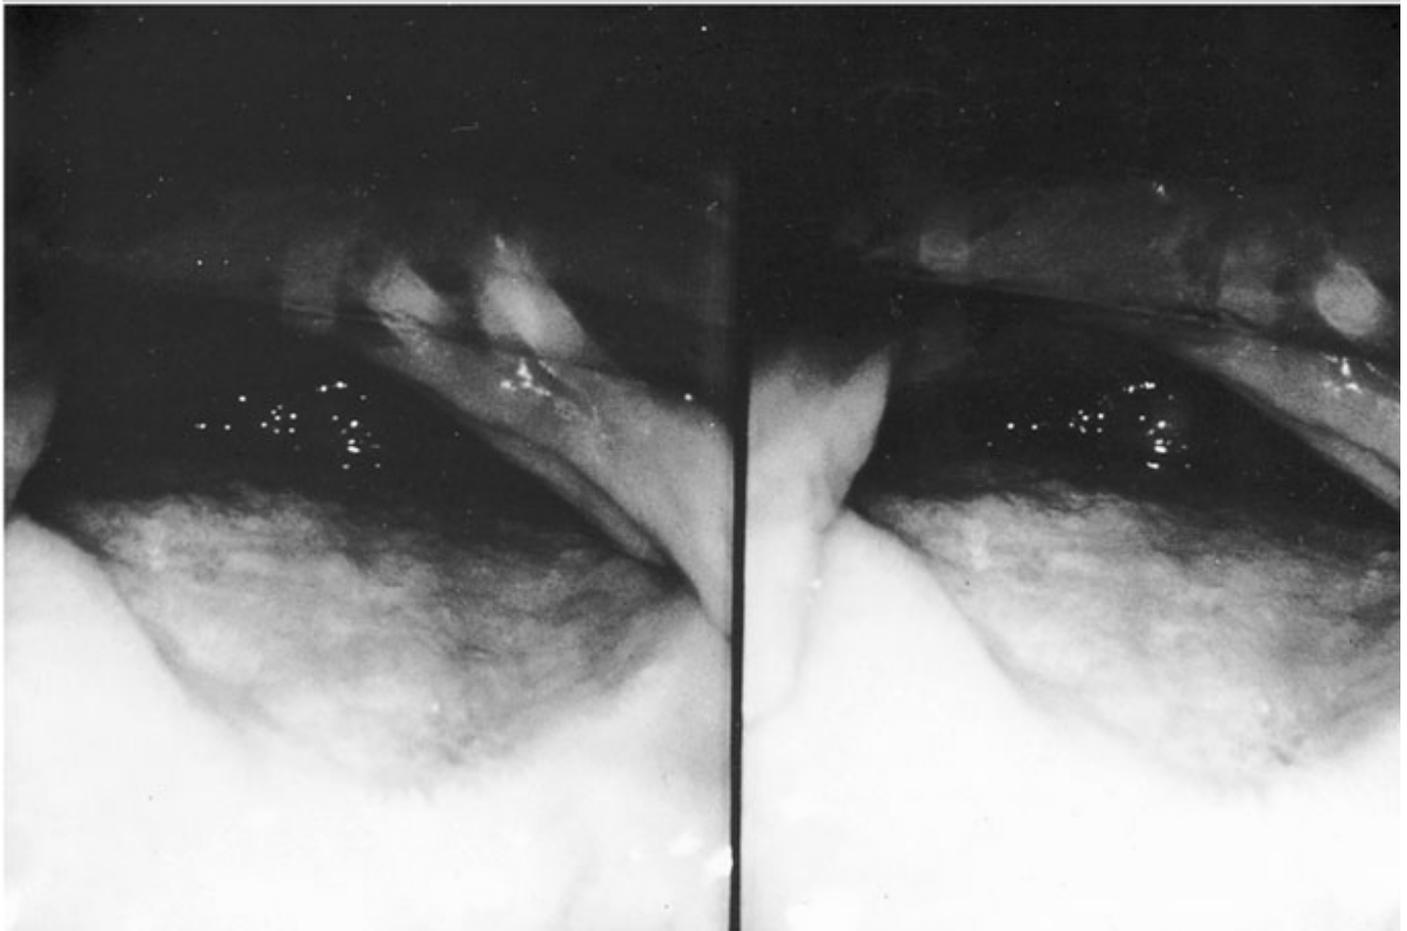

Treatment includes intravaginal application of estrogen cream. Approximately one-third of the vaginal estrogen is systemically absorbed; therefore, this treatment may be contraindicated in women with a history of breast or endometrial cancer. The estradiol vaginal ring, which is changed every 90 days, may provide a more preferable route of administration for some women, or estradiol hemihydrate (Vagifem) 1 tablet intravaginally daily for 2 weeks and then 2 times per week for at least 3–6 months may be less messy. Systemic estrogen therapy should be considered if there are no contraindications.

Foreign Bodies

Foreign bodies commonly cause vaginal discharge and infection in preadolescent girls. Paper, cotton, or other materials may be placed in the vagina and cause secondary infection. Children may require vaginal examination under anesthesia to identify or rule out a foreign body or tumor high in the vaginal vault. The vaginal canal can be flushed in the office using a small catheter in an attempt to remove a foreign body. In adults, a forgotten menstrual tampon or contraceptive device may cause a malodorous discharge. The diagnosis usually can be made by pelvic examination.

Clinical symptoms associated with foreign bodies include abnormal vaginal discharge and intermenstrual spotting. Symptoms are generally secondary to drying of the vaginal epithelium and micro-ulcerations, which can be detected by colposcopy. Ulcerative lesions, particularly associated with tampon use, are typically located in the vaginal fornices and have rolled, irregular edges with a red granulation tissue base (Fig 37–7). Regenerating epithelium at the ulcer edge may shed cells that may be interpreted as atypical, suggesting dysplasia. The lesions heal spontaneously once tampon use is discontinued. A foreign body retained in the vagina for a prolonged period may erode into the bladder or rectum.

Figure 37–7.

Copyright ©2006 by The McGraw-Hill Companies, Inc.
All rights reserved.

Colposcopic view of ulcer anterior to cervix caused by prolonged use of a vaginal tampon.

Treatment involves removal of the foreign body. Rarely, antibiotics are required for ulcerations or cellulitis of the vulva or vagina. Dryness or ulceration of the vagina secondary to use of menstrual tampons is transient and heals

spontaneously.

Toxic shock syndrome (see Chapter 41) is the most serious complication of improper use of vaginal tampons. The syndrome has been linked to staphylococcal vaginal infection in healthy young women who use high-absorbency tampons continuously throughout the menstrual period. Some of the clinical manifestations are secondary to the release of staphylococcal exotoxins. Symptoms consist of a high fever (≈ 38.9 C [102 F]) possibly accompanied by severe headache, sore throat, myalgia, vomiting, and diarrhea. The disease may resemble meningitis or viremia. Palmar erythema and a diffuse sunburn-like rash have been described. The skin rash usually disappears within 24–48 hours, but occasionally a patient has a recurrent maculopapular, morbilliform eruption between days 6 and 10. Superficial desquamation of the palms and soles often follows within 2–3 weeks. Progressive hypotension may occur and proceed to shock levels within 48 hours. Multisystem organ failure may occur, including renal and cardiac dysfunction. The incidence of toxic shock syndrome was 1 in 100,000 among females 15 to 44 years old in 1986. Any menstruating woman who presents with sudden onset of a febrile illness should be evaluated and treated for toxic shock syndrome. The tampon should be removed, cultures sent, and the vagina cleansed to decrease the organism inoculum. Appropriate supportive measures should be provided and β -lactamase-resistant penicillin or vancomycin (if the patient is allergic to penicillin) administered. Women who have been treated for toxic shock syndrome are at considerable risk for recurrence. Therefore, these women should avoid tampon use until *Staphylococcus aureus* has been eradicated from the vagina.

Desquamative Inflammatory Vaginitis

This disorder demonstrates clinical and microscopic features of postmenopausal atrophic vaginitis; however, it presents in premenopausal women with normal estrogen levels. The cause is unknown. Patients complain of a profuse purulent vaginal discharge, vaginal burning or irritation, dyspareunia, and occasional spotting. The process is patchy and usually localized to the upper half of the vagina. The purulent discharge contains many immature epithelial and pus cells without any identifiable cause. Vaginal erythema is present and synechiae may develop in the upper vagina, causing partial occlusion. The diagnosis is one of exclusion. Vaginal pH may be elevated, with wet mount and Gram's stain demonstrating an increased number of parabasal cells, an absence of gram-positive bacilli, and presence of gram-positive cocci, usually streptococci. Treatment often is unsatisfactory but has included local application of estrogen, antibiotics (particularly clindamycin cream 2% 5 g intravaginally daily for 7 days), and corticosteroids.

Noninfectious Vaginitis

Chemical vaginitis secondary to multiple irritating offenders, including topical irritants (sanitary supplies, spermicides, feminine hygiene supplies, soaps, perfumes), allergens (latex, antimycotic creams), and possibly excessive sexual activity can cause pruritus, irritation, burning, and vaginal discharge. The etiology may be confused with vulvovaginal candidiasis. The offending agent should be removed for treatment. A short course of corticosteroid treatment may be used along with sodium bicarbonate sitz baths and topical vegetable oils.

Cervical Mucorrhea or Vaginal Epithelial Discharge

Cervicitis due to cervical polyps or cervical or vaginal cancer can cause a mucopurulent discharge and bleeding. Excessive cervical ectropion may cause excessive discharge of cervical mucus from normal endocervical cells. Vaginal adenosis may cause the same type of clear, mucoid-type discharge with no associated symptoms. Excessive desquamation of the vaginal epithelium may produce a diffuse gray-white pasty vaginal discharge, which may be confused with candidiasis. Vaginal pH is normal. Microscopic evaluation shows normal bacterial flora, mature vaginal squamata, and no increase in the number of leukocytes. Excessive but normal vaginal discharge should be treated with reassurance and, if required at times, with cryosurgery or carbon dioxide treatment of the cervix. Continuous use of a tampon should be avoided.

Parasitic Infection

Less common causes of vaginitis are parasitic infections with pinworms (*Enterobius vermicularis*) and with *Entamoeba histolytica*. Pinworm infection usually is seen in children. Fecal contamination at the introitus is the source of infection. The perineal area is extremely pruritic. The parasite is generally detected by pressing a strip of adhesive cellulose tape to the perineum. The tape is then adhered to a slide, allowing the double-walled ova to be identified under the microscope. *E. histolytica* infection of the vagina and cervix is rare in the United States but is quite common in developing countries. Severe infection may resemble cervical cancer, but symptoms generally are due to vulvar involvement. Trophozoites of *E. histolytica* may be demonstrated on wet-mount preparations or occasionally on a Papanicolaou smear.

PRINCIPLES OF DIAGNOSIS OF VULVAR DISEASES

A complete history of potential causes of vulvar irritation, such as creams, powders, soaps, type of underwear, and cleansing techniques, should be reviewed. Physical examination should include careful inspection, palpation, and liberal use of colposcope at low magnification, followed by biopsy of any suspicious areas, lesions, or discolorations if indicated.

Pruritus

Pruritus is the most common symptom of vulvar disease. The term pruritus vulvae denotes intense itching of the vulvar epithelium and mucous membranes from any cause. Specific diagnosis depends on a thorough history and a physical examination that includes inspection of all body surfaces, and, in some cases, a biopsy.

Ulceration, Tumor, Dystrophy

Ulcerative lesions suggest a granulomatous sexually transmitted disease or cancer. Therefore, appropriate tests for sexually transmitted disease should be conducted along with biopsy to rule out primary or coexisting cancer. Well-circumscribed solid tumors should be excised widely and submitted for microscopic evaluation. Diffuse, dystrophic white lesions may demonstrate great histologic variability. A colposcope at low magnification or a simple magnifying glass should be used to select the most suitable biopsy site(s). A satisfactory full-thickness biopsy of the skin and tumor can be obtained with a dermatologic punch biopsy of the skin under local anesthesia.

Abnormalities of Pigmentation

WHITE

The color of vulvar epithelium or lesions depends principally on the vascularity of the dermis, the thickness of the overlying epidermis, and the amount of intervening pigment, either melanin or blood pigments. A dystrophic lesion of the vulva may have a white appearance primarily due to a decrease in the vascularity (lichen sclerosus) or an increase in the keratin layer (squamous hyperplasia) that has undergone maceration from the increased moisture in the vulvar area. During the acute phase of lichen sclerosus, the vulvar epithelium is moderately erythematous. As the lesion matures, it becomes hyperkeratotic and develops a typical white appearance resembling cigarette paper. The epidermal thickening of neoplasia obscures the underlying vasculature and, in conjunction with the macerating effects of the moist environment, usually produces a hyperplastic white lesion. A diffuse white lesion of the vulva is also produced by the loss or absence of melanin pigmentation as with vitiligo, a hereditary disorder. Leukoderma is a localized white lesion resulting from transient loss of pigment in a residual scar after healing of an ulcer.

RED

A red lesion results from thinning or ulceration of the epidermis, the vasodilation of inflammation or an immune response, or the neovascularization of a neoplasia. With ulceration of the epithelium, epidermal areas are lost, and the vascular dermis is apparent. Acute candidal vulvovaginitis, as seen with diabetes, is a typical example of vulvar erythema secondary to inflammation and the local immune response. Paget's disease (adenocarcinoma in situ of the vulva) is characterized by the velvety red lesion that spreads over the vulvar skin. Psoriasis involving

the vulva is another lesion that can take on a red appearance.

BLUE/BLACK

Dark lesions are the result of an increased amount or concentration of melanin or blood pigments, which may occur following trauma. A persistent dark lesion on the vulva skin likely represents a nevus or a melanoma. Melanosis, or lentigo, is a benign, darkly pigmented flat lesion that may be mistaken for a melanoma. With carcinoma in situ of the vulva, the atypical squamous cells are unable to contain the melanin pigment. Instead it is concentrated in the local macrophages, causing dark coloration of the tumor. Vulvar epithelium may darken following use of estrogen cream or oral contraceptive pills.

VULVAR DISORDERS

See Table 37–6.

Table 37–6. Vulvar Disorders.

Vascular and lymphatic diseases

Varicosities, hematoma, edema, granuloma pyogenicum, hemangioma, lymphangioma

Vulvar manifestation of systemic diseases

Leukemia, dermatologic disorders (disseminated lupus erythematosus, pemphigus vulgaris, contact dermatitis, psoriasis), obesity, diabetes mellitus, Behet's syndrome

Viral infections

Herpes genitalis, herpes zoster, molluscum contagiosum, condyloma acuminatum

Infestations of the vulva

Pediculosis pubis, scabies, enterobiasis

Mycotic infections of the vulva

Candidiasis, fungal dermatitis

Other infections of the vulva

Impetigo, furunculosis, erysipelas, hidradenitis, tuberculosis

Vulvar nonneoplastic epithelial disorders

Lichen sclerosus, squamous cell hyperplasia, other dermatoses (lichen planus, lichen simplex chronicus)

Benign cystic tumors

Epidermal cysts, sebaceous cysts, apocrine sweat gland cysts, Skene duct cyst, urethral diverticulum, inguinal hernia, Gartner's duct cyst, Bartholin's duct cyst and abscess

Benign solid tumors

Acrochordon, pigmented nevi, leiomyoma, fibroma, lipoma, neurofibromas, granular cell myoblastoma

Vascular & Lymphatic Diseases

The vulva and vagina have a rich vascular and lymphatic blood supply. These channels may undergo obstruction, dilatation, rupture, or infection, or they may develop into tumorous lesions, which usually are malformations rather than true neoplasms.

VARI COSIT IES

Varicosities of the vulva involve 1 or more veins. Severe varicosities of the legs and vulva may be aggravated during pregnancy. Symptomatic vulvar varices in a patient who is not pregnant are uncommon and may signify underlying vascular disease in the pelvis, either primary or secondary to a tumor in the pelvis. Regardless of the cause, varicosities can cause considerable discomfort, consisting of pain, pruritus, and a sense of heaviness. On examination a large mass of veins may be apparent, which is best diagnosed with the patient standing to distend the veins. Rupture of a vulvar varicosity during pregnancy may cause profuse hemorrhage. Pain and tenderness may be caused by acute phlebitis or thrombosis.

Treatment of vulvar and vaginal varicosities is seldom necessary, although symptoms might be quite severe during pregnancy. Support clothing such as panty hose or leotards usually provides adequate relief of symptoms. Operative intervention is usually required only in cases of rupture and hemorrhage, which are rare. Management of the pregnancy should be guided by standard obstetric care, with vaginal delivery advised. Persistent postpartum cases may be alleviated by injection of a sclerosing agent.

HEMATOMA

The vulva has a rich blood supply arising predominately from the pudendal vessels. If a vessel is ruptured, especially in a pregnant patient, significant bleeding and hematoma formation can occur because of the distensible nature of the vulvar tissue. Following trauma, an ice pack should be applied. If the hematoma continues to expand, the area should be incised and any bleeders (which may be multiple) ligated. The wound can be packed and left open or closed with a drain in place, if appropriate. Antibiotics should be administered on an individual basis, depending on the initiating event and contamination in the area.

EDEMA

The loose integument of the vulva predisposes to the development of edema. Vascular or lymphatic obstruction may be the result of an underlying neoplasm or infection such as LGV, which can cause extensive lymphatic obstruction and gross deformity of the vulvar tissues. If edema persists following appropriate antibiotic treatment, vulvectomy may be indicated.

Accidental trauma from a bicycle accident (saddle injury) in a young girl or a kick to the pudendum may cause painful swelling. An ice pack applied to the perineum after an acute trauma tends to retard the development of significant edema. Warm packs or warm sitz baths may then be applied after 1–2 days to help resolve the associated inflammation and/or hematoma.

Severe generalized vulvar edema may represent an underlying systemic illness such as congestive heart failure, nephrotic syndrome, preeclampsia, or eclampsia. Acute development of edema may result from a systemic or local allergic reaction. Dependent edema is occasionally seen with prolonged bed rest.

GRANULOMA PYOGENICUM

Pyogenic granuloma is considered to be a variant of a capillary hemangioma. It usually is single, raised, and dull red. Its size seldom exceeds 3 cm (Fig 37–8). Pyogenic granuloma is important because it tends to bleed easily and is easily traumatized. Wide excisional biopsy is indicated to alleviate symptoms and to rule out a malignant melanoma.

Figure 37–8.

Pyogenic granuloma.

HEMANGIOMA

Senile

Senile (cherry) hemangiomas usually are multiple, small, dark blue, asymptomatic papules discovered incidental during examination of the older patient. Excision biopsy is needed only if the hemangiomas bleed repeatedly. A cryosurgical probe or carbon dioxide laser can also be used.

Childhood

Childhood hemangiomas usually are diagnosed in the first few months of life. They may vary in size from small strawberry hemangiomas to large cavernous ones. They tend to be elevated and bright red or dark, depending on their size and the thickness of the overlying skin. Those that tend to increase in size during the first few months of life often will become static or regress without therapy after approximately age 18 months. Although most of these hemangiomas can be observed without therapy, larger ones may require treatment with cryosurgery, argon laser therapy, or sclerosing solutions.

LYMPHANGIOMA

Lymphangiomas are tumors of the lymphatic vessels. They may be difficult to differentiate from hemangiomas microscopically unless blood cells are present within the blood vessels. Lymphangioma cavernosum may cause a diffuse enlargement of 1 side of the vulva and extend down over the remainder of the vulva and perineum. A tumor that is sufficiently enlarged should be surgically excised. Lymphangioma simplex tumors (circumscription tumors) usually are small, soft, white or purple nodules or small wartlike lesions most commonly seen on the

labia majora. They usually are asymptomatic and do not require excision unless intense pruritus and excoriation are present and are not alleviated with topical measures.

Vulvar Manifestation of Systemic Diseases

LEUKEMIA

Rarely, nodular infiltration and ulceration of the vulva and rectovaginal septum occur with acute leukemia.

DERMATOLOGIC DISORDERS

Recurrent ulcerations of the mucous membranes of the mouth and vagina may be a manifestation of disseminated lupus erythematosus. Bullous eruptions of apparently normal skin and mucous membrane surfaces of the vulva may be one of the first signs of pemphigus vulgaris (a rare, chronic autoimmune disease).

Contact dermatitis is an inflammatory response of the vulvar tissue to agents that may either be locally irritating or induce sensitivity on contact. The local reaction to a systemically administered drug is called dermatitis medicamentosa.

Psoriasis is a chronic relapsing dermatosis that may also affect the scalp, the extensor surfaces of the extremities, the trunk, and the vulva. The vulvar skin may be the only body surface affected, and the primary lesions are raised and appear typically erythematous, resembling a candidal infection. Most lesions are sharply demarcated. The silver scaly crusts that are present on other parts of the body usually are absent (Fig 37–9). Treatment includes topical corticosteroids.

Figure 37–9.

Typical lesions of psoriasis with a sharp outline and bright red surface.

OBESITY

Acanthosis nigricans is a benign hyperpigmented lesion characterized by papillomatous hypertrophy. It may be associated with an underlying adenocarcinoma. Pseudoacanthosis nigricans is a benign process that may appear on the skin of the vulva and inner thighs in obese and darkly pigmented women. Glucose intolerance, insulin resistance, chronic anovulation, and androgen disorders may be associated. Intertrigo is an inflammatory reaction involving the genitocrural folds or the skin under the abdominal panniculus. It is common in obese patients and results from persistent moistness of the skin surfaces. An associated superficial fungal or bacterial infection may be present. The area may be either erythematous or white from maceration. Measures to promote dryness, such as wearing absorbent cotton undergarments and dusting with cornstarch powder, may be helpful.

DIABETES MELLITUS

Diabetes mellitus is the systemic disease most commonly associated with chronic pruritus vulvae. The chronic vulvitis that develops may be termed diabetic vulvitis. It is caused by a chronic vulvovaginal candidiasis. A diagnosis of diabetes should be considered in any patient who responds poorly to antifungal treatment or who has recurrent fungal infections. Such patients should undergo glucose tolerance testing. In uncontrolled diabetes, the vulvar epithelium often undergoes lichenification and secondary bacterial infection. Occasionally, a vulvar abscess, chronic subcutaneous abscesses, and draining sinuses develop from a bacterial infection. Treatment should include controlling the underlying diabetes and specific therapy for the bacterial or fungal infection. Suppressive antifungal therapy using fluconazole should be initiated in diabetic patients with recurrent vulvovaginal candidiasis.

Necrotizing fasciitis is seen most commonly in diabetics. It is an uncommon, acute, rapidly spreading, frequently fatal polymicrobial infection of the superficial fascia and subcutaneous fascia. It may be seen following a surgical procedure such as an episiotomy or after minor trauma. It presents as an extremely painful, tender, and indurated region with central necrosis and peripheral purplish erythema. Treatment requires surgical debridement and systemic antibiotics.

BEHET'S SYNDROME

Behet's syndrome is a rare inflammatory disorder of unknown cause characterized by recurrent oral and genital ulcerations and uveitis. The painful genital ulcers are preceded by small vesicles or papules and last for variable periods. The borders are irregular, with deep ulcers that, following healing, may result in scarring. Ocular lesions begin as superficial inflammation and may proceed to iridocyclitis and even blindness. Monoarticular arthritis and central nervous system symptoms are manifestations of severe disease. Susceptibility to Behet's disease is strongly associated with the presence of the *HLA-B51* allele and is primarily seen in Eastern Europe and the Mediterranean. The exact etiology is unknown, but it likely represents an underlying autoimmune process. No specific viral infection has been implicated.

Behet's syndrome, together with disseminated lupus erythematosus and pemphigus, should be included in the differential diagnosis of recurrent aphthous ulcers of the oral and vaginal mucosa. There is no specific therapy—only palliative care. Topical and systemic corticosteroids provide the most consistent relief. Patients with Behet's syndrome require consultation and long-term management by a dermatologist.

Viral Infections

Systemic infections in children, such as varicella and rubeola, may involve the skin and mucosa of the vulva. The principal viruses that affect the vulva are DNA viruses, primarily of the herpesvirus, poxvirus, and papovavirus types. In adults, the principal viral infections of the lower genital tract are herpes genitalis, herpes zoster, molluscum contagiosum, and condyloma acuminatum.

HERPES GENITALIS

Herpesvirus hominis infection of the lower genital tract (herpes genitalis) is the most common cause of genital ulcer disease in the United States. In private practice 10% of women demonstrate serologic prior exposure to the virus. Approximately 85% of primary infections are secondary to herpesvirus hominis type II, with the remainder by type I.

Infection occurs through direct contact with secretions or mucosal surfaces contaminated with the virus. The virus enters the skin through cracks or other lesions but can enter through an intact mucosa. The virus initially replicates in the dermis and epidermis. Incubation time is 2–7 days. Prodromal symptoms of tingling, burning, or itching may occur shortly before vesicular eruptions appear. The vesicles erode rapidly, resulting in painful ulcers: distributed in small patches, or they may involve most of the vulvar surfaces (Fig 37–10). Bilateral inguinal adenopathy may be present. Dysuria or other urinary symptoms may develop, including urinary retention. Approximately one-third of patients demonstrate systemic manifestations such as fever, malaise, headaches, and myalgia. In other cases the primary infection is asymptomatic. Lesions may persist for 2–6 weeks with no subsequent scarring.

Figure 37–10.

Copyright ©2006 by The McGraw-Hill Companies, Inc.
All rights reserved.

Ulcerating vesicles of herpes genitalis.

Diagnosis is based on clinical presentation and laboratory results. The virus can be cultured from vesicle fluid during the acute phase. However, organisms usually cannot be cultured after the primary vesicles heal, which occurs by 2 weeks. A scraping taken from the ulcer and stained Giemsa or Papanicolaou stain (Tzanck test) can

also demonstrate the characteristic giant cells indicative of viral infection. This test is less sensitive than the culture.

Approximately 85% of patients develop immunoglobulin (Ig)M antibodies to type II virus within 21 days of exposure. Serologic tests are best used to determine whether the patient has been infected in the past. A 4-fold or higher increase in neutralizing complement fixation antibody titers between acute and convalescent sera may be useful to document a primary infection. Only 5% of patients with recurrent infection demonstrate a 4-fold or higher rise in antibody titer. New type-specific serologic tests for herpes simplex virus are available. The serologic type-specific glycoprotein G–based assays should be specifically requested when serology is performed to distinguish between herpes simplex types I and II.

Despite the presence of adequate humoral and cell-mediated immunity, reactivation of the virus occurs. Following replication in the skin, the viral particles are transported along the peripheral sensory nerves to the dorsal root ganglion, where latent infection is established. Exogenous factors known to contribute to activation of herpesvirus include fever, emotional stress, and menstruation. Immunocompromised patients are prone to develop extensive local disease and systemic dissemination. Whether frequent coitus promotes recurrent disease is unknown. Type II virus is more likely to recur than is type I virus, with men more likely to have recurrent symptoms than women. Approximately 50% of patients will have a recurrence within 6 months of the primary infection. The ulcers tend to be smaller, fewer in number, and confined to 1 area in the vulva, cervix, or vagina. Healing is generally complete in 1–3 weeks. Virus is not recoverable within 7 days after healing of recurrent lesions. Inguinal adenopathy and systemic symptoms generally do not occur. Primary infection usually can be distinguished from secondary infection based on clinical findings. Extragenital sites, such as the fingers, buttocks, and trunk (eczema herpeticum), have been described.

Pregnancy

The incidence of neonatal simplex virus infection ranges from 1 in 5000 to 1 in 20,000 live births. Infection in the newborn is associated with a 60% mortality rate, and at least half of the survivors have significant neurologic and/or ocular sequelae. The risk of infection to an infant born vaginally in a mother with active primary genital infection is 40–50%; for recurrent infection the risk is 5%. However, most infants who develop herpetic infection are born to women who have no history or clinical evidence of infection during pregnancy. Therefore, identifying women whose infants may be in jeopardy is difficult. All pregnant women should be asked whether they or their partners have had genital herpetic lesions. Women with a history of herpes can deliver vaginally if no clinical signs or symptoms of infection are present. Obtaining routine vaginal cultures to detect herpes is not standard. However, suppressive antiviral therapy may be initiated at 36 weeks to decrease the need for cesarean section (Table 37–7).

Table 37–7. Oral Treatment of Herpes Genitalis.

First episode of genital herpes

Acyclovir

400 mg orally 3 times daily for 7–10 days

Famciclovir

250 mg orally 3 times daily for 7–10 days

Valacyclovir

1000 mg orally twice daily for 10 days

Recurrent genital herpes

Acyclovir

400 mg orally 3 times daily for 5 days

Famciclovir

125 mg orally twice daily for 5 days

Valacyclovir

500 mg orally twice daily for 5 days

Genital herpes prophylaxis

Acyclovir

400 mg orally twice daily

Famciclovir

250 mg orally twice daily

Valacyclovir

500–1000 mg orally daily

Treatment

The lesions of herpesvirus infection are self-limiting, and they heal spontaneously unless they become infected secondarily. Symptomatic treatment includes good genital hygiene, loose-fitting undergarments, cool compresses or sitz baths, and oral analgesics. Indications for hospitalization for a severe primary infection include urinary retention, severe headache or other systemic symptoms, and temperature greater than 38.3 C (101 F).

Immunosuppressed patients are more prone to systemic dissemination and should be carefully managed.

Treatment includes intravenous acyclovir for hospitalized patients and oral and/or topical antivirals for outpatient treatment. Recurrent herpes should be treated at the onset of prodromal symptoms or vesicle formation. Studies have indicated a decrease in the frequency and severity of recurrences with antiviral treatment. Once-daily dosing may be considered for frequent recurrent outbreaks, with 40–70% of patients free of recurrence at 1 year (Table 37–7).

Avoidance of direct contact with active lesions prevents spread of the disease. However, contact with an individual with subclinical disease can result in primary infections. The general rules for prevention of dissemination are as follows:

1. Precautions are unnecessary in the absence of active lesions.
2. Small lesions situated away from the oral or vaginal orifices can be covered with adhesive or paper tape during coitus.
3. In the presence of active lesions, whether or not the partner contracts the disease depends on previous exposure to herpes. A nonimmune partner usually will be infected. If a regular partner has had genital herpes or has not been infected after prolonged exposure, no precautions are necessary. If a casual partner has had a history of genital herpes, a contraceptive cream or foam should be used, followed by genital cleansing with soap and water. If a partner has no past history of genital herpes, a condom can be used but may be of limited value.

HERPES ZOSTER (SHINGLES)

Herpes zoster is an inflammatory disorder in which a painful eruption of groups of vesicles is distributed over an area of skin corresponding to the course of 1 or more peripheral sensory nerves. The causative agent is varicella zoster virus. The lesion is commonly unilateral and not infrequently attacks 1 buttock, 1 thigh, or 1 side of the vulva. The vesicles may rupture and crust over, although they usually dry, forming a scab that ultimately separates. The primary purposes of treatment (antivirals) are alleviation of pain, resolution of vesicles, and prevention of secondary infection and ulceration.

MOLLUSCUM CONTAGIOSUM

These benign epithelial poxvirus-induced tumors are dome-shaped, often umbilicated, and vary in size up to 1 cm. The lesions often are multiple and are mildly contagious. The microscopic appearance is characterized by numerous inclusion bodies (molluscum bodies) in the cytoplasm of the cells. Each lesion can be treated by desiccation, freezing, or curettage and chemical cauterization of the base. Topical imiquimod can be used as alternative therapy.

CONDYLOMA ACUMINATUM

Condylomata acuminata (genital warts) are caused by the papovavirus group. Papillary growths, small at first, tend to coalesce and form large cauliflower-like masses that may proliferate profusely during pregnancy.

Before treatment is undertaken, the entire lower genital tract should be examined with the colposcope and a cytologic smear taken from the cervix. Considering the frequent coexistence of other sexually transmitted diseases, appropriate studies are indicated. There is considerable variation in the oncogenic potential of human papovaviruses; therefore, a biopsy may be indicated. The incubation period for appearance of clinical disease after exposure is 3 months or longer. Apparent clinical disease may represent only a small area of the infected surface. Prompt recurrences after treatment may represent reinfection or clinical manifestation of latent disease. During treatment, the patient should keep the area as clean as possible and abstain from sexual intercourse or have her partner use a condom. If clinical disease recurs, then the sexual partner should be examined and treated as necessary. Penile, urethral, and perianal warts in the male may be overlooked.

Standard treatment is to cover the wart with bichloroacetic or trichloroacetic acid every week until the wart is gone. Alternative forms of treatment include cryosurgery, electrosurgical destruction, excision, and laser vaporization. Some authors recommend laser ablation of all visible lesions plus a margin of normal adjacent skin under colposcopic guidance. Intralesional interferon has been shown to be effective in refractory cases. Self-administered medication includes podofilox 0.5% solution or gel or imiquimod 5% cream (Table 37-5). Chemotherapeutic agents such as 5-fluorouracil ointment or bleomycin in the form of intralesional injections can be used as second-line therapies. Vaccine against certain high-risk HPV types has been recently developed. Preliminary studies have proved the vaccine to be safe and effective in the prevention of persistent HPV infection as well as cervical intraepithelial neoplasia (CIN).

Condyloma lata, a variation of secondary syphilis, should be considered in the differential diagnosis of condyloma acuminata.

Condylomatous warts may grow rapidly during pregnancy. Warts at the vaginal introitus may bleed during delivery and predispose the newborn to genital warts or laryngeal papillomatosis. Condylomata recognized early pregnancy should be treated early enough to allow healing prior to delivery. If treatment is not successful, delivery by cesarean section should be considered.

Infestations of the Vulva

PEDICULOSIS PUBIS

The crab louse (*Phthirus pubis*) is transmitted through sexual contact or from shared infected bedding or clothing. The louse eggs are laid at the base of a hair shaft near the skin. The eggs hatch in 7-9 days, and the louse must attach to the skin of the host to survive. The result is intense pubic and anogenital itching.

Minute pale-brown insects and their ova may be seen attached to terminal hair shafts. Treatment consists of permethrin 1% cream, lindane 1% shampoo, or pyrethrins with piperonyl butoxide. Lindane is not recommended for pregnant or lactating women or for children younger than 2 years. Treat all contacts and sterilize clothing that has been in contact with the infested area.

SCABIES

Sarcoptes scabiei causes intractable itching and excoriation of the skin surfaces in the vicinity of minute skin burrows where parasites have deposited ova. The itch mite is transmitted, often directly, from infected persons. The patient should take a hot soapy bath, scrubbing the burrows and encrusted areas thoroughly. Treatment consists of permethrin cream (5%), which should be applied to the entire body from the neck down, with particular attention to the hands, wrists, axillae, breasts, and anogenital region. It should be washed off after 8-14 hours. Alternatively, lindane (1%) in the lotion or cream form can be applied in a thin layer to all areas of the body and washed off after 8 hours. All potentially infected clothing or bedding should be washed or dry-cleaned. All contacts or persons in the family must be treated in the same way to prevent reinfection. Therapy

should be repeated in 10–14 days if new lesions develop.

ENTEROBIASIS (PINWORM, SEATWORM)

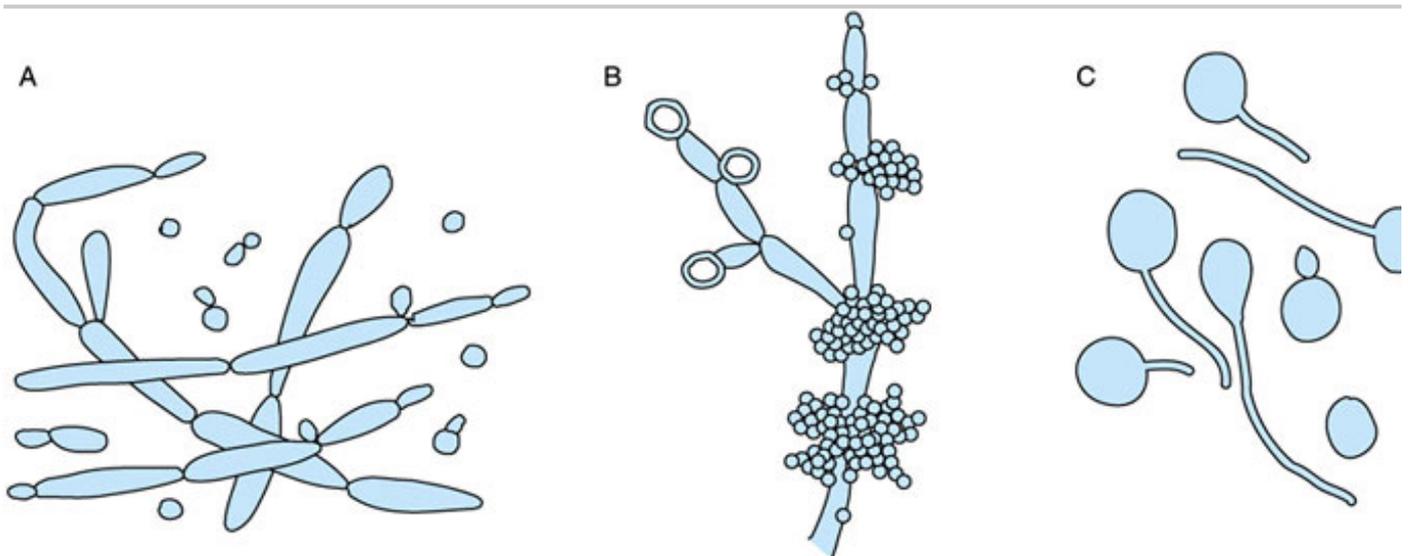

E. vermicularis infection is common in children. Nocturnal perineal itching is described by the patient, and perianal excoriation may be observed. Apply adhesive cellulose tape to the anal region, stick the tape to a glass slide, and examine under the microscope for ova. Patients should wash their hands and scrub their nails following each defecation. Underclothes must be boiled. Apply ammoniated mercury ointment to the perianal region twice daily for relief of itching. Pinworms succumb to systemic treatment with pyrantel pamoate, mebendazole, or pyrivinium pamoate.

Mycotic Infections of the Vulva

FUNGAL DERMATITIS (DERMATOPHYTOSES)

Tinea cruris is a superficial fungal infection of the genitocrural area that is more common in men than in women. The most common organisms are *Trichophyton mentagrophytes* and *Trichophyton rubrum*. The initial lesions usually are located on the upper inner thighs and are well circumscribed, erythematous, dry, scaly areas that coalesce. Scratching causes lichenification and a gross appearance similar to neurodermatitis. The diagnosis depends on microscopic examination (as for *Candida*) (Fig 37–11). Culture on Sabouraud's medium confirms the diagnosis. Treatment with 1% haloprogin, tolnaftate, or a similar agent is effective. Topical imidazole preparation at twice-daily application for 2–3 weeks also is highly effective.

Candida albicans. A: Blastospores and pseudohyphae in exudate. B: Blastospores, pseudohyphae, and conidia in culture at 20 C. C: Young culture forms germ tubes when placed in serum for 3 hours at 37 C.

(Reproduced, with permission, from Brooks GF, Butel JS, Ornston LN: *Jawetz, Melnick, & Adelberg's Medical Microbiology*, 19th ed. Appleton & Lange, 1991.)

Tinea versicolor usually involves the skin of the trunk, although occasionally the vulvar skin is involved. The lesions usually are multiple and may have a red, brown, or yellowish appearance. Diagnosis is the same as for other fungal infections. Treatment with selenium sulfide suspension daily for 5–7 days usually is curative. Topical imidazole preparations are most effective when used for 4 weeks. Ketoconazole has been used in recalcitrant cases.

DEEP CELLULITIS CAUSED BY FUNGI

Blastomycosis and actinomycosis are examples of deep mycoses that usually affect internal organs but also may involve the skin. Involvement of the vulvar epithelium in these diseases is rare in the United States. The diagnosis usually is made by laboratory exclusion of the granulomatous sexually transmitted diseases, tuberculosis, and other causes of chronic infection.

Treatment of blastomycosis with amphotericin B or hydroxystilbamidine is not very satisfactory. Actinomycosis usually can be treated successfully with penicillin.

Other Infections of the Vulva

IMPETIGO

Impetigo is caused by the hemolytic *S aureus* or streptococci. The disease is autoinoculable and spreads quickly to other parts of the body, including the vulva. Thin-walled vesicles and bullae develop that display reddened edges and crusted surfaces after rupture. The disease is common in children, particularly on the face, hands, and vulva.

The patient must be isolated and the blebs incised or crusts removed aseptically. Neomycin or bacitracin should be applied twice daily for 1 week. Bathing with an antibacterial soap is recommended.

FURUNCULOSIS

Vulvar folliculitis is caused by a staphylococcal infection of hair follicles. Furunculosis occurs if the infection spreads into the perifollicular tissues, producing a localized cellulitis. Some follicular lesions are palpable as tender subcutaneous nodules that resolve without suppuration. A furuncle begins as a hard, tender subcutaneous nodule that ruptures through the skin, discharging blood and purulent material. After expulsion of a core of necrotic tissue, the lesion heals. New furuncles may appear sporadically over years.

Minor infections can be treated by applications of topical antibiotic lotions. Deeper infections can be brought to a head with hot soaks, after which the pustules should be incised and drained. Appropriate systemic antibiotics are warranted when extensive furunculosis is present.

ERYSIPELAS

Erysipelas is a rapidly spreading erythematous lesion of the skin caused by invasion of the superficial lymphatics by β -hemolytic streptococci. Erysipelas of the vulva is exceedingly rare and is most commonly seen after trauma to the vulva or a surgical procedure. Systemic symptoms of chills, fever, and malaise associated with an erythematous vulvitis suggest the diagnosis. Vesicles and bullae may appear, and erythematous streaks leading to the regional lymph nodes are typical.

The patient should be given systemic (preferably parenteral) penicillin or tetracycline orally in large doses.

HIDRADENITIS

Hidradenitis suppurativa is a refractory process of the apocrine sweat glands, usually associated with staphylococci or streptococci. The apocrine sweat glands of the vulva become active following puberty. Impassation of secretory material and secondary infection may be related to occlusion of the ducts. Initially, multiple pruritic subcutaneous nodules appear that eventually develop into abscesses and rupture. The process tends to involve the skin of the entire vulva, resulting in multiple abscesses and subsequent chronic draining sinuses and scars. Treatment early in the disease consists of drainage and administration of antibiotics based on organism sensitivity testing. Long-term therapy with isotretinoin may be considered. Antiandrogen therapy with cyproterone acetate or ethinyl estradiol may be an alternate but highly effective treatment. Severe chronic infections may not respond to medical therapy, and the involved skin and subcutaneous tissues must be removed down to the deep fascia. This may necessitate a filet and curettage or a complete vulvectomy. The area generally will not heal after a primary closure; therefore, the wound must be left open and allowed to heal by secondary intention, or a split-thickness graft may be placed. Squamous cell carcinoma is rarely associated with hidradenitis.

suppurativa.

TUBERCULOSIS (VULVOVAGINAL LUPUS VULGARIS)

Pudendal tuberculosis is manifested by chronic, minimally painful, exudative "sores" that are tender, reddish, raised, moderately firm, and nodular, with central "apple jelly"-like contents. Ulcerative, necrotic discharging lesions develop later. There is some tendency toward healing with heavy scarring. Induration and sinus formation are common in the scrofulous type of infection. Cancer and sexually transmitted disease must be ruled out, and evaluation for tuberculosis at other sites must be performed.

Wet compresses of aluminum acetate solution (Burow's solution) are helpful. Systemic antituberculosis therapy should be given.

Vulvar Nonneoplastic Epithelial Disorders

The term vulvar dystrophies was previously used to define the nonneoplastic epithelial disorders of the vulva. As characterized by the International Society for the Study of Vulvovaginal Disease (ISSVD), these lesions include (1) lichen sclerosus (previously lichen sclerosus et atrophicus), (2) squamous cell hyperplasia (previously hyperplastic dystrophy), and (3) other dermatoses (lichen simplex chronicus, lichen planus). These lesions present classically with intense pruritus with or without pain and vulvar epithelial changes. Differentiating among these disorders and ruling out an underlying malignant process require histopathologic diagnosis. The risk of an underlying malignancy is less than 5%. Patients must be reexamined periodically, and one should not hesitate to take additional biopsy specimens. Table 37–8 lists a classification of these lesions.

Table 37–8. Nonneoplastic Epithelial Disorders of the Vulva.

Lichen sclerosus

Thin, white, wrinkled tissue, with a cigarette-paper appearance

Agglutination of the labia minora and prepuce

Introital stenosis

Epidermis—Hyperkeratosis, epithelial atrophy, and flattening of the rete pegs; cytoplasmic vacuolization of the basal layer of cells

Upper dermis—Edematous, pale-staining, acellular, homogenous collagen tissue

Deeper dermis—Inflammatory infiltrate, mainly lymphocytic

Clobetasol propionate 0.05% twice daily for 1 month, then once daily for 2 months

Not proven—2% testosterone cream, 1.25% topical progesterone

Squamous cell hyperplasia

Circumscribed, single or multifocal

Raised white lesion on vulva or adjacent tissue (generally of labia majora and clitoris)

Epidermis—Hyperkeratosis and acanthosis, producing thickening of the epithelium and elongation of the rete pegs

Dermis—No inflammatory infiltrate present

Medium-potency topical steroids twice daily

Lichen simplex chronicus

Thickened white epithelium on vulva

Generally unilateral and localized

Epidermis—Hyperkeratosis and acanthosis, producing thickening of the epithelium and elongation of the rete pegs

Superficial dermis—Chronic inflammatory cells, fibrosis, and collagenization

Presence of cellular atypia signifies vulvar intraepithelial neoplasia (VIN I–III)

Medium-potency topical steroids twice a daily

Lichen planus

Erosive lesions at vestibule vaginal synechiae resulting in stenosis

May have associated oral mucocutaneous lesions and desquamative vaginitis

Mild, localized, lichenoid, chronic inflammatory process at the epidermal-dermis junction to ulcerative process with fibrosis

Immunofluorescent staining should be considered to exclude pemphigus and pemphigoid

Vaginal hydrocortisone suppository 25 mg

Betamethasone cream 0.1% vaginally at bedtime for 2 weeks

Vaginal estrogen cream in cases of atrophic epithelium

Vaginal dilators in cases of stenosis

Psoriasis

Red moist lesions scales

Epidermis—Parakeratosis with clubbing of the rete pegs

Dermis—Microabscesses of Munro

Topical corticosteroids

Dermatosis	Physical Exam	Histology	Treatment
------------	---------------	-----------	-----------

LICHEN SCLEROSUS

Lichen sclerosus is a benign, chronic, inflammatory process and the most common vulvar dermatologic disorder. Although its etiology is unknown, a multifactorial process is most likely involved in its development. Kerner's phenomenon occurs in lichen sclerosus; therefore, scarring or trauma may elicit its development. The skin of the vulva is most commonly involved, although other sites may be affected. Lichen sclerosus can affect both sexes and individuals of any age. However, the disease is clinically more prevalent in older patients. During the acute phase, the lesion may appear red or purple and classically involves the non-hair-bearing areas of the vulva, perineum, and perianal area in an hourglass pattern (Fig 37–12). With acute disease, erythema and edema of vulvar skin occur. The patient experiences intense pruritus leading to scratch cycle, ulcerations, and ultimately scar formation. With chronic disease, the skin is thin, wrinkled, and white and has a cigarette-paper appearance. The vulvar structures contract with agglutination of the labia minora and prepuce and introital stenosis. Symptoms of pain, including dyspareunia, may occur, mostly from decreased skin elasticity with loss of elastin from the upper dermis. Although skin atrophy ultimately may develop, the underlying disease is inflammatory in nature, and consequently areas of dysplasia may develop. Therefore, suspicious areas must be biopsied (Fig 37–13). Repeat biopsies should be taken as indicated because this is a chronic condition. Patients should be monitored for possible malignant changes because of an estimated 4–6% risk of developing squamous cell carcinoma.

Advanced lesion of lichen sclerosus. The labia minora and prepuce of the clitoris have blended into the labial skin. Focal dysplasia was present in the posterior third of the right labium majus.

,

Definitive diagnosis depends on histologic examination of the biopsy. The differential diagnosis includes pemphigoid, pemphigus, advanced scleroderma, lupus erythematosus, advanced lichen planus, and radiation fibrosis. In the well-developed lesion, lichen sclerosus is characterized by hyperkeratosis, epithelial atrophy, and flattening of the rete pegs. The upper dermis is edematous, pale staining with fibrin deposition. The deeper dermis has an inflammatory infiltrate, mainly monocytic. Beneath the epidermis is a zone of homogenized collagenous tissue that is acellular and pink in appearance (Fig 37-14).

Figure 37-14.

All rights reserved.

Microscopic appearance of lichen sclerosus, characterized by hyperkeratosis, flattened epidermis, and hyalinization of the dermis.

Treatment involves initially stopping the itch-scratch cycle and minimizing the dermal inflammation. An oral antihistamine agent can be given at bedtime. Several studies have found treatment with ultra-potent steroid cream or ointment to be very effective in treating lichen sclerosus. Clobetasol propionate 0.05%, twice daily for month and then daily for 3 months, has been shown to be most effective for treatment of lichen sclerosus, with approximately 75% success. A subsequent taper to lower-potency topical steroids is necessary for maintenance therapy. Atrophic degeneration of the skin secondary to the steroid paradoxically does not occur. Although 2% testosterone or progesterone cream have been used to treat lichen sclerosus, they are minimally effective and should not be used as first-line therapy. In addition, patients should avoid tight undergarments, they should cleanse daily with mild soap, and they should use a hair dryer to keep the vulvar skin dry. In refractory cases, intralesional injection of steroids may be attempted. Other alternative therapies for refractory lichen sclerosus include tacrolimus cream, retinoids, cryotherapy, antimalarial agents, and photodynamic therapy. Surgical therapy should be limited to treatment of introital narrowing, pseudocysts, and associated squamous cell carcinoma.

SQUAMOUS CELL HYPERPLASIA

Vulvar squamous cell hyperplasia is known by various names—hyperplastic dystrophy, atopic dermatitis, atopic eczema, and neurodermatitis. The benign epithelial thickening and hyperkeratosis may be the result of chronic vulvovaginal infections or other causes of chronic irritation. During the acute phase, as in diabetic vulvitis, the lesions may be red and moist and demonstrate evidence of secondary infection. The condition is exacerbated by the accompanying pruritus, which leads to rubbing and scratching. This becomes involuntary over time. As epithelial thickening develops, the environment of the vulva causes maceration, and a raised white lesion may be circumscribed or diffuse and may involve any portion of the vulva, adjacent thighs, perineum, or perianal skin. Biopsy must be performed to eliminate intraepithelial neoplasm or invasive tumor. With squamous cell hyperplasia, histologic examination demonstrates hyperkeratosis and acanthosis, producing thickening of the epithelium and elongation of the rete pegs. No dermal inflammatory infiltrate is present as with lichen sclerosus. Atypical hyperplasia or cancer is characterized by nuclear pleomorphism and loss of cellular polarity in the epithelium.

Treatment of squamous cell hyperplasia seeks to achieve symptomatic relief. Sitz baths and lubricants can help restore moisture to cells and reconstruct the epithelial barrier. Oral antihistamines or antidepressants (ie, selective serotonin reuptake inhibitors) may help relieve pruritus. Local application of medium-potency topical

steroids twice per day can decrease the inflammation and pruritus. Vulvar epithelium takes at least 6 weeks to heal. In intractable cases, subcutaneous intralesional injection of steroids can be considered. Differential diagnosis includes lichen simplex chronicus, lichen planus, condyloma acuminatum, psoriasis, and vulvar intraepithelial neoplasia.

OTHER DERMATOSES

Lichen planus of the vulva is a relatively common mucocutaneous dermatosis characterized by the presence of sharply margined violaceous, flat-topped papules on the skin and less sharply marginated white plaques on oral and genital mucous membranes. The pathogenesis is unknown. In the vulva two clinical aspects can be observed: classic leukoplakic lesions and erosive lesions. Vulvar erosive lichen planus seems to be more frequent but often ignored. The clinical appearance of vaginal erosive lichen planus is similar to that of desquamative inflammatory vaginitis. It is a chronic, recalcitrant disease with associated vulvar burning and pruritus that is only partially ameliorated by therapy. Although mild forms are sometimes controlled with topical corticosteroids, the course of usual erosive lichen planus is one of exacerbations with slow healing. Treatment of lichen planus is mainly topical using fluorinated corticosteroids or ultra-potent corticosteroids for the vulva and hydrocortisone foam for the vagina (Colofoam). Careful and frequent examination of the vagina for early adhesions is important. In cases of severe pruritus and intensive mucocutaneous involvement, systemic steroids should be used. Recently, topical treatment with tacrolimus 0.1% has been tried with success. Introital stenosis and vaginal adhesions sometimes benefit from home use of vaginal dilators in graduated sizes or from surgical release of scars.

Lichen simplex chronicus is another chronic inflammatory process of the vulva that presents as a white lesion associated with vulvar pruritus. Biopsy is generally necessary for the diagnosis. Histologically, the features are similar to those of squamous cell hyperplasia. Again, treatment is with medium-strength topical corticosteroid cream.

Benign Cystic Tumors

The diagnosis of small cystic structures on the vulva is ordinarily made by clinical examination or by excision biopsy, which also serves as treatment.

EPIDERMAL CYSTS

Cysts of epidermal origin are lined with squamous epithelium and filled with oily material and desquamated epithelial cells. Epidermal inclusion cysts may result from traumatic suturing of skin fragments during closure of the vulvar mucosa and skin after trauma or episiotomy. However, most epidermal cysts arise from occlusion of pilosebaceous ducts. These cysts usually are small, solitary, and asymptomatic.

SEBACEOUS CYSTS

A sebaceous cyst develops when the sebaceous gland's duct becomes occluded and accumulation of the sebaceous material occurs. These cysts are frequently multiple and almost always involve the labia majora. They are generally asymptomatic; however, acutely infected cysts may require incision and drainage.

APOCRINE SWEAT GLAND CYSTS

Apocrine sweat glands are numerous in the skin of the labia majora and the mons pubis. They become functional after puberty. Occlusion of the ducts with keratin results in an extremely pruritic, microcystic disease called Fox Fordyce disease. Chronic infection in the apocrine glands, usually with staphylococci or streptococci, results in multiple painful subcutaneous abscesses and draining sinuses. This condition is called hidradenitis suppurativa, which is generally treated with a broad-spectrum antibiotic. Hidradenoma and syringoma are included in a diverse group of benign cystic or solid tumors of apocrine sweat gland origin present as small subcutaneous and asymptomatic tumors.

BARTHOLIN'S DUCT CYST AND ABSCESS

Obstruction of the main duct of Bartholin's gland results in retention of secretions and cystic dilatation. Infection

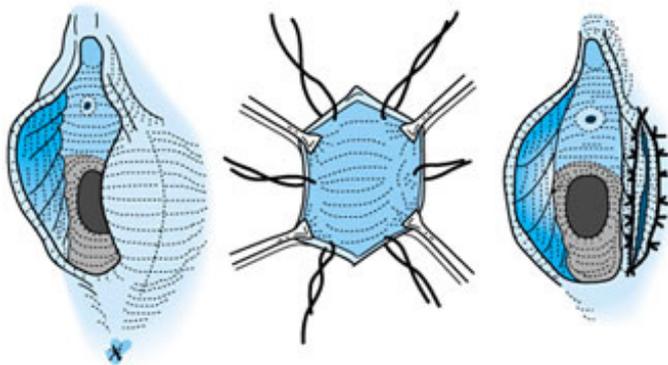

an important cause of obstruction; however, other causes include inspissated mucus and congenital narrowing of the duct. Secondary infection may result in recurrent abscess formation.

The gland and duct are located deep in the posterior third of each labium majus. Enlargement in the postmenopausal patient may represent a malignant process (although the incidence is < 1%), and biopsy should be considered.

Acute symptoms ordinarily result from infection, which leads to pain, tenderness, and dyspareunia. The surrounding tissues become edematous and inflamed. A fluctuant, tender mass is usually palpable. Unless an extensive inflammatory process is present, systemic symptoms or signs of infection are less likely.

Primary treatment consists of drainage of the infected cyst or abscess, preferably with insertion of a Word catheter (an inflatable bulb-tipped catheter) or by marsupialization (Fig 37–15). Simple incision and drainage may provide temporary relief. However, the end may become obstructed and recurrent cystic dilatation may recur. Appropriate antibiotics should be given if considerable surrounding inflammation develops. Excision of the cyst may be required in recurrent cases or in the postmenopausal patient.

Figure 37–15.

Copyright ©2006 by The McGraw-Hill Companies, Inc.
All rights reserved.

Marsupialization of a vestibular duct (Bartholin's) cyst.

Recurrent infection resulting in cystic dilatation of the duct is the rule unless a permanent opening for drainage is established.

OTHER

A variety of other infrequent cystic vulvar tumors must be considered in the differential diagnosis. Anteriorly, a Skene duct cyst or urethral diverticulum may be visible, suggesting a vulvar tumor. An inguinal hernia may extend into the labium majus, causing a large cystic dilatation. Occlusion of a persistent processus vaginalis (canal of Nuck) may cause a cystic tumor or hydrocele. Dilatation of the mesonephric duct vestiges produces lateral vaginal wall cysts, Gartner's duct cyst. Supernumerary mammary tissue that persists in the labia majora may form a cystic or solid tumor or even an adenocarcinoma; engorgement of such tissue in the pregnant patient can be symptomatic.

Benign Solid Tumors

A benign solid tumor may be an incidental finding at the time of pelvic examination, or it may be of sufficient size to cause symptoms of irritation and/or bleeding. The diagnosis should be established by excision or biopsy to rule out an underlying malignancy.

ACROCHORDON

An acrochordon is a flesh-colored, soft polypoid tumor of the vulvar skin that has been called a *fibroepithelial*

polyp or simply a *skin tag*. The tumor does not become malignant and is of no clinical importance, unless it becomes traumatized, causing bleeding. Simple excision biopsy in the office is ordinarily adequate therapy.

PIGMENTED NEVUS

Pigmented lesions, suggestive of nevi, should be removed by wide local excision or biopsied to diagnose or exclude a melanoma. A nevus on the vulvar skin may be flat, slightly elevated, papillomatous, dome-shaped, or pedunculated. Melanomas of the vulva are uncommon neoplasms constituting only 1–3% of vulvar cancers. They are extremely aggressive malignant lesions and may arise from pigmented nevi of the vulva. Melanosis of the vaginal or vulvar epithelium is a benign, flat, darkly pigmented lesion that usually can be differentiated from a nevus without histologic examination.

LEIOMYOMA, FIBROMA, AND LIPOMA

Tumors of mesodermal origin occur infrequently on the vulva, but they can become extremely large. Leiomyomas arise from muscle in the round ligament and appear as firm, symmetric, freely mobile tumors deep in the substance of the labium majus. Fibromas arise from proliferation of fibroblasts and vary in size from small subcutaneous nodules found incidentally to large polypoid tumors. Large tumors often undergo myxomatous degeneration and are very soft and cystic to palpation. Lipomas consist of a combination of mature fat cells and connective tissue. They cannot be differentiated from degenerated fibromas except by histopathologic examination.

Small tumors can be removed under local anesthesia in the office. Large tumors require general anesthesia and operating room facilities. The diagnosis of sarcoma depends on histologic examination.

NEUROFIBROMA

Neurofibromas are fleshy polypoid lesions and may be solitary, solid tumors of the vulva or associated with generalized neurofibromatosis (Recklinghausen's disease). They arise from the neural sheath and usually are small lesions of no consequence. Multiple disfiguring tumors of the vulva may interfere with sexual function and require excision or vulvectomy.

GRANULAR CELL MYOBLASTOMA (SCHWANNOMA)

Granular cell myoblastoma is usually a solitary, painless, slow-growing, infiltrating but benign tumor of neural sheath origin, most commonly found in the tongue or integument, although approximately 7% involve the vulva. The usual picture consists of small subcutaneous nodules 1–4 cm in diameter. With increasing size, they erode through the surface and result in ulcerations that may be confused with cancer. The margins of the tumor are indistinct, and wide local excision is necessary to completely excise the cells extending into contiguous tissues. The area of resection must be periodically re-examined and secondary excision performed promptly if recurrence is suspected.

VULVAR PAIN SYNDROME

Vulvar pain in the absence of relevant, visible physical findings is termed *vulvodynia*. The patient suffering from vulvodynia describes her symptoms as burning, rawness, irritation, dryness, and hyperpathia (pain provoked by very light touch). Approximately 16% of the female population has experienced vulvodynia and approximately 1.5% currently suffer from the disorder. The ISSVD has classified vulvodynia into generalized vulvodynia (provoked or unprovoked) and localized vulvodynia (provoked and unprovoked). When interviewing a patient suffering from vulvodynia, a detailed history and examination are important to help determine the etiology (Table 37–9) and to direct the diagnosis and treatment.

Table 37–9. Etiologies of Vulvodynia.

Infections

Bartholin's gland abscess, vulvovaginal candidiasis, herpes, herpes zoster, human papillomavirus, molluscum contagiosum, trichomoniasis

Trauma

Sexual assault, prior vaginal deliveries, hymenectomy

Systemic Illness

Behet's disease, Crohn's disease, Sjgren's syndrome, systemic lupus erythematosus

Neoplasia

Vulvar intraepithelial neoplasia and invasive squamous cell carcinoma

Allergens/toxic medications

Soaps, sprays, douches, antiseptics, suppositories, creams, laser treatment, podophyllin, trichloroacetic acid, 5-fluorouracil

Dermatologic conditions

Allergic and contact dermatitis, eczema, hidradenitis suppurativa, lichen planus, lichen sclerosus, pemphigoid, pemphigus, psoriasis, squamous cell hyperplasia

Urinary tract syndromes

Interstitial cystitis and urethral syndrome

Neurologic

Referred pain from urethra, vagina, and bladder; dysesthesias secondary to herpes zoster, spinal disk problems; specific neuralgias (pudendal, genitofemoral)

Psychological

Sexual/physical abuse history

The time of onset, the type of pain (burning, stinging, irritation), timing (constant or cyclic), associated activities (eg, intercourse), inciting agents (eg, perfumes, lotions, detergents, clothing), and relieving factors (eg, antifungal medications) should be elicited. In addition, past or current infections (HPV, herpes, *Candida*), medications (eg, trichloroacetic acid, 5-fluorouracil), local and systemic dermatologic disorders, neurologic disorders (eg, herniated disks, herpes zoster, pudendal or genitofemoral neuralgia), urologic disorders (eg, interstitial cystitis, urethral syndrome), and physical trauma (eg, vaginal delivery, episiotomy, vaginal surgery) should be ascertained. In many cases the vulva appears normal on physical examination. The patient should be tested for allodynia and hyperalgesia in the vulvar area. Mapping of tender surfaces should be performed using a cotton-tipped swab. Vaginal pH and microscopic examination of vaginal secretions with KOH and normal saline can help evaluate for vaginitis. Acetowhite changes with application of 5% acetic acid should be biopsied as well as any distinct lesions to evaluate for an underlying dermatosis, infectious, or neoplastic process.

Localized Provoked Vulvodynia

The condition was formerly known as vulvar vestibulitis and clitorodynia. The vestibule is the nonpigmented, nonkeratinized squamous epithelium of the vulva between the labia minora and the hymen. Localized provoked vulvodynia is characterized by 3 criteria: (1) introital pain on vestibular or vaginal entry (entry dyspareunia), (2) vestibular erythema or inflammation of the vestibule, commonly involving the posterior fourchette, and (3) vestibular tenderness—pressure from a cotton-tipped applicator at the vestibule reproduces the pain. This syndrome generally affects women in their 20s and 30s who complain of introital dyspareunia (severe pain on vaginal penetration by their partner). It may present as persistent vaginal discharge and burning. On biopsy, the subepithelial tissue demonstrates a nonspecific, chronic inflammatory infiltrate, consisting predominately of lymphocytes without direct glandular inflammation. The etiology remains undetermined.

Although numerous medical options are available for treatment, the success of many of these modalities are not substantiated by properly conducted studies (Table 37–10). Patients should be instructed on proper vulvar hygiene (cotton underwear, keeping area dry, avoidance of constrictive garments and irritating agents). The initial conservative approach to therapy includes topical estradiol with twice-daily application, 5% lidocaine ointment daily, calcium citrate 400 mg 3 times daily to decrease the urinary oxalate crystal concentration, oral antifungal therapy using fluconazole 150 mg weekly, and pelvic floor therapy with biofeedback. The injectable forms of therapy include intralesional interferon injection to treat possible HPV, trigger point injections with long-acting injectable anesthetics, and injection of botulinum toxin to treat vaginismus as the source of vulvodynia. The surgical treatment of localized provoked vulvodynia in the form of vulvar vestibulectomy with vaginal advancement is most effective (70% success rate) in patients who have been refractory to more conservative therapies.

Table 37–10. Treatment of Vulvodynia.

Supportive measures—warm sitz baths, Burrow's solution, topical anesthetic agents (2% topical xylocaine gel or 5% ointment) and other lubricants with intercourse

Vulvar hygiene—cotton underwear, avoidance of constrictive garments

Treat underlying cause:

Human papillomavirus (HPV)¹ —trichloroacetic acid, topical 5-fluorouracil, interferon 1 million IU per injection site with total of 12 injection sites over 4 weeks, laser, and cream

Candida—fluconazole 150 mg once per week for 6 weeks then once per month for 6 months (for cyclic vulvodynia)

Allergens—avoidance of agent (also of local creams and suppositories containing propylene glycol), hydroxyzine or other antihistamine, hydrocortisone 1% cream twice daily, 5% aspirin cream

Atrophy—topical estrogen vaginal cream, oral hormone replacement therapy

Diet modification—low-oxalate diet with calcium citrate 400 mg orally twice daily

Tricyclic antidepressants—amitriptyline 10–25 mg three times daily (use lowest dose possible)

Psychological and behavioral pain management

Biofeedback

Surgery—vestibuloplasty, partial vestibulectomy with vaginal advancement, total vestibulectomy with vaginal advancement

¹ Current studies do not substantiate HPV as a causative factor in vulvodynia; however, its treatment, particularly with interferon, is still supported in the literature.

CO₂ laser vaporization is no longer recommended for this condition.

Up to two-thirds of patients may be cured following a variety of treatments. Recalcitrant cases even subsequent to surgery may occur, resulting in continued dyspareunia. In these cases, acupuncture and referral to a pain treatment center may be an option.

Generalized Unprovoked Vulvodynia

This condition was formerly known as pudendal neuralgia. Its etiology is unknown. The pain involves a larger surface area than that of localized vulvodynia. The average patient is in her 40s. The typical patient complains of intermittent or constant burning sensation with periods of unexplained relief and/or flares. The diagnosis is made by exclusion. Infections and dermatosis should be ruled out. A test for allodynia and hyperalgesia using a cotton tipped swab should be performed. It is believed to be a neuropathic pain, but other organic causes, including pudendal nerve entrapment, pudendal nerve injury due to child birth, referred pain from ruptured disk, neuropathic viruses such as herpes simplex or varicella-zoster, and neurologic disease such as multiple sclerosis are possible.

Treatment of generalized unprovoked vulvodynia is mostly unsuccessful. The patient should be counseled on elimination of irritants and on self-care. Topical local anesthetics, tricyclic antidepressants, or anticonvulsants such as gabapentin can be tried. If the patient is refractory to such treatment, acupuncture or referral to a pain center may be attempted.

Current OB/GYN >Chapter 38. Benign Disorders of the Uterine Cervix>

CONGENITAL ANOMALIES OF THE CERVIX

The cervix develops from the paramesonephric ducts in the sixth week of embryologic development. After fusion of the 2 müllerian ducts in the midline, there is resorption of the septum (Fig 38–1). In the absence of the development of paramesonephric ducts, there is agenesis of the cervix and uterus. Other anomalies may result from incomplete fusion of these ducts or failure of resorption of the midline septum.

Figure 38–1.

Fusion of müllerian ducts to form cervix and corpus uteri.

Cervical Agenesis

Cases of an absent uterine cervix with a normal uterine corpus and normal vagina have been reported. These cases presumably result from either failure of müllerian duct canalization or abnormal epithelial proliferation after canalization. More common is the absence of a cervix along with the absence of a uterine corpus and upper vagina. Because most of the vagina is derived from müllerian ducts, the vagina may be shortened in müllerian aplasia. Women with müllerian aplasia have normal ovaries and are able to contribute oocytes for in vitro fertilization with their partner's sperm. This allows for a transfer to a uterus of a surrogate woman who may carry the pregnancy to term. Female offspring of women with müllerian aplasia have been studied to identify a possible genetic contribution to this disorder. Because no offspring with müllerian aplasia have been reported, this disorder is assumed to be result from a polygenic multifactorial inheritance pattern.

Cervical agenesis with a normal functioning uterine corpus must be differentiated from müllerian aplasia (Figs 38–2 and 38–3). In the former, menstrual blood may accumulate, leading to retrograde flow and development of endometriosis. Ultrasonography, magnetic resonance imaging (MRI), and laparoscopy can help with the diagnosis by defining the anatomy. Many of these patients also have urinary tract abnormalities and require an intravenous pyelogram.

Cervical aplasia with hematometra and retrograde menstruation.

Nonsurgical treatment involves the use of vaginal dilators. Using a bicycle stool designed by Ingram, special dilators are placed that are under constant perineal pressure. The most common surgical approach is the McIndoe technique for creation of a neovagina. The Vecchiotti operation combines a surgical and nonsurgical approach to creating a neovagina and has been recently performed by laparoscopy.

Incomplete Müllerian Fusion

If the Müllerian ducts fail to completely fuse and canalize, a variety of anomalies may occur. Complete failure of fusion of the ducts results in uterine didelphys; there are 2 separate uterine horns, each with a distinct cervix and vagina. The 2 vaginas are separated by a midline septum. If incomplete fusion results in a uterine horn ending blindly, a hematocolpos can develop (Fig 38–4).

Uterus didelphys with blind vagina hematocolpos, hematometra, hematosalpinx, and retrograde menstruation.

Bicornuate uterus and arcuate uterus are due to partial incomplete fusion of the Müllerian ducts. In the bicornuate uterus, 2 discrete uterine cavities lead to the same cervix (Fig 38–5). The arcuate uterus may demonstrate minimal depression of the uterine fundus and is often clinically insignificant. Renal abnormalities are found in 20–30% of women with Müllerian defects.

Figure 38–5.

Complete bicornuate uterus with fibromuscular septum at the level of internal cervical os.

Failure of Resorption

After fusion of the müllerian ducts, resorption of the intervening septum proceeds both caudal and cephalic. A septate uterus results from failure of resorption of the intervening septum (Fig 38–6). The septum may project from the uterine fundus through the cervical canal, completely dividing the uterine cavity in 2, or it may be segmental.

Figure 38–6.

All rights reserved.

Complete septate uterus.

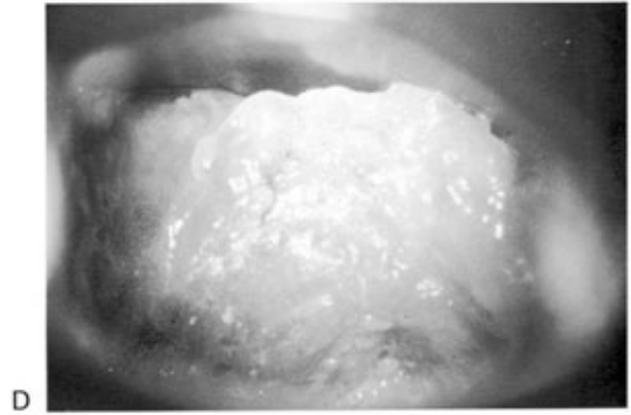

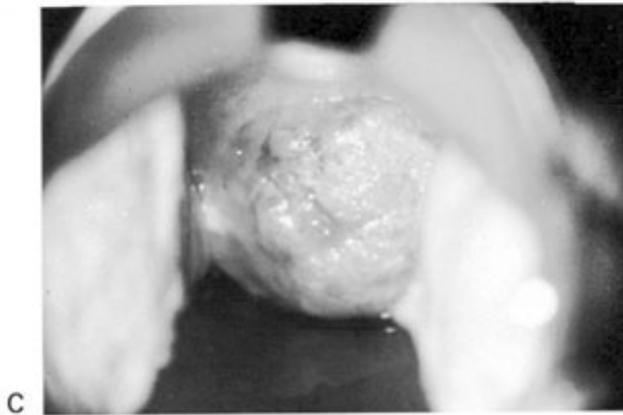

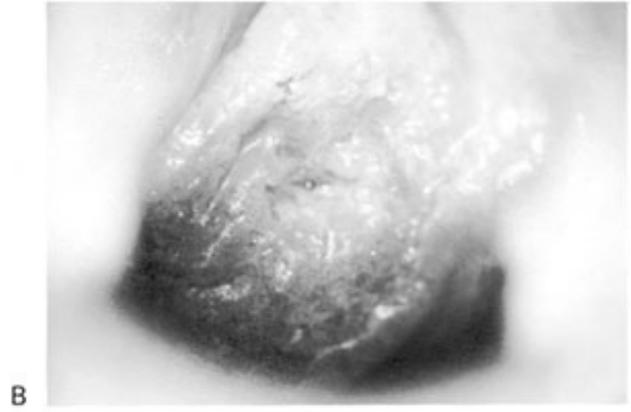

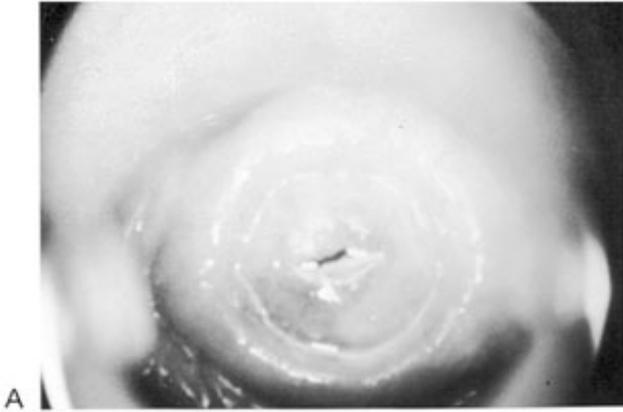

The septum consists of fibromuscular tissue. Failure or incomplete resorption of this septum is associated with reproductive and obstetric complications. First- and second-trimester spontaneous miscarriages are common and usually occur between 8 and 16 weeks' gestation. It is hypothesized that the septum interferes with placental implantation. Obstetric complications can include premature labor, malpresentation, and intrauterine growth restriction. Approximately 15–25% of spontaneous miscarriages are due to Müllerian abnormalities, and the majority are associated with the septate uterus (70–88%).

If a septate uterus is identified in association with reproductive or obstetric complications, surgical therapy is recommended. Imaging studies including ultrasound, MRI, sonohysterography, and hysterosalpingogram provide information to differentiate the septate uterus from other uterine abnormalities. Combined laparoscopy and hysteroscopy remains the most reliable method for accurately differentiating the septate uterus from a bicornuate uterus. Hysteroscopic resection of the uterine septum has been demonstrated to improve reproductive outcome in women with recurrent spontaneous miscarriages. Whether a hysteroscopic metroplasty improves fertility in those infertile women is controversial.

CERVICAL ABNORMALITIES DUE TO DIETHYLSTILBESTROL EXPOSURE IN UTERO

Diethylstilbestrol (DES) is a synthetic nonsteroidal estrogen that was first synthesized in 1938. Although the number of pregnant women treated with DES is unknown, estimates range from 2–10 million. DES has been shown to cause uterine and cervical abnormalities. Common structural changes of the cervix include collars, hoods, cockscombs, and pseudopolyps (Fig 38–7). Multiple anomalies of the uterus and vagina are also reported in association with DES exposure in utero.

Figure 38–7.

Cervical changes in women exposed to diethylstilbestrol in utero. A: Circular sulcus. B: Central depression and ectopy. C: Portio vaginalis covered by columnar epithelium (ectopy). D: Anterior cervical protuberance (rough). E: Anterior cervical protuberance (smooth).

Women who are exposed to DES in utero and have cervical abnormalities are at increased risk for infertility. These women are also at increased risk for adverse outcomes in pregnancy, including miscarriage, ectopic pregnancy, and premature delivery. The use of prophylactic cervical cerclage for cervical incompetence related

to DES exposure in utero is not recommended.

CERVICAL INJURIES

Lacerations

Cervical lacerations most frequently occur after a normal or abnormal vaginal delivery, but they can occur in the nonobstetric patient as well. With delivery, the most common tears occur at the 3 and 6 o'clock positions. Lacerations are more commonly found after an operative vaginal delivery requiring forceps or vacuum. It is important to carefully inspect the entire cervix after delivery to identify any lacerations. Most lacerations can be easily repaired with suture technique. Often a laceration is asymptomatic and does not require repair. More severe lacerations that may extend into the broad ligament have been reported and may require more extensive surgical repair.

Performance of dilatation and curettage (D&C), particularly on the postmenopausal patient, can result in cervical laceration. The use of cervical laminaria preoperatively may decrease the risk of trauma and laceration of the cervix. Preoperative use of misoprostol to reduce the force required to dilate the cervix, potentially reducing the incidence of cervical lacerations, has been reported.

Cervical lacerations are reported with use of the resecting loop in hysteroscopic surgery. Use of the rollerball and other instruments for ablating the endometrium for treatment of menorrhagia has been found to increase the incidence of cervical lacerations. Excessive traction on the anterior lip of the cervix with a single-tooth tenaculum may lead to a laceration.

Perforations

Perforation of the cervix may occur during self-induced abortion with sharp objects (eg, wires or darning or knitting needles), or inadvertently during sounding of the uterus, cervical dilatation, insertion of radioactive sources, or conization of the cervix. The urinary bladder and the rectum are at risk for injury because of their close proximity to the cervix.

Ulcerations

Ulceration of the cervix may result from pressure necrosis due to a vaginal pessary or a cervical stem pessary. Cervical ulceration may also develop with uterine prolapse when the cervix protrudes through the vaginal introitus.

Cervical Stenosis

Cervical stenosis usually occurs at the level of the internal os and may lead to significant symptoms. In the premenopausal woman, cervical stenosis may be responsible for obstruction of menstrual flow, leading to amenorrhea and pelvic pain. Additionally, infertility may result from cervical stenosis. A postmenopausal woman with cervical stenosis may have pyometra, requiring evacuation of uterine contents and biopsy to rule out endometrial carcinoma.

Cervical surgery such as cone biopsy, loop excision, or ablative techniques for treatment of dysplasia may lead to cervical stenosis. Excision by loop diathermy tends to remove less cervical stroma and therefore is less likely to cause cervical stenosis than a cold knife cone biopsy. Radiation therapy, neoplasia, and atrophic changes are more common causes in the postmenopausal woman.

The diagnosis of cervical stenosis is made by the inability to pass a small cervical dilator. Ultrasonography may indicate the presence of uterine contents that are obstructed. Treatment is usually with dilators under ultrasound guidance. Use of various techniques such as laser treatment, loop diathermy, and the hysteroscope with resecting loop to remove areas of cervical stenosis has been reported. After successful dilatation, placement of a pediatric Foley catheter in the cervix for a few weeks may be beneficial in order to maintain

patency.

Annular Detachment

Annular detachment of the cervix is a rare complication resulting from compression necrosis of the cervix during labor. It occurs when the external os fails to dilate and the blood supply is compromised by pressure of the fetal head. The diagnosis is made when the detached ring or portion of cervix is expelled prior to delivery of the presenting part of the fetus.

Complications of Cervical Injuries

Hemorrhage is the most immediate and serious complication of cervical laceration. Although external bleeding usually is present, intraperitoneal or extraperitoneal hemorrhage may occur when the cervical tear extends into the uterus. The clinical picture is that of hypovolemic shock out of proportion to visible blood loss.

Cervical incompetence results from unrecognized or improperly repaired lacerations at the level of the internal os. Repeated or habitual abortion, often occurring during the second trimester of pregnancy, may be due to cervical incompetence.

CERVICAL INFECTIONS

General Considerations

Advances in colposcopy and sensitive testing for infectious diseases has allowed better assessment of the causes of acute and chronic cervicitis. Hypervascularity, erythema, and ectopy are more consistent with squamous metaplasia than is an inflammatory change requiring therapy. Histologic diagnosis of cervicitis is common enough to be considered a normal finding. The cervix is in direct contact with the vagina and therefore is exposed to viral, bacterial, fungal, and parasitic agents. Cervical infections of these types may be found in the absence of vaginal disease. The cervix is a reservoir for infections with *Neisseria gonorrhoeae*, *Chlamydia trachomatis*, herpes simplex virus (HSV), human papillomavirus (HPV), and *Mycoplasma* spp. Because many of these women are asymptomatic, screening of women at risk is important.

Etiology and Pathogenesis

C trachomatis is sexually transmitted and invades the columnar epithelium of the cervix; thus, the condition is best categorized as endocervicitis. With the cervix as a reservoir, the organism may infect the fetus during its passage through the birth canal, or it may ascend via the endometrial cavity to the fallopian tubes to cause salpingitis as well as pelvic and perihepatic peritonitis. It has been implicated as the agent responsible for the Fitz-Hugh and Curtis syndrome (violin-string adhesions between the liver and the parietal peritoneum). *C trachomatis* and *N gonorrhoeae* often are coinfecting agents in the etiology of acute and chronic cervicitis and salpingitis. *C trachomatis* may be transmitted to the eyes, where it causes trachoma and inclusion conjunctivitis.

N gonorrhoeae is a common cause of cervicitis also infecting the columnar epithelium of the endocervix. The mature squamous epithelium of the adult cervix and vagina is resistant to the invading organism. As in the case of *Chlamydia* infections, the cervix acts as a nidus for ascending infection of the endometrium and the fallopian tubes, with upward invasion often occurring after a menstrual period and loss of the protective mucus plug.

HSV infection produces cervical lesions similar to those found on the vulva. The lesion is vesicular at first and then becomes ulcerative. Primary infections may be extensive and severe, producing constitutional symptoms of low-grade fever, myalgia, and malaise lasting approximately 2 weeks. The ulcers eventually heal, but recurrences of lesser severity and duration are common. Herpes simplex virus type 2 (HSV-2) is the etiologic agent in more than 90% of genital herpes infections; the remainder are due to herpes simplex virus type 1 (HSV-1), the cause of the common cold sore or fever blister. Orogenital contact is thought to be responsible.

After the initial infection has healed, the virus continues to reside in the epithelial cells of the cervix, and viral shedding occurs in asymptomatic patients. Infection of infants during their passage through the birth canal has led to the practice of cesarean section in women who have evidence of active infection at term. Women with antibodies to HSV-2 have a higher incidence of intraepithelial neoplasia as well as invasive malignancy, although a direct etiologic link has not been established.

The cervical lesions of HPV are sexually transmitted. They are flatter and moister than the typical genital warts (condylomata acuminata) seen on the vulva and perianal skin. In fact, they often are invisible to the naked eye, becoming visible only after application of a dilute solution of acetic acid (acetowhite epithelium) or by colposcopic examination (white epithelium, mosaicism, and coarse punctation). More than 65 types of HPV have been identified. Benign lesions of the cervix are associated with types 6, 11, 42, 43, 44, 53, 54, and 55, whereas types 16, 18, 31, 33, 35, 39, 45, and 56 are more often found in association with cervical intraepithelial neoplasia and invasive cancers.

Approximately one-third of women with HPV infection have coexistent cervicitis caused by other organisms. The presence of cervicitis does not significantly affect the clinical course of HPV lesions.

Cytopathology

The Papanicolaou (Pap) smear often reflects the pathologic changes of cervical infections. A few inflammatory cells normally are seen on the smear, particularly immediately before, during, and immediately after the menses. However, the presence of large numbers of polymorphonuclear leukocytes and histiocytes indicate an acute cervicitis. At times the inflammatory exudate may be so dense that it obscures the epithelial cells, in which case the smear should be repeated after the inflammatory process has been treated and cleared. Epithelial cell changes are commonly associated with cervical inflammation and must be distinguished from those related to neoplastic disease. Nuclear enlargement, clumping of chromatin, hyperchromatism, and nucleoli, as well as cytoplasmic eosinophilia and poorly defined cell membranes, are often seen. These are the findings of "cytologic atypia" and are nonspecific. Frequently, however, a specific diagnosis can be made either by directly identifying the offending organism(s) or by noting typical changes in the epithelial cells characteristic of a specific type of infection. For example, the organism of trichomoniasis and moniliasis can be identified directly on the Pap smear. HPV cannot be seen, but the infection is characterized by squamous epithelial cell enlargement, multinucleation, and the perinuclear "halo" effect of koilocytosis. The so-called "balloon cell" is almost pathognomonic of this condition. Cellular changes of mild dysplasia (low-grade squamous intraepithelial lesion [SIL]), moderate or severe dysplasia (carcinoma in situ [CIS], high-grade SIL), and even invasive cancer may be associated findings.

Greatly enlarged, multinucleated cells with ground-glass cytoplasm and nuclei containing characteristic inclusion bodies are indicative of HSV infection.

Histopathology of Cervical Infections

Histopathologic findings of cervical infection are both nonspecific and specific. Characteristically, both *N gonorrhoeae* and *C trachomatis* infections produce a nonspecific acute inflammatory reaction. Because of edema and increased vascularity, the cervix becomes swollen and reddened. Stromal edema and infiltration by polymorphonuclear leukocytes are seen microscopically, and there may be focal loss of overlying mucous membrane.

As the acute process subsides, the swelling and redness disappear, and the polymorphonuclear leukocytes are replaced by lymphocytes, plasma cells, and macrophages—the histologic picture of chronic cervicitis. Irritation due to infection causes the glandular epithelium to hyperfunction, and mucus mixed with inflammatory cells produces a copious purulent or mucopurulent exudate, which may be clinically apparent only by introducing a cotton swab into the cervical canal. Because the infected clefts and crypts drain poorly, they become dilated

and often obstructed, leading to microabscess formation. With longstanding inflammation, proliferation of fibrous connective tissue in the cervical stroma occurs. This results in hypertrophy and elongation of the cervix. If this process is extreme, the portio vaginalis may actually protrude beyond the vaginal introitus, giving the impression of a prolapse of the uterus.

On numerous occasions a histopathologic diagnosis of chronic cervicitis is made based on the finding of small collections of lymphocytes in the cervical stroma. This finding is characteristic of the cervix of almost all parous women and probably is not significant unless some clinical manifestation of cervicitis is present.

The gross appearance of acute cervicitis must be distinguished clinically and at times histologically from the red, granular inflamed-appearing cervix of cervical ectopy, in which variable portions of the cervical portio vaginalis are covered by endocervical, mucus-secreting epithelium or by a thin layer of immature metaplastic epithelium. Particularly in younger women, the squamocolumnar junction, instead of being located at or near the external os, is found on the surface of the portio. Being covered only by a single layer of columnar cells, the underlying vascular stroma is clearly visible, producing a red, granular appearance. In the past this has been called a cervical "erosion." "Erosion" is not a proper term for cervical redness except as an acute, limited denudation of mucous membrane as might be seen with an especially virulent acute cervicitis or following punch biopsy, cauterization, cryotherapy, laser treatment, loop excision, cone biopsy, or radiation therapy.

The location of squamocolumnar tissue of the cervix is not static throughout life; instead it undergoes continuous change. Through the process of squamous metaplasia, columnar epithelium on the portio vaginalis is gradually converted to stratified squamous epithelium. Initially the stratified metaplastic epithelium is thin and immature, but with time it becomes thicker and more mature, eventually taking on the appearance of original squamous epithelium. Microscopically, the squamocolumnar junction rarely demonstrates an abrupt transition from squamous to columnar epithelium, but instead is marked by a zone of immature squamous metaplasia (Figs 38–8 and 38–9). This change from a mucous membrane covered by a single layer of columnar epithelium to one of the stratified squamous epithelium is not only a continuously ongoing process but is accelerated during 3 periods of a woman's life: fetal existence, adolescence, and during the first pregnancy.

Abrupt transition, squamocolumnar junction.

Figure 38–9.

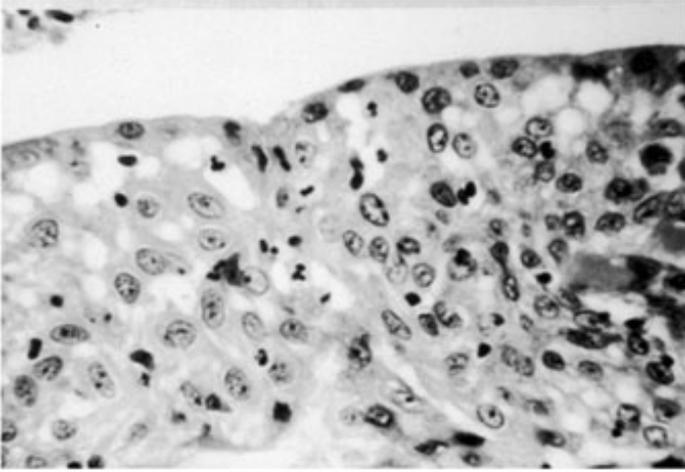

Copyright ©2006 by The McGraw-Hill Companies, Inc.
All rights reserved.

Metaplastic epithelium at the squamocolumnar junction.

By the time a woman reaches her fifth decade, the squamocolumnar junction has receded into the endocervical canal, and the portio vaginalis is completely covered by squamous epithelium. In the process, however, the deeper crypts and clefts of columnar epithelium are bridged over and occluded by metaplastic epithelium, obstructing the egress of mucus, producing the common, typical nabothian cysts of the cervix. To the naked eye, the presence of nabothian cysts indicates that this area at one time was occupied by columnar epithelium that has undergone transformation. Therefore, the nabothian cyst is the hallmark of the "transformation zone," the area in which epithelial neoplasia first appears.

Certain pathologic findings are specific in that they implicate specific organisms. For example, microscopic examination of a cervical biopsy obtained from a vesicular lesion may demonstrate intraepithelial, multinucleated giant cells containing nuclear inclusions surrounded by a clear halo typical of HSV infection. Colposcopically directed biopsy of an area of white epithelium, coarse punctation, or mosaicism may show a flat, thickened, squamous epithelium whose superficial layers are occupied by cells demonstrating large cytoplasmic vacuoles that are devoid of glycogen, surrounding shrunken, hyperchromatic nuclei, and cell membranes that are thickened and eosinophilic. These are the typical histologic findings of HPV infection (Fig 38–10). They may be associated with the findings of intraepithelial neoplasia (see Chapter 50).

Clinical Findings

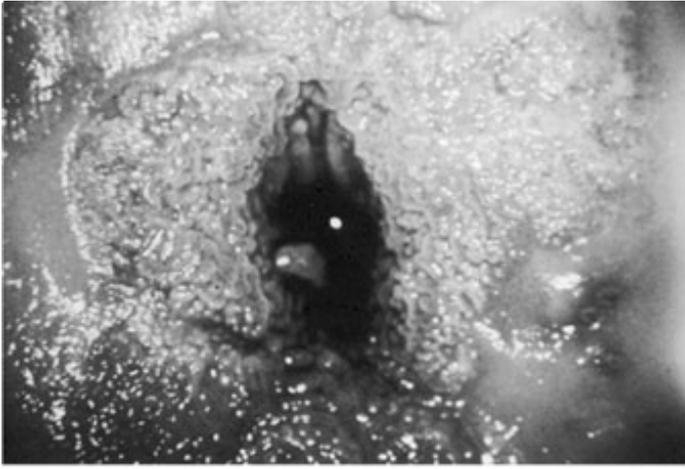

SYMPTOMS AND SIGNS

Acute Cervicitis

The primary symptom of acute cervicitis is a purulent vaginal discharge. The appearance of the discharge is variable—often thick and creamy as in gonorrheal infection; foamy and greenish-white as in trichomonal infection; white and curdlike as in candidiasis; and thin and gray as in bacterial vaginosis. Chlamydia infections often produce a purulent discharge from an angry, reddened, congested cervix. The discharge is often indistinguishable from that due to gonorrheal cervicitis and has been characterized as mucopurulent. Other pathogens that have recently been identified as possible causes of cervicitis are *Mycoplasma genitalium*, HSV-1 and HSV-2, cytomegalovirus, and bacterial vaginosis. Mucopurulent cervicitis, however, may be present in 40–60% of women in whom no infection is identified.

Inspection of the cervix initially infected by *N gonorrhoeae* generally reveals an acutely inflamed, edematous cervix with a purulent discharge escaping from the external os. In trichomonal infection, the classic strawberry-like appearance may be visible on the squamous epithelial surface of the portio vaginalis as well as the adjacent vaginal mucosa. In candidiasis, there is likely to be a white cheesy exudate that is difficult to wipe away and, if scraped off, usually leaves punctate hemorrhagic areas. Colposcopic findings of acute cervicitis are those primarily of an altered microangioarchitecture with marked increase in the surface capillaries, which when viewed end-on may show a pattern of diffuse "punctation." Trichomoniasis is typified by characteristic double-hairpin capillaries. The capillary pattern of inflammation should not be confused with that of neoplasia. In an inflammatory process, the colposcopic picture is diffuse with ill-defined margins in contrast with the localized and sharply demarcated vascular changes associated with intraepithelial neoplasia. It should be emphasized that invasive cancers often are secondarily infected, so in addition to the colposcopic changes associated with frank malignancy, those related to inflammation are also present. Colposcopy also readily identifies the fine villiform pattern of cervical ectopy (Fig 38–11).

Figure 38–11.

All rights reserved.

Colposcopic view of villiform pattern of cervical ectopy.

Infertility may be a consequence of cervicitis. A thick, glutinous, acidic, pus-laden cervical mucus is noxious to sperm and prevents fertilization.

Vulvar burning and itching may be prominent symptoms. Gonorrheal cervicitis may be accompanied by urethritis with frequency, urgency, and dysuria. If associated with acute salpingitis, the symptoms and signs will be those of pelvic peritonitis. Hyperemia of the infected cervix may be associated with freely bleeding areas. Cervical ooze may account for intermenstrual (often postcoital) spotting. Bleeding commonly occurs due to cervical friability when endocervical smears are obtained.

Chronic Cervicitis

In chronic cervicitis, leukorrhea may be the chief symptom. Although it may not be as profuse as in acute cervicitis, the discharge may cause vulvar irritation. The discharge may be frankly purulent and variable in color, or it may present simply as thick, tenacious, turbid mucus. Intermenstrual bleeding may occur.

Associated eversion may present as a velvety to granular redness or as patchy erythema due to scattered squamous metaplasia (epithelialization or epidermization). Nabothian cysts in the area of the so-called transformation zone often occur. The Schiller test may show poorly staining or nonstaining areas. Often some tenderness and thickening in the region of the uterosacral ligaments are noted on pelvic examination, and motion of the cervix may be painful.

Lower abdominal pain, lumbosacral backache, dysmenorrhea, or dyspareunia may occur occasionally related to an associated parametritis. Infertility may be due to inflammatory changes that result in a tacky cervical mucus that is acidic and otherwise hostile (toxic) to sperm. Urinary frequency, urgency, and dysuria may be seen in association with chronic cervicitis. These symptoms are related to an associated subvesical lymphangitis, not to cystitis.

Inspection of the chronically infected cervix often reveals only abnormal discharge. Fibrosis and stenosis of the cervix may follow chronic cervical infection. Patulousness of the deeply lacerated external os often exposes the endocervical canal, which may bleed when wiped with a cotton applicator. The portio and the upper vagina usually appear normal in cervicitis.

LABORATORY FINDINGS

Stains and Smears

Mucopurulent cervicitis is defined as gross evidence of purulent material at an inflamed cervix along with a microscopic presence of 10 or more polymorphonuclear leukocytes per microscopic field on Gram's stain of

material obtained from the endocervical canal. In the absence of mucopurulent discharge, routine use of Gram's stain is not recommended because of its low sensitivity in detecting infection. Cervicovaginal infections with *Trichomonas vaginalis* can often be identified on wet smear preparations by identification of the motile flagellated organisms. Bacterial vaginosis can be seen on wet mount by the hallmark trait of a speckled periphery to the epithelial "clue cells." Candidal infections can be seen on potassium hydroxide preparations, with the distinctive presence of hyphae.

In acute cervicitis with *N gonorrhoeae*, the sensitivity of Gram's stain for detection is only 50%.

Detection of *N Gonorrhoeae* and *C Trachomatis*

Previously, culture of *C trachomatis* was the preferred method for detection of infection and was considered the gold standard for diagnosis. Although it has excellent specificity, the sensitivity is no higher than 70% in females. Variables are involved in the testing, such as the manner of specimen collection, transport condition, culture procedures, and identification of a positive culture.

More recently, new techniques for detection of *C trachomatis* include nucleic acid amplification methods such as polymerase chain reaction (PCR), transcription-mediated amplification (TMA), and strand displacement amplification (SDA). The benefit of using nucleic acid amplification is its high sensitivity (82–100%) and specificity. The specimen can be noninvasively obtained from either a vulvar swab or urine. These tests also allow for simultaneous detection of *N gonorrhoeae* from the same specimen, although sensitivity with urine samples is not as high as with cervical swab. Enzyme immunoassay (EIA) and direct fluorescent antibody (DFA) rely on antigen detection and have a sensitivity ranging from 70–80%, but the specimen still requires invasive testing using a swab from the cervix or urethra.

N gonorrhoeae may also be diagnosed by direct culture of the endocervical mucus. The culture is performed on Thayer-Martin or blood agar medium. Proper transport medium and timing are essential for accurate diagnosis. Most laboratories are moving toward nonculture assays such as PCR, which offer high sensitivity and specificity.

Blood Studies

In uncomplicated cervicitis not accompanied by salpingitis, the white count may be normal, or the leukocytosis sedimentation rate may be slightly elevated.

Patients with gonorrhea or chlamydia are at risk for infection with other sexually transmitted diseases (STDs). Counseling and testing should be offered for syphilis, hepatitis B, and human immunodeficiency virus (HIV).

Differential Diagnosis

Noninfectious cervicitis is most commonly due to the effects of endogenous or exogenous hormones on the maintenance of integrity of cervicovaginal mucosa. Bimanual examination should be performed to distinguish the signs and symptoms of pelvic tenderness, induration, and mass formation about the cervix when discharge is noted from the cervix.

Cervicitis must be distinguished from early neoplastic processes. This may not be easy because inflammatory conditions may alter the epithelial cells to produce atypia on cytologic examination. Colposcopy is useful (see Chapter 50). Cervical cytology and histologic examination by endocervical curettage and biopsy should be performed to help distinguish chronic cervicitis from developing cancer of the cervix.

Lesions of syphilis and chancroid as well as the chronic granulomatous ulcerations of tuberculosis and granuloma inguinale also should be considered.

Complications

Leukorrhea, cervical stenosis, and infertility are sequelae of chronic cervicitis. Patients with acute or chronic cervicitis may complain of vaginal discharge and vaginal bleeding, most frequently after sexual intercourse.

With *N gonorrhoeae* or *C trachomatis* cervicitis, salpingitis is a common complication, with long-term consequences including infertility and chronic pelvic pain. Gonorrheal and chlamydial cervicitis causing increased shedding of HIV 1 in HIV infected women has been reported. A history of genital infections is more common among women with carcinoma of the cervix; however, no current evidence suggests that these agents increase the risk of developing cancer in women with cervicitis.

Prevention

Gonorrheal, herpetic, and chlamydial cervicitis can be prevented by educating those at risk about ways to reduce their risk. Avoidance of sexual contact with infected persons and the use of condoms for protection during coitus are the most important recommendations for changing the sexual behaviors of women at risk for infection. Clinicians should be aware of the importance of detection in the asymptomatic patient, followed by effective treatment and counseling of the patient and her sexual partners. The avoidance of surgical or obstetric trauma and the prompt recognition and proper repair of cervical lacerations help to prevent the subsequent development of a chronically infected cervix.

When surgical removal of the corpus of the uterus is indicated, the cervix should also be removed if this is feasible. Recommendations to retain the cervix at the time of hysterectomy in order to maintain sexual function or vaginal support are controversial.

Treatment

Selection of the most appropriate treatment depends on the age of the patient and her desire for pregnancy; whether she is presently pregnant or is breastfeeding; the severity of the cervical infection; the presence of complicating factors (eg, salpingitis); and previous treatment. Instrumentation and vigorous topical therapy should be avoided during the acute phase of cervicitis and before the menses, when ascending infection may occur.

ACUTE CERVICITIS

When acute cervicitis is associated with vaginitis due to a specific organism, treatment must be directed accordingly. Metronidazole is specific for treatment of *T vaginalis* infection. Metronidazole can be administered as 2 g orally in a single dose or alternatively as 500 mg twice daily for 7 days. This has resulted in cure rates of approximately 90–95%. Ensuring treatment of sex partners might increase the cure rate. Topical forms of metronidazole appears to be less efficacious than the oral preparations. Candidiasis is most effectively treated with topically applied azole drugs. This will result in relief of symptoms and negative cultures in 80–90% of patients. Treatment may continue for 1, 3, or 7 days, depending on the severity of infection. Oral fluconazole in a 150-mg oral tablet has been shown to be effective treatment.

Bacterial vaginosis can be treated with oral metronidazole 500 mg twice daily for 7 days, or with topical clindamycin cream or metronidazole gel. Treatment of bacterial vaginosis in pregnancy is particularly important because of its association with adverse outcomes such as preterm labor and premature rupture of the membranes. Pregnant women without risk of premature delivery should be treated if they have symptomatic bacterial vaginosis. High-risk women should be tested and treated regardless of the presence of symptoms. Treatment in pregnancy is metronidazole 250 mg orally 3 times daily for 7 days. Metronidazole has not been shown to be teratogenic in humans.

C trachomatis can be treated with azithromycin 1 g orally in a single dose or alternatively with doxycycline 100 mg twice daily for 7 days. Alternative treatments with erythromycin or ofloxacin are suggested. In pregnancy, azithromycin may be given. Amoxicillin for 7 days has also been shown to be effective and well tolerated.

Cervicitis due to *N gonorrhoeae* can be treated with single oral doses of ofloxacin 400 mg or ciprofloxacin 500 mg. An intramuscular injection of ceftriaxone 125 mg may also be used. In pregnancy, fluoroquinolones should be avoided. Fluoroquinolones also should not be used in patients residing in, or who may have acquired

infections in, Asia, the Pacific (including Hawaii), or California. This is due to increasing quinolone-resistant *N gonorrhoeae* (QRNG) in these areas (see Chapters 41 and 42 and the 2002 Centers for Disease Control guidelines for treatment of STDs for full recommendations). Because of the high rate of coinfection with *C trachomatis* (up to 42%), it is recommended that patients also receive treatment for *C trachomatis* when *N gonorrhoeae* infection is found.

CHRONIC CERVICITIS

Several studies using more sensitive testing for *N gonorrhoeae* and *C trachomatis* have demonstrated that microscopic findings of 10 or more polymorphonuclear leukocytes per high-power field do not correlate with infection. Therefore it is not necessary to treat an asymptomatic patient with chronic cervicitis who does not test positive for an STD.

Surgical procedures may be useful for treatment of symptomatic chronic cervicitis or in the absence of an infectious pathogen or evidence of dysplasia. Techniques including cryosurgery, electrocauterization, and laser therapy may be of use, although significant disadvantages include the high risk for recurrence and risk for cervical injury.

Treatment of Complications

CERVICAL HEMORRHAGE

This may follow electrocauterization, loop excision, cryosurgery, or laser vaporization and may require suture and ligation of the bleeding vessels. Usually, point coagulation of bleeding areas with Monsel's solution or silver nitrate applied topically is successful. Repeat electrocauterization may also be beneficial.

SALPINGITIS

Inflammation of the uterine tubes usually necessitates the administration of a broad-spectrum antibiotic.

LEUKORRHEA

Significant cervical discharge may be due to persistent infection with a pathogen. Appropriate testing should be performed and selective antibiotic treatment administered.

CERVICAL STENOSIS

The gentle passage of graduated sounds through the cervical canal at weekly intervals during the intermenstrual phase for 2–3 months following treatment will prevent or correct stenosis.

INFERTILITY

The absence of cervical mucus necessary for sperm migration often causes infertility and may be due to extensive destruction (cauterization, freezing, or vaporization) or removal (conization or loop excision) of the endocervical glandular cells. Treatment includes low-dose estrogen for 1 week prior to ovulation or intrauterine insemination with washed and incubated sperm.

Prognosis

With conservative, systemic, and persistent therapy, cervicitis can almost always be cured. With neglect or overtreatment, the prognosis is poor.

GRANULOMATOUS INFECTIONS OF THE CERVIX

Tuberculosis, tertiary syphilis, and granuloma inguinale may on rare occasions be manifested by chronic cervical lesions. These lesions usually take the form of nodules, ulcerations, or granulation tissue. They produce a chronic inflammatory exudate characterized histologically by lymphocytes, giant cells, and histiocytes. They may simulate carcinoma of the cervix and must be distinguished from this and other neoplastic diseases.

Tuberculosis

Since 1986, the steadily decreasing incidence of tuberculosis in the United States over the previous several

decades has reversed, and the risk has increased, particularly for blacks, Hispanics, and Asians. Some of this increase has been attributed to the epidemic spread of HIV.

Genitourinary tuberculosis is almost always secondary to infection elsewhere in the body, usually pulmonary, but active pulmonary disease can be documented in only one-third of patients. Vascular dissemination is responsible for infection of the fallopian tubes in almost all patients with genital tuberculosis, and involvement of the endometrium follows in 90%. Cervical disease can occur by direct extension or lymphatic spread but is rare, occurring in only 1% of cases. In the past, genital tuberculosis has accounted for only 1% of patients with pelvic inflammatory disease; however, in European and Asian countries, the occurrence ranges from 5–13%. With increasing numbers of immigrants to the United States and with the rise in incidence of AIDS in American women, an increase in the incidence of pelvic tuberculosis can be expected.

The chief clinical manifestations of pelvic and cervical involvement are abdominal pain, irregular bleeding, and constitutional symptoms. The cervix may be hypertrophied and nodular, without any visible lesion on the portio vaginalis. Speculum examination may demonstrate either an ulcerative or a papillary lesion, thus resembling neoplastic disease.

The diagnosis of tuberculosis of the cervix must be made by biopsy. Histologically, the disease is characterized by tubercles undergoing central caseation. Because such lesions may be caused by other entities such as amoebiasis, schistosomiasis, brucellosis, tularemia, sarcoidosis, and foreign body reaction, the tubercle bacillus must be demonstrated by acid-fast stains or culture.

The reader is referred to other texts for the details of medical therapy of genital tuberculosis. Most patients are cured by medical management alone. Patients who respond poorly or who have other problems (eg, tumors, fistulas) may require total hysterectomy and bilateral salpingo-oophorectomy after a trial of chemotherapy.

RARE INFECTIOUS DISEASES OF THE CERVIX

Lymphogranuloma venereum, a chlamydial infection, and chancroid, caused by *Haemophilus ducreyi*, may attack the cervix along with other areas of the reproductive tract.

Cervical actinomycosis may occur as a result of contamination by instruments and by intrauterine devices. The cervical lesion may be a nodular tumor, ulcer, or fistula. Prolonged penicillin or sulfonamide therapy is recommended.

Schistosomiasis of the cervix usually is secondary to involvement of the pelvic and uterine veins by the blood fluke *Schistosoma haematobium*. Cervical schistosomiasis may produce a large papillary growth that ulcerates and bleeds on contact, simulating cervical cancer. In other instances, it may be found in endocervical polyps, causing intermenstrual and postcoital bleeding. An ovum occasionally can be identified in a biopsy specimen taken from the granulomatous cervical lesion. However, the diagnosis usually is made by recovering the parasite from the urine or feces. Chemical, serologic, and intradermal tests for schistosomiasis are available.

Echinococcal cysts may involve the cervix. Treatment consists of surgical excision.

CYSTIC ABNORMALITIES OF THE CERVIX

Nabothian Cysts

Nabothian cysts develop when a tunnel or cleft of tall columnar endocervical epithelium becomes covered by squamous metaplasia. They appear grossly as translucent or yellow and may vary in diameter from a few millimeters to 3 cm.

Mesonephric Cysts

Microscopic remnants of the mesonephric (wolffian) duct are often seen deep in the stroma externally in the

normal cervix. Occasionally they become cystic, forming structures up to 2.5 mm in diameter, lined by ragged cuboid epithelium. They may be confused with deeply situated nabothian cysts, but their location and the wolffian-type cells lining the cysts serve as useful distinguishing features.

CERVICAL STENOSIS

Cervical stenosis of congenital, inflammatory, neoplastic, or surgical origin may be partially or even completely occlusive. Most cases of cervical stenosis follow extensive surgical manipulation of the cervix (eg, electrocoagulation, cryotherapy, laser vaporization, conization, or cervical amputation) or radiation therapy. Cervical stenosis is not uncommon, however, in postmenopausal women with prolonged estrogen deficiency. Marked to complete obstruction of menstrual drainage will result in hematometra, typified by cryptomenorrhea or amenorrhea; abdominal discomfort; and a soft, slightly tender midpelvic mass. Pyometra may develop in the postmenopausal woman with cervical stenosis and always raises the suspicion of an associated endometrial carcinoma. Both hematometra and pyometra are readily confirmed by pelvic ultrasonography.

Cautious dilatation of the cervix is recommended, with drainage of the entrapped fluid. Cultures and sensitivity tests should be performed and, with appropriate antibiotic coverage, cervical endometrial tissue or both should be obtained to rule out cancer. The endocervical canal should receive minimal caustic therapy or electrotherapy for chronic cervicitis to prevent cervical stenosis. Removal of the cicatrix by laser vaporization and loop excision has been effective in cases of postconization stenosis.

BENIGN NEOPLASMS OF THE CERVIX

Microglandular Hyperplasia of the Endocervical Mucosa

Microglandular hyperplasia (MGH) usually occurs in women of reproductive age, but 6% of known cases are detected in postmenopausal women. MGH has been linked to hormonal stimulus of oral contraceptive use and pregnancy, although reports have questioned this association. MGH also may result from inflammation. Grossly, adenomatous hyperplasia appears as exuberant granular tissue within the cervical canal, often extruding beyond the cervical os. The disorder may be mistaken for cancer, but biopsy should be performed to make the distinction. Microscopically, it presents as a collection of closely packed cystic spaces lined by nonneoplastic columnar epithelium and filled with mucus.

Cervical Polyps

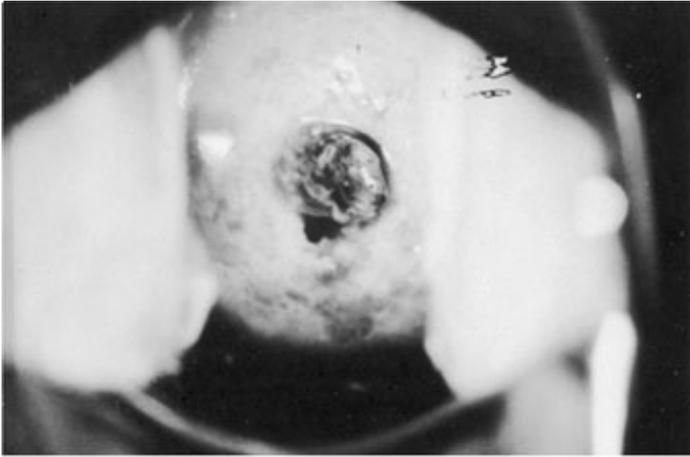

Essentials of Diagnosis

- Intermenstrual or postcoital bleeding.
- A soft, red pedunculated protrusion from the cervical canal at the external os.
- Microscopic examination confirms the diagnosis of benign polyp.

General Considerations

Cervical polyps are small, pedunculated, often sessile neoplasms of the cervix. Most originate from the endocervix; a few arise from the portio (Fig 38–12). They are composed of a vascular connective tissue stroma and are covered by columnar, squamocolumnar, or squamous epithelium. Polyps are relatively common, especially in multigravidas over 20 years of age. They are rare before menarche, but an occasional polyp may develop after menopause. Asymptomatic polyps often are discovered on routine pelvic examination. Most are benign, but all should be removed and submitted for pathologic examination because malignant change may occur. Moreover, some cervical cancers present as a polypoid mass.

Figure 38–12.

Cervical polyp.

Polyps arise as a result of focal hyperplasia of the endocervix. Whether this is due to chronic inflammation, an abnormal local responsiveness to hormonal stimulation, or a localized vascular congestion of cervical blood vessels is not known. They are often found in association with endometrial hyperplasia, suggesting that hyperestrogenism plays a significant etiologic role.

Endocervical polyps usually are red, flame-shaped, fragile growths. The polyps vary from a few millimeters in length and diameter to larger tumors 2–3 cm in diameter and several centimeters long. These polyps usually are attached to the endocervical mucosa near the external os by a narrow pedicle, but occasionally the base is broad. On microscopic examination, the stroma of a polyp is composed of fibrous connective tissue containing numerous small vessels in the center. There is often extravasation of blood and marked infiltration of the stroma by inflammatory cells (polymorphonuclear neutrophils, lymphocytes, and plasma cells). The surface epithelium resembles that of the endocervix, varying from typical picket-fence columnar cells to areas that show squamous metaplasia and mature stratified squamous epithelium. The surface often is thrown into folds, as is much of the normal endocervical mucosa.

Ectocervical polyps are pale, flesh-colored, smooth, and rounded or elongated, often with a broad pedicle. They arise from the portio and are less likely to bleed than are endocervical polyps. Microscopically, they are more fibrous than endocervical polyps, with few or no mucus glands. They are covered by stratified squamous epithelium.

Metaplastic alteration is common. Inflammation, often with necrosis at the tip (or more extensively), is typical of both polyp types.

The incidence of malignant change in a cervical polyp is estimated to be less than 1%. Squamous cell carcinoma is the most common type, although adenocarcinomas have been reported. Endometrial cancer may involve the polyp secondarily. Sarcoma rarely develops within a polyp.

Botryoid sarcoma, an embryonal rhabdomyosarcoma tumor of the cervix (or vaginal wall) resembling small pink or yellow grapes, contains striated muscle and other mesenchymal elements. It is extremely malignant. Most polypoid structures are vascular, often are infected, and are subject to displacement or torsion. Discharge commonly results, and bleeding, often metrorrhagia of the postcoital type, follows.

Chronic irritation and bleeding are annoying and cause cervicitis, endometritis, and parametritis. Salpingitis may develop if conditions these are not treated successfully.

Because polyps are a potential focus of cancer, they must be examined routinely for malignant characteristics upon removal.

Clinical Findings

SYMPTOMS AND SIGNS

Intermenstrual or postcoital bleeding is the most common symptom of cervical polyps. Leukorrhea and hypermenorrhea have also been associated with cervical polyps.

Abnormal vaginal bleeding is often reported. Postmenopausal bleeding is frequently described by older women. Infertility may be traceable to cervical polyps and cervicitis.

Cervical polyps appear as smooth, red, fingerlike projections from the cervical canal. They usually are approximately 1–2 cm in length and 0.5–1 cm in diameter. Generally they are too soft to be felt by the examiner's finger.

X-RAY FINDINGS

Polyps high in the endocervical canal may be demonstrated by hysterosalpingogram or saline infusion sonohysterography. They often are significant findings in hitherto unexplained infertility.

LABORATORY FINDINGS

Vaginal cytology will reveal signs of infection and often mildly atypical cells. Blood and urine studies are not helpful.

SPECIAL EXAMINATION

A polyp high in the endocervical canal may be seen with the aid of a special endocervical speculum or by hysteroscopy. Some polyps are found only at the time of diagnostic D&C in the investigation of abnormal bleeding.

Differential Diagnosis

Masses projecting from the cervix may be polypoid but not polyps. Adenocarcinoma of the endometrium or endometrial sarcoma may present at the external os or even beyond. Discharge and bleeding usually occur.

Typical polyps are not difficult to diagnose by gross inspection, but ulcerated and atypical growths must be distinguished from small submucous pedunculated myomas or endometrial polyps arising low in the uterus. These often result in dilatation of the cervix, presenting just within the os and resembling cervical polyps. The products of conception, usually decidua, may push through the cervix and resemble a polypoid tissue mass, but other signs and symptoms of recent pregnancy generally are absent. Condylomata, submucous myomas, and polypoid carcinomas are diagnosed by microscopic examination.

Complications

Cervical polyps may be infected, some by virulent staphylococci, streptococci, or other pathogens. Serious infections occasionally follow instrumentation for the identification or removal of polyps. A broad-spectrum antibiotic should be administered at the first sign or symptom of spreading infection.

Acute salpingitis may be initiated or exacerbated by polypectomy.

It is unwise to remove a large polyp and then perform a hysterectomy several days thereafter. Pelvic peritonitis may complicate the latter procedure. A delay of several weeks or 1 month between polypectomy and hysterectomy is recommended.

Treatment

MEDICAL MEASURES

Appropriate testing for cervical discharge should be performed as indicated and treatment administered if

infection is identified.

SPECIFIC MEASURES

Most polyps can be removed in the physician's office. This is done with little bleeding by grasping the pedicle with a hemostat or long grasping instrument and twisting it until the growth is avulsed. Large polyps and those with sessile attachments may require excision in an operating room. This will allow for administration of anesthesia for further visualization, treatment using the hysteroscope, and control of any hemorrhage.

If the cervix is soft, patulous, or definitely dilated and the polyp is large, hysteroscopy should be performed, especially if the pedicle is not readily visible. Exploration of the cervical and uterine cavities with the hysteroscope allows for further identification of other polyps. All tissue must be sent to a pathologist to be examined for possible underlying malignant or premalignant conditions.

Prognosis

Simple removal of cervical polyps is usually curative.

Papillomas of the Cervix

Essentials of Diagnosis

- Asymptomatic.
- Papillary projection from the exocervix.
- The presence of koilocytes with or without cytologic atypia.
- Colposcopic identification.

General Considerations

Cervical papillomas are benign neoplasms found on the portio vaginalis of the cervix. The neoplasms consist of 2 types. (1) The typical solitary papillary projection from the exocervix, composed of a central core of fibrous connective tissue covered by stratified squamous epithelium. This is a true benign neoplasm, and the cause is unknown. (2) Condylomata of the cervix, which may be present in various forms ranging from a slightly raised area on the exocervix that appears white after acetic acid application (on colposcopy) to the typical condyloma acuminatum. These usually are multiple and are caused by HPV infection, an STD. Similar lesions of the vagina and vulva are often, but not always, present. Evidence of HPV infection can be found in 1–2% of cytologically screened women. The incidence is much higher in women attending STD clinics.

Clinical Findings

SYMPTOMS AND SIGNS

There are no characteristic symptoms of cervical papillomas; they are often discovered on routine pelvic examination or colposcopic examination for dysplasia revealed by Pap smear.

LABORATORY FINDINGS

Cytologic findings of koilocytes—squamous cells with perinuclear clear halos—are strongly suggestive of HPV infection. Dysplastic squamous cells are frequently found in association with koilocytes. Biopsy of involved epithelium reveals papillomatosis and acanthosis. Mitoses may be frequent, but in the absence of neoplastic change, the cells are orderly with regular nuclear features. Koilocytes predominate in the superficial cells.

Complications

Intraepithelial neoplasia is associated with certain types of HPV infection (see Cervical Intraepithelial Neoplasia, Chapter 50). The presence of condylomata of the portio vaginalis substantially increases the risk for squamous cell carcinoma of the cervix.

Prevention

Contraception with condoms and other barrier methods may prevent primary infection and reinfection.

Treatment

Solitary papillomas should be surgically excised and submitted for pathologic examination. Likewise, biopsies of flat condylomata should be submitted for histopathologic examination. Flat condylomata may be completely removed with a biopsy instrument if they are small. More extensive lesions may require cryotherapy, loop excision, or laser vaporization. Dysplasia associated with HPV infection should be managed according to the severity and extent of the dysplastic process (see Cervical Intraepithelial Neoplasia, Chapter 50).

Prognosis

Because the entire lower genital tract is a target area for HPV infection, long-term follow-up with attention to the cervix, vagina, and vulva is necessary. Excision of solitary, non-PV-related papillomas is curative.

Leiomyomas of the Cervix

The paucity of smooth muscle elements in the cervical stroma makes leiomyomas that arise in the cervix uncommon. The corpus leiomyoma/cervical leiomyoma ratio is in the range of 12:1.

Although myomas usually are multiple in the corpus, cervical myomas are most often solitary and may be large enough to fill the entire pelvic cavity, compressing the bladder, rectum, and ureters (Fig 38–13). Grossly and microscopically they are identical to leiomyomas that arise elsewhere in the uterus.

Figure 38–13.

Copyright ©2006 by The McGraw-Hill Companies, Inc.
All rights reserved.

Large cervical leiomyoma filling true pelvis.

Clinical Findings

SYMPTOMS AND SIGNS

Cervical leiomyomas are often silent, producing no symptoms unless they become very large. Symptoms result from pressure on surrounding organs such as the bladder, rectum, or soft tissues of the parametrium, or

obstruction of the cervical canal. Frequency and urgency of urination are the result of bladder compression. Urinary retention occasionally occurs as a result of pressure against the urethra. Hematometra may develop with obstruction of the cervix.

If the direction of growth is lateral, there may be ureteral obstruction with hydronephrosis. Rectal encroachment causes constipation. Dyspareunia may occur if the tumor occupies the vagina. In pregnancy, because of their location, large cervical leiomyomas, unlike those involving the corpus, are apt to cause soft-tissue dystocia, preventing descent of the presenting part in the pelvis. Cervical leiomyomas of significant size can be readily palpated on bimanual examination.

IMAGING

A plain film may demonstrate the typical mottled calcific pattern associated with cervical leiomyomas. Hystero-graphy may define distortion of the endocervical canal. Intravenous urography may demonstrate ureteral displacement or obstruction. MRI is diagnostic.

Treatment

Small, asymptomatic cervical leiomyomas do not require treatment. If the leiomyomas become symptomatic, removal may be possible via hysteroscopic resection. If additional multiple leiomyomas are present that cannot be resected with the hysteroscope, uterine artery embolization, abdominal myomectomy, or hysterectomy may be indicated, depending on the patient's desire for preservation of fertility.

Because of the proximity of the pelvic ureter to the cervix, this structure may be in jeopardy in any operation involving a cervical leiomyoma, and precautions should be taken to prevent its injury.

Prognosis

Recurrence of cervical myomas after surgical removal is rare.

Current OB/GYN >Chapter 39. Benign Disorders of the Uterine Corpus>

LEIOMYOMA OF THE UTERUS (FIBROMYOMA, FIBROID, MYOMA)

Essentials of Diagnosis

- Mass: irregular enlargement of the uterus.
- Bleeding: menorrhagia, metrorrhagia, dysmenorrhea.
- Pain: torsion or degeneration.
- Pressure: symptoms from neighboring organs.

General Considerations

Uterine leiomyomas are benign clonal neoplasms arising from smooth muscle cells in the uterine wall. They contain increased amount of extracellular collagen and elastin. A thin pseudocapsule composed of areolar tissue and connective muscle fibers surrounds the tumor. Leiomyomas may enlarge to cause significant distortion of the uterine surface. These tumors are present in 20–25% of reproductive-age women. However, for unknown reasons, leiomyomas occur 3–4 times more frequently in black than in white women. By their fifth decade, as many as 50% of black women will have leiomyomata.

Leiomyomas are not detectable before puberty and, being hormonally responsive, normally grow only during the reproductive years. Although they can occur as isolated growths, they are more commonly multiple. They usually are less than 15 cm in size but in rare cases may reach enormous proportions, weighing more than 45 kg (100 lb).

Although usually asymptomatic, leiomyomata can produce a wide spectrum of problems, including metrorrhagia, menorrhagia, pain, and infertility. Excessive uterine bleeding from leiomyomas is one of the most common indications for hysterectomy in the United States.

Asymptomatic leiomyomas may mask other concomitant and potentially lethal pelvic tumors, so the physician should be deceived into following "asymptomatic myomas" without verifying that an underlying uterine tube, ovarian, or colorectal carcinoma does not coexist. Occasionally it is necessary to differentiate leiomyomata from leiomyosarcoma. The latter occurs infrequently (<1% of cases) and is malignant.

Pathogenesis

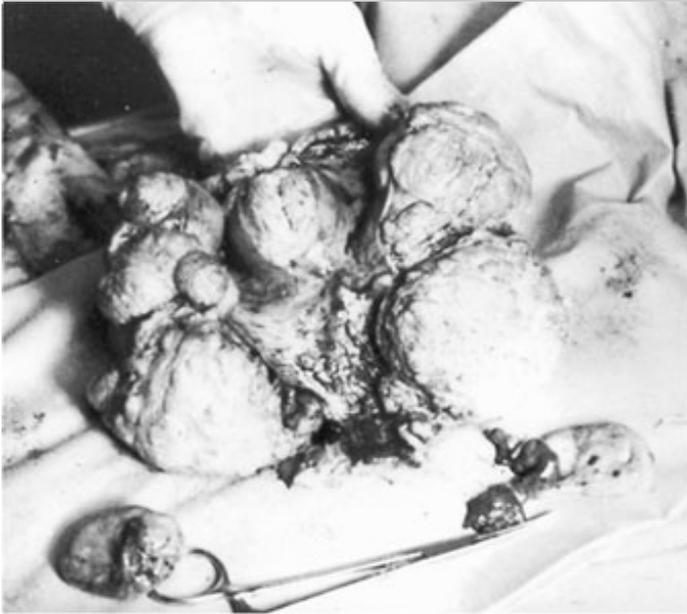

The cause of uterine leiomyomata is not known. Glucose-6-phosphate dehydrogenase studies suggest that each leiomyoma is unicellular in origin (monoclonal). Although no evidence suggests that estrogens cause leiomyoma formation, estrogens certainly are implicated in growth of myomas. Leiomyomas contain estrogen receptors in higher concentrations than the surrounding myometrium but in lower concentrations than the endometrium. Progesterone increases the activity of myomas in young women. Progesterone may allow for tumor enlargement by downregulating apoptosis in the tumor. Estrogens may contribute to tumor enlargement by increasing the production of extracellular matrix. Leiomyomas may increase in size with estrogen therapy and during pregnancy but do not always do so. There is speculation that leiomyoma growth in pregnancy is related to synergistic activity of estradiol and human placental lactogen (hPL).

usually decrease in size after menopause.

Pathology

Leiomyomas are usually multiple, discrete, and either spherical or irregularly lobulated. Their pseudocapsule usually demarcates them from the surrounding myometrium. They can be often easily and cleanly enucleated from the surrounding myometrial tissue. On gross examination in transverse section, they are buff-colored, rounded, smooth, and usually firm. Generally, they are lighter in color than the myometrium (Fig 39–1). When a fresh specimen is sectioned, the tumor surface projects above the surface of the surrounding musculature, revealing the pseudocapsule.

Multiple leiomyomas. Cervix is opened at the bottom.

CLASSIFICATION

Uterine leiomyomas originate in the myometrium and are classified by anatomic location (Fig 39–2). Submucous leiomyomas lie just beneath the endometrium and tend to compress it as they grow toward the uterine lumen. They impact on the endometrium and its blood supply most often leads to irregular uterine bleeding. Leiomyomata may have pedicles and protrude fully into the uterine cavity. Occasionally they pass through the cervical canal while still attached within the corpus by a long stalk. When this occurs, leiomyomata are subject to torsion or infection, conditions that must be taken into consideration before treatment.

Figure 39–2.

Myomas of the uterus.

Intramural or interstitial leiomyomas lie within the uterine wall, giving it a variable consistency. Subserous or subperitoneal leiomyomata may lie just at the serosal surface of the uterus or may bulge outward from the myometrium. The leiomyomata may become pedunculated. If such a tumor acquires an extrauterine blood supply from omental vessels, the pedicle may atrophy and resorb; the tumor is then said to be *parasitic*. Subserous tumors arising laterally may extend between the 2 peritoneal layers of the broad ligament to become intraligamentary leiomyomas. This may lead to compromise of the ureter and/or pelvic blood supply.

MICROSCOPIC STRUCTURE

Nonstriated muscle fibers are arranged in interlacing bundles of varying size running in different directions (whorled appearance). Individual cells are spindle-shaped, have elongated nuclei, and are uniform in size. Varying amounts of connective tissue are intermixed with the smooth muscle bundles. Leiomyomata are sharply demarcated from surrounding normal musculature by a pseudocapsule of areolar tissue and compressed myometrium. The arterial density of a leiomyoma is less than that of the surrounding myometrium, and the small arteries that supply the tumor are fewer than are the adjacent radial arteries. The arteries penetrate the myoma randomly on its surface and are oriented in the direction of the muscle bundles; thus, they present no regular pattern. One or 2 major vessels may be found in the pedicle. The venous pattern appears to be even more sparse, but this may be in part artifactual because of the contraction encountered in filling the venous circulation under artificial conditions.

SECONDARY CHANGES

There may be areas of hyalinization, liquefaction (cystic degeneration), calcification, hemorrhage, fat, or inflammation within leiomyomata. Although these secondary alterations are histologically interesting, they usually have little clinical significance. Whether leiomyosarcomas are a malignant alteration within a mature leiomyoma, as is commonly said, or arise de novo remains an unsettled issue. Extraordinarily cellular myomas have often been misinterpreted as sarcoma because the criteria used to differentiate leiomyoma from sarcoma are imprecise and often subjective. Ultrastructural studies suggest that leiomyoma and leiomyosarcoma are distinct entities and that the cellular leiomyoma is merely a variety of the common leiomyoma.

Benign Degeneration

Benign degeneration consists of the following types:

ATROPHIC

Signs and symptoms regress or disappear as tumor size decreases at menopause or after pregnancy.

HYALINE

Mature or "old" leiomyomas are white but contain yellow, soft, and often gelatinous areas of hyaline change. They are usually asymptomatic.

CYSTIC

Liquefaction follows extreme hyalinization, and physical stress may cause sudden evacuation of fluid contents into the uterus, the peritoneal cavity, or the retroperitoneal space.

CALCIFIC (CALCAREOUS)

Subserous leiomyomata are most commonly affected by circulatory deprivation, which causes precipitation of calcium carbonate and phosphate within the tumor.

SEPTIC

Circulatory inadequacy may cause necrosis of the central portion of the tumor followed by infection. Acute pain, tenderness, and fever result.

CARNEOUS (RED)

Venous thrombosis and congestion with interstitial hemorrhage are responsible for the color of a leiomyoma undergoing red degeneration (Fig 39–3). During pregnancy, when carneous degeneration is most common, edema and hypertrophy of the myometrium occur. The physiologic changes in the leiomyoma are not the same as in the myometrium; the relative anatomic discrepancy impedes the blood supply, resulting in aseptic degeneration and infarction. The process is accompanied by pain but is self-limited. Potential complications of degeneration in pregnancy include preterm labor and, rarely, initiation of disseminated intravascular coagulation.

Figure 39–3.

Carneous (red) degeneration. Note the congested, dark appearance compared with Figure 39–1.

MYXOMATOUS (FATTY)

This uncommon and asymptomatic degeneration follows hyaline and cystic degeneration.

Metastasizing Leiomyomata

Rarely, myomas spread beyond the uterus to distant locations such as the peritoneum, distant vasculature, and Histologically these leiomyomas appear benign and have a low mitotic rate, and they are often asymptomatic. Most with these tumors have undergone a prior dilatation and curettage (D&C), myomectomy, or hysterectomy, suggesting possibility of surgically induced vascular spread of leiomyoma cells. Another theory suggests a multifocal origin of smooth muscle in blood vessels anywhere in the body.

Clinical Findings

SYMPTOMS

Symptoms are present in only 35–50% of patients with leiomyomas. Thus, most leiomyomata do not produce symptoms and even very large ones may remain undetected, particularly in obese patients. Symptoms from leiomyomas depend on their location, size, state of preservation, and whether the patient is pregnant.

Abnormal Uterine Bleeding

Abnormal uterine bleeding is the most common and most important clinical manifestation of leiomyomas, being present in up to 30% of patients. The abnormal bleeding commonly produces iron deficiency anemia, which may not be controllable even with iron therapy if the bleeding is heavy and protracted.

Bleeding from a submucous leiomyoma may occur from interruption of the blood supply to the endometrium, distention and congestion of the surrounding vessels, particularly the veins, or ulceration of the overlying endometrium. Most commonly, the patient has prolonged, heavy menses (menorrhagia), premenstrual spotting, or prolonged light menses following menses; however, any type of abnormal bleeding is possible.

Minor degrees of metrorrhagia (intermenstrual bleeding) may be associated with a tumor that has areas of endometrial venous thrombosis and necrosis on its surface, particularly if it is pedunculated and partially extruded through the cervical canal.

Pain

Leiomyomata may cause pain when vascular compromise occurs. Thus, pain may result from degeneration associated with vascular occlusion, infection, torsion of a pedunculated tumor, or myometrial contractions to expel a subserous leiomyoma.

from the uterine cavity. The pain associated with infarction from torsion or red degeneration can be excruciating and produce a clinical picture consistent with acute abdomen.

Large tumors may produce a sensation of heaviness or fullness in the pelvic area, a feeling of a mass in the pelvis, or a feeling of a mass palpable through the abdominal wall. Tumors that become impacted within the bony pelvis may compress nerves and create pain radiating to the back or lower extremities; however, backache is such a common general symptom that it is usually difficult to ascribe it specifically to myomas.

Pain with intercourse may result, depending on the position of the tumors and the pressure they exert on the vagina. **Pressure Effects**

Pressure effects are unusual and difficult to directly relate to leiomyomata, unless the tumors are very large. Intraligamentous leiomyomata may distort or obstruct other organs. Parasitic tumors may cause intestinal obstruction if they are large or involve omentum or bowel. Cervical tumors may cause serosanguineous vaginal discharge, vaginal bleeding, dyspareunia, and infertility. Large tumors may fill the true pelvis and displace or compress the ureters, bladder, or rectum.

Compression of surrounding structures may result in urinary symptoms or hydronephrosis. Large tumors may cause venous congestion and lower extremity edema or constipation. Rarely, a posterior fundal leiomyoma carries the uterus into extreme retroflexion, distorting the bladder base and causing urinary retention. This may present as intermittent urinary incontinence produced by elongation of the urethra with loss of sphincter control—a situation identical to prolapsed uterus during early pregnancy. The condition is relieved by dislodging the uterus from the true pelvis with the patient in the knee–chest position.

Infertility

The relationship between fibroids and infertility remains uncertain. Between 27% and 40% of women with multiple leiomyomas are reported to be infertile, but other causes of infertility are present in a majority of cases. When fibroids are entirely or mostly endocavitary, a strong rationale supports the use of surgery to improve fertility.

Spontaneous Abortion

The incidence of spontaneous abortion secondary to leiomyoma is unknown but is possibly 2 times the incidence in pregnant women. For example, the incidence of spontaneous abortion prior to myomectomy is approximately 40%, and following myomectomy is approximately 20%.

EXAMINATION

Most myomas are discovered by routine bimanual examination of the uterus or sometimes by palpation of the lower abdomen. Uterine retroflexion and retroversion may obscure the physical examination diagnosis of even moderate leiomyomata. When the cervix is pulled up behind the symphysis, large fibroids are usually implicated. The diagnosis is obvious when the normal uterine contour is distorted by 1 or more smooth, spherical, firm masses, but often it is difficult to be absolutely certain that such masses are part of the uterus. A pelvic ultrasound generally assists in establishing the diagnosis, as does excluding pregnancy as a cause of uterine enlargement. Magnetic resonance imaging (MRI) can delineate the size and position of myomas but is not always clinically necessary.

LABORATORY FINDINGS

Anemia is a common consequence of leiomyomata due to excessive uterine bleeding and depletion of iron reserves. However, occasional patients display erythrocytosis. Hematocrit levels return to normal following removal of the tumor, and elevated erythropoietin levels have been reported in such cases. Moreover, the recognized association of polycythemia and renal disease has led to speculation that leiomyomas compress the ureters, causing ureteral back pressure and inducing renal erythropoietin production.

Leukocytosis, fever, and an elevated sedimentation rate may be present with acute degeneration or infection.

IMAGING

Pelvic ultrasound examinations are useful in confirming the diagnosis of leiomyomata. Although ultrasound should be a substitute for a thorough pelvic examination, it can be extremely helpful in identifying leiomyomata, detailing the size and location of other pelvic masses, and identifying pregnancy. Moreover, ultrasonography is particularly useful in obese individuals. Saline sonohysterography can identify submucosal myomas that may be missed on ultrasound.

Large leiomyomata typically appear as soft tissue masses on x-ray films of the lower abdomen and pelvis; however, attention is sometimes drawn to the tumors by calcifications. Hysterosalpingography may be useful in detailing the location of an intrauterine leiomyoma in the infertile patient.

Intravenous urography may be useful in the work-up of any pelvic mass because it frequently reveals ureteral displacement and identifies urinary anomalies. MRI can also be used to evaluate the urinary tract and is highly accurate in depicting the number, size, and location of leiomyomata.

SPECIAL EXAMINATIONS

Hysteroscopy may assist in identification, and may also be used for removal, of submucous leiomyomata. Laparoscopy is often definitive in establishing the precise origin of leiomyomata and is increasingly being used for myomectomy (see later).

Differential Diagnosis

The diagnosis of uterine myoma usually is not difficult, although any pelvic mass, including pregnancy, may be mistaken for a leiomyoma. Indeed, leiomyoma is a common preoperative diagnosis for ovarian carcinoma, endolymphatic metastasis, tubo-ovarian abscess, and endometriosis. Modern imaging techniques may clarify the diagnosis, particularly in obese women or in patients in whom palpation is difficult for other reasons, eg, when the abdominal muscles are tense.

Ovarian cysts or neoplasia must be considered in the differential diagnosis of uterine leiomyomata. Other adnexal considerations include tubo-ovarian inflammatory or neoplastic masses. Uterine enlargement simulating leiomyomata may be due to pregnancy (including subinvolution), endometrial cancer, adenomyosis, myometrial hypertrophy, or congenital anomalies. Adnexa, omentum, or bowel adherent to the uterus may be erroneously diagnosed as leiomyomata. In the presence of a fetus within an obviously myomatous uterus, a pregnancy test should be obtained in all women of childbearing age with a suspected pelvic mass.

The most common symptom of leiomyomata, recurrent abnormal bleeding, may be caused by any of the numerous conditions that affect the uterus. Adenocarcinoma of the endometrium or uterine tube, uterine sarcomas, and ovarian carcinomas are the most lethal and therefore the most important to be excluded. Hyperplasia, polyps, irregular or dysfunctional (nonorganic) bleeding, ovarian neoplasms, endometriosis, adenomyosis, and exogenous estrogens may all cause abnormal bleeding.

The definitive diagnosis in cases of uterine bleeding usually can be established by endometrial biopsy or fractionation. Some form of endometrial evaluation should be considered essential in the work-up of any patient with abnormal uterine bleeding or a pelvic mass, particularly those over age 35 years, in whom endometrial cancer may be a serious concern. In the presence of uterine leiomyomas, other conditions can coexist and must be ruled out before definitive therapy is undertaken.

Complications

MYOMAS AND PREGNANCY

Slightly less than two-thirds of women with uterine leiomyomas and otherwise unexplained infertility conceive after myomectomy, and approximately half of these women go on to deliver term infants. However, comparisons with nonmyomatous pregnancies are needed before drawing conclusions on the effectiveness of the procedure.

During the second and third trimesters of pregnancy, myomas may rapidly increase in size and undergo vascular deprivation and subsequent degenerative changes. Clinically this most commonly leads to pain and localized tenderness (see Benign Degeneration—Carneous) but also may initiate preterm labor. Expectant management with bed rest

narcotics almost always is successful in alleviating the pain, but tocolytics may be necessary to control the uterine contractions. Once the acute episode is over, most patients can carry to term without further complications.

During labor, leiomyomas may produce uterine inertia, fetal malpresentation, or obstruction of the birth canal. If leiomyomas tend to rise out of the pelvis as pregnancy progresses, and vaginal delivery may be accomplished. Nevertheless, a large cervical or isthmic myoma may be immobile and may necessitate cesarean delivery. Leiomyomas may interfere with effective uterine contraction immediately after delivery; therefore, the possibility of postpartum hemorrhage should be anticipated.

COMPLICATIONS IN NONPREGNANT WOMEN

Heavy bleeding with anemia is the most common complication of myomas. Urinary or bowel obstruction from large parasitic myomas is much less common, and malignant transformation is rare. Ureteral injury or ligation is a well recognized complication of surgery for leiomyomas, particularly cervical.

Precautions

Exogenous hormones must be used with caution in postmenopausal patients with leiomyomas. The dose should be the lowest necessary to control symptoms, and the size of the tumors should be closely followed with pelvic examination (every 6 months) and imaging studies as necessary. No evidence links oral contraceptive use with an increase in size. However, close clinical follow-up of these patients is reasonable given the potential for exogenous hormone growth of myomas.

Treatment

Asymptomatic leiomyomas are usually managed expectantly. Choice of treatment depends on the patient's symptoms, age, parity, pregnancy status, reproductive plans, and general health, as well as the size and location of the leiomyoma. Other causes of pelvic masses must be ruled out.

EMERGENCY MEASURES

Blood transfusions may be necessary to correct anemia. Transfusion of packed red blood cells is preferred over whole blood. Surgery is usually indicated for these patients when they become hemodynamically unstable. Emergency surgery is indicated for infected leiomyomata, acute torsion, or intestinal obstruction caused by a pedunculated or parasitic leiomyoma.

SPECIFIC MEASURES

Medical Therapy

The goal of medical treatment is to relieve or reduce symptoms. Although no definitive medical therapy is currently available for leiomyomata, the gonadotropin-releasing hormone (GnRH) agonists have proven very useful for limiting growth or temporarily decreasing tumor size. GnRH agonists induce hypogonadism through pituitary desensitization and downregulation of receptors, and inhibition of gonadotropins. GnRH treatment of uterine fibroids for 3 months usually achieves maximal shrinkage of the myomatous uterus to approximately 35–60% of its volume and amenorrhea with resulting improvement in hematologic parameters. GnRH treatment is limited by hypoestrogenic side effects and especially with treatment for more than 6 months. There is a rapid resumption of uterine volume and menses upon discontinuation of therapy. GnRH agonists may be useful for controlling bleeding from leiomyomata (acutely or preoperatively); improving the preoperative hematocrit level, act as a temporizing measure until surgery can be performed or menopause is anticipated; or shrinking myomas sufficiently to allow vaginal hysterectomy. Oral contraceptives are commonly prescribed to control abnormal uterine bleeding, but they do not appear to be effective in the treatment of fibroids. They may assist in treating coexisting conditions such as pelvic pain or anovulatory bleeding, which may be contributed to leiomyomas.

Small observational studies have shown good results with use of the levonorgestrel-releasing intrauterine device for treatment of menorrhagia related to multiple smaller leiomyomata.

SURGICAL MEASURES

Surgery is the mainstay of treatment of leiomyomas. Imaging most often must be accompanied by endometrial sampling to rule out other pelvic neoplastic processes. All patients should undergo cervical Papanicolaou smear test and sampling of the endometrium if bleeding is irregular. Before definitive surgery, necessary blood volume should be replenished. Other measures such as administration of prophylactic antibiotics or heparin should be considered. Mechanical and antibiotic bowel preparation can be used when difficult pelvic surgery is anticipated.

Myomectomy

Myomectomy is an option for the symptomatic patient who wishes to preserve fertility or conserve the uterus. The disadvantage is the significant risk for future leiomyomas. Five years postmyomectomy, 50–60% of patients will have myomas detected on ultrasound, and up to 25% will require a second major surgery. Couples should undergo an infertility evaluation before the woman undergoes myomectomy to improve fertility.

Most women are counseled to delay pregnancy for 3–6 months after abdominal myomectomy and to plan for cesarean deliveries after removal of a transmural fibroid. The risk of uterine rupture prior to labor after abdominal myomectomy is reported to be 0.0002%. Myomectomy is increasingly being performed through the hysteroscope in cases of submucosal leiomyomata and through the laparoscope for small numbers of subserous or intramural leiomyomata. These less invasive procedures are liberalizing the surgical indications for myomectomy. The strength of the uterine closure in laparoscopic myomectomies is controversial, and uterine rupture has been reported starting at 33 weeks' gestation. Patients should be counseled carefully regarding these risks.

A pedunculated submucous myoma protruding into the vagina can sometimes be removed vaginally with a loop snare or by hysteroscopy. This is most useful if other tumors do not obviously require removal. If the peduncula cannot be removed vaginally, careful biopsy should be performed to rule out leiomyosarcoma or a mixed mesodermal sarcoma. Both of these tumors are known to protrude through the cervix in older women and may be clinically indistinguishable from an infarcted prolapsed myoma (Fig 39–4).

Figure 39–4.

Prolapsed and partially infarcted myoma.

Surgical intervention for properly diagnosed uterine fibroids should normally be avoided in pregnancy. The only indication for myomectomy in pregnancy is torsion of a pedunculated fibroid in which transection and hemostasis of the stalk can be achieved with relative safety. Similarly, myomectomy has traditionally been discouraged during cesarean section perhaps to facilitate access to the lower uterine segment. A few small studies have recently challenged the theory of an increased risk for hemorrhage and transfusion.

Hysterectomy

Leiomyomas are the most common indication for hysterectomy, with a cumulative risk of 7% for all women between 20 and 45 years old. More than 50% of hysterectomies in black women are performed for fibroids, with a cumulative risk of 20% until age 45 years. Hysterectomy eliminates the symptoms and recurrence.

Uteri with small myomas may be removed by total vaginal hysterectomy, particularly if vaginal relaxation demonstrates a cystocele, rectocele, or enterocele.

When numerous large tumors (especially intraligamentary myomas) are found, total abdominal hysterectomy is indicated. Ovaries generally are preserved in premenopausal women. There is no consensus about the virtue of conserving or removing ovaries in postmenopausal women.

Uterine Fibroid Embolization

Embolization of the uterine arteries is an alternative to major surgery in premenopausal women not desiring pregnancy but who wish to retain their uterus or avoid the side effects of medical therapy. In this procedure, an arteriogram is performed to identify the blood supply to the fibroid. A catheter is then advanced into the distal uterine artery under fluoroscopic guidance, usually through the right femoral artery. The artery is infused with an embolizing agent (polyvinyl alcohol particles or tris-acryl gelatin microspheres) until flow ceases. The average procedure lasts 1 hour. Long-term follow-up is currently available for 5 years, with reports indicating that 95% of patients have significant improvement in symptoms and quality of life. Seven percent experience amenorrhea. Observational studies suggest the treatment to be as effective as hysterectomy and myomectomy, with more frequent minor complications, fewer major complications, and shorter hospital stays. Frequency of leiomyoma recurrence is lower with embolization (10–15%) compared to myomectomy (20–50%).

Endometrial Ablation

For women not desiring fertility, ablation of the endometrium may control the symptoms of bleeding. The procedure is more effective when combined with myolysis.

Myolysis

This technique of laparoscopic thermal coagulation of leiomyomas does not require suturing and is easy to perform. Localized tissue destruction may contribute to increase postoperative adhesions or chance of rupture during pregnancy.

Laparoscopic Uterine Artery Occlusion

This method of cauterizing the uterine arteries at laparoscopy (with or without concurrent myomectomy) has been reported. Experience is limited.

Magnetic Resonance-Guided Focused Ultrasound Surgery

This method was approved by the Food and Drug Administration (FDA) in October 2004 for the treatment of leiomyomas in premenopausal women who have completed childbearing. The outpatient procedure uses MRI for real-time thermal monitoring of the thermoablative technique, which converges multiple waves of ultrasound energy on a small volume of tissue to be destroyed. Studies of long-term outcomes of this procedure are ongoing.

Prognosis

Hysterectomy with removal of all leiomyomas is curative. Following myomectomy, the uterus and its cavity gradually

return to normal contour. One major concern is the risk of recurrence after myomectomy. Recent studies suggest 2–3% per year of symptomatic myomas after myomectomy.

ADENOMYOSIS

Essentials of Diagnosis

- Premenstrual and comenstrual dysmenorrhea.
- Uniform and symmetric uterine enlargement.
- Menorrhagia.

General Considerations

Adenomyosis is defined by the presence of endometrial glands and stroma within the myometrium of the uterus beneath the basement membrane. It may exist as either diffuse disease detected at hysterectomy only by microscope as distinct nodules known as *adenomyomas*. Adenomyosis is generally thought to affect 20% of women, although meticulous sectioning of hysterectomy specimens has yielded an incidence as high as 65%.

In adenomyosis, the uterus becomes diffusely enlarged and globular due to induced hypertrophy and hyperplasia of smooth muscle elements adjacent to the ectopic glands.

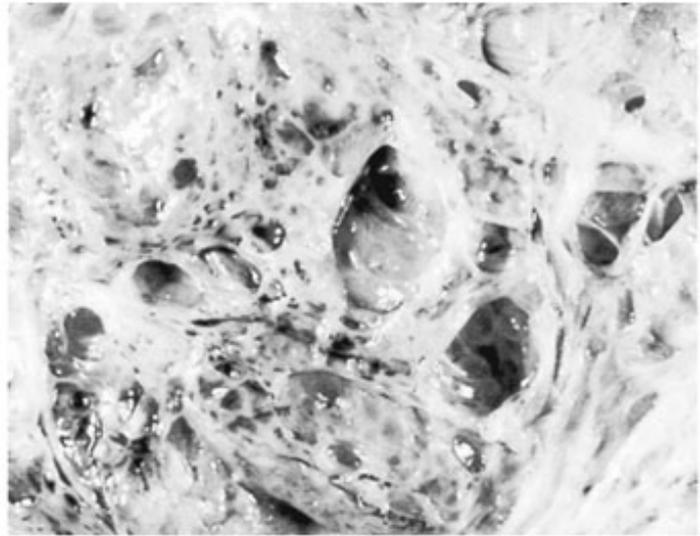

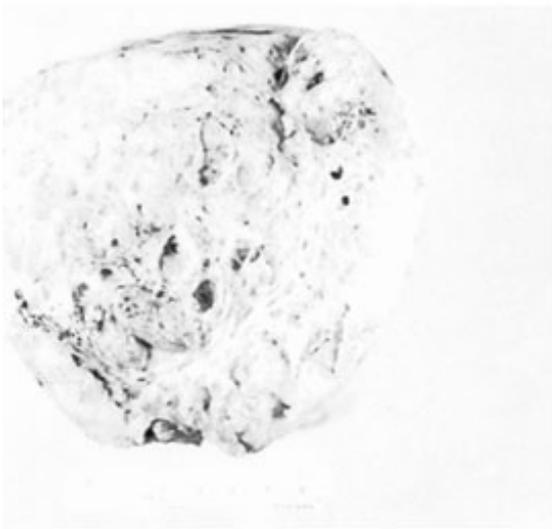

The pathogenesis of adenomyosis is unknown. It is more common in women with a history of childbirth, although increasing parity does not seem to correlate with a higher risk for the disease. It is thought that postpartum endometrial invasion might cause the initial break in the normal boundary, allowing endomyometrial invasion of the endometrium. A theory of metaplastic origin speculates an arrest of müllerian cells in the myometrium and later de novo development of endometrial glands in this site. Animal models suggest prolactin and follicle-stimulating hormone stimulate growth of adenomyosis and play a role in its pathogenesis.

Adenomyosis causes symptoms in approximately 70% of proved cases; approximately 30% of cases are asymptomatic and are discovered incidentally. Symptoms typically develop in patients between 40 and 50 years of age and later reappear after menopause.

Pathology

On gross inspection, the uterus is uniformly enlarged and boggy. The myometrial thickening produced by adenomyosis is of uniform consistency rather than irregularly nodular, as seen with leiomyomas. The fundus generally is the site of adenomyosis. It may involve either or both walls of the uterus, creating a globular enlargement (usually 10–12 cm in diameter; Fig 39–5, left). The uterus has enhanced vascularity. The cut surface appears convex (bulging) and edematous. The cut surface may have a whorl-like or granular trabecular pattern, and coarse stippling or granular trabeculae with small yellow or brown cystic spaces containing fluid or blood may be seen (Fig 39–5, right). Small hemorrhages represent endometrial islands in which menstrual bleeding has occurred. The endometrial–myometrial junction is indistinguishable, making excision of adenomyosis difficult. Leiomyomas and adenomyosis coexist in the same specimen in up to 50% of cases.

Figure 39–5.

Adenomyosis. Left: Gross view showing globular mass. Right: Close-up view showing stippled trabeculation with cystic spaces containing fluid or blood.

The microscopic pattern is one of endometrial islands scattered throughout the myometrium, at a distance of less than 1 mm from the basement membrane of the endometrium (some experts demand a distance of 2 mm). Depth of penetration can be graded. Endometrial ablation distorts the normal endometrium–myometrium junction and makes the diagnosis of adenomyosis more difficult.

Myometrial hypertrophy and hyperplasia are almost invariably apparent around the endometrial islets, and phagocytosis of hemosiderin occasionally is seen in the muscularis. The ectopic endometrium usually has an immature proliferative phase, but if the degree of involvement is marked, the embedded endometrium may show cyclic changes identical to those of normal endometrium. The ectopic glands appear to respond fairly well to estrogen and to progesterone to a lesser degree. The ectopic endometrium may participate in the decidual changes characteristic of pregnancy.

Although both adenomyosis and endometriosis are disorders of ectopic endometrium, the 2 diseases are unrelated and frequently coexist.

Clinical Findings

SYMPTOMS AND SIGNS

Significant degrees of adenomyosis are associated with menorrhagia in 60% of patients, and approximately 25% with a severe form of dysmenorrhea. One-third of patients are asymptomatic. The classic patient with adenomyosis is a parous, middle-aged woman with menorrhagia and dysmenorrhea who has a symmetrically enlarged uterus.

Despite widespread knowledge of the major symptoms of adenomyosis, the correct preoperative diagnosis is made in less than one-third of all instances. Failure to make the diagnosis preoperatively usually results from attributing symptoms to coexisting lesions. Leiomyomas, endometrial polyps, endometrial hyperplasia, endometrial carcinoma, and endometriosis may all disguise the symptomatology.

Menorrhagia

It is claimed that even minimal myometrial invasion by endometrial glands in the subbasalis may produce hypermenorrhea in a high proportion of cases. There is direct correlation between the degree of involvement of adenomyosis (as opposed to depth of penetration), vascularity of the uterus, and the occurrence of menorrhagia. The increased surface area of the endometrium in the enlarged uterus likely contributes to the menorrhagia.

Dysmenorrhea

Dysmenorrhea is directly related to the depth of penetration and degree of involvement. It probably results from myometrial contractions invoked by premenstrual swelling and menstrual bleeding in endometrial islands. The uterus is usually tender and slightly softened under bimanual examination performed premenstrually (Halban's sign).

IMAGING

Transvaginal ultrasonography may suggest the diagnosis but is not highly accurate (sensitivity 83% and specificity 83%). MRI is the most accurate noninvasive diagnostic test for detecting adenomyosis, but the cost of the procedure is weighed against the information gathered. It is best reserved for the symptomatic patient with a negative or equivocal sonogram or for the patient with leiomyomas.

Differential Diagnosis

Pregnancy can be ruled out with a pregnancy test.

Submucous leiomyomas may be present in 50–60% of cases of adenomyosis. Leiomyomas may cause excessive progressive menorrhagia and pain. The uterus is usually firm and nontender, even during menstruation, unless degenerating myomas are a confounder. Diagnosis is confirmed by hysteroscopy and/or curettage. Endometrial adenomyosis is diagnosed by endometrial biopsy or curettage.

Pelvic congestion syndrome (Taylor's syndrome) is characterized by chronic complaints of continuous pelvic pain and menorrhagia. In some instances, the uterus is enlarged, symmetric, and minimally softened; the cervix may be cyanotic and patulous. At operation, the pelvic vessels may appear enlarged or tortuous.

Pelvic endometriosis is marked by premenstrual and intramenstrual dysmenorrhea, adherent adnexal masses, a cul-de-sac or uterosacral ligament nodulations. The disorder is often associated with adenomyosis.

Complications

Chronic severe anemia may result from persistent menorrhagia.

Primary adenocarcinoma has rarely been observed in islands of aberrant endometrium within myometrium, provided surface endometrium is normal. On the other hand, endometrial adenocarcinoma is often associated with islands of malignant glands in the muscularis, but it may be impossible to determine whether myometrial metastasis from primary surface tumor or development of carcinoma within a focus of adenomyosis has occurred. However, if the tumor is markedly anaplastic and the myometrial islets exhibit well-differentiated glands, it seems reasonable to assume that the latter are not metastases.

When the stromal component of endometrium, without glands, invades the myometrium, the resulting "tumor" is known as *endolymphatic stromal myosis*, or stromatosis. This entity is not dependent on ovarian hormonal production and therefore is not truly comparable to adenomyosis.

Prevention

Adenomyosis cannot be prevented.

Treatment

HYSTERECTOMY

Although focal adenomyomas occasionally can be successfully removed, hysterectomy is the only other definitive treatment of adenomyosis. Hysterectomy is also the only method for establishing the diagnosis with certainty. Whether ovaries should be removed depends, as in many other situations, on the patient's age and the presence of obvious lesions or generalized pelvic endometriosis. Small series on uterine artery embolization suggest hysterectomy is an effective treatment.

HORMONAL THERAPY

Medical treatment with hormones has not been successful in the treatment of adenomyosis. Some foci of adenomyosis

have shown pseudodecidual reaction to progestins with no symptomatic relief. GnRH agonists can provide temporary relief of symptoms if the focus of adenomyosis is estrogen- and progesterone-receptor positive. However, symptoms recur when the medication is discontinued. Oral contraceptives may exacerbate the symptoms.

Prognosis

Hysterectomy is curative.

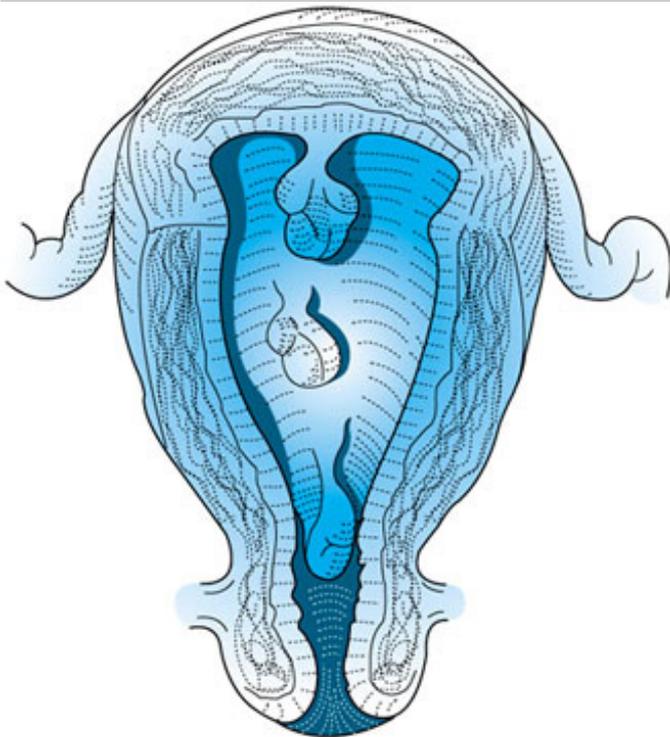

ENDOMETRIAL POLYPS

Essentials of Diagnosis

- Menometrorrhagia or postmenopausal bleeding.
- Visualization by imaging and/or biopsy.

General Considerations

"Polyp" is a general descriptive term for any mass of tissue that projects outward or away from the surface of surface tissues. An endometrial polyp is a hyperplastic overgrowth of endometrial glands visible as a spheroidal or cylindrical structure that may be either pedunculated (attached by a slender stalk) or sessile (relatively broad-based) (Fig : **Figure 39–6.**

Endometrial polyps.

Benign endometrial polyps are rare among women younger than 20 years. Their incidence increases directly with age, peaking in the fifth decade, and slowly declines after menopause. Risk factors include hypertension and obesity. An incidence of endometrial polyps is noted in patients undergoing tamoxifen therapy for breast cancer. Endometrial polyps must be differentiated from submucous myomas, malignant neoplasms (especially mixed sarcomas), and even fragments of placental tissue (which may grossly assume a polypoid architecture).

Polyps may be single or multiple and may range in diameter from a few millimeters to masses that fill or even distend the uterine cavity. Most polyps arise in the fundal region and extend downward. Occasionally, an endometrial polyp prolapses through the external cervical os and even extends to the vaginal introitus (Fig 39–7). Postmortem examinations have shown that approximately 10–24% of uteri contain presumably asymptomatic polyps.

Figure 39–7.

Copyright ©2006 by The McGraw-Hill Companies, Inc.
All rights reserved.

Large, partially infarcted endometrial polyp prolapsed through the cervical os.

Polyps rarely undergo malignant change, and isolated endometrial carcinomas and sarcomas have been identified in solitary polyps. When this occurs, the prognosis is more favorable than for uterine carcinoma or sarcoma in general, providing there is no evidence of spread beyond the polyp on analysis of the hysterectomy specimen. In one large study of 509 women undergoing hysteroscopic resection of polyps, 70% were benign, 26% had hyperplasia without atypia, 2% had hyperplasia with atypia, and 0.8% harbored a malignancy.

The histogenesis of endometrial polyps is not clear. Unresponsive areas of endometrium often remain in situ, at least at the basalis, during menstrual shedding, and such an area may serve as the nidus of a polyp. However, not even the smallest polyps studied by histologic sectioning have given a wholly acceptable clue as to the precise mechanism of formation. Polyps are considered to be estrogen-sensitive; their response to estrogen is similar to that of the surrounding endometrium, and their association with other proliferative endometrial lesions (eg, hyperplasia and endometrial carcinoma) is well recognized.

Pathology

Grossly, an endometrial polyp is a smooth, red or brown, ovoid body with a velvety texture, ranging from a few to many centimeters in widest diameter. A large polyp usually tapers to an obvious pedicle. A small polyp, when cut longitudinally, often presents a cylindrical silhouette, with rounding at the distal end. Uterine polyps are the same color as the surrounding endometrium unless they are infarcted, in which case they are dark red. A sectioned polyp may have a spongy appearance if it contains many dilated glandular spaces.

The microscopic pattern of an endometrial polyp is a mixture of (1) generally dense fibrous tissue—the stroma, (2) impressively large and thick-walled vascular channels, and (3) glandlike spaces, of variable size and shape, lined by endometrial epithelium. The relative amounts of these 3 components vary considerably. The surface of an intact, functioning uterus usually is covered by a layer of endometrium resembling that of the remainder of the endometrium, but beneath this exterior are glandular components that are seemingly much older but apparently do not participate in menstrual shedding.

Squamous metaplasia of the surface epithelium is not uncommon. The subsurface epithelial spaces are often crowded with basal endometrial glands unresponsive to progesterone, but they tend to form bizarre shapes and become cystic. Hence, a fragment of polyp may be mistaken for the cystic variety of endometrial hyperplasia ("Swiss cheese" endometrium). The distal or dependent portion of a polyp may show marked engorgement of blood vessels, hemorrhage into the stroma, inflammatory cells, and ulceration at the surface.

Adenocarcinoma may develop within an otherwise benign polyp, usually at some distance from its base or pedicle. On the other hand, a benign polyp may exist in an area of endometrial carcinoma. Thus, recovery from the bleeding uterus of a postmenopausal woman does not guarantee that a more serious lesion does not exist elsewhere in the cavity.

Polyps that contain interlacing bands of smooth muscle are called *pedunculated adenomyomas*. Generally, these have broad bases and are associated with adenomyosis of the uterus. In the same uterine cavity, endometrial polyps may coexist with pedunculated leiomyomas. In cases of hyperplasia of the endometrium, the abundant overgrowth of polyps may produce a gross pattern called *multiple polyposis*. Curettage of such lesions may suggest the presence of adenocarcinoma because of the unexpected volume of tissue obtained.

Clinical Findings

SYMPTOMS AND SIGNS

Metrorrhagia (irregular bleeding) is the most common presentation of symptomatic polyps, occurring in half of patients. Menorrhagia, postmenopausal bleeding, or a prolapsed mass may also be the presenting complaint. Presumably, the polyp, with its central vascular component, contributes to menstrual bleeding and adds greatly to the total blood loss. Polyps may be the source of minor premenstrual and postmenstrual bleeding, allegedly because the dependent portion of the polyp is the first endometrial area to degenerate and the last to obtain a new epithelial covering and cease bleeding. The polyp sheds the menstrual slough.

In the postmenopausal woman, bleeding from polyps is usually light and is often described as "staining" or "spotting." A polyp should be suspected when bleeding continues following a D&C that has produced only benign normal tissue.

IMAGING

Sonohysterography is the most useful imaging modality used to evaluate for the presence of polyps in women with abnormal uterine bleeding. It has a higher sensitivity (93% vs 65%) and specificity (94% vs 76%) than transvaginal ultrasound. Polyps appear as a homogeneous hyperechoic intracavitary mass on both transvaginal ultrasound and sonohysterogram. Polyps may be evident on hysterosalpingogram as irregularities in the outline of the uterine cavity or filling defects. However, this technique has largely been replaced by office hysteroscopy and saline sonohysterography. This imaging modality can reliably distinguish between benign and malignant polyps.

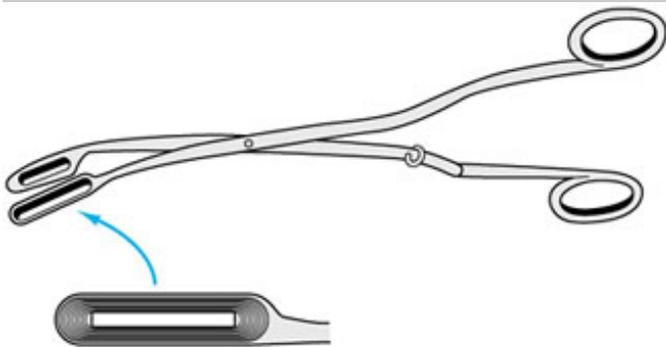

Treatment

SURGICAL EXCISION

Hysteroscopic resection of polyps followed by curettage is the gold standard for diagnosis and treatment of symptomatic polyps, as small polyps can be missed on blind curettage. Direct visualization of polyps by hysteroscopy has greatly improved their identification and removal. The stalk may be identified, and hysteroscopic instruments used under direct visualization to remove the polyp. With larger polyps, sectioning the tumor into portions that can be removed through the cervix may be necessary. Many authorities recommend curettage of the point of insertion of the stalk into the endometrium–myometrium. Direct visualization of the endometrium and selected biopsies can rule out endometrial hyperplasia or dysplasias.

If hysteroscopy is not available and a blind curettage is planned, the endometrial cavity must be explored separately using grasping forceps (such as an Overstreet polyp forceps [Fig 39–8] or a Randall stone clamp), preferably at the beginning of the curettage procedure.

Figure 39–8.

Copyright ©2006 by The McGraw-Hill Companies, Inc.
All rights reserved.

Overstreet polyp forceps.

Despite this precaution, polyps are frequently missed and remain in the uterus after curettage, only to be discovered when menorrhagia persists and a hysterectomy is performed. At other times, only a portion of a polyp is removed by curettage, and brisk bleeding continues postoperatively from the residual basal portion of the lesion. A very large polyp may have to be severed at its base using a wire snare or scissors. In all cases, a fractional curettage should follow a nonvisualizing attempt at polyp removal, whether or not it was successful, in order to rule out endometrial carcinoma. A polyp should be labeled as such, preserved separately in fixative solution, and sent to the pathology laboratory as a separate specimen because it may prove to be the most significant portion of the total tissue sample. If it is intermingled with other curettings or biopsies, there is no assurance that the polyp specimen will be part of the material chosen for histologic sectioning.

Hysteroscopic resection of polyps prior to intrauterine insemination in infertility patients has been associated with a significantly higher pregnancy rate (63% vs 28% in controls), even when the polyp is asymptomatic. Therefore, patients should be offered excision of polyps before initiating assisted reproductive technologies.

MEDICAL THERAPY

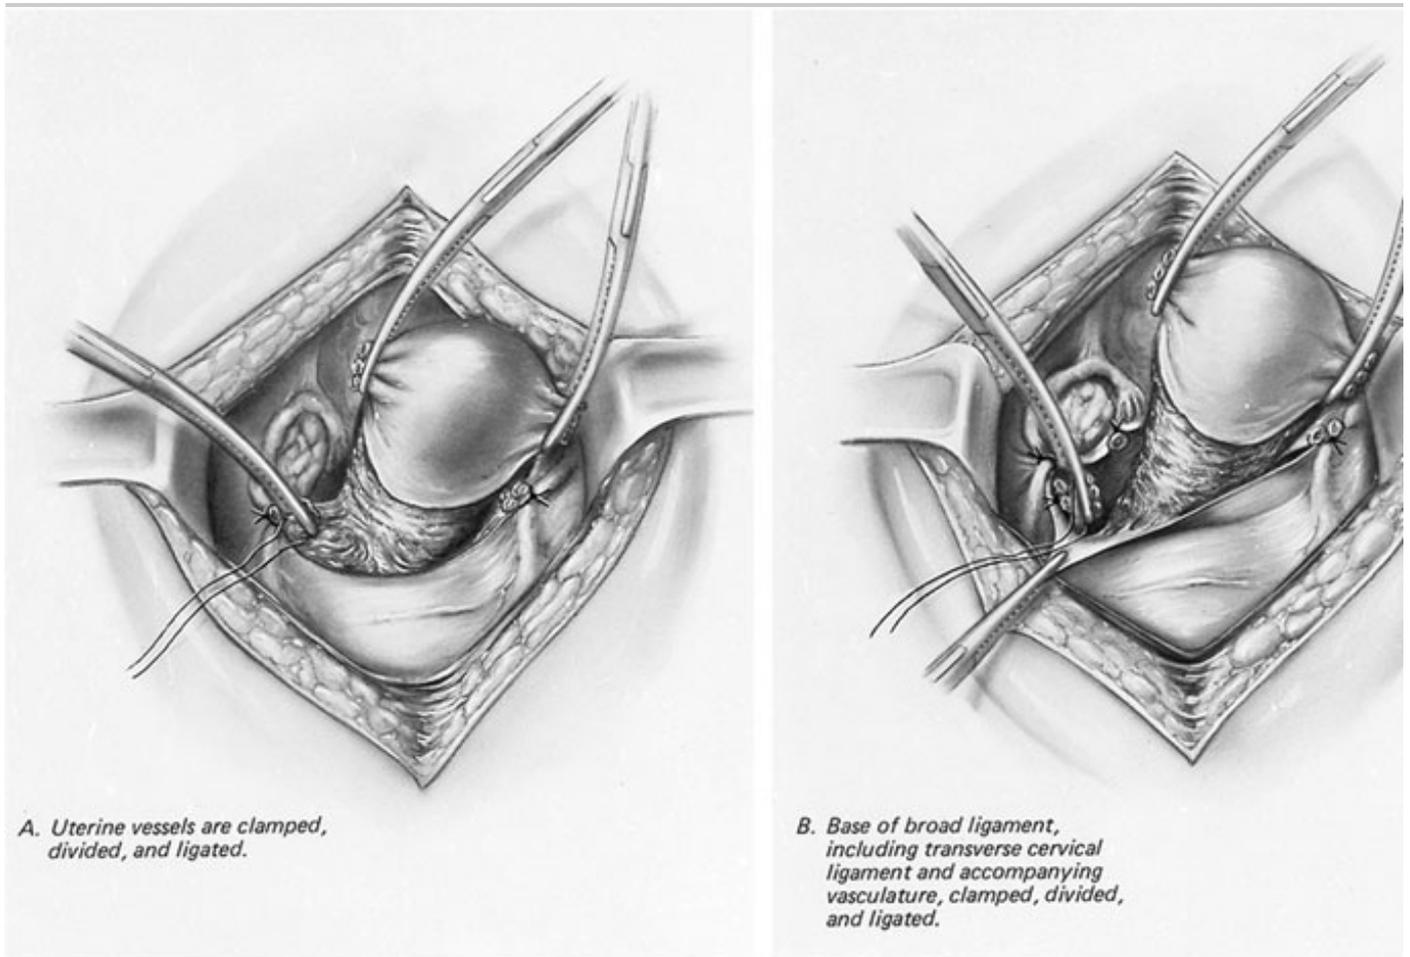

GnRH agonists may be useful for short-term treatment of polyps, but symptoms tend to recur after cessation of therapy. Progestin therapy may also cause some regression. Prospective studies have shown that some polyps less than 1 cm regress spontaneously.

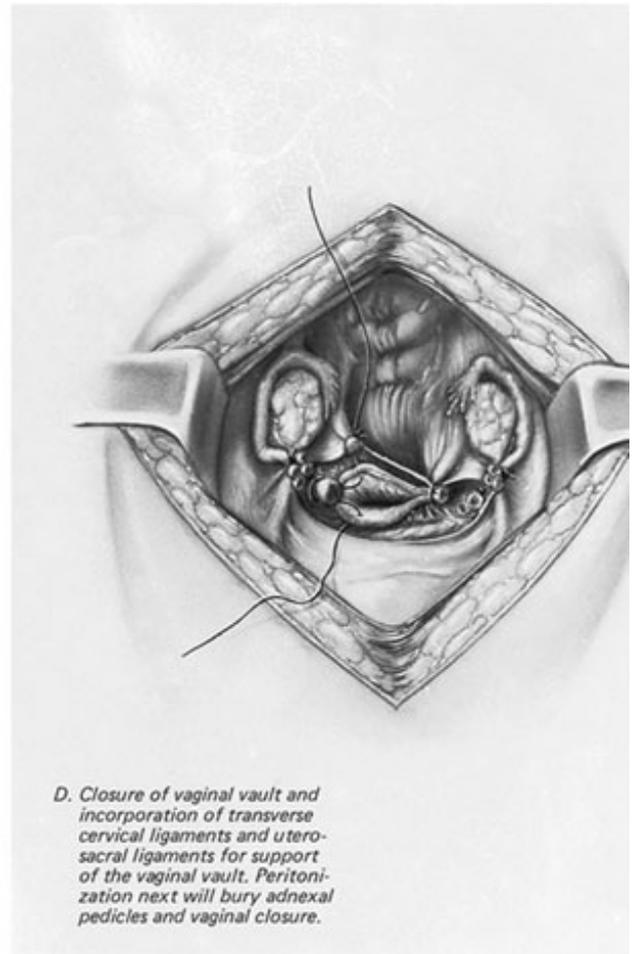

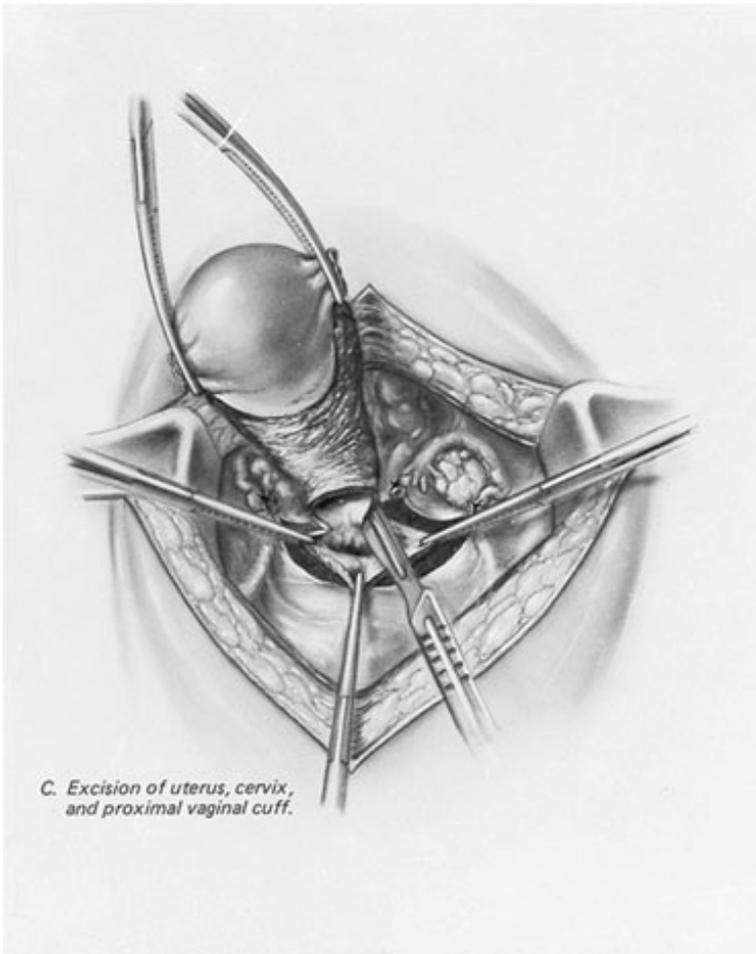

HYSTERECTOMY

Simple excision is adequate for a benign polyp, but if areas of carcinoma or sarcoma are discovered, hysterectomy

be performed. In a premenopausal patient, persistence of abnormal uterine bleeding after removal of an apparent polyp (or some portion of it) may require further diagnostic steps and/or more invasive treatment (Fig 39–9). Uteruses removed for this reason occasionally contain additional polyps, submucous leiomyomata, or rarely a small area of carcinoma in a relatively inaccessible location.

Figure 39–9.

All rights reserved.

Richardson technique for conservative hysterectomy.

Prognosis

Removal is curative for that polyp, but recurrence is frequent. Hysterectomy is definitive but usually unnecessary if the polyp has been ruled out.

Current OB/GYN > Chapter 40. Benign Disorders of the Ovaries & Oviducts >

BENIGN DISORDERS OF THE OVARIES & OVIDUCTS: INTRODUCTION

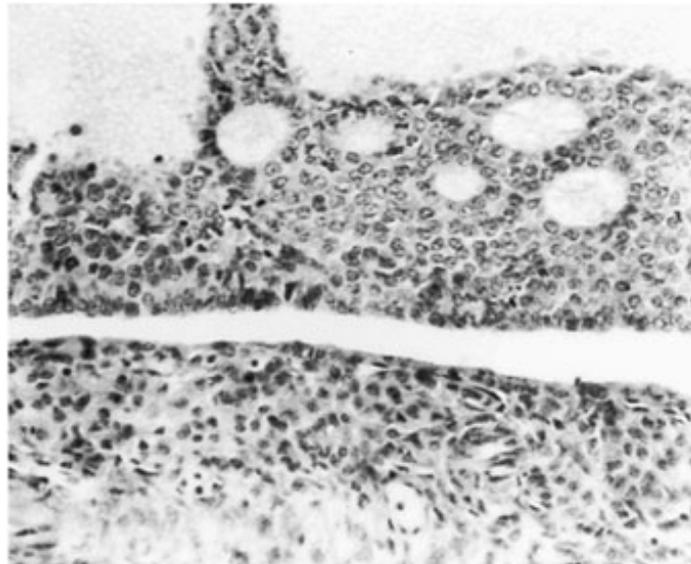

Benign adnexal masses are common in women in the reproductive age group and are caused by physiologic cysts or benign neoplasms. The management of these benign masses is dictated by their presentation. Operative intervention is indicated when a patient is symptomatic because of hemorrhage of a ruptured cyst or ovarian torsion. Most adnexal masses, however, are discovered incidentally, and the risk of malignancy must always be assessed and excluded (see Chapter 52 for proper evaluation). For instance, sonographic indices such as septations, solid components, and Doppler flow within a neoplasm are suspicious for malignancy. When malignancy is not suspected, expectant management is indicated, as many of these cysts are physiologic in nature and thus are expected to regress over time. Patients should be re-evaluated 6 weeks after initial presentation, and persistent masses should be considered potentially benign or malignant neoplasms that warrant operative evaluation. Pathologic diagnosis by frozen section during surgery can aid in making a final diagnosis and determining what type of surgery is indicated. For most benign ovarian cysts, laparoscopy is the preferred method because of its shorter recovery time, as well as less pain, blood loss, and overall cost compared to laparotomy. Even extremely large ovarian cysts (reaching the umbilicus and higher) currently are being managed laparoscopically. Laparoscopic approach is recommended if the cyst appears benign by preoperative evaluation. For most patients, ovarian cystectomy is favored over oophorectomy in order to retain fertility.

FUNCTIONAL CYSTS

Follicular Cysts

Follicular cysts (Fig 40–1) are common and vary in diameter from 3 to 8 cm. Histologically, they are seen to be lined by an inner layer of granulosa cells and an outer layer of theca interna cells that may or may not be luteinized. These cysts result from a failure in ovulation, most likely secondary to disturbances in the release of the pituitary gonadotropins. The fluid of the incompletely developed follicle is not reabsorbed, producing an enlarged follicular cyst. Typically they are asymptomatic, although bleeding and torsion can occur. Large cysts may cause aching pelvic pain, dyspareunia, and occasionally abnormal uterine bleeding associated with a disturbance of the ovulatory pattern. Most follicular cysts disappear spontaneously within 60 days without treatment. Use of oral contraceptive pills (OCPs) has often been recommended to help establish a normal rhythm; however, recent data show that this practice may not produce more rapid resolution than expectant management.

Figure 40–1.

All rights reserved.

Wall of a follicular cyst showing the proliferating granulosa cells with tiny cystic Call-Exner bodies in the upper portion of the figure. They have artifactually pulled away from the underlying theca cells.

Corpus Luteum (Granulosa Lutein) Cysts

These are thin-walled unilocular cysts ranging from 3–11 cm in size. Following normal ovulation, the granulosa cells lining the follicle become luteinized. In the stage of vascularization, blood accumulates in the central cavity, producing the corpus hemorrhagicum. Resorption of the blood then results in a corpus luteum, which is defined as a cyst when it grows larger than 3 cm. A persistent corpus luteum cyst may cause local pain or tenderness. It can also be associated with either amenorrhea or delayed menstruation, thus simulating the clinical picture of an ectopic pregnancy. A corpus luteum cyst may be associated with torsion of the ovary, causing severe pain; or it may rupture and bleed, in which case laparoscopy or laparotomy is usually required to control hemorrhage into the peritoneal cavity. Unless acute complications develop, symptomatic therapy is indicated. As with follicular cysts, corpus luteum cysts usually regress after 1 or 2 months in menstruating patients, and OCPs have been recommended but may be of questionable benefit.

Theca Lutein Cysts

Elevated levels of chorionic gonadotropin can produce theca lutein cysts and thus are seen in patients with hydatidiform mole or choriocarcinoma and in patients undergoing chorionic gonadotropin or clomiphene therapy. Rarely, they are seen in normal pregnancy. The cysts are lined by theca cells that may or may not be luteinized, and they may or may not have granulosa cells. They are usually bilateral and are filled with clear, straw-colored fluid. Abdominal symptoms are minimal, although a sense of pelvic heaviness or aching may be described. Rupture of the cyst may result in intraperitoneal bleeding. Continued signs and symptoms of pregnancy, especially hyperemesis and breast paresthesias, are reported. The cysts disappear spontaneously following termination of the molar pregnancy, treatment of the choriocarcinoma, or discontinuation of fertility therapy; however, such resolution may take months to occur. Surgery is reserved for complications such as torsion and hemorrhage.

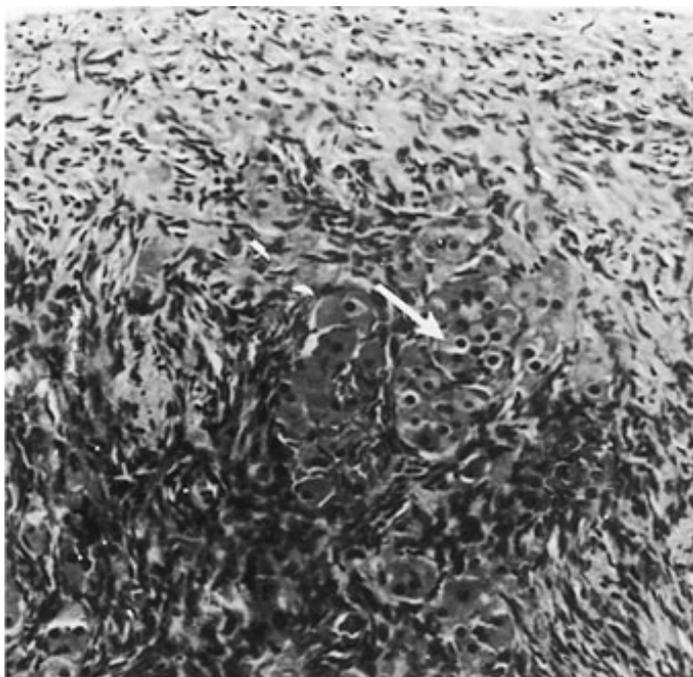

Endometriomas

In women with endometriosis, ovarian endometrial cysts can develop and grow up to 6–8 cm. These endometriomas are also referred to as "chocolate cysts" because they contain thick, brown blood debris inside.

HYPERTHECOSIS

Hyperthecosis, or thecomatosis, commonly produces no gross enlargement of the ovary (Fig 40–2). Thus, the lesions are demonstrable only by histologic examination of the excised gonad. They are characterized by nests of stromal cells demonstrating increased cytoplasm, simulating the changes seen in the normal theca after stimulation by pituitary gonadotropin. In the premenopausal woman, hyperthecosis is associated with virilization and clinical findings similar to those seen in polycystic ovarian disease (see following text). These alterations may also be associated with postmenopausal bleeding and endometrial hyperplasia.

Figure 40–2.

Copyright ©2006 by The McGraw-Hill Companies, Inc.
All rights reserved.

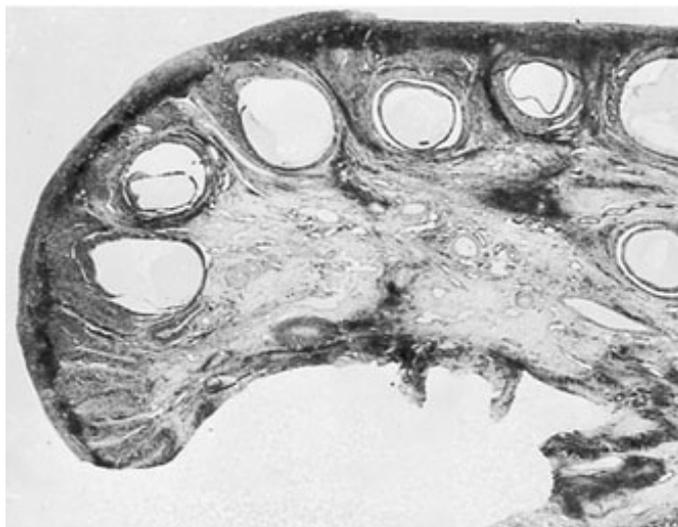

In hyperthecosis, nests of rounded eosinophilic luteinized stroma cells are found in the ovarian cortex.

POLYCYSTIC OVARIAN SYNDROME (STEIN-LEVENTHAL SYNDROME)

Polycystic ovarian syndrome (PCOS) is characterized by persistent anovulation that can lead to clinical manifestations, including enlarged polycystic ovaries, secondary amenorrhea or oligomenorrhea, and infertility. The syndrome has a prevalence of 5–10%, with variance among races and ethnicities. Approximately 50% of patients are hirsute, and 30–75% are obese. A presumptive diagnosis of PCOS often can be made based on the history and initial examination. According to an international consensus group, the syndrome can be diagnosed if at least 2 of the following conditions are present: oligomenorrhea or amenorrhea, hyperandrogenism, and polycystic ovaries on ultrasound. Polycystic ovaries have been called "oyster ovaries" because they are enlarged and "sclerocystic" with smooth, pearl-white surfaces without indentations. Many small, fluid-filled follicle cysts lie beneath the thickened fibrous surface cortex (Fig 40–3). Luteinization of the theca interna is usually observed, and occasionally

focal stromal luteinization is seen. Laboratory testing often reveals mildly elevated serum androgen levels, an increased ratio of luteinizing hormone to follicle-stimulating hormone (LH/FSH), lipid abnormalities, and insulin resistance. Anovulation is identified in women with persistently high concentrations of LH and low concentrations of FSH, a low day-21 progesterone level, or on sonographic follicular monitoring. PCOS is presumably related to hypothalamic pituitary dysfunction and insulin resistance. A primary ovarian contribution to the problem has not been clearly defined.

Figure 40–3.

Copyright ©2006 by The McGraw-Hill Companies, Inc.
All rights reserved.

Polycystic ovary with a thickened capsule and prominent subcapsular cysts. Note lack of corpora lutea or corpora albicantia due to anovulation.

Most patients with PCOS seek treatment for either hirsutism or infertility. The hirsutism can be treated with any agent that lowers androgen levels, and OCPs are typically the first choice in patients not desiring pregnancy. Infertility in PCOS patients is often responsive to clomiphene citrate. In the recalcitrant case, the experienced clinician can add human menopausal gonadotropin to produce the desired ovulation. Recent studies indicate that therapy with metformin improves fertility rates both when given alone and, even more so, when given in conjunction with clomiphene. Studies show that a small reduction in body weight, as little as 2–7%, is associated with improved ovulatory function in women with PCOS. As patients with PCOS are chronically anovulatory, the endometrium is stimulated by estrogen alone. Thus endometrial hyperplasia, both typical and atypical, and endometrial carcinoma are more frequent in patients with PCOS and long-term anovulation. Many of these markedly atypical endometrial features can be reversed by large doses of progestational agents, such as megestrol acetate 40–60 mg/d for 3–4 months. Follow-up endometrial biopsy is mandatory to determine endometrial response and subsequent recurrence.

LUTEOMA OF PREGNANCY

Tumorlike nodules of lutein cells may form in the ovaries during pregnancy and are often both multifocal and bilateral. The nodules range up to 20 cm in diameter, but most often they range from 5–10 cm. On section they reveal well-delineated, soft, brown masses with focal hemorrhage. Microscopically, they are formed of sheets of large luteinized cells with abundant cytoplasm and relatively uniform nuclei with occasional mitoses. Clinically, they appear ominous to the obstetrician, who becomes aware of them only when the abdomen is open at the time of cesarean delivery. Unilateral salpingo-oophorectomy can be performed for frozen section in the belief that the large masses are malignant. A confirmatory biopsy is adequate, and follow-up will reveal total regression a few months later.

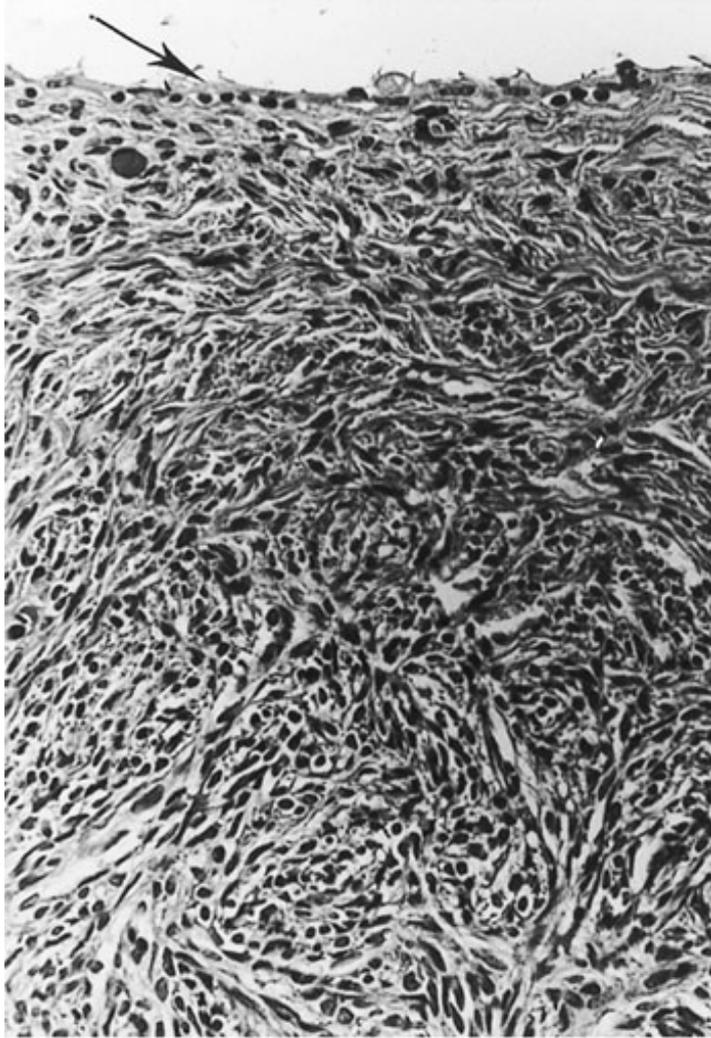

TREATMENT OF OVARIAN TUMORS

The preferred treatment of all ovarian tumors is surgical excision with careful exploration of the abdominal contents. If the risk of malignant neoplasia is confidently low, laparoscopy is preferred. In patients requesting future fertility, cystectomy is performed if possible; otherwise a unilateral oophorectomy is performed. Frozen section is helpful in identifying the type and neoplastic potential of the tumor. However, because adequate sampling of a large ovarian neoplasm often is impossible, final opinion and prognosis *must* be based on analysis of permanent, rather than frozen, sections. Therefore, in a patient desirous of retaining fertility, the surgeon must err on the side of retention of the uterus and contralateral ovary if the pathologist has the slightest doubt as to tumor malignancy.

EPI THELIAL TUMORS

Epithelial tumors account for approximately 60–80% of all true ovarian neoplasms and include the common serous, mucinous, endometrioid, clear cell, and transitional cell (Brenner) tumors, and the stromal tumors with an epithelial element. The epithelium of these tumors arises from a common anlage, ie, the mesothelium lining the coelomic cavity and ovarian surfaces (Fig 40–4). This basic thesis explains the similarity of the epithelia of the upper genital canal—endocervix, endometrium, and endosalpinx—to those found in the ovarian tumors. Most tumors presumably arise from invaginated surface epithelium (Fig 40–4) and proliferation or malignant degeneration in the epithelial lining of the resulting surface inclusion cyst (Fig 40–5). The epithelial tumors are classified on the basis of their histologic appearance.

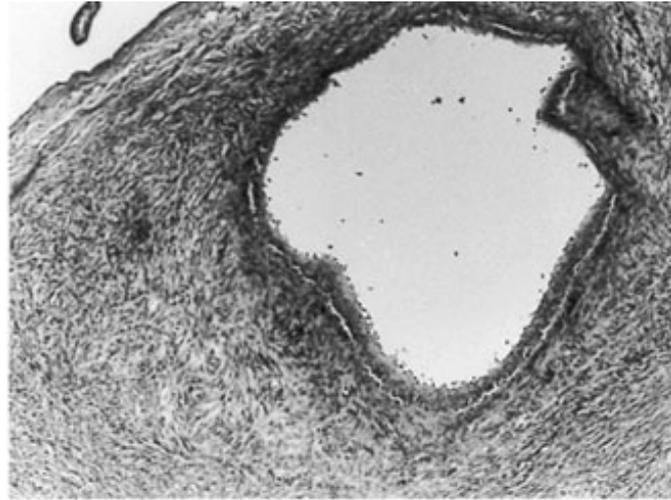

Figure 40–4.

Surface epithelium (mesothelium; indicated by the arrow) of the ovary forms an inconspicuous, usually flat, layer of cells over the underlying ovarian cortex.

Figure 40–5.

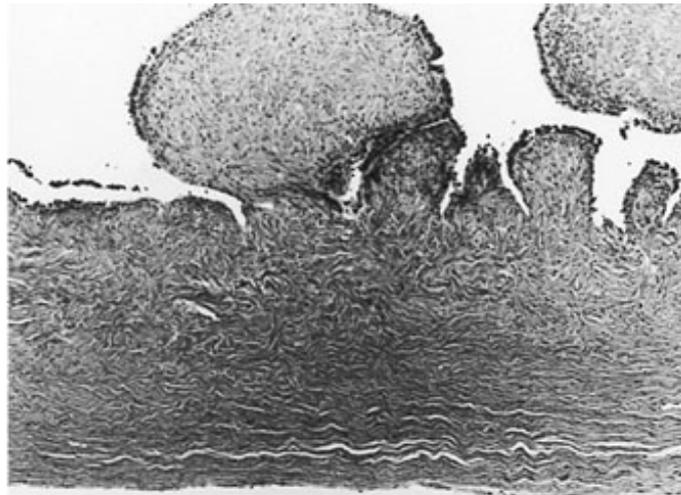

Copyright ©2006 by The McGraw-Hill Companies, Inc.
All rights reserved.

Most surface (germinal) inclusion cysts, such as the one shown here, undergo a serous (tubal) metaplasia. By definition, cysts larger than 1 cm in diameter are termed cystadenomas.

Serous Tumors

Serous tumors have been reported in all age groups and are responsible for approximately 30% of all epithelial ovarian neoplasms. Low-grade neoplasms generally are found in patients in their 20s and 30s, whereas their anaplastic counterparts occur more commonly in perimenopausal and postmenopausal women. Serous cystadenomas are benign lesions, commonly unilocular, with a smooth surface, and containing thin, clear yellow fluid. The cells lining the cyst are a mixed population of ciliated and secretory cells similar to those of the endosalpinx. They may grow large enough to fill the abdominal cavity, but usually they are smaller than their mucinous counterparts. Approximately 10–15% are bilateral. Focal proliferation of the underlying stroma may produce firm papillary projections into the cyst, forming a serous cystadenofibroma (Fig 40–6). It is important to study these papillary projections thoroughly to rule out atypical proliferation. Some serous tumors consist of benign stromal proliferation interspersed with tiny serous cysts; these are known as *serous adenofibromas*.

Figure 40–6.

Copyright ©2006 by The McGraw-Hill Companies, Inc.
All rights reserved.

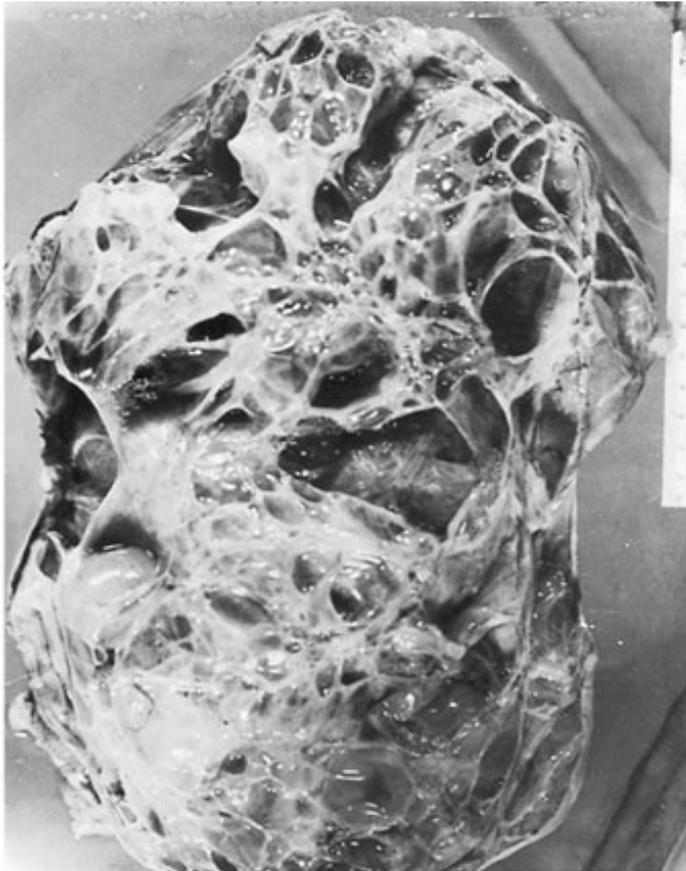

Serous cystadenofibromas usually form unilocular cysts with firm white papillations protruding into the cyst, seen here microscopically.

Mucinous Tumors

Mucinous tumors account for approximately 10–20% of all epithelial ovarian neoplasms, of which approximately 75%–85% are benign. The benign tumors are typically found in women in their 30s through 50s. Bilateral tumor development occurs in 8–10% of all cases, whether the tumors are benign or malignant. They are the largest tumors found in the human body; 15 reported tumors have weighed more than 70 kg (154 lb). Consequently, the more massive the tumor, the greater the possibility that it is mucinous. They generally are asymptomatic, and patients present with either an abdominal mass or nonspecific abdominal discomfort. In postmenopausal patients, luteinization of the stroma rarely may result in hormone production (usually estrogen) leading to associated endometrial hyperplasia with vaginal bleeding. During pregnancy, hormonal stimulation may result in virilization.

Histologically, they are usually smooth-walled; true papillae are rare (compared with the serous variety). The tumors generally are multilocular, and the mucus-containing locules appear blue through the tense capsule (Fig 40–7). The internal surface is lined by tall columnar cells with dark, basally situated nuclei and mucinous cytoplasm (Fig 40–8).

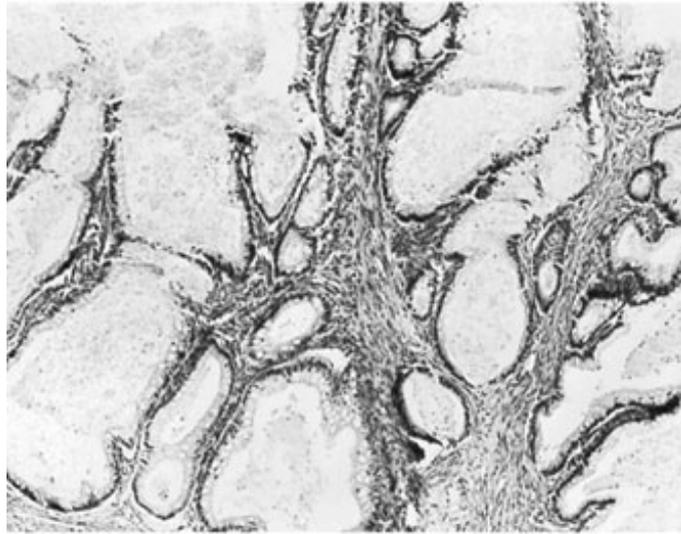

Figure 40–7.

All rights reserved.

Multilocular mucinous cystadenoma of the ovary.

Figure 40–8.

Copyright ©2006 by The McGraw-Hill Companies, Inc.
All rights reserved.

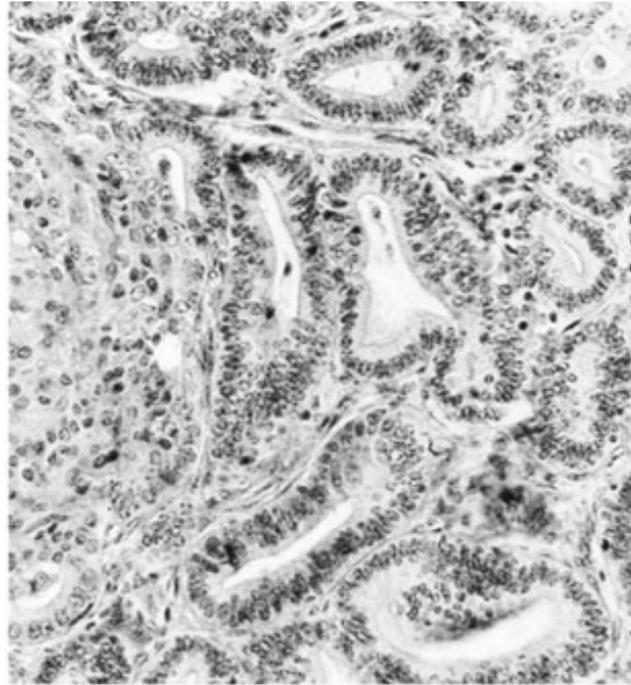

Mucinous cystadenoma. The lining cells are tall and columnar with basally situated nuclei. Generous sampling of these tumors is necessary to rule out a higher-grade lesion.

The epithelium of mucinous cysts resembles that of the endocervix in approximately 50% of cases; in the other 50%, mucin-containing goblet cells resembling intestinal epithelial cells are present. Careful study of mucinous neoplasms has shown that the histologic appearance may vary greatly from area to area; some areas appear benign whereas others are of low malignant potential or are frankly malignant. Hence, sampling must be more extensive than in the typical serous tumor. Metastases from appendiceal and other primary tumors may simulate closely a mucinous cystadenoma.

Endometrioid Lesions

Endometrioid tumors are characterized by proliferation of benign nonspecific stroma in which bland endometrial-type glands may be found. The only clearly recognizable benign endometrioid tumors are the uncommon endometrioid adenofibroma and the proliferative endometrioid adenofibroma. If the epithelial growth is exuberant but cytologically benign, it is termed a *proliferative* rather than a low malignant potential tumor as the prognosis appears to be invariably excellent (Fig 40–9).

Figure 40–9.

Copyright ©2006 by The McGraw-Hill Companies, Inc.
All rights reserved.

Endometrioid cystadenomas contain a proliferation of bland endometrial-like glands without the stroma of endometriosis.

Endometriosis of the ovary (see Chapter 43) represents a benign "tumorlike" condition rather than a true neoplasm.

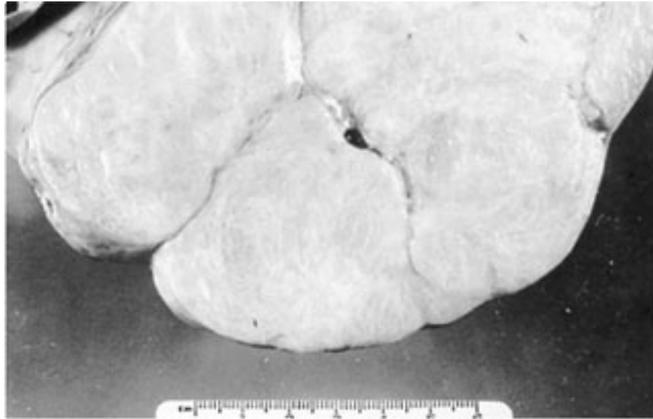

Clear Cell (Mesonephroid) Tumors

Like the endometrioid tumors, clear cell tumors in their benign form are rare and are virtually limited to clear cell adenofibromas in which a solid proliferation of nonspecific stroma contains small cytologically bland glands formed by columnar cells with clear cytoplasm. Clinically they appear like any other benign ovarian mass and are diagnosed only on histologic examination. The prognosis is excellent.

Transitional Cell (Brenner) Tumors

Transitional cell tumors are adenofibromas in which the proliferating epithelial element has a transitional cell appearance, which represents metaplasia. Brenner tumors account for 1–2% of primary ovarian tumors; more than 98% are benign, and nearly 95% of cases are unilateral. They frequently are so small that they are incidental operative findings. However, the tumor may reach 5–8 cm in diameter and present as an adnexal mass on pelvic examination. On section they are firm and pale yellow or white (Fig 40–10). The epithelium is composed of nests of cells with ovoid nuclei having a prominent longitudinal groove ("coffee-bean nuclei"; Fig 40–11). Occasionally there is a mucinous metaplasia of the cells in the center of one or more of these nests, which may account for the 10% incidence of mucinous cystadenomas found associated with Brenner tumors.

In a transitional cell (Brenner) tumor, islands of bland transitional cells (arrows) proliferate, accompanied by prominent proliferation of benign spindly fibroblast-like cells.

SEX CORD-STROMAL TUMORS

Thecoma

This type of tumor can occur at any age, although they are most commonly found in postmenopausal women. They account for only 2% of all ovarian tumors and may not be a true neoplasm but instead a condition of hyperplasia of the cortical stroma. Histologically, the mass is filled with lipid-containing cells that are similar to theca cells, and the tumor is known to produce estrogen. As such, these tumors often present with dysfunctional uterine bleeding or postmenopausal bleeding. Occasionally they have presented with adenocarcinoma of the endometrium given the unopposed estrogen production by the tumor. The tumors range from nonpalpable to more than 20 cm in size. They are rarely bilateral and rarely malignant.

Fibroma

Unlike thecomas, fibromas produce no hormones. They can occur at any age but most often in the years prior to menopause. They range in size from incidental findings to greater than 20 cm. They are multinodular and whorled, and they are formed from bundles of collagen-producing spindle cells. They can be found as part of Meigs' syndrome, in which a patient is found to have a pelvic mass in concert with ascites and hydrothorax. Fibromas are also part of a hereditary basal cell nevus syndrome in which basal cell carcinoma is found with mesenteric cysts, calcification of the dura, and keratocysts of the jaw.

Hilus Cell Tumor

These tumors are a subset of Leydig cell tumors, which originate from the ovarian hilum or less frequently from the ovarian stroma. The typical presentation includes hirsutism, virilization, and menstrual irregularities. Hilus cell tumors rarely attain a palpable size. Histologically, groups of steroid cells containing eosinophilic cytoplasm and lipochrome pigment are found. For the tumor to be defined as a Leydig cell neoplasm, elongated eosinophilic crystalloids of Reinke must be found.

GERM CELL TUMORS

Mature Teratomas

Mature cystic teratomas, commonly referred to as *dermoid cysts*, compose some 40–50% of all benign ovarian neoplasms. They contain well-differentiated tissue derived from any of the 3 germ cell layers, including hair and teeth as ectodermal derivatives. They account for the majority of benign ovarian neoplasms in reproductive-age women and usually are asymptomatic unless complications such as torsion or rupture occur. Transvaginal ultrasound is known to be very accurate in the diagnosis of dermoid cysts, with the hair and sebum, rather than calcium, creating highly reflective irregular solid components within fluid-containing masses.

Studies have detailed several advantages to the laparoscopic approach to removal of dermoids, including less postoperative pain and blood loss, shorter hospital stay, and lower overall cost. Recent studies have shown that dermoid cysts can usually be removed laparoscopically without intraperitoneal spillage. If intraoperative spillage does occur, the potential for chemical peritonitis or excess adhesion formation has led to the recommendation of copious saline irrigation until the lavage is clear. The risk of peritonitis, however, is quite low (< 0.2%) with laparoscopic removal of dermoid cysts.

Although most mature teratomas contain cells from all germ cell layers, a subset of monodermal teratomas exists. Those tumors composed mostly or entirely of thyroid tissue are called *struma ovarii*. These tumors account for only 3% of all teratomas, and only 5% of these will produce symptoms of thyrotoxicosis.

BENIGN TUMORS OF THE OVIDUCT: INTRODUCTION

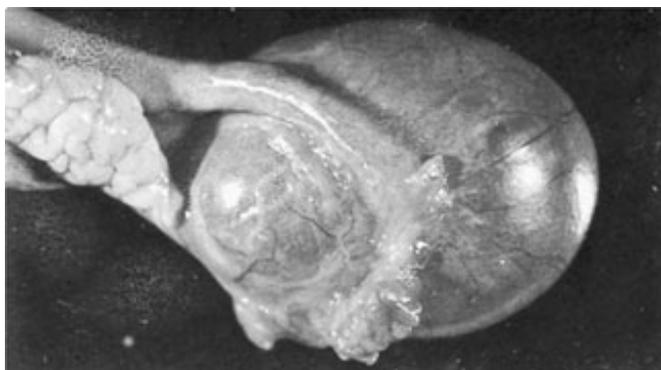

Benign lesions of the uterine tube are routinely asymptomatic and rarely large enough to be palpable—with the exception of the paratubal or parovarian cyst—so the diagnosis is made incidentally at the operating table or in the pathology laboratory.

CYSTIC TUMORS

Hydatid cysts of Morgagni are cystic tumors of the uterine tube located at or near the fimbriated end. They are lined by tubal-type epithelium, filled with clear fluid, and are usually approximately 1 cm in diameter. They are most often found inadvertently during a pelvic operative procedure. On rare occasions, torsion produces an acute surgical emergency.

Occasionally, larger paratubal or parovarian cysts develop, especially in the broad ligament (Fig 40–12). These cysts are almost always serous tumors of low malignant potential with a benign clinical outcome.

Figure 40–12.

All rights reserved.

Parovarian cyst. Note the orientation of the cyst to the fimbriated end of the oviduct.

A third type of cyst associated with the fallopian tubes is the *Walthard rest*. This type is found as a 1-mm cyst beneath the serosa of the fallopian tube. It appears to represent an inclusion cyst in which the mesothelium has undergone metaplasia similar to transitional cell (Brenner) tumors.

EPI THELIAL TUMORS

Benign epithelial tumors of the uterine tube are extremely rare. The polyps that occur in the cornual portion appear to be of endometrial rather than tubal origin.

ADENOMATOID TUMORS

The adenomatoid tumor probably is the most common benign tumor found in the uterine tube. It actually represents a benign mesothelioma, but the compact nature of the adenomatous pattern may be mistaken for malignancy (Fig 40–13). Adenomatoid lesions rarely measure more than 1–1.5 cm. They are always incidental findings when the adnexa are removed for other purposes. Similar lesions, usually cystic, may involve the myometrium or ovary.

Figure 40–13.

Copyright ©2006 by The McGraw-Hill Companies, Inc.
All rights reserved.

Adenomatoid tumor (benign mesothelioma) with tiny slitlike spaces and glands invading the muscular wall of the tube.

OTHER BENIGN TUBAL AND PARATUBAL TUMORS

Other benign tubal tumors, such as leiomyomas and teratomas, are rare, as are benign adnexal tumors of probable wolffian origin. Adrenal cortical nests, however, are common incidental embryologic rests found in the broad ligament, seen as yellowish ovoid nodules 3–4 mm in diameter.

SUMMARY

Ovarian neoplasms may arise from any histologic element of the ovary and are most often benign, especially in premenopausal women. The characteristics of the mass and the age of the patient are important factors guiding diagnosis and treatment. The overall risk of malignancy of an ovarian cyst is 13% in a premenopausal woman versus 45% in a postmenopausal woman. Therefore, vigilant work-up of these masses with the aid of ultrasound and close follow-up is essential. Use of cancer antigen-125 (CA-125) for diagnostic purposes is controversial. With the increased use of imaging studies has come discovery of incidental, asymptomatic, small ovarian cysts. These cysts should be evaluated by ultrasound. If they do not contain septa or solid components, they can be closely followed. However, any mass that enlarges or changes in character, especially in postmenopausal women, should be explored surgically.

Current OB/GYN > Chapter 41. Sexually Transmitted Diseases & Pelvic Infections > Sexually Transmitted Diseases >

SEXUALLY TRANSMITTED DISEASES: INTRODUCTION

The term "sexually transmitted diseases" is used to denote disorders spread principally by intimate contact. Although this usually means sexual intercourse, it also includes close body contact, kissing, cunnilingus, anilingus, fellatio, mouth–breast contact, and anal intercourse. Many sexually transmitted diseases (STDs) can be acquired by transplacental spread, by passage through the birth canal, and via lactation during the neonatal period. The organisms involved are peculiarly adapted to growth in the genital tract and are present in body secretions or blood.

Physicians have a critical role in preventing as well as treating STDs. The clinician's role is 4-fold. First, to understand the microbiology of STDs in order to appropriately diagnose and treat patients. Second, to alleviate the symptoms and prevent future sequelae. Third, to prevent the transmission to others including health care professionals. Finally, to do all of the above combined with patient education and counseling. As the future continues to bring advancements in therapy, the physician must be able to adapt to these changes. Today, preexposure vaccinations appear to be the trend in future therapy. For now, however, prevention through lifestyle and behavioral modification is the primary weapon against the spread of STDs. Multiple cohort studies have demonstrated the protective effects of both male and female condoms.

The list of organisms traditionally thought of as causing STDs has been extended to include cytomegalovirus, herpes simplex virus type 1 (HSV-1) and type 2 (HSV-2), *Chlamydia*, group B *Streptococcus*, molluscum contagiosum virus, *Sarcoptes scabiei*, hepatitis viruses, and human immunodeficiency virus (HIV). Some diseases spread by body contact but not necessarily by coitus—eg, pediculosis pubis and molluscum contagiosum—are discussed with the dermatitides rather than here; herpes genitalis is discussed in Chapter 37.

VULVAR LESIONS & GENITAL ULCERS

Genital herpes, syphilis, and chancroid are the most prevalent ulcerative lesions in the United States. The diagnosis is difficult to make by physical examination alone. Thus, the work-up for all genital ulcers should include serologic screening for syphilis, culture/antigen testing for HSV-1 and HSV-2, and culture for *Haemophilus ducreyi*. More than one infectious etiology may be present in a single lesion. In today's environment it is important to recognize HIV as a risk factor for genital ulcers.

Herpes Simplex

Vulvovaginal infections with HSV have assumed a primary role in STDs. HSV (types 1 and 2) is a highly prevalent (5 million cases in the United States), incurable, recurrent viral disease. Patient education and clinical skills are mandatory in obstetrics in order to prevent vertical transmission to the fetus or newborn. Systemic antiviral agents are commonly used during the first clinical episode to reduce symptoms, shorten duration of the lesion, and decrease the number of cesarean deliveries among infected mothers. These infections are discussed in Chapter 37.

Condylomata Acuminata (Venereal Warts)

See Chapter 37.

Chancroid (Soft Chancre)

Essentials of Diagnosis

- Painful, tender genital ulcer.
- Culture positive for *H ducreyi*.
- Inguinal adenitis with erythema or fluctuance.

General Considerations

Chancroid is an STD characterized by a painful genital ulcer. However, studies have shown asymptomatic carriers among commercial sex workers. Although this condition can be difficult to diagnosis clinically, suppurative inguinal adenopathy with painful ulcers is pathognomonic and may assist with a preculture diagnosis. It is endemic in many areas of the United States, although it occurs more frequently in Africa, the West Indies, and Southeast Asia. The causative organism is the gram-negative rod *H ducreyi*. Exposure is usually through coitus, but accidentally acquired lesions of the hands have occurred. The incubation period is short: the lesion usually appears in 3–5 days or sooner. An increased rate of HIV infection has been reported among patients with this genital ulcer disease; chancroid is a cofactor for HIV transmission. Moreover, 10% of patients with genital chancroid may have coinfection with herpes or syphilis.

Clinical Findings

SYMPTOMS AND SIGNS

The early chancroid lesion is a vesicopustule on the pudendum, vagina, or cervix. Later, it degenerates into a saucer-shaped ragged ulcer circumscribed by an inflammatory wheal. Typically, the lesion is very tender and produces a heavy, foul discharge that is contagious. A cluster of ulcers may develop. Lesions typically occur on the vulva, cervix, and perianal area in women.

Painful inguinal adenitis is noted in over 50% of cases. The buboes may become necrotic and drain spontaneously.

LABORATORY FINDINGS

Syphilis must first be ruled out. Clinical diagnosis is more reliable than smears or cultures because of the difficulty of isolating this organism. Isolation of *H ducreyi* is diagnostic, but isolation occurs in less than one-third of cases. Aspirated pus from a bubo is the best material for culture. Serum adsorption enzyme immunoassays have been evaluated and currently have a limited sensitivity. However, polymerase chain reaction (PCR) testing of genital samples is becoming widely available. Multiplex PCR is a technique that can simultaneously screen for HSV, *Treponemapallidum*, and *H ducreyi* using a single swab but is not yet commercially available.

Differential Diagnosis

Syphilis, granuloma inguinale, lymphogranuloma venereum, and herpes simplex may coexist with chancroid and must be ruled out.

Prevention

Chancroid is a reportable disease. Routine antibiotic prophylaxis is not warranted. Condoms can give protection. Liberal use of soap and water is relatively effective. Education is essential.

Treatment

LOCAL TREATMENT

Good personal hygiene is important. The early lesions should be cleansed with mild soap solution. Sitz baths are beneficial.

ANTIBIOTIC TREATMENT

The susceptibility of *H ducreyi* to antimicrobial agents varies by locality. Consultation with the nearest STD clinic may reveal information about current susceptibilities and effective treatment regimens. Guidelines issued by the Centers for Disease Control and Prevention (CDC) for genital chancroid are as follows. *Recommended regimen*—(a) azithromycin 1 g orally once; (b) ceftriaxone 250 mg intramuscularly (IM) as a single dose; (c) erythromycin base 500 mg orally 3 times daily for 7 days; and (d) ciprofloxacin 500 mg orally twice daily for 3 days in nonpregnant patients over age 17 years who are not lactating. The course may have to be repeated. Fluctuant lymph nodes may need to be aspirated through normal adjacent skin. Incision and drainage of the nodes is not recommended because it will delay healing.

Prognosis

Untreated or poorly managed cases of chancroid may persist, and secondary infection may develop. Frequently, the ulcers heal spontaneously. They should improve within 7–10 days. If no improvement is noted, coinfection, HIV, resistant strains, and noncompliance must be considered. If not treated, they may cause deep scarring with sequelae in men.

Granuloma Inguinale (Donovanosis)

Essentials of Diagnosis

- Ulcerative vulvitis, chronic or recurrent.
- Donovan bodies revealed by Wright's or Giemsa's stain.

General Considerations

Granuloma inguinale is a chronic ulcerative granulomatous disease that usually develops in the vulva, perineum, and inguinal regions (Fig 41–1). The disease is almost nonexistent in the United States. It is most common in India, Brazil, the West Indies, some South Pacific islands, and parts of Australia, China, and Africa. The causative organism is *Calymmatobacterium granulomatis* (Donovan body). Donovan bodies are bacteria encapsulated in mononuclear leukocytes. Transmission is via coitus, and the incubation period is 8–12 weeks.

Figure 41–1.

Granuloma inguinale.

Clinical Findings

SYMPTOMS AND SIGNS

Although granuloma inguinale most often involves the skin and subcutaneous tissues of the vulva and inguinal regions, cervical, uterine, orolabial, and ovarian sites have been reported. A malodorous discharge is characteristic. The disorder often begins as a papule, which then ulcerates, with the development of a beefy-red granular zone with clean, sharp edges. The ulcer shows little tendency to heal, and the patient usually has no local or systemic symptoms. Healing is very slow, and satellite ulcers may unite to form a large lesion. Lymphatic permeation is rare, but lymphadenitis may result when the cutaneous lesion becomes superimposed on lymphatic channels. Inguinal swelling is common, with late formation of abscesses (buboes). Rarely, granuloma inguinale is manifested by chronic cervical lesions. These lesions usually take the form of redness or ulceration, or they form granulation tissue. They produce a chronic inflammatory exudate characterized histologically by lymphocytes, giant cells, and histiocytes. They may mimic carcinoma of the cervix and must be distinguished from this as well as other neoplastic diseases.

The chronic ulcerative process may involve the urethra and the anal area, causing marked discomfort. Introital contraction may make coitus difficult or impossible; walking or sitting may become painful. The possibility of the coexistence of another venereal disease must be considered. Spread to other areas occurs in approximately 7% of patients.

LABORATORY FINDINGS

Direct smear from beneath the surface of an ulcer may reveal gram-negative bipolar rods within mononuclear leukocytes. These are seen best in Wright-stained smears. When smears are negative, a biopsy specimen should be taken. Biopsy of the lesion generally shows granulation tissue infiltrated by plasma cells and scattered large macrophages with rod-shaped cytoplasmic inclusion bodies (Mikulicz cells). Pseudoepitheliomatous hyperplasia often is seen at the margin of the ulcer.

The diagnosis of granuloma inguinale is made by demonstrating, in biopsy or smear material stained with Wright's, Giemsa's, or silver stain, large mononuclear cells having one or more cystic inclusions containing the so-called Donovan bodies—small round or rod-shaped particles that stain purple in traditional hematoxylin and eosin preparations.

Prevention

Personal hygiene is the best method of prevention. Therapy immediately after exposure may abort the infection.

Treatment

Trimethoprim-sulfamethoxazole, 1 double-strength tablet orally twice daily for at least 3 weeks or doxycycline 100 mg twice daily for 3 weeks are the CDC-recommended agents. Ciprofloxacin 750 mg twice daily for 3 weeks, erythromycin base, 500 mg 4 times daily for 2–3 weeks, or azithromycin 1 g orally once per week for 3 weeks are alternate regimens. Penicillin is not effective.

Sex partners must be considered for treatment. Partners who had sexual contact during the 60 days preceding the onset of symptoms or are clinically symptomatic should be treated by 1 of the regimens. Special consideration for HIV and gravid women should be made. Recommendations to add intravenous gentamicin to the oral protocol have been made.

Lymphogranuloma Venereum

Essentials of Diagnosis

- Rectal ulceration, inguinal lymphadenopathy, or rectal stricture.
- Positive complement fixation test.

General Considerations

The causative agent of lymphogranuloma venereum is 1 of the aggressive L serotypes (L1, L2, or L3) of *Chlamydia trachomatis*. It is encountered more frequently in the tropical and subtropical nations of Africa and Asia but is also seen in the southeastern United States. Transmission is via sexual contact; men are affected more frequently than are women (6:1). The incubation period is 7–21 days.

Clinical Findings

SYMPTOMS AND SIGNS

(Fig 41–2) Early in the course of the disease, a vesicopustular eruption may go undetected. With inguinal (and vulvar) ulceration, lymphedema, and secondary bilateral invasion, excruciating conditions arise. Sitting or walking may cause pain. During the inguinal bubo phase, the groin is exquisitely tender. A hard cutaneous induration (red to purplish-blue) is a notable feature. This usually occurs within 10–30 days after exposure and may be bilateral. Anorectal lymphedema occurs early; defecation is painful, and the stool may be blood-streaked.

Figure 41–2.

Lymphogranuloma venereum. Note involvement of perineum and spread over buttocks.

Later, as the lymphedema and ulceration undergo cicatrization, rectal stricture makes defecation difficult or impossible. Vaginal narrowing and distortion may end in severe dyspareunia. In the late phase, systemic symptoms—fever, headache, arthralgia, chills, and abdominal cramps—may develop.

LABORATORY FINDINGS

The diagnosis can be proved only by isolating *C trachomatis* from appropriate specimens and confirming the immunotype. These procedures are seldom available, so less specific tests are used.

A complement fixation test using a heat-stable antigen that is group-specific for all *Chlamydia* species is available. This test is positive at a titer $\geq 1:16$ in more than 80% of cases of lymphogranuloma venereum. If acute or convalescent sera are available, a rise in titer is particularly helpful in making the diagnosis. Application of the microimmunofluorescent test may also be useful.

Differential Diagnosis

As with any disseminated disease, the systemic symptoms of lymphogranuloma venereum may resemble meningitis, arthritis, pleurisy, or peritonitis. The cutaneous lesions must be differentiated from those of granuloma inguinale, tuberculosis, early syphilis, and chancroid. In the case of colonic lesions, proctoscopic examination and mucosal biopsy are needed to rule out carcinoma, schistosomiasis, and granuloma inguinale.

Complications

Perianal scarring and rectal strictures—late complications—can involve the entire sigmoid, but the urogenital diaphragm is rarely involved. Vulvar elephantiasis (esthiomene) produces marked distortion of the external genitalia.

Prevention

Lymphogranuloma venereum is reportable. Avoiding infectious contact with a carrier is achieved by use of a condom or by refraining from coitus. Definite exposure can be treated with sulfonamides or

tetracyclines.

Treatment

CHEMOTHERAPY

Doxycycline 100 mg twice daily orally should be given for 21 days according to tolerance. If disease persists, the course should be repeated. An alternative regimen is erythromycin 500 mg orally 4 times daily for 21 days.

LOCAL AND SURGICAL TREATMENT

Anal strictures should be dilated manually at weekly intervals. Severe stricture may require diversionary colostomy. If the disease is arrested, complete vulvectomy may be done for cosmetic reasons. Abscesses should be aspirated, not excised.

Syphilis

Essentials of Diagnosis

PRIMARY SYPHILIS

- Painless genital sore (chancre) on labia, vulva, vagina, cervix, anus, lips, or nipples.
- Painless, rubbery, regional lymphadenopathy followed by generalized lymphadenopathy in the third to sixth weeks.
- Dark-field microscopic findings.
- Positive serologic test in 70% of cases.

SECONDARY SYPHILIS

- Bilaterally symmetric extragenital papulosquamous eruption.
- Condyloma latum, mucous patches.
- Dark-field findings positive in moist lesions.
- Positive serologic test for syphilis.
- Lymphadenopathy.

TERTIARY SYPHILIS

- Cardiac, neurologic, ophthalmic, and auditory lesions.
- Gummas.

CONGENITAL SYPHILIS

- History of maternal syphilis.
- Positive serologic test for syphilis.
- Stigmata of congenital syphilis (eg, x-ray changes of bone, hepatosplenomegaly, jaundice, anemia).
- Normal examination or signs of intrauterine infection.
- Often stillborn or premature.
- Enlarged, waxy placenta.

LATENT SYPHILIS

- History or serologic evidence of previous infection.

- Absence of lesions.
- Serologic test usually reactive; titer may be low.

General Considerations

According to CDC data, the rate of primary and secondary syphilis in the United States declined by 90% during 1990–2000, but the rate increased from 2000–2004. Overall increases in rates during 2000–2004 were observed only among men. In 2004, for the first time in more than 10 years, the rate of primary and secondary syphilis among women did not decrease; it remained the same between 2003 and 2004 at 0.8 cases per 100,000 population. Syphilis is caused by *T. pallidum*, which is transmitted by direct contact with an infectious moist lesion. Treponemes pass through intact mucous membranes or abraded skin. Ten to 90 days after the treponemes enter, a primary lesion (chancre) develops. The chancre persists for 1–5 weeks and then heals spontaneously, but it may persist with signs of secondary disease. Serologic tests for syphilis are usually nonreactive when the chancre first appears but become reactive 1–4 weeks later. Two weeks to 6 months (average, 6 weeks) after the primary lesion appears, the generalized cutaneous eruption of secondary syphilis may appear. The skin lesions heal spontaneously in 2–6 weeks. Serologic tests are almost always positive during the secondary phase. Latent syphilis may follow the secondary stage and may last a lifetime, or tertiary syphilis may develop. The latter usually becomes manifest 4–20 or more years after disappearance of the primary lesion.

In one-third of untreated cases, the destructive lesions of late (tertiary) syphilis develop. These involve skin or bone (gummas), the cardiovascular system (aortic aneurysm or insufficiency), and the nervous system (meningitis, tabes dorsalis, paresis). The complications of tertiary syphilis are fatal in almost one-fourth of cases, but one-fourth never show any ill effects.

Clinical Findings

SYMPTOMS AND SIGNS

Primary Syphilis

The chancre (Fig 41–3) is an indurated, firm, painless papule or ulcer with raised borders. Groin lymph nodes may be enlarged, firm, and painless. Genital lesions are not usually seen in women unless they occur on the external genitalia; however, careful examination may reveal a typical cervical or vaginal lesion. Primary lesions may occur on any mucous membrane or skin area of the body (nose, breast, perineum), and dark-field examination is required for all suspect lesions. Serologic tests should be done every week for 6 weeks or until positive.

Figure 41–3.

Chancre of primary syphilis (arrow).

Secondary Syphilis

Signs of diffuse systemic infection become evident as the spirochetes spread hematogenously. A "viral syndrome" presentation, often with diffuse lymphadenopathy, is not uncommon. The characteristic dermatitis appears as diffuse, bilateral, symmetric, papulosquamous lesions that often involve the palms and soles. Lesions may also cover the trunk and be macular, maculopapular, papular, or pustular. Other systemic manifestations include patchy alopecia, hepatitis, and nephritis. Moist papules can be seen in the perineal area (condyloma lata). Mucous patches may also be seen; like condyloma lata, they are dark-field–positive, infectious lesions. Serologic tests for syphilis are invariably reactive in this stage.

Latent Syphilis

With resolution of the lesions of primary and secondary infection or the finding of a reactive serologic test without a history of therapy, a patient passes into latency. Persons are infectious in the first 1–2 years of latency, with clinical relapses resembling the secondary stage occurring in approximately 25% of cases in the first year. The U.S. Public Health Service defines early latent syphilis as disease of less than 1 year's duration and includes it in the category of "early or infectious syphilis, with primary and secondary lues." Late latent syphilis is an infection of indeterminate or greater than 1 year's duration; consideration must be given to possible asymptomatic neurosyphilis in this setting, and cerebrospinal fluid (CSF) examination is recommended.

Neurosyphilis

Although the central nervous system is always vulnerable to *T pallidum*, it is most commonly infected during latent syphilis. Neurologic involvement of ophthalmic and auditory systems can be detected. Cranial nerve palsy and meningeal signs should be evaluated on physical examination. All patients require CSF sampling with laboratory testing for cell count, protein, Venereal Disease Research Laboratory (VDRL), and fluorescent treponemal antibody absorption (FTA-ABS). FTA-ABS is less specific but very sensitive when diagnosing neurosyphilis.

Syphilis during Pregnancy

The course of syphilis is unaltered by pregnancy, but misdiagnoses are common. The chancre is often unnoticed or internal and not brought to medical attention. Chancres, mucous patches, and condyloma lata are often thought to be herpes genitalis. The dermatoses can resolve prior to diagnosis, or they may be misdiagnosed.

The effect of syphilis on pregnancy outcome can be profound. The risk of fetal infection depends on the degree of maternal spirochetemia (greater in the secondary stage than in the primary or latent stages) and the gestational age of the fetus. Treponemes may cross the placenta at all stages of pregnancy, but fetal involvement is rare before 18 weeks because of fetal immunoincompetence. After 18 weeks, the fetus is able to mount an immunologic response, and tissue damage may result. The earlier in pregnancy the fetus is exposed, the more severe the fetal infection and the greater the risk of premature delivery or stillbirth. Antepartum infection in late pregnancy does not necessarily result in congenital infection, as only 40–50% of such infants will have definite congenital infection. Placental infection can occur with resultant endarteritis, stromal hyperplasia, and immature villi. Grossly, the placenta looks hydropic (pale yellow, waxy, and enlarged). Because hydramnios is frequently associated with symptomatic congenital infection, fetuses are ultrasonographically followed throughout pregnancy.

Congenital Syphilis

Between 2003 and 2004, the overall rate of congenital syphilis decreased 17.8% in the United States, from 10.7 to 8.8 cases per 100,000 live births, which reflects the overall decrease in primary and secondary syphilis in women over the past decade. Most infants with congenital syphilis are born to women of low socioeconomic status with inadequate or no prenatal care. Either these neonates may be affected at birth from intrauterine infection (hepatosplenomegaly, osteochondritis, jaundice, anemia, skin lesions, rhinitis, lymphadenopathy, nervous system involvement), or symptoms may develop weeks or months later. The clinical spectrum of congenital infection is analogous to adult secondary disease, as the disease is systemic from onset due to transplacental hematogenous inoculation.

Because the antibodies from the maternal compartment are of the immunoglobulin (Ig)G class, they freely cross the placenta, giving most neonates a reactive serologic test if the mother's test was reactive. With symptomatic neonatal infection, often the cord blood serologic test will be higher in titer than the maternal test. No clinically reliable neonatal IgM serologic test is available. Other diagnostic aids include long-bone survey and lumbar puncture, which may help diagnose asymptomatic systemic infection requiring more intense therapy.

The newborn may have lymphadenitis and an enlarged liver and spleen. The bones usually reveal signs of osteochondritis and an irregular epiphyseal juncture on x-ray. The eyes, central nervous system structures, and other organs may reveal abnormalities at birth, or defects may develop later in untreated cases.

Any infant with the stigmata of syphilis should be placed in isolation until a definite diagnosis can be made and treatment administered.

Newborns with congenital syphilis may appear healthy at birth but often develop symptoms weeks or

months later. Examine the body for stigmata of syphilis at intervals of 3 weeks to 4 months. If the mother's serologic test is positive at delivery, the baby's test will also be positive. Obtain serial quantitative serologic tests of the infant's blood for 4 months. A rising titer indicates congenital syphilis, and treatment is indicated.

LABORATORY FINDINGS

Identification of the Organism

T pallidum can usually be identified by dark-field examination of specimens from cutaneous lesions, but the recovery period of the treponeme is brief; in most cases, diagnosis depends on the history and serologic tests. An immunofluorescent technique is now available for dried smears. Silver staining for *T pallidum* of biopsy specimens, placental sections, or autopsy material may confirm the diagnosis in difficult cases. Motile spirochetes can be identified in amniotic fluid obtained transabdominally in women with syphilis and fetal death. PCR is extremely specific for detection of *T pallidum* in amniotic fluid and neonatal serum and spinal fluid. Newer techniques involving molecular methods are now being used to diagnosis early syphilis. Multiplex PCR is such an assay that can simultaneously detect *T pallidum*, *H ducreyi*, and herpes simplex but is not yet commercially available.

Serologic Tests

Diagnostic tests after the primary or secondary moist lesion has disappeared are confined largely to serologic testing. Serologic tests become positive several weeks after the primary lesion appears.

NONTREPONEMAL TESTS

These measure reaginic antibody detected by highly purified cardiolipin-lecithin antigen. They can be performed rapidly, relatively easily, and inexpensively. Nontreponemal tests are used principally for syphilis screening, but they are relatively specific, so they are not absolute for syphilis, and false-positive reactions may occur. Nontreponemal tests currently in use are flocculation procedures that include the VDRL slide test, rapid reagin test, and automated reagin test for screening procedures in the field. The latter tests are more sensitive but less specific than the VDRL. If they are positive, the activity should be verified, and the degree of reactivity should be checked by the VDRL test. Complement fixation tests (eg, Kolmer) are no longer used in the United States.

The VDRL test (the nontreponemal test in widest use) generally becomes positive 3–6 weeks after infection, or 2–3 weeks after the appearance of the primary lesion; it is almost invariably positive in the secondary stage. The VDRL titer is usually high in secondary syphilis and tends to be lower or even nil in late forms of syphilis, although this is highly variable. A 4-fold falling titer in treated early syphilis or a falling or stable titer in latent or late syphilis indicates satisfactory therapeutic progress. False-positive serologic reactions are frequently encountered in a wide variety of situations, including collagen diseases, infectious mononucleosis, malaria, many febrile diseases, leprosy, vaccination, drug addiction, old age, and possibly pregnancy. False-positive reactions are usually of low titer and transient and may be distinguished from true-positive results by specific treponemal antibody tests.

TREPONEMAL ANTIBODY TESTS

The FTA-ABS test and microhemagglutination assay for *Treponema pallidum* (MHA-TP) detect antibody against *Treponema* spirochetes. Both tests are more sensitive and specific than nontreponemal tests (except the MHA-TP test with primary disease; Table 41–1). These tests remain positive despite therapy, so they are not given in titers or used to follow serologic response to treatment.

Table 41–1. Percent Sensitivity of Serologic Tests in Untreated Syphilis.

Type of Test	Stage of Disease			
	Primary	Secondary	Latent	Late
VDRL	59–87	100	73–91	37–94
FTA–ABS	86–100	99–100	96–99	96–100
MHA–TP	64–87	96–100	96–100	94–100

Differential Diagnosis

Primary syphilis must be differentiated from chancroid, granuloma inguinale, lymphogranuloma venereum, herpes genitalis, carcinoma, scabies, trauma, lichen planus, psoriasis, drug eruption, aphthosis, mycotic infections, Reiter's syndrome, and Bowen's disease.

Secondary syphilis must be differentiated from pityriasis rosea, psoriasis, lichen planus, tinea versicolor, drug eruption, "id" eruptions, perlèche, parasitic infections, iritis, neuroretinitis, condyloma acuminatum, acute exanthems, infectious mononucleosis, alopecia, and sarcoidosis.

Prevention

If the patient is known to have been exposed to syphilis, do not wait for the disease to develop to the clinical or reactive serologic stage before giving preventive treatment. Even so, every effort should be made to reach a diagnosis, including a complete physical examination, before administering preventive treatment. It is recommended that any patient who is exposed and becomes symptomatic within 90 days of sexual contact and is seronegative should still be treated. Also, if the exposure occurred more than 90 days earlier and seroconversion takes place, the exposed person should be treated. Finally, if the duration since exposure is unknown and the nontreponemal antibody titer is greater than 1:32, treatment is indicated.

Prenatal care is often underutilized or unavailable in geographic areas where congenital syphilis occurs. Education on the preventive value of prenatal care in these high-risk, generally low socioeconomic groups is essential. All pregnant women should undergo a routine serologic test for syphilis at the first visit. The test should be repeated between 28 and 32 weeks' gestation in high-risk regions. If the test result is positive, attention must be given to the patient's prior serologic test and therapy (if any) for syphilis. If doubt exists as to whether the patient has active syphilis, repeat therapy is far better than the risk of congenital syphilis.

Syphilis is still a serious public health problem. Teaching young people about the disease and its consequences is still the best method of control. Use of a condom, together with soap and water decontamination after coitus, would prevent most cases. If a lesion develops, a physician should be notified at once. All exposed persons must be sought and treated and the case reported to the communicable disease service in the city or state. The United States Preventive Services Task Force (USPSTF) updated syphilis screening guidelines in 2004. Further evidence was found to support the strategy of screening all pregnant women and people at higher risk for acquiring syphilis (men who have sex with men who engage in high-risk behaviors, commercial sex workers, persons who exchange sex for drugs, and those in adult correctional facilities). Several new screening tests are currently being studied, including the immunochromatographic strip (ICS), line immunoassay (LIA), enzyme-linked

immunosorbent assay (ELISA), rapid plasma reagent (RPR) card, and rapid syphilis test (RST). New screening tests currently being studied for use in pregnant women and infants include IgM immunoblotting and PCR assay of serum and CSF for central nervous system infection in infants, placenta histopathology, and umbilical cord blood testing.

Treatment

EARLY SYPHILIS AND CONTACTS

Primary, secondary, and early latent syphilis (<1 year's duration):

1. Benzathine penicillin G 2.4 million units IM once.
2. Tetracycline hydrochloride 500 mg orally 4 times daily or 100 mg doxycycline twice daily for 14 days, for nonpregnant penicillin-allergic patients.

Erythromycin estolate should not be administered to pregnant women because of potential drug-related hepatotoxicity.

Ceftriaxone 1 g daily IM or IV for 8–10 days may be effective, but data on this regimen are limited.

LATE SYPHILIS

Includes latent syphilis of indeterminate duration or more than 1 year's duration, except neurosyphilis.

1. Benzathine penicillin G 2.4 million units IM weekly for 3 successive weeks (7.2 million units total).
2. Tetracycline hydrochloride 500 mg orally 4 times daily or 100 mg doxycycline twice daily for 14 days, for penicillin-allergic patients.

SYPHILIS IN PREGNANCY

Treat as indicated above, except that tetracycline or erythromycin is not recommended. If serologic tests are equivocal (eg, possible biologic false-positive result), it is better to err on the side of early treatment. Because of the increased risk for treatment failure, a second dose of 2.4 million units of penicillin IM is often recommended. Penicillin-allergic patients can be given oral desensitization therapy using gradually larger doses of phenoxymethyl penicillin suspension to achieve a temporary tolerant state that allows parenteral penicillin therapy. This is particularly useful in circumventing compliance problems due to hyperemesis or drug-induced gastric upset.

CONGENITAL SYPHILIS

Adequate maternal treatment before 16–18 weeks' gestation prevents congenital syphilis. Treatment thereafter may arrest fetal syphilitic infection, but some stigmata may remain.

1. Benzathine penicillin G 50,000 U/kg IM as a single injection, for asymptomatic infants without neurosyphilis.
2. Aqueous crystalline penicillin G 50,000 U/kg IV every 8–12 hours, or procaine penicillin G 50,000 U/kg IM once daily for 10–14 days, for symptomatic infants or those with neurosyphilis.

JARISCH-HERXHEIMER REACTION

A febrile reaction may occur in 50–75% of patients with early syphilis treated with penicillin. This occurs 4–12 hours after injection and is completed by 24 hours. Its cause is uncertain but may involve a release of treponemal toxic products upon organism lysis. The reaction is generally benign but may trigger labor or fetal distress. Prophylaxis with antipyretics or corticosteroids is of unknown value.

COEXISTING INFECTION WITH HIV

No specific changes in treatment are currently necessary, but close follow-up is necessary to ensure adequate treatment. Recommendations include serology tests every 3 months for 1 year and twice during the second year.

VAGINITIS

Vaginitis is a clinical syndrome characterized by vaginal discharge, vulvar irritation, or malodorous discharge. This is often broken down into 2 entities: infectious vaginitis and atrophic vaginitis. This chapter focuses on infectious vaginitis. Infectious vaginitis is most frequently caused by 1 of 3 diseases: trichomoniasis, bacterial vaginosis, or candidiasis.

Bacterial Vaginosis (*Corynebacterium vaginale* Vaginitis; *Gardnerella vaginalis* Vaginitis)

Although bacterial vaginosis is the most prevalent vaginal infection, almost 50% of affected women are asymptomatic. The term *bacterial vaginosis* refers to the intricate changes of vaginal bacterial flora with a loss of lactobacilli, an increase in vaginal pH (pH > 4.5), and an increase in multiple anaerobic and aerobic bacteria. Clinical criteria for diagnoses include (1) homogeneous white, noninflammatory discharge; (2) microscopic presence of > 20% clue cells; (3) vaginal discharge with pH > 4.5; and (4) fishy odor with or without addition of 10% potassium hydroxide (KOH). *Gardnerella vaginalis* (formerly designated *Corynebacterium vaginale* and *Haemophilus vaginalis*) is a small, nonmotile, nonencapsulated, pleomorphic rod that stains variably with Gram's stain. It may be spread by sexual contact and, although of low virulence, causes vaginitis. The disorder may be atypical and even more troublesome when *G vaginalis* coexists with more virulent organisms. *G vaginalis* is not the only cause of bacterial vaginosis. The characteristic fishy odor of bacterial vaginosis is due to anaerobic bacteria, such as *Bacteroides*, *Prevotella*, *Peptostreptococcus*, and *Mobiluncus* spp., and genital mycoplasmas.

G vaginalis infection is often overlooked. It may be suspected on the basis of the microscopic appearance of unstained exfoliated vaginal cells in a wet preparation that appears to be dusted with many small dark particles, actually *G vaginalis* organisms. These "clue cells" are presumptive evidence of the presence of this organism. In case of mixed infection (eg, with *Candida albicans*), it may not be possible to make the diagnosis except by culture. Gram's stain is another method useful for making the diagnosis of bacterial vaginosis. Observational studies have consistently shown an association between bacterial vaginosis and adverse pregnancy outcomes, including preterm delivery, preterm premature rupture of membranes, spontaneous abortion, and preterm labor. However, 2 large randomized, placebo-controlled trials demonstrated that treatment of bacterial vaginosis in asymptomatic, pregnant women with metronidazole does not prevent preterm deliveries. The CDC recommends that pregnant women with a history of preterm delivery and asymptomatic bacterial vaginosis be evaluated for treatment.

Treatment

Specific therapy for vaginal infection caused by *G vaginalis* and *C vaginale* has been neglected, in part because of the rather innocuous symptoms reported. Therapy should always be initiated for symptomatic relief. Pregnant women who are at high risk for preterm labor may benefit from treatment. Treatment is recommended for low-risk groups during pregnancy if patients are infected and symptomatic. A third cohort of patients who are thought to benefit from therapy are asymptomatic carriers before pelvic/abdominal surgery. Guidelines issued by the CDC for therapy are as follows. (1) *Recommended regimen*—(a) oral metronidazole 500 mg twice daily for 7 days; (b) clindamycin cream 2%, 1 applicatorful (5 g) intravaginally at night for 7 days; and (c) metronidazole gel 0.75%, 1 applicatorful (5 g) intravaginally once daily for 5 days. (2) *Alternative regimens*—(a) oral metronidazole 2 g in a single dose; (b) oral clindamycin 300 mg twice daily for 7 days; (c) clindamycin ovules 100 g intravaginally once at bedtime for 3 days. Four randomized controlled trials have demonstrated overall cure rates of 95% for the 7-day metronidazole regimen and 84% for the single 2-g regimen. During pregnancy, oral treatment is preferred to local agents to ensure adequate tissue levels of the bactericidal drug. The recommended regimen is metronidazole 250 mg orally 3 times daily for 7 days or clindamycin 300 mg

orally twice daily for 7 days.

Trichomonas Vaginalis

See Chapter 37.

Candidiasis

See Chapter 37.

URETHRITIS AND CERVICITIS

Urethral mucopurulent or purulent discharge is commonly caused by *Neisseria gonorrhoeae*, *C trachomatis*, or genital herpes. Although asymptomatic infections are common, some patients experience slow-onset dysuria with vaginal discharge and/or irregular bleeding. Urethritis and cervicitis are often coinfections. Both are reportable STDs, and clinicians must mandate that partners of patients obtain diagnostic and therapeutic interventions.

Cervicitis is an inflammation of either the ectocervical cells or the glandular cells composing the cervical epithelium. The ectocervical squamous cells are contiguous with the vaginal epithelium and can be infected by the same organisms that cause inflammatory vaginitis. The glandular cells of the endocervix are more commonly inflamed by *N gonorrhoeae* and *C trachomatis*.

Gonorrhea

Essentials of Diagnosis

- Most affected women are asymptomatic carriers.
- Purulent vaginal discharge.
- Urinary frequency and dysuria.
- Recovery of organism in selective media.
- May progress to pelvic infection or disseminated infection.

General Considerations

N gonorrhoeae is a gram-negative diplococcus that forms oxidase-positive colonies and ferments glucose. The organism may be recovered from the urethra, cervix, anal canal, or pharynx. Optimal recovery of the organism is with use of Thayer-Martin or Martin-Lester (Transgrow) medium. *N gonorrhoeae* is rapidly killed by drying, sunlight, heat, and most disinfectants.

The columnar and transitional epithelium of the genitourinary tract is the principal site of invasion. The organism may enter the upper reproductive tract (Fig 41–1), causing salpingitis with its attendant complications. Approximately 600,000 new infections occur each year in both men and women. It has been estimated that after exposure to an infected partner, 20–50% of men and 60–90% of women become infected. Without therapy, 10–17% of women with gonorrhea develop pelvic infection. Depending on the geographic location and population involved, *N gonorrhoeae* is often present with other STDs. Traditionally, women with gonorrhea are considered to be at risk for incubating syphilis. It has been shown that 20–40% also have *Chlamydia* infection.

Clinical Findings

SYMPTOMS AND SIGNS

Early Symptoms

Most women with gonorrhea are asymptomatic. When symptoms occur, they are localized to the lower genitourinary tract and include vaginal discharge, urinary frequency or dysuria, and rectal discomfort.

The incubation period is only 3–5 days.

Discharge

The vulva, vagina, cervix, and urethra may be inflamed and may itch or burn. Specimens of discharge from the cervix, urethra, and anus should be taken for culture from the symptomatic patient. A stain of purulent urethral exudate may demonstrate gram-negative diplococci in leukocytes. Similar findings in a purulent cervical discharge are less conclusively diagnostic of *N gonorrhoeae*.

Bartholinitis

Unilateral swelling in the inferior lateral portion of the introitus suggests involvement of Bartholin's duct and gland. In early gonococcal infections, the organism may be recovered by gently squeezing the gland and expressing pus from the duct. Enlargement, tenderness, and fluctuation may develop, signifying abscess formation. *N gonorrhoeae* is then less frequently recovered; however, the prevalence of infection with other bacteria merits a search for these pathogens. Spontaneous evacuation of pus often occurs if the incision is not drained. The infection may result in asymptomatic cyst formation.

Anorectal Inflammation

Anal itching, pain, discharge, or bleeding occurs rarely. Most women are asymptomatic and acquire infection by perineal spread of vaginal secretions rather than by anal intercourse.

Pharyngitis

Acute pharyngitis and tonsillitis rarely occur; most infections are asymptomatic.

Disseminated Infection

For unknown reasons, asymptomatic carriers can develop systemic infection. Commonly, a triad of polyarthralgia, tenosynovitis, and dermatitis is seen, or purulent arthritis without dermatitis. Septicemia is more common in the former clinical setting and *N gonorrhoeae* cultured from joint aspirates in the latter. Endocarditis and meningitis have been described.

Conjunctivitis

In adults, ophthalmic infection is usually due to autoinoculation. Ophthalmia neonatorum may result from delivery through an infected birth canal.

Vulvovaginitis in Children

Gonococcal invasion of nonkeratinized membranes in prepubertal girls produces severe vulvovaginitis. The typical sign is a purulent vaginal discharge with dysuria. The genital mucous membranes are red and swollen. Infection is commonly introduced by adults, and in such cases the physician must consider the possibility of child abuse.

LABORATORY FINDINGS

A presumptive diagnosis of gonorrhea can be made based on examination of the stained smear; however, confirmation requires positive identification on selective media. Secretions are examined under oil immersion for presumptive identification. Gram-negative diplococci that are oxidase-positive and obtained from selective media (Thayer-Martin or Transgrow) usually signify *N gonorrhoeae*. Carbohydrate fermentation tests may be performed, but in addition to being time-consuming and expensive, they occasionally yield other species of *Neisseria*. Therefore, cultures are reported as "presumptive for *N gonorrhoeae*." Chlamydial cultures or direct smear testing (ELISA or immunofluorescent staining) of the cervix and a serologic test for syphilis should also be obtained. In addition, other techniques for detecting gonorrhea include enzyme immunoassay from cervical swab or urine specimens, DNA probes from endocervical swabs, and nucleic acid amplification tests (NAATs) from endocervical swabs, liquid Papanicolaou (Pap) specimens, vaginal swabs, and urine specimens.

Complications

The major complication in the female is salpingitis and the complications that may arise from salpingitis (see Acute Salpingitis-Peritonitis). *N gonorrhoeae* can be recovered from the cervix in approximately 50% of women with salpingitis. It is important to note that asymptomatic carriers can also develop tubal scarring, infertility, and increased risk for ectopic gestations. Resistant strains of *N gonorrhoeae* have emerged in some geographic areas because of their capacity to produce penicillinase or because of chromosome-mediated resistance. Some strains are resistant to spectinomycin and tetracycline. Follow-up cultures are essential in these settings, at least by 7 days to 3 weeks after completion of therapy.

Differential Diagnosis

See Chapter 37.

Prevention

Gonorrhea is a reportable disease that can be controlled only by detecting the asymptomatic carrier and treating her and her sexual partners. It is crucial to instruct patients to abstain from sexual relations for the 7 days after therapy is initiated. All high-risk populations should be screened by routine cultures. Re-examination 3 weeks after treatment is mandatory to rule out reinfection or failure of therapy. Use of condoms will protect against gonorrhea.

Treatment

Any patient with gonorrhea must be suspected of having other STDs (eg, syphilis, HIV, and chlamydial infection) and managed accordingly. Treatment should cover *N gonorrhoeae*, *C trachomatis*, and incubating syphilis. Dual therapy has contributed greatly to the declining prevalence of chlamydial infections. Therefore, if chlamydial infection is not ruled out, the following regimens should be given with doxycycline (for nonpregnant patients) or azithromycin.

Quinolone-resistant *N gonorrhoeae* is common in parts of Asia and the Pacific. It is becoming increasingly common in areas on the west coast of the United States, particularly California. Because of this, quinolones are no longer recommended for treatment of gonorrhea acquired in Asia and the Pacific (including Hawaii). Quinolones may not be advisable for treatment of gonorrhea acquired in California.

UNCOMPLICATED INFECTIONS

Guidelines issued by the CDC for therapy of uncomplicated infection in adults are as follows. (1)

Recommended regimens—(a) ceftriaxone 125 mg IM once, plus doxycycline 100 mg orally twice daily for 7 days (for nonpregnant patients), or azithromycin 1 g orally in a single dose if chlamydial infection is not ruled out; (b) cefixime 0.4 g orally once, plus doxycycline or azithromycin as above; and (c) ofloxacin 0.4 g, levofloxacin 0.25 g, or ciprofloxacin 0.5 g orally once in nonpregnant, nonlactating patients over 17 years old, plus doxycycline or azithromycin as above. Quinolones should not be given to patients residing in, or who may have acquired infection in, Asia and the Pacific (including Hawaii). Use of fluoroquinolones in California probably is inadvisable. According to one study, the advantage of oral cefixime over ceftriaxone is the reduced potential for needlesticks (HIV, hepatitis C) and increased patient comfort. (2) *Alternative regimens*—(a) spectinomycin 2 g IM once, followed by doxycycline or azithromycin as above, for patients who cannot take cephalosporins or quinolones (not reliable for pharyngeal infection); (b) ceftizoxime 0.5 g, cefotaxime 0.5 g, or cefoxitin 2 g IM once with probenecid 1 g orally, plus doxycycline or azithromycin as above; and (c) gatifloxacin 0.4 g, norfloxacin 0.8 g, or lomefloxacin 400 mg orally once in nonpregnant, nonlactating patients over 17 years old, plus doxycycline or azithromycin as above. Azithromycin 2 g orally is equally effective for *N gonorrhoeae* but may be limited because of its higher cost and potential for gastrointestinal distress.

Pregnant women should not be treated with quinolones or tetracyclines. They should be treated with a recommended or alternate cephalosporin. If cephalosporins are not tolerated, spectinomycin 2 g IM

should be given along with treatment for diagnosed or presumptive *C trachomatis*.

The incidence of penicillinase-producing strains of *N gonorrhoeae* (PPNGs) is increasing and is spreading from coastal areas to the center of the United States. They are unresponsive to previously recommended conventional therapy such as penicillin, ampicillin, or amoxicillin. Currently recommended cephalosporins and quinolones and regimens with β -lactamase inhibitors are effective therapy against PPNG strains.

ACUTE SALPINGITIS

See Acute Salpingitis-Peritonitis.

DISSEMINATED INFECTIONS

Disseminated gonococcal infection should be treated in the hospital initially. Evidence for endocarditis or meningitis should be sought. Recommended regimens include ceftriaxone 1 g IM or IV every 24 hours, or cefotaxime or ceftizoxime 1 g IV every 8 hours. For patients with β -lactamase allergy, spectinomycin 2 g IM every 12 hours can be used. Testing for chlamydia should be performed or therapy given. Therapy should be given for a total of 1 week; oral medications include cefixime 0.4 g every 12 hours, ciprofloxacin 0.5 g every 12 hours, ofloxacin 0.4 g every 12 hours, or levofloxacin 0.5 g once daily in women who are not pregnant or lactating.

NEONATES AND CHILDREN

Infants born to women with untreated gonorrhea should be treated with ceftriaxone 25–50 mg/kg IV or IM, not to exceed 125 mg. It should be given cautiously to premature or hyperbilirubinemic infants.

Prognosis

The prognosis is excellent for patients with gonorrhea who receive prompt treatment. Infertility may result from even a single episode. Fewer cases have been reported to the CDC in recent years than previously reported.

Chlamydial Infections

Essentials of Diagnosis

- Mucopurulent cervicitis.
- Salpingitis.
- Urethral syndrome.
- Nongonococcal urethritis in males.
- Neonatal infections.
- Lymphogranuloma venereum.

General Considerations

The spectrum of genital infections caused by serotypes of *C trachomatis* has only recently become appreciated. *C trachomatis* infections are the most commonly reported notifiable disease in the United States. In 2004, 929,462 chlamydia infections were reported to the CDC, which is 2.5 times greater than the number of cases of gonorrhea. Genital infection with this organism is the most common sexually transmitted bacterial disease in women. Chlamydiae are obligate intracellular microorganisms that have a cell wall similar to that of gram-negative bacteria. They are classified as bacteria and contain both DNA and RNA. They divide by binary fission, but like viruses they grow intracellularly. They can be grown only by tissue culture. With the exception of the L serotypes, chlamydiae attach only to columnar epithelial cells without deep tissue invasion. As a result of this characteristic, clinical infection may not be apparent. For example, infections of the eye, respiratory tract, or genital tract are accompanied by discharge,

swelling, erythema, and pain localized to these areas only. *C trachomatis* infections are associated with many adverse sequelae due to chronic inflammatory changes as well as fibrosis (eg, tubal infertility and ectopic pregnancy). The proposed mechanism for the pathogenesis of chlamydial disease is an immune-mediated response. This mechanism has been supported *C trachomatis* vaccine studies in humans and monkeys as well as other animal model studies. Evidence indicates that a 57-kDa chlamydial protein, which is a member of 60-kDa heat shock proteins, plays a role in the immunopathogenesis of chlamydial disease.

Certain factors may be predictive of women with a greater likelihood of acquiring *C trachomatis*. Sexually active women younger than 20 years have chlamydial infection rates 2–3 times higher than the rates of older women. The number of sexual partners and, in some studies, lower socioeconomic status are associated with higher chlamydial infection rates. Persons who use barrier contraception are less frequently infected by *C trachomatis* than are those who use no contraception, and women who use oral contraceptives may have a higher incidence of cervical infection than women not using oral contraceptives. Cervical infection in pregnant women varies from 2–24% and is most prevalent in young, unmarried women of lower socioeconomic status in inner-city environments. The CDC recommends screening sexually active adolescent girls at their routine yearly gynecologic examination, as well as women 20–24 years old, especially those who have new or multiple partners, and those who inconsistently use barrier contraceptives.

Clinical Findings

SYMPTOMS AND SIGNS

Women with chlamydial infection not uncommonly are asymptomatic. Women with cervical infection generally have a mucopurulent discharge with hypertrophic cervical inflammation. Salpingitis may be unassociated with symptoms.

LABORATORY FINDINGS

The diagnosis of chlamydial infection is based solely on laboratory tests. Diagnosis of *C trachomatis* using cell culture isolation has a sensitivity of 70–90%; however, this specialized modality is not widely available. Cell culture is the detection method of greatest specificity (almost 100%), but the cost can be prohibitive, and a 3- to 7-day delay in diagnosis is required. Despite its disadvantages, cell culture is presently the standard for quality assurance of nonculture chlamydia tests. The CDC recommends cell culture for specimens from the urethra, rectum, and vagina of prepubertal girls and from the nasopharynx of infants. In infants with inclusion conjunctivitis, Giemsa stain of purulent discharge from the eye is used to identify chlamydial inclusions, but similarly stained slides of exudates in adults with genital infections are only approximately 40% accurate in the diagnosis of these infections. Serologic methods, either the complement fixation or microimmunofluorescence test, are not totally accurate, as 20–40% of sexually active women have positive antibody titers. In fact, most women with microimmunofluorescent antibody do not have a current infection.

Moss and colleagues examined antibody responses to chlamydia species in patients who attended a genitourinary clinic and found that up to 50% of all chlamydia IgG-positive cases were due to nongenital chlamydiae (*C pneumoniae* and *C psittaci*). The low specificity of the chlamydia serology tests is attributed to these antibodies as well as to the presence of group-specific antibodies. Therefore, it is of utmost importance to use serologic tests capable of distinguishing antibodies to *C trachomatis* from antibodies to *C pneumoniae* and *C psittaci* (nongenital chlamydial pathogens). Direct smear fluorescent antibody testing requires a fluorescence microscope, and processing time is only 30–40 minutes. Sensitivity is 90% or higher, with a specificity of 98% or higher if an experienced microscopist and a satisfactory specimen are available. This test appears to be the most promising, and when tissue samples

(endometrial or uterine tube) are being evaluated, it has been reported to be more accurate. PCR, ligase chain reaction, and current DNA probes used for detection of *C trachomatis* may be more rapid and less expensive. Nucleic acid hybridization methods (DNA probe) require only 2–3 hours of processing time. The DNA probe assay is specific for *C trachomatis*; cross-reactivity with *C pneumoniae* and *C psittaci* has not been reported. To ensure high specificity, a competitive probe assay has been produced and is currently being evaluated in clinical trials. Recent reports indicate PCR positivity with negative culture. PCR may be the most sensitive and specific test method for chlamydia.

Differential Diagnosis

Mucopurulent cervicitis is frequently caused by *N gonorrhoeae*, and selective cultures for this organism should be performed. As discussed above, *C trachomatis* alone may be associated with as many as 20–35% of cases of acute salpingitis in the United States. In both cervicitis and salpingitis, cultures frequently may be positive for both organisms.

Complications

Adverse sequelae of salpingitis, specifically infertility due to tubal obstruction and ectopic pregnancy, are the most dire complications of these infections. Pregnant women with cervical chlamydial infection can transmit infections to their newborns; evidence indicates that up to 50% of infants born to such mothers will have inclusion conjunctivitis. In perhaps 10% of infants, an indolent chlamydial pneumonitis develops at 2–3 months of age. This pathogen may cause otitis media in the neonate. Whether maternal cervical infection with *Chlamydia* causes significantly increased fetal and perinatal wastage by abortion, premature delivery, or stillbirth is uncertain.

Increasing evidence indicates that chlamydial infection in pregnancy is a risk marker for premature delivery and postpartum infections. Women at greatest risk are those with recent chlamydial infection detected by antichlamydial IgM. Those with chronic or recurrent infection do not have increased risk for preterm delivery. It is hypothesized that asymptomatic cervicitis predisposes to mild amnionitis. This event activates phospholipase A₂ to release prostaglandins, which cause uterine contractions that may lead to premature labor. Chlamydial infection is associated with higher rates of early postpartum endometritis as well as delayed infection from *Chlamydia* that often presents several weeks postpartum.

Treatment

In most cases, *Chlamydia* can be eradicated from the cervix by doxycycline 100 mg orally twice daily for 7 days (for nonpregnant patients), or azithromycin 1 g orally as a single dose. Compliance with treatment may play a major role in controlling chlamydial infections. One group of researchers evaluated the compliance with antichlamydial and antigonorrheal therapy and found that 63% of patients treated with the standard 7-day regimen of tetracycline or erythromycin were compliant. An alternate regimen is erythromycin base 500 mg or erythromycin ethylsuccinate 800 mg orally 4 times daily given for a minimum of 7 days. Patients who cannot tolerate erythromycin should consider ofloxacin 300 mg twice daily or levofloxacin 500 mg orally once daily for 7 days. Administration of high doses of ampicillin has resulted in elimination of *C trachomatis* from the cervixes of women with acute salpingitis. Addition of the irreversible β -lactamase enzyme inhibitor sulbactam increases in vitro antichlamydial activity.

Pregnant women are advised to take erythromycin base 500 mg 4 times daily for 7 days, or amoxicillin 500 mg 3 times daily for 7 days. Alternate regimens include erythromycin base 250 mg orally 4 times daily for 14 days, erythromycin ethylsuccinate 800 mg orally 4 times daily for 7 days, erythromycin ethylsuccinate 400 mg orally 4 times daily for 14 days, or azithromycin 1 g orally as a single dose.

Current studies indicate that 3–5% of pregnant women and as many as 15% of sexually active nonpregnant women have an asymptomatic chlamydial cervical colonization. Whether attempts

to eradicate asymptomatic colonization will prevent chlamydial cervicitis, salpingitis, or neonatal infections is not known. Posttreatment cultures are not usually advised if doxycycline, azithromycin, or ofloxacin is taken as described above and symptoms are not present; cure rates should be higher than 95%. Retesting may be considered 3 weeks after completing treatment with erythromycin. A positive posttreatment culture is more likely to represent noncompliance by the patient or sexual partner or reinfection rather than antibiotic resistance. It is important to ensure that the sexual partner is treated, as most posttreatment reinfections occur because the sexual partner was not treated. Clinicians should advise all women with chlamydial infection to be re-screened 3–4 months after treatment.

PELVIC INFECTIONS

Because of their common occurrence and often serious consequences, infections are among the most important problems encountered in the practice of gynecology. A wide variety of pelvic infections, ranging from uncomplicated gonococcal salpingo-oophoritis to septicemic shock following rupture of a pelvic abscess, confront the general physician as well as the gynecologist.

The following is a general classification of pelvic infections by frequency of occurrence:

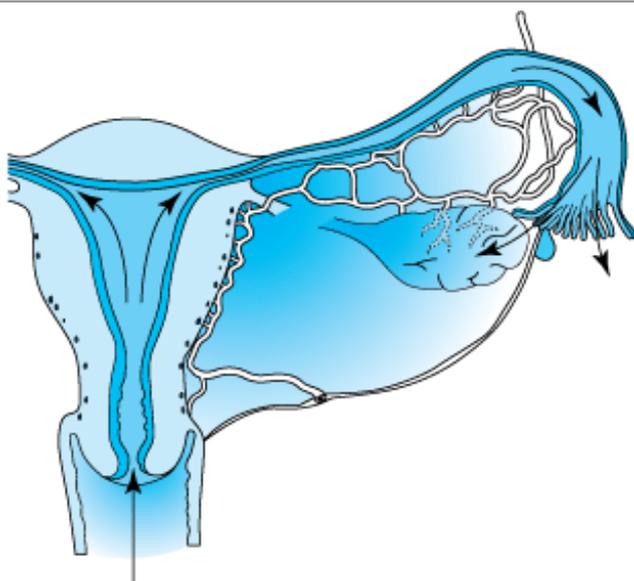

1. Pelvic inflammatory disease
 - a. Acute salpingitis
 - i. Gonococcal
 - ii. Nongonococcal
 - b. Intrauterine device (IUD)-related pelvic cellulitis
 - c. Tubo-ovarian abscess (TOA)
 - d. Pelvic abscess
2. Puerperal infections
 - a. Cesarean section (common)
 - b. Vaginal delivery (uncommon)
3. Postoperative gynecologic surgery
 - a. Cuff cellulitis and parametritis
 - b. Vaginal cuff abscess
 - c. TOA
4. Abortion-associated infections

- a. Postabortal cellulitis
- b. Incomplete septic abortion
- 5. Secondary to other infections
 - a. Appendicitis
 - b. Diverticulitis
 - c. Tuberculosis

Pelvic inflammatory disease (PID) is a general term for acute, subacute, recurrent, or chronic infection of the oviducts and ovaries, often with involvement of adjacent tissues. Most infections seen in clinical practice are bacterial, but viral, fungal, and parasitic infections occur. The term PID is vague at best and should be discarded in favor of more specific terminology, which should include identification of the affected organs, the stage of the infection, and, if possible, the causative agent. This specificity is especially important in light of the rising incidence of venereal disease and its complications.

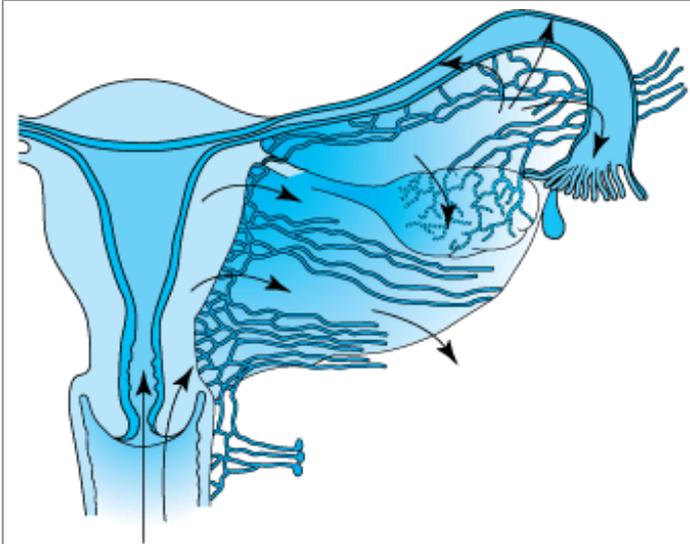

The three proposed pathways of dissemination of microorganisms in pelvic infections are depicted in Figs 41–4, 41–5, and 41–6. Lymphatic dissemination (Fig 41–5), typified by postpartum, postabortal, and some IUD-related infections, results in extraperitoneal parametrial cellulitis. In Fig 41–4, the endometrial-endosalpingeal-peritoneal spread of microorganisms is depicted. This represents more common forms of nonpuerperal PID, in which pathogenic bacteria gain access to the lining of the uterine tubes, with resultant purulent inflammation and egress of pus through tubal ostia into the peritoneal cavity. These infections are represented by endometritis, adnexal infection, and peritonitis. In rare instances, certain diseases (eg, tuberculosis) may gain access to pelvic structures by hematogenous routes (Fig 41–6).

Figure 41–4.

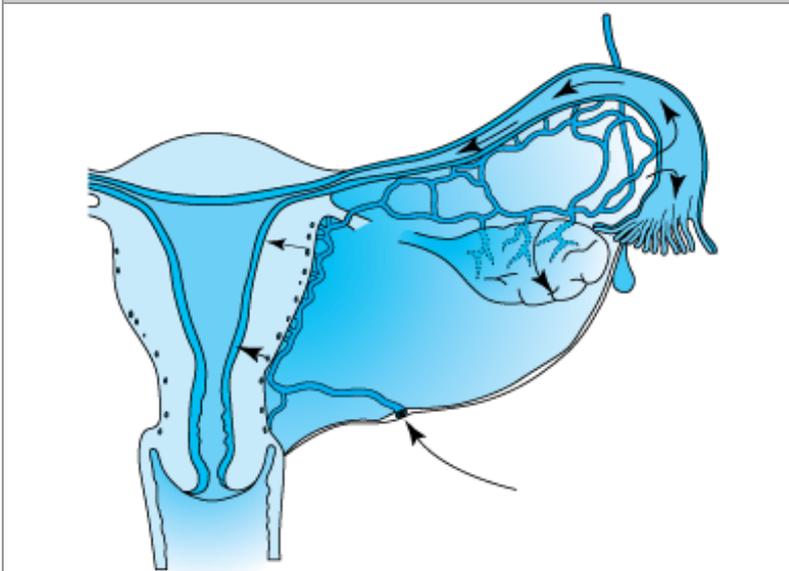

Intra-abdominal spread of gonorrhea and other pathogenic bacteria.

Figure 41–5.

Lymphatic spread of bacterial infection.

Figure 41–6.

Hematogenous spread of bacterial infection (eg, tuberculosis).

Early recognition and treatment of the various entities that constitute PID are mandatory so that specific therapy can be instituted to prevent damage to the reproductive system. Laparoscopic studies have confirmed a 65–90% positive predictive value for tubal disease among patients with the diagnosis of presumed PID. Repeated sexual contacts with multiple partners predispose to subsequent reinfection or superinfection, spreading the disease throughout the reproductive system and resulting in sterility and an

increased risk for tubal pregnancy.

The initial gonococcal infection (more common in young single women of low parity) may be relatively asymptomatic, and the patient may not be seen until recurrent infection with irreversible pathologic changes has occurred. Gonorrhea involving only the lower genital tract and urethra is often asymptomatic; severe symptomatic gonorrhea implies tubal and peritoneal involvement. If the initial infection is limited to the lower tract, proper therapy may prevent further sequelae. The presence of endosalpingitis or ovarian infection carries a graver prognosis with regard to future fertility.

Originally, gonococcus was thought to be the only organism responsible for nonpuerperal acute pelvic inflammation. More recent data indicate that *N gonorrhoeae* is isolated in only 40–60% of women with acute salpingitis. In Sweden, *C trachomatis* was estimated to cause 60% of cases of salpingitis. Although direct evidence of such infection, eg, recovery from tubal culture, is lacking in most studies performed in the United States, authorities believe that this pathogen may be responsible for 20–35% of such pelvic infections. How frequently salpingitis is caused by chlamydiae alone or by chlamydia in association with other invasive microorganisms is unclear. Regardless of the initiating factors, nongonococcal pathogens that compose the normal vaginal flora may be involved in many cases of acute salpingitis-peritonitis.

N gonorrhoeae was present alone or with other pathogens in 65% of the specimens. One group of researchers reported positive cul-de-sac fluid cultures in 18 (90%) of 20 patients with acute salpingitis compared with 8 normal patients with negative results.

If the infectious process continues, pelvic adhesions become more pronounced, and tissue planes are lost. Identification of the tubes and ovaries in the inflammatory mass, which may include omental and intestinal attachments, becomes difficult. Further progression causes tissue necrosis with abscess formation. Containment of the purulent exudate under pressure becomes impossible at certain sites, and pus is released into the peritoneal cavity. This usually is at the site of an adhesion to a nearby organ, and the point of rupture often can be identified at operation. Abscess formation may be localized in either or both of the tubes and ovaries without leakage or rupture. Another possibility is accumulation of purulent material walled off in the cul-de-sac.

Recent observations have shown these pelvic infections are polymicrobial with mixed anaerobic and aerobic bacteria. Anaerobes predominate and frequently coexist with aerobes. In some cases, aerobes alone are isolated. With further advanced disease, such as abscess formation, anaerobic organisms seem to predominate. All these bacteria are members of the normal vaginal and endocervical flora and include *Bacteroides*, *Escherichia coli*, aerobic streptococci, and anaerobic cocci (*Peptostreptococcus* and *Peptococcus*). Virtually any organism indigenous to the normal vaginal or gastrointestinal flora may be isolated if specific techniques are used. Direct immunofluorescent antibody testing of cervical smears of 500 asymptomatic women showed *C trachomatis* in 10%. Moreover, among women recently treated as outpatients for acute salpingitis, 16% had *C trachomatis* in endocervical specimens and 8% had the organism in the endometrial cavity (obtained with a double-lumen catheter-protected brush). These numbers should not be taken lightly when considering the cost of chlamydia-related PID. Also, many retrospective studies point to recurrent infections and delays in treatment as the major behavioral risk factors contributing to PID. From the same sites, *N gonorrhoeae* was identified in 68% and 65% of specimens, respectively. Great numbers of both aerobes and anaerobes were recovered from endometrial cultures; 10% had group B *Streptococcus*, 10% had *Bacteroides fragilis*, 55% had *Streptococcus faecalis*, 65% had *Staphylococcus epidermidis*, 75% had anaerobic *Streptococcus* spp., and 65% had *Prevotella bivia* in that location. Whether this is a result of infection or is flora from the lower tract and endometrium is under evaluation.

Many factors may account for adverse sequelae of these pelvic infections, eg, infertility and pain. Delay

in initiation of treatment is associated with later symptomatology. Likewise, inadequate therapy because of improper antimicrobial selection, insufficient dosage, or inadequate duration of therapy may be responsible for subsequent problems. An inflammatory process that is allowed to continue—for whatever reason—results in anatomic derangements with adhesive attachments to nearby organs. An ovulation site in an ovary may serve as a portal of entry for extension of the infection into the ovarian stroma, and this sets the stage for formation of TOAs.

The most important factor in the diagnosis of women with pelvic infections is clinical awareness by the physician. For patients with high-risk factors (eg, postoperative pelvic surgery, postpartum, or postabortal), fever is usually the first clue. For women without these factors, a high index of suspicion is important. If gonorrhea is suspected, a Gram-stained smear of endocervical purulent material or fluid obtained by culdocentesis may be helpful. The Gram-stained smear may be lifesaving, especially in the woman seen with a rare serious infection due to *Clostridium perfringens*. Except for isolation of *N gonorrhoeae* with specialized media, cultures taken from women with pelvic infections currently are not useful for clinical management. Because these infections are usually polymicrobial, sophisticated techniques are necessary for microbiologic identification. These techniques are time-consuming, and by the time the results become available to the clinician, the woman has usually been cured with empiric antimicrobial drug therapy.

PELVIC INFLAMMATORY DISEASE

Acute Salpingitis-Peritonitis

Essentials of Diagnosis

- Onset of lower abdominal and pelvic pain, usually following onset or cessation of menses and associated with vaginal discharge, abdominal, uterine, adnexal, and cervical motion tenderness, plus one or more of the following:
 - a. Temperature above 38.3 °C (101 °F).
 - b. Leukocyte count greater than 10,000/ μ L or elevated C-reactive protein.
 - c. Inflammatory mass (examination or sonography).
 - d. Gram-negative intracellular diplococci in cervical secretions.
 - e. Purulent material (white blood cells) from peritoneal cavity (culdocentesis or laparoscopy).
 - f. Elevated erythrocyte sedimentation rate.

General Considerations

There is generally an acute onset of pelvic infection, often associated with invasion by *N gonorrhoeae* and involving the uterus, tubes, and ovaries, with varying degrees of pelvic peritonitis. In the acute stage, there is redness and edema of the tubes and ovaries with a purulent discharge oozing from the ostium of the tube.

Clinical Findings/Diagnosis

SYMPTOMS AND SIGNS

The insidious or acute onset of lower abdominal and pelvic pain usually is bilateral and only occasionally is unilateral. There may be a sensation of pelvic pressure, with back pain radiating down 1 or both legs. In most cases, symptoms appear shortly after the onset or cessation of menses. There is often an associated purulent vaginal discharge.

Nausea may occur, with or without vomiting, but these symptoms may be indicative of a more serious

problem (eg, acute appendicitis). Headache and general lassitude are common complaints.

Fever is not necessary for the diagnosis of acute salpingitis, although its absence may indicate other disorders, specifically ectopic pregnancy. In 1 study, only 30% of women with laparoscopically confirmed acute salpingitis had fever. Although standardization of criteria for diagnosis of acute salpingitis to include fever greater than 38.3 °C (101 °F) may greatly aid clinical research, such a distinction may result in many women with acute pelvic infection being erroneously diagnosed and inadequately treated.

Abdominal tenderness is often encountered, usually in both lower quadrants. The abdomen may be somewhat distended, and bowel sounds may be hypoactive or absent. Pelvic examination may demonstrate inflammation of the periurethral (Skene) or Bartholin's glands as well as a purulent cervical discharge. Bimanual examination typically elicits extreme tenderness on movement of the cervix and uterus and palpation of the parametria.

LABORATORY FINDINGS

Leukocytosis with a shift to the left is usually present; however, the white blood cell count may be normal. A smear of purulent cervical material may demonstrate gram-negative kidney-shaped diplococci in polymorphonuclear leukocytes. These organisms may be gonococci, but definitive cultures on selective media are advised. Penicillinase production should be confirmed.

Culdocentesis generally is productive of "reaction fluid" (cloudy peritoneal fluid) that, when stained, reveals leukocytes with or without gonococci or other organisms. Culture and sensitivity testing of organisms from culdocentesis samples may be done.

RADIOLOGIC FINDINGS

X-ray examination of the abdomen may show signs of ileus, but this finding is nonspecific. Air may be seen under the diaphragm with a ruptured tubo-ovarian or pelvic abscess and demands immediate laparotomy in addition to combination antimicrobial therapy.

ULTRASOUND

With the introduction of transvaginal sonography, the female reproductive tract now can be visualized at bedside. Markers for acute and chronic PID can be differentiated. Incomplete septation of the tubal wall ("cogwheel sign") is a marker for acute disease, and a thin wall ("beaded string") indicates chronic disease. Thickening is noted in the pelvic areas during the inflammatory process. Ultrasound diagnosis is approximately 90% accurate compared with laparoscopic diagnosis. Ultrasonography is most valuable in following the progression or regression of an abscess after it has been diagnosed. The borders of an abscess conform to the surrounding pelvic structures and as such do not give a well-defined border as noted in an ovarian cyst.

CULDOCENTESIS

Culdocentesis (cul-de-sac tap) may be helpful in the diagnosis of suspected pelvic infection. Other conditions that may simulate infection can be ruled out using this simple procedure. The rectouterine pouch (of Douglas) is punctured with a long spinal needle to obtain a sample of the contents of the peritoneal cavity after vaginal membrane preparation with povidone-iodine or similar agents. Culdocentesis is easy to perform and can be performed with or without local anesthesia in the hospital or in the office. One milliliter of sterile saline anesthetizes the vaginal membrane and peritoneum. Culdocentesis is indicated whenever peritoneal material is needed for diagnosis. Cultures for aerobic and anaerobic organisms may also be obtained. Contraindications include a cul-de-sac mass or a fixed retroflexed uterus. The differential evaluation of fluid obtained by culdocentesis is given in Table 41-2.

Table 41–2. Differential Evaluation of Fluid Contained by Culdocentesis.

Finding	Implications for Diagnosis
Blood	Ruptured ectopic pregnancy. Hemorrhage from corpus luteum cyst. Retrograde menstruation. Rupture of spleen or liver. Gastrointestinal bleeding. Acute salpingitis.
Pus	Ruptured tubo–ovarian abscess. Ruptured appendix or viscus. Rupture of diverticular abscess. Uterine abscess with myoma.
Cloudy	Pelvic peritonitis (such as is seen with acute gonococcal salpingitis). Twisted adnexal cyst. Other causes of peritonitis: appendicitis, pancreatitis, cholecystitis, perforated ulcer, carcinomatosis, echinococcosis.

Differential Diagnosis

Acute salpingitis must be differentiated from acute appendicitis, ectopic pregnancy, ruptured corpus luteum cyst with hemorrhage, diverticulitis, infected septic abortion, torsion of an adnexal mass, degeneration of a leiomyoma, endometriosis, acute urinary tract infection, regional enteritis, and ulcerative colitis.

Complications

Complications of acute salpingitis include pelvic peritonitis or generalized peritonitis, prolonged adynamic ileus, severe pelvic cellulitis with thrombophlebitis, abscess formation (pyosalpinx, TOA, cul-de-sac abscess) with adnexal destruction and subsequent infertility, and intestinal adhesions and obstruction. Rarely, dermatitis, gonococcal arthritis, or bacteremia with septic shock occurs.

Prevention

Approximately 15% of women with asymptomatic gonococcal cervical infection develop acute salpingitis. Detection and treatment of these women and their sexual partners should therefore prevent a substantial number of cases of gonococcal pelvic infection. Early diagnosis and eradication of minimally symptomatic disease (cervicitis, urethritis) also usually prevent salpingitis.

Treatment

As with most female pelvic infections, the microbial etiologic agents are not readily apparent when clinical infection is diagnosed, and because of the myriad of pathogens described, empiric therapy is given as soon as a presumptive diagnosis is made. It is important to note that negative cultures do not preclude upper reproductive tract disease. The majority of women who present with acute salpingitis-peritonitis have clinical disease of mild to moderate severity that usually responds well to outpatient antibiotic

therapy. Hospitalization usually is warranted for women who are more severely ill as well as for women in whom the exact diagnosis is uncertain. Prepubertal children and pregnant women with this diagnosis should be hospitalized for therapy, as should women with a suspected abscess, women unable to tolerate outpatient oral therapy, and women who have not responded to outpatient therapy. Although it has not been clinically proved that inpatient therapy is associated with improved future fertility, women who desire future fertility may benefit from inpatient therapy if only by reason of compliance. Some authors believe that all women with this infection should receive inpatient therapy.

OUTPATIENT THERAPY

Outpatient therapy for women with acute salpingitis may be undertaken if the temperature is less than 39 °C (102.2 °F), lower abdominal findings are minimal, and the patient is not "toxic" and can take oral medication. These women can be treated with antibiotics, IUD removal, analgesics, and bed rest. Regimens recommended by the CDC include (1) ofloxacin 400 mg orally twice daily or levofloxacin 500 mg orally once daily for 14 days, plus clindamycin 450 mg orally 4 times daily or metronidazole 500 mg orally twice daily for 14 days; (2) ceftriaxone 250 mg IM or equivalent cephalosporin (eg, ceftizoxime or cefotaxime) IM, with probenecid 1 g orally, followed by 14 days of doxycycline 100 mg orally twice daily, with or without metronidazole 500 mg twice daily; or (3) cefoxitin 2 g IM, plus probenecid 1 g orally, followed by 14 days of doxycycline 100 mg orally twice daily, with or without metronidazole 500 mg twice daily. If a response to therapy is not observed after 72 hours, the patient should be admitted for inpatient therapy. Refer the patient to the city or county health department or STD clinic for contact surveillance. All male sexual partners of women treated for this acute infection should be examined for STDs and promptly treated with a regimen effective against uncomplicated gonococcal and chlamydial infections.

INPATIENT THERAPY

Inpatient therapy is prudent for patients with a temperature over 39 °C (102.2 °F), for those with guarding and rebound tenderness in lower quadrants, or for patients who look "toxic." Hospitalization of these patients is necessary to administer therapy and to observe for signs of complications or deterioration. Patients who do not respond to outpatient therapy should be evaluated for a suspected TOA. The following measures should be taken:

- (1) Maintain bed rest.
- (2) Restrict oral feeding.
- (3) Administer intravenous fluids to correct dehydration and acidosis.
- (4) Use nasogastric suction in the presence of abdominal distention or ileus.
- (5) No standardization of inpatient antimicrobial therapy for women with acute salpingitis has been established. Symptomatic response and adverse sequelae are related to the severity of tubal inflammatory disease and the development of adnexal abscesses. The CDC recommends one of the following regimens: (1) doxycycline 100 mg IV or orally twice daily, plus cefoxitin 2 g IV 4 times daily, or cefotetan 2 g IV twice daily, for at least 24 hours after the patient shows clinical improvement, followed by doxycycline 100 mg orally twice daily to complete 14 days of therapy; (2) clindamycin 900 mg IV 3 times daily, plus gentamicin 2 mg/kg IV and then 1.5 mg/kg IV every 8 hours (single daily dosing of gentamicin may be substituted), given as above in women with normal renal function, followed by doxycycline 100 mg twice daily or clindamycin 450 mg orally 4 times daily for 14 days. The incidence of infertility after the first episode of salpingitis is approximately 12%. Because infertility increases with the degree of inflammatory response, intensive broad-spectrum therapy should reduce complications. If suspicion for TOA is elevated, a regimen consisting of metronidazole or clindamycin should be used both for inpatient therapy and for continued outpatient therapy for increased anaerobic coverage.

(6) Exploratory laparotomy should be performed if there is clinical suspicion of abscess rupture. More gynecologists are successfully performing just a linear salpingostomy, as might be done for ectopic pregnancy, when pyosalpinx is identified. Percutaneous drainage may avoid operation.

(7) Continual evaluation by the same experienced clinician is of paramount importance to maintain accuracy and continuity of clinical observation.

Prognosis

A favorable outcome is directly related to the promptness with which adequate therapy is begun. For example, the incidence of infertility is directly related to the severity of tubal inflammation judged by laparoscopic examination. A single episode of salpingitis has been shown to cause infertility in 12–18% of women. Tubal occlusion was demonstrated in only approximately 10% of these patients regardless of the presence of a gonococcal or nongonococcal infection. Nongonococcal infection predisposed more commonly to ectopic pregnancy and thus carried a worse prognosis for subsequent viable pregnancy. The ability and willingness of patients to cooperate with their physicians are important to the outcome of patients with milder cases who are adequately treated on an outpatient basis. Follow-up care and education are necessary to prevent reinfection and complications.

Recurrent or Chronic Pelvic Infection

Essentials of Diagnosis

- History of acute salpingitis, pelvic infection, or postpartum or postabortal infection.
- Recurrent episodes of acute reinfection or recurrence of symptoms and physical findings less than 6 weeks after treatment for acute salpingitis.
- Chronic infection may be relatively asymptomatic or may provoke complaints of chronic pelvic pain and dyspareunia.
- Generalized pelvic tenderness on examination; usually less severe than with acute infection.
- Thickening of adnexal tissues, with or without hydrosalpinx (often).
- Infertility (commonly).

General Considerations

Recurrent PID begins as does primary disease, but preexisting tubal tissue damage may result in more severe infection. Chronic pelvic infection implies the presence of tissue changes in the parametria, tubes, and ovaries. Adhesions of the peritoneal surfaces to the adnexa as well as fibrotic changes in the tubal lumen are usually present. Hydrosalpinx or tubo-ovarian "complexes" may be present. Chronic inflammatory lesions usually are secondary to changes induced by previous acute salpingitis but may represent an acute reinfection.

The diagnosis of chronic pelvic infection generally is difficult to make clinically. It has been erroneously applied to almost any cause of chronic pelvic pain. However, it may be the cause of pain in less than 50% of such women.

Clinical Findings

SYMPTOMS AND SIGNS

Recurrent infection usually has the same manifestations as acute salpingitis, and a history of pelvic infection can usually be obtained. Pain may be unilateral or bilateral, and dyspareunia and infertility are often reported. The patient may be febrile, with tachycardia; however, unless an acute reinfection is present, the fever is minimal. Tenderness is noted upon movement of the cervix, uterus, or adnexa. Adnexal masses may be present, as well as thickening of the parametria.

LABORATORY FINDINGS

Cultures from the cervix usually do not show gonococci unless reinfection is present. Leukocytosis may be demonstrated if active infection is superimposed on chronic changes.

Differential Diagnosis

Any patient with suspected chronic pelvic infection who presents with pelvic tenderness but without fever must be suspected of having an ectopic pregnancy. Other conditions to be considered include endometriosis, symptomatic uterine relaxation, appendicitis, diverticulitis, regional enteritis, ulcerative colitis, ovarian cyst or neoplasm, and acute or chronic cystourethritis.

Complications

The complications of chronic or recurrent pelvic infection include hydrosalpinx, pyosalpinx, and TOA; infertility or ectopic pregnancy; and chronic pelvic pain of varying degrees.

Prevention

Prompt and adequate treatment of acute pelvic infections is the essential preventive measure. Education about avoidance of STDs is also important.

Treatment

RECURRENT CASES

Treat as for acute salpingitis. If an IUD is in place, it should be removed and treatment started.

CHRONIC CASES

Long-term antimicrobial administration is of questionable benefit but is worthy of trial in young women of low parity. Therapy with a tetracycline, ampicillin, or a cephalosporin occasionally is beneficial, but changes responsible for symptoms are usually not due to active infection. Symptomatic relief can be achieved with analgesics such as ibuprofen or acetaminophen with or without codeine. Careful follow-up, preferably by the same physician, may detect serious sequelae, eg, TOA.

If the patient remains symptomatic after 3 weeks of antibiotic therapy, other causes must be considered. Consider laparoscopy or exploratory laparotomy to rule out other causes, eg, endometriosis.

If infertility is a problem, verify tubal patency by hysterosalpingography or laparoscopy and retrograde injection of methylene blue solution. It is important to prescribe antibiotics prior to and following either procedure because acute retrograde reinfection is common.

Total abdominal hysterectomy with bilateral adnexectomy may be indicated if the disease is far advanced and the woman is symptomatic or if an adnexal mass is demonstrated. Consideration can be given to resection or drainage of the abscess if preservation of fertility is desired. In many instances, computed tomography (CT)- or ultrasound-directed percutaneous drainage may avoid laparotomy.

Prognosis

With each succeeding episode of recurrent pelvic infection, the prognosis for fertility dramatically decreases. Likewise, the chances of an ectopic gestation increase with ensuing episodes of acute infection. These sequelae are undoubtedly due to chronic infection, which is the postinflammatory end result of 1 or multiple infections. Superimposition of acute infection on chronic disease is also associated with a higher incidence of tubo-ovarian and other pelvic abscesses.

Pelvic (Cul-De-Sac) Abscess

Pelvic abscess is an uncommon complication of chronic or recurrent pelvic inflammation. It may occur as a sequela to acute pelvic or postabortal infection. Abscess formation is frequently associated with

organisms other than gonococcus, commonly anaerobic species, especially *Bacteroides*. Occasionally, resistant gram-negative bacteria such as *Bacteroides bivius* and *Bacteroides fragilis* are found.

Any of the symptoms of acute or chronic pelvic inflammation may be present together with a fluctuant mass filling the cul-de-sac and dissecting into the rectovaginal septum. These patients usually have more severe symptoms. They may complain of painful defecation and severe back pain, rectal pain, or both. The severity of symptoms is often directly proportionate to the size of the abscess, but occasionally even a large pelvic abscess may be totally asymptomatic. One woman who was admitted to the obstetric service with "fetal heart tones" ultimately was drained of 3000 mL of pus through a colpotomy incision.

Differential Diagnosis

The following conditions must be considered in the differential diagnosis: TOA, periappendiceal abscess, ectopic pregnancy, adnexal torsion, ovarian neoplasm, uterine leiomyoma (especially those undergoing torsion or degeneration), retroflexed and incarcerated uterus, endometriosis, carcinomatosis, and diverticulitis with perforation.

Treatment

In addition to the measures already outlined, the following are required:

(1) Antibiotics to include anaerobic as well as aerobic microorganisms: (a) penicillin G 20–30 million units or ampicillin 2 g IV 4 times daily; clindamycin 900 mg IV 3 times daily; and gentamicin, 5 mg/kg IV per 24 hours. Metronidazole can be substituted for clindamycin at a dose of 15 mg/kg loading dose, then 7.5 mg/kg 4 times daily; (b) cefoxitin, 8–12 g IV per 24 hours (2 g every 4–6 hours), and gentamicin or tobramycin 5 mg/kg IV per 24 hours; (c) cefotaxime, 6–8 g IV per 24 hours in divided doses. With almost any effective therapeutic regimen, antibiotic-associated enterocolitis (diarrhea) is a complication that demands immediate evaluation, including testing for the presence of *Clostridium difficile* toxin. Pseudomembranous colitis is rare.

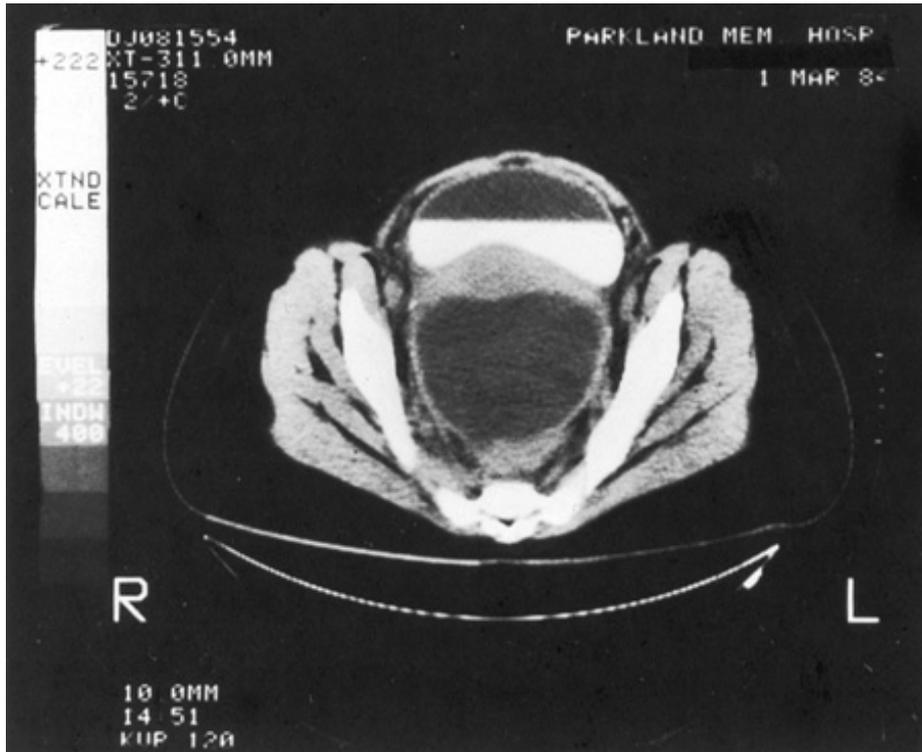

(2) Re-evaluate abdominal findings frequently to detect peritoneal involvement.

(3) If the abscess is dissecting the rectovaginal septum and is fixed to the vaginal membrane, colpotomy drainage with dissection of sacculations is indicated. This space should be actively drained with a large catheter, such as a Cook catheter, and preferably irrigated with sterile saline solution every 4 hours until the space is obliterated.

(4) If fever persists in the face of altered antimicrobial therapy but no evidence of abscess rupture or dissection of the rectovaginal septum is seen, percutaneous drainage and irrigation may obviate laparotomy (Figs 41–7, 41–8, and 41–9).

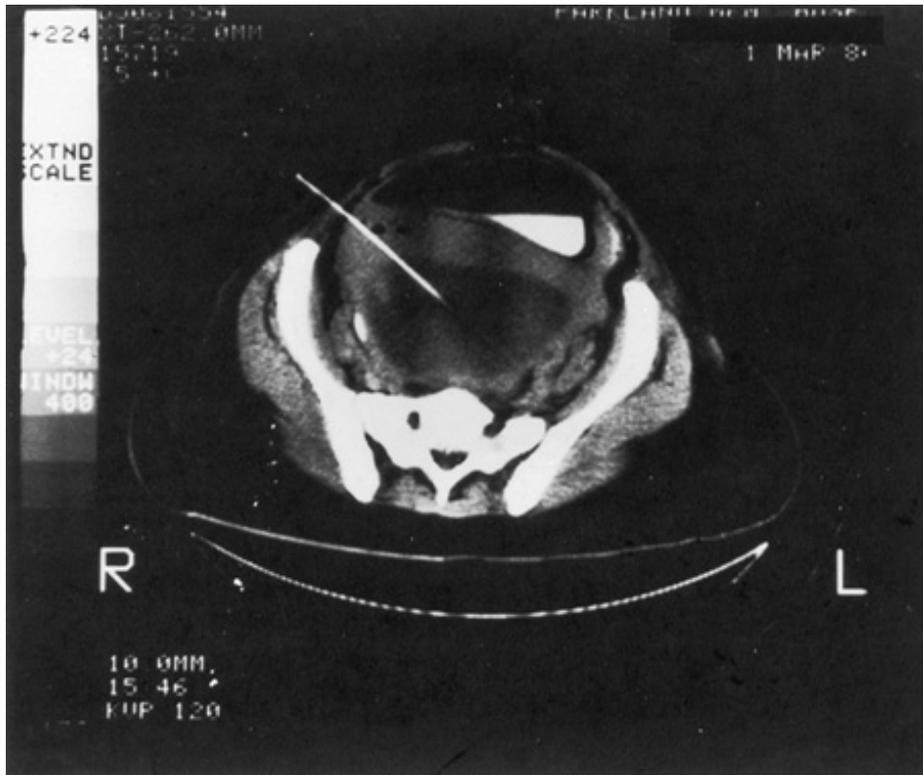

(5) If the patient's condition deteriorates despite aggressive management, perform exploratory laparotomy. In patients with recurrent infections and loss of reproductive function, total abdominal hysterectomy with bilateral salpingo-oophorectomy and lysis of adhesions offers the only cure. The patient's age and parity and the degree of involvement of the tubes and ovaries determine the extent of surgery when there is some likelihood of preservation of reproductive function. Clinical judgment is difficult and tends to favor surgery. Conservative surgery for women desiring future fertility is appropriate in many cases.

Pelvic CT scan, with bladder and contrast medium on top, uterus and thickened broad ligaments centrally, and the posterior pelvis filled with abscess.

Figure 41-8.

Pelvic CT scan with percutaneous drainage in process.

Figure 41-9.

Cook catheter in abscess cavity. Note mild bilateral hydronephrosis caused by abscess compression at the pelvic brim.

Prognosis

With early treatment, the prognosis for the woman with a well-localized abscess is good. Antibiotic treatment is essential; drainage may be necessary. Rupture into the peritoneum is a serious complication and demands immediate abdominal exploration. The prognosis for fertility is very poor following this type of abscess.

Tubo-Ovarian Abscess

Essentials of Diagnosis

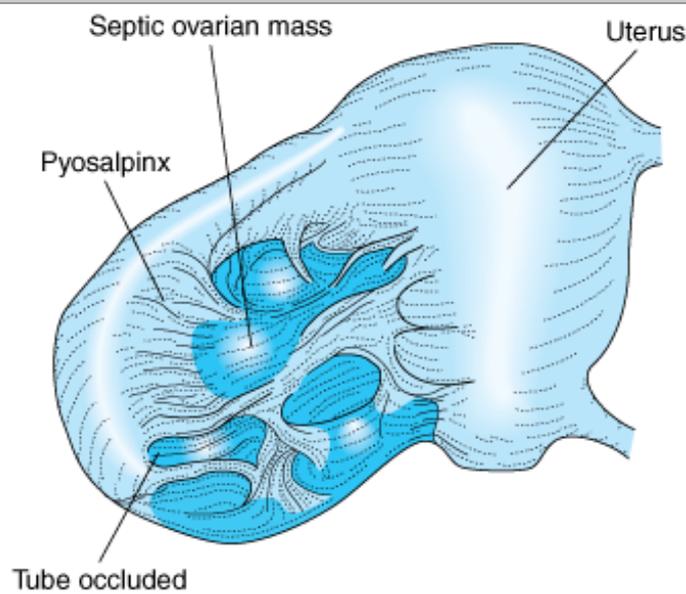

- History of pelvic infection. TOA may present as a complication of acute salpingitis, including the initial episode.
- Lower abdominal and pelvic pain of varying degrees.
- Nausea and vomiting.
- Adnexal mass, usually extremely tender.
- Fever and tachycardia.
- Rebound tenderness in lower quadrants.
- Adynamic ileus.
- Culdocentesis productive of gross pus in case of rupture. (Contraindicated in cases of posterior

pelvic abscess.)

General Considerations

TOA formation may occur following an initial episode of acute salpingitis, but it is usually seen with recurrent infection superimposed on chronically damaged adnexal tissue. It is strongly believed that fallopian tube necrosis and epithelial damage by bacterial pathogens create the environment necessary for anaerobic invasion and growth. Initially there is salpingitis with or without ovarian involvement. The inflammatory process may subside spontaneously or in response to therapy; however, the result may be anatomic derangement, with fibrinous attachments to nearby organs (Figs 41–10 and 41–11). Involvement of the adjacent ovary, usually at an ovulation site, may serve as the portal of entry for extension of infection and abscess formation. Pressure of the purulent exudate may cause rupture of the abscess with resultant fulminating peritonitis, necessitating emergency laparotomy.

Figure 41–10.

Tubo-ovarian abscess.

(Reproduced, with permission, from Benson RC: *Handbook of Obstetrics & Gynecology*, 8th ed. Lange, 1983.)

Figure 41–11.

Uterus with myoma, unruptured right tubo-ovarian abscess, and chronic inflammatory left tubo-ovarian cyst.

Slow leakage of the abscess may cause formation of a cul-de-sac abscess (see previous text). Culdocentesis into an abscess of this type will yield exudate like that of a ruptured TOA. Clinical appraisal usually will differentiate the 2 conditions, but if any doubt exists, treatment should be as specified for ruptured TOA.

These abscesses may occur in association with IUD use or in the presence of granulomatous infection (eg, tuberculosis, actinomycosis). Disease can be bilateral, although unilateral disease is more common than previously observed and may account for up to 60% of such abscesses even in the absence of IUD usage. Abscesses are usually polymicrobial.

Actinomyces israelii, a normal anaerobic commensal of the gastrointestinal tract, has been identified in 8–20% of women who have an IUD. Most patients are asymptomatic, but up to 25% reportedly develop symptoms of pelvic infection. Controversy exists as to whether an IUD should be removed from an asymptomatic woman with evidence of *Actinomyces* on Pap smear or culture. If the IUD is removed, a new IUD should not be inserted until the organism is no longer present; this rarely takes longer than 1 menstrual cycle. Antimicrobial therapy with penicillin should be reserved for symptomatic patients. Surgical drainage is usually required for actinomycotic abscesses, which are almost always the result of intestinal infections such as appendicitis but may be associated with IUD use.

Clinical Findings

SYMPTOMS AND SIGNS

The clinical spectrum varies greatly and may range from total absence of symptoms in a woman who, on routine pelvic examination, is found to have an adnexal mass to a moribund patient presenting with acute abdomen and septicemic shock.

The typical patient with TOA is usually young and of low parity, with a history of previous pelvic infection. However, no age group is exempt. The duration of symptoms for these women is usually approximately 1 week, and the onset is usually approximately 2 weeks or more after a menstrual period. This in contrast to what occurs in uncomplicated acute salpingitis, in which symptoms usually appear shortly after the

onset or cessation of menses. The typical symptoms are pelvic and abdominal pain, fever, nausea and vomiting, and tachycardia. Four-quadrant abdominal tenderness and guarding may be present. Adequate pelvic examination is often impossible because of tenderness, but an adnexal mass may be palpated. Culdocentesis may lacerate (rupture) a pelvic abscess, so this procedure must be performed with extreme caution, if at all.

Signs and symptoms of ruptured TOA may resemble those of any acute surgical abdomen. A careful history and an alert clinician are essential to ensure an accurate diagnosis. Signs of actual or impending septic shock frequently accompany a ruptured abscess and include fever (occasionally hypothermia), chills, tachycardia, disorientation, hypotension, tachypnea, and oliguria.

LABORATORY FINDINGS

Laboratory findings are generally of little value. The white count may vary from leukopenia to marked leukocytosis. Urinalysis may demonstrate pyuria without bacteriuria. Mean erythrocyte sedimentation rate of at least 64 mm/h and mean acute C-reactive protein level of at least 20 mg/L can assist in making the diagnosis of TOA. Monitoring these levels has proven useful in following disease course.

X-RAY FINDINGS

Plain films of the abdomen (kidneys, ureter, bladder [KUB]) usually demonstrate findings of a dynamic ileus and may arouse suspicion of adnexal mass. Free air may be seen under the diaphragm with ruptured TOA.

ULTRASONOGRAPHY

Ultrasonography is the radiologic modality of choice and can be used with fewer complications to the patient. It can be of great help in following the patient and detecting changes that may occur, such as progression, regression, formation of pus pockets, and rupture.

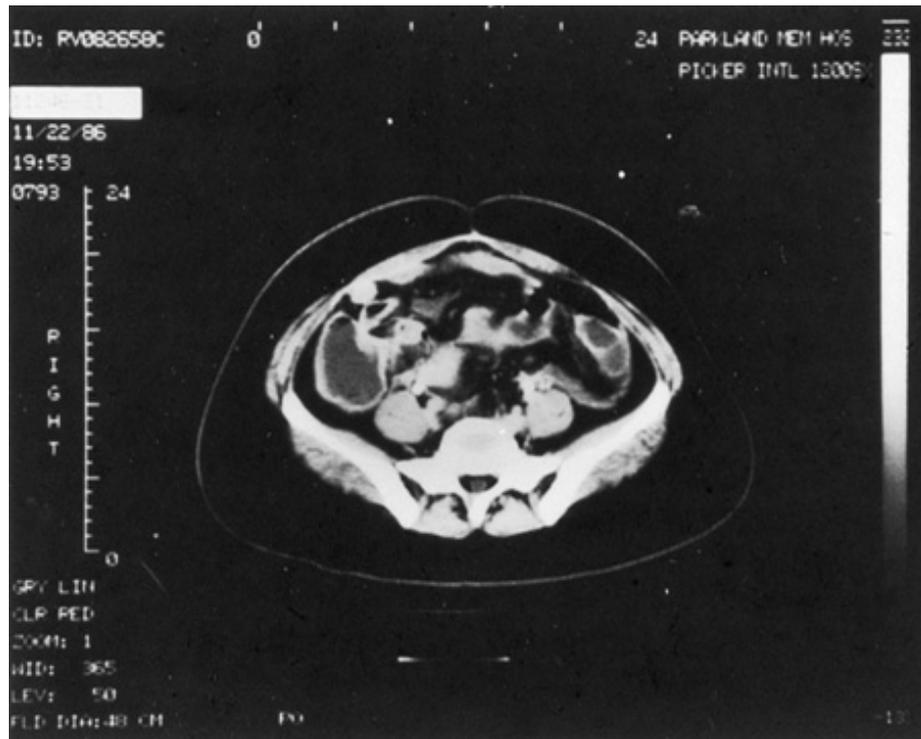

SPECIAL EXAMINATIONS

Culdocentesis fluid obtained in a woman with an unruptured TOA may demonstrate the same cloudy "reaction fluid" seen in acute salpingitis. With a leaking or ruptured TOA, however, grossly purulent material may be obtained.

Differential Diagnosis

An unruptured TOA must be differentiated from an ovarian cyst or tumor with or without torsion, unruptured ectopic pregnancy, periappendiceal abscess, uterine leiomyoma, hydrosalpinx, perforation of the appendix, perforation of a diverticulum or diverticular abscess, perforation of peptic ulcer, and any systemic disease that causes acute abdominal distress (eg, diabetic ketoacidosis, porphyria). If an abscess does not respond to medical therapy and colpotomy is not possible, CT or magnetic resonance imaging (MRI) scanning may disclose the cause (Fig 41–12).

Figure 41–12.

CT scan showing thickened appendix with intraluminal purulence. The source of this woman's pelvic abscess was a ruptured appendix.

Complications

Unruptured TOA may be complicated by rupture with sepsis, reinfection at a later date, bowel obstruction, infertility, and ectopic pregnancy.

Ruptured TOA is a surgical emergency and is frequently complicated by septic shock, intra-abdominal abscess (eg, subphrenic abscess), and septic emboli with renal, lung, or brain abscess.

Treatment

UNRUPTURED ASYMPTOMATIC TUBO-OVARIAN ABSCESS

Treatment is similar to that of chronic salpingitis: long-term antibacterial therapy and close follow-up. If the mass does not begin to subside within 15–21 days or becomes larger, drainage is indicated. At exploration, total hysterectomy and bilateral adnexectomy are usually performed; however, in selected cases, unilateral salpingo-oophorectomy or linear salpingostomy with copious irrigation and suction drainage may be considered (see Recurrent or Chronic Pelvic Infection).

UNRUPTURED SYMPTOMATIC TUBO-OVARIAN ABSCESS

Treatment consists of immediate hospitalization, bed rest in the semi-Fowler position, close monitoring of vital signs and urinary output, frequent gentle abdominal examination, nasogastric suction if necessary, and intravenous sodium-containing fluids. Intensive antimicrobial therapy should be instituted and should include either clindamycin or metronidazole because of their specific activity against anaerobes. The following combinations, given in appropriate intravenous doses, are recommended for these severely ill patients: penicillin G or ampicillin, and gentamicin plus metronidazole or clindamycin. One group of researchers suggests a regimen of 48–72 hours of triple antibiotics. If the patient demonstrates clinical

rupture (peritonitis), an increase in the size of the abscess, or persistent fever, she should be taken to the operating room.

Laparoscopy or laparotomy is mandatory in all cases of suspected leakage or rupture as well as in all cases that do not respond to medical management and percutaneous drainage.

If initial therapy is successful, the patient is maintained on antibiotics (eg, oral tetracycline 500 mg 4 times daily, or doxycycline 100 mg twice daily) for a minimum of 10–14 days and must have frequent follow-up examinations. If the abscess persists—and many do—laparotomy may be necessary. The reported incidence of surgery for clinically diagnosed, unruptured TOA varies from 30–100%. On one service, approximately 57% of cases undergo surgery, and the remaining 43% seemingly respond to aggressive medical management. A recent prospective study found that aggressive antimicrobial treatment with cefotaxime was successful in 95% of 40 women, with abscesses ranging in size from 4 x 4 cm to 13 x 15 cm. Only 12% of these patients underwent hysterectomy and bilateral adnexectomy 1–33 months following initial therapy because of a persistent adnexal mass. These patients did not wish to retain reproductive function. Of the remainder, 7 conceived and delivered a mean of 26 months after study entry; 6 of the 7 had bilateral abscesses at sonography. These data support the theory that conservative therapy can be successful.

RUPTURED TUBO-OVARIAN ABSCESS

This is an acute life-threatening catastrophe requiring immediate medical therapy associated with operation. The following steps may be necessary:

- (1) Monitoring of hourly urinary output with an indwelling catheter in place.
- (2) Monitoring of central venous pressure.
- (3) Administration of oxygen by mask.
- (4) Rapid replacement of fluid and perhaps blood to maintain blood pressure and ensure urine output of 30 mL/h.
- (5) Rapid evaluation and preparation for immediate operation. The patient's systemic deficiencies should first be corrected by intravenous fluids and blood if needed.
- (6) Surgical measures: The anesthesiologist must be well informed of the patient's condition. A low midline incision is made to allow for cephalad extension. When the abdomen is opened, pus is obtained for aerobic and anaerobic cultures. The bowel is inspected and all loculated abscesses identified and drained. The subphrenic and subhepatic spaces are explored and loculations lysed to allow drainage of pus. Careful irrigation and suction are performed to minimize spread of infection. Total hysterectomy and bilateral salpingo-oophorectomy were standard treatment; however, occasional supracervical hysterectomy may significantly shorten the operating time. The abscess wall is dissected from the adjacent structures. This is usually thick, indurated, and densely adherent to bowel, in which case it is best to dissect within the abscess wall, leaving a small portion of outer rim, rather than risk perforation of bowel wall. Careful surgical technique is necessary to avoid perforation of the bowel or ligation and transection of the ureters. The vaginal cuff is left open after a hemostatic interlocking continuous suture has been applied around the edge of the cuff.

Active drainage of the pelvis is performed routinely. Active suction through the abdominal wall provides the best result with the least contamination. The drains are left in place as long as purulent material is recovered. The fascia is closed with wide monofilament synthetic or wire sutures. Retention sutures may be used. The subcutaneous space is left open. In some cases, only drainage may be possible.

Prognosis

UNRUPTURED ABSCESS

Generally the patient with an unruptured abscess has an excellent prognosis. Medical therapy, followed by judicious surgical treatment, yields good results in most cases. Unruptured localized abscesses that do not respond to aggressive medical management by improvement in signs and symptoms and decreasing size are best drained or removed surgically if inaccessible to percutaneous or transvaginal drainage. Many clinically diagnosed unruptured TOAs may represent only acute salpingitis with omental and intestinal adhesions, which respond promptly to adequate antibiotic therapy. Serial ultrasonography may help to identify true unruptured TOAs. The outlook for fertility, however, is greatly reduced, ranging from 5–15% from retrospective analysis. There is also an increased risk for ectopic pregnancy. The risk of reinfection must be considered if definitive surgical treatment has not been performed, but the incidence of reinfection in our prospectively studied patient population is less than 10%.

RUPTURED ABSCESS

Before effective means of treating overwhelming septicemia became available and the need for immediate surgical intervention was recognized, the mortality rate from ruptured TOA was 80–90%. With modern therapeutic resources, both medical and surgical, the mortality rate should be less than 2%.

Postoperative Pelvic Infections

Essentials of Diagnosis

- Recent pelvic surgery.
- Pelvic or low abdominal pain or pressure.
- Fever and tachycardia.
- Purulent, foul discharge.
- Constitutional symptoms: malaise and chills.
- Vaginal cuff tenderness with cellulitis or abscess.

General Considerations

Patients who have undergone gynecologic surgery, especially hysterectomy, may develop postoperative infections of the remaining pelvic structures. These infections include simple cuff induration (cellulitis), infected cuff hematoma (cuff abscess), salpingitis, pelvic cellulitis, suppurative pelvic thrombophlebitis, and TOA with or without rupture. The incidence of such infections has been significantly reduced, from 32% after abdominal hysterectomy and 57% after vaginal hysterectomy in women given placebo to approximately 5% in women given a single dose of antimicrobial prophylaxis. It is important to note that severe pelvic abscess formation may occur following the relatively benign procedure of oocyte pickup used with in vitro fertilization.

The pathogenesis of posthysterectomy infection is simple and straightforward. The apex of the vaginal vault consists of crushed, devitalized tissue, and the loose areolar tissue in the parametrial areas usually oozes postoperatively. These conditions provide an ideal medium for the myriad of pathogens that normally inhabit the vagina and are inoculated into the operative site during surgery.

The term "pelvic cellulitis" implies that the soft tissue of the vaginal apex and adjacent parametrial tissues have been invaded by bacteria. In addition, the serum and blood at the cuff apex may become infected, resulting in an infected hematoma, which in essence is a cuff abscess. The infection is treated at this point by establishing adequate drainage combined with antibiotic therapy. Infection may extend via lymphatic channels to the adnexa, resulting in salpingitis. Pelvic veins may become involved in the infectious process, particularly if *Bacteroides* or anaerobic streptococci are predominant pathogens. Rarely, septic emboli to the lungs, brain, spleen, and elsewhere occur.

Clinical Findings

The diagnosis of postoperative pelvic infection is made clinically. Laboratory studies may be useful in establishing the specific etiologic diagnosis and determining the sensitivity of the recovered bacteria to various antibiotics.

SYMPTOMS AND SIGNS

Any postoperative gynecologic patient who develops fever may have atelectasis, phlebitis, upper urinary tract infection, or pelvic infection. These conditions may or may not require antimicrobial therapy. Although some investigators have stated that fever due to postoperative pelvic infection usually does not occur before the third or fourth postoperative day, up to 50% of patients develop temperatures of 38.3–39.4 °C (101–103 °F) by the 24th–36th postoperative hour. Recurrent temperature elevation without symptoms occurs a mean of 50 hours after hysterectomy in our patient population and disappears without therapy. Temperature elevations associated with symptoms and physical findings of infection occur later. The mean time of this diagnosis in our patients is approximately 80 hours. Patients who ultimately require parenteral antimicrobial therapy do not experience early asymptomatic temperature elevation.

Within 2 days following hysterectomy, the surgical margin of the vagina (vaginal cuff) appears hyperemic and edematous, and there is almost always a purulent or seropurulent exudate, regardless of the clinical condition of the patient and the presence of fever. When palpated, this site is usually indurated and tender—findings common to most healing wounds and not indicative of the need for antimicrobial therapy. When natural defense mechanisms of the host are inadequate for the inoculum, lymphatic extension of the infection to adjacent tissues results in pelvic cellulitis, demonstrable on pelvic examination as tender induration in the parametrial areas. The infection may involve the tubes and ovaries, with resultant abscess formation in unresponsive patients. At this point, the patient begins to complain of lower abdominal, pelvic, or back pressure or pain. Abdominal distention due to ileus may develop, as may urinary symptoms due to perivesical irritation.

The diagnosis of suppurative pelvic thrombophlebitis is rare and usually is not apparent until after the sixth postoperative day, at which time the patient continues to have hectic spiking fever of 39–40.5 °C (102.2–105 °F) with a diurnal variation. The pelvic findings are usually unrevealing except for mild pelvic tenderness. Surprisingly, the woman's general health often is good unless septic embolization has occurred. CT scan is the diagnostic tool of choice for these diagnoses.

An infected pelvic hematoma is impossible to palpate early, but it can be diagnosed by sonography. Recurring temperature elevation is the principal indicator of this type of infection. Rarely do these patients have symptoms, and their examination is usually unremarkable. This problem can be suspected when the hematocrit level is lower than anticipated. Onset frequently is the same time as when other pelvic infections begin.

LABORATORY FINDINGS

Unfortunately, the polymicrobial nature of these infections prohibits accurate identification of the offending microorganisms in a reasonable time. For this reason, broad-spectrum empirical antimicrobial administration is necessary.

Serial complete blood counts (CBCs) usually demonstrate leukocytosis but occasionally enable the physician to detect concealed hemorrhage, which may harbor a large pelvic abscess. Urinalysis is rarely helpful.

X-RAY FINDINGS

Chest films are unrevealing in most cases but can be useful if pulmonary complications are suspected.

ULTRASONOGRAPHY

Pelvic sonograms may prove helpful in detecting hematomas or either retroperitoneal or TOAs that develop as a complication of cuff infection.

Differential Diagnosis

Pulmonary atelectasis may become manifest within 12–36 hours after operation. This can usually be detected by auscultation and confirmed by chest x-ray film. Aspiration pneumonitis must always be considered if pulmonary problems develop.

Deep vein thrombophlebitis of the lower extremities is rarely detected clinically and, when present, is seldom accompanied by significant fever. Superficial phlebitis of the upper extremity due to an indwelling venous catheter may cause significant pyrexia. Long-term (48–72 hours) infusion of intravenous antimicrobials increases the likelihood of phlebitis. Routine changing of the intravenous site every 48 hours may prevent this complication, but if it develops it will respond to warm soaks and anti-inflammatory drugs, such as aspirin.

Upper urinary tract infection may account for the fever. Because of the liberal use of indwelling catheters in gynecologic surgery, significant bacteriuria commonly develops; however, this rarely causes fever unless pyelonephritis develops.

Fever from abdominal wound infection usually becomes manifest on or after the fourth postoperative day. Examination of the abdominal wound is mandatory in all febrile patients. Careful probing of the abdominal incision may be necessary, regardless of the incision's appearance, especially if the pelvic examination is unrevealing.

Complications

Complications of postoperative pelvic infection include extensive pelvic or intra-abdominal abscesses, TOA with or without rupture, intestinal adhesions and obstruction, septic pelvic thrombophlebitis with metastatic abscesses, and septicemia.

Prevention

Many attempts have been made to decrease infectious morbidity following gynecologic surgical procedures. None has been uniformly successful, but the following measures may be helpful:

- (1) Preoperative insertion of antibacterial vaginal creams or suppositories, especially if cervicitis, bacterial vaginosis, or vulvovaginitis is present.
- (2) Preparation of the vagina with hexachlorophene or povidone-iodine solution just prior to surgery.
- (3) Meticulous attention to hemostasis at operation and gentle handling of tissues. Use of large, strangulating hemostatic sutures should be avoided; nonreactive suture material should be used.
- (4) If hemostasis is less than desirable but is maximal under given circumstances, suction drainage of that area should be accomplished. This can be done with the vaginal surgical margin left open or closed at hysterectomy.
- (5) Antimicrobial prophylaxis beginning preoperatively has been shown by many to significantly reduce pelvic infectious morbidity following vaginal and abdominal hysterectomy. However, some controversy regarding this treatment still exists. Before prophylaxis is used, consider these guidelines. (a) Morbidity on a specific service should be significant enough to warrant attempts to decrease it. (b) Antimicrobials of relatively insignificant toxicity but proved value should be used. (c) The first dose should be given preoperatively to ensure adequate tissue concentrations at the time of surgery. Increasingly, studies show that a single preoperative dose is as effective as multiple doses in preventing major infection. Use of many different antimicrobials has been associated with dramatic lowering of pelvic infection morbidity

rates. Recent comparative studies indicate that the newer, more expensive semisynthetic cephalosporins and penicillins are more effective than the older agents. In otherwise uncomplicated cases, pelvic infections developing despite prophylaxis generally are mild in nature, although severe infections and resultant complications are not always prevented.

(6) Severe, more advanced infections may be prevented by early diagnosis, drainage (including an open vaginal cuff), and prompt treatment of mild infections.

Treatment

If a cuff hematoma or abscess is found, adequate drainage can be established by separating the apposed vaginal edges with ring forceps or some other suitable instrument. Care must be taken not to disrupt the intact peritoneum. The usual supportive measures are instituted, and antibiotic therapy is begun. Many of the newer semisynthetic cephalosporins and expanded spectrum penicillins have proved valuable as single-agent therapy for these infections. Rarely, the addition of metronidazole to these regimens is necessary to effect a cure.

In most cases, the patient with postoperative pelvic infection becomes afebrile within 48–72 hours. If a large, infected pelvic hematoma has developed, more prolonged treatment will be necessary. Large hematomas can be drained and irrigated from below by means of a Foley catheter or Penrose drain introduced into the abscess cavity. Suction drains should be used whenever possible.

A postoperative TOA is treated expectantly as outlined for unruptured TOA. If intra-abdominal rupture of a pelvic abscess or TOA is suspected, immediate laparotomy is indicated.

Persistent fever and clinical signs of unresponsiveness to therapy may indicate septic pelvic thrombophlebitis, which is generally a diagnosis of exclusion after a 7- to 10-day course of antibiotics. Intermittent intravenous heparin therapy, 5000 U every 4 hours, should be given. Persistence of fever in spite of heparin therapy suggests abscess formation. Abscesses—as well as septic thrombophlebitis—are usually associated with anaerobic bacteria, and antimicrobial therapy should include clindamycin or metronidazole in addition to other agents effective against aerobic microorganisms.

Pelvic Tuberculosis

Essentials of Diagnosis

- Infertility.
- Active or healed pulmonary tuberculosis.
- Findings by hysterosalpingography or laparoscopy.
- Recovery of *Mycobacterium tuberculosis* from either menstrual fluid or biopsy specimen.

General Considerations

In the United States, pelvic tuberculosis is becoming a rare entity. When it does occur, it usually represents secondary invasion from a primary lung infection via the lymphohematogenous route (Fig 41–6). The overall incidence of pelvic tuberculosis in patients with pulmonary tuberculosis is approximately 5%. Prepubertal tuberculosis rarely results in genital tract infection.

After the pelvic organs become affected (Fig 41–13), direct extension to adjacent organs may occur. Older studies in the United States indicated that the oviducts were most frequently involved (90%) and the endometrium next most frequently (70%). More recent studies in Scotland, where the disease is still prevalent, showed endometrial involvement in more than 90% of cases and tubal involvement in only 5%.

Figure 41–13.

Miliary tuberculosis involving the uterus and peritoneum.

Clinical Findings

SYMPTOMS AND SIGNS

The only complaint may be infertility, although dysmenorrhea, pelvic pain, and evidence of tuberculous peritonitis may also be present. Endometrial involvement may result in amenorrhea or some other disturbance of the cycle. Abdominal or pelvic pain from this infection is commonly associated with low-grade fever, asthenia, and weight loss. The diagnosis can usually be established on the basis of a complete history and physical examination, chest x-ray and lung scan, and appropriate tests such as a tuberculin (Mantoux) test, sputum smears, and sputum cultures. Tuberculosis of the female genital tract is usually secondary to hematogenous spread involving the endometrium, tubes, and ovaries. The manifestations are usually those of chronic pelvic disease and sterility. Gross ascites with fluid containing more than 3 g of protein per 100 mL of peritoneal fluid is characteristic of tuberculous peritonitis.

Pelvic tuberculosis is usually encountered in the course of a gynecologic operation performed for other reasons. Although pelvic tuberculosis may be mistaken for chronic pelvic inflammation, some distinguishing features usually can be found: extremely dense adhesions without planes of cleavage, segmental dilatation of the tubes, and lack of occlusion of the tubes at the ostia. If the internal genitalia are involved, with disseminated granulomatous disease of the serosal surfaces, ascites usually is present. Clinical diagnosis is difficult.

LABORATORY FINDINGS

The best direct method of diagnosis in suspected genital tuberculosis is detection of acid-fast bacteria by Ziehl-Neelsen stain followed by culture on Lowenstein-Jensen medium. The specimen may be from menstrual discharge, from curettage or biopsy, or from peritoneal biopsy in cases where ascites is present. A rapid sedimentation rate, peripheral blood eosinophilia, and a strongly positive Mantoux test are additional evidence of tuberculous infection.

X-RAY FINDINGS

Chest X-Ray Film

A chest x-ray film should be taken in any patient with proved or suspected tuberculosis of other organs or tissues.

Hysterosalpingography

The tubal lining may be irregular, and areas of dilatation may be present. Saccular diverticula extending from the ampulla and giving the impression of a cluster of currants are characteristic of granulomatous salpingitis. Other findings that should arouse suspicion are calcifications of the periaortic or iliac lymph nodes.

SPECIAL EXAMINATIONS

Visual inspection (laparoscopy) as well as aspiration of fluid for culture and biopsy of affected areas is possible and often diagnostic.

Differential Diagnosis

Pelvic tuberculosis should be differentiated from schistosomiasis, enterobiasis, lipoid salpingitis, carcinoma, chronic pelvic inflammation, and mycotic infections.

Complications

Sterility and tuberculous peritonitis are possible sequelae of pelvic tuberculosis.

Treatment

MEDICAL MEASURES

To prevent the emergence of drug-resistant strains, the initial therapy of tuberculous infection should include 4 drugs. The drug regimen for the first 2 months of treatment should include isoniazid, rifampin, pyrazinamide, and streptomycin or ethambutol. Once drug susceptibility results are available, the drug regimen can be appropriately changed. Treatment should be continued for 24–36 months because extrapulmonary tuberculosis is more difficult to eradicate.

SURGICAL MEASURES

The primary mode of treatment for pelvic tuberculosis is medical therapy; however, surgical intervention may be necessary. Medical therapy should be attempted for 12–18 months prior to evaluation for surgery. The ultimate indications for surgery include (1) masses not resolving with medical therapy, (2) resistant or reactivated disease, (3) persistent menstrual irregularities, and (4) fistula formation.

Prognosis

The prognosis for life and health is excellent if chemotherapy is instituted promptly, although the prognosis for fertility is poor.

Toxic Shock Syndrome

Essentials of Diagnosis

- Fever of 38.9 °C (102 °F) or higher.
- Diffuse macular rash.

- Desquamation (1–2 weeks after onset of illness; particularly affects palms and soles).
- Hypotension (systolic < 90 mm Hg for adults or orthostatic syncope).
- Involvement of 3 or more of the following organ systems: gastrointestinal, muscular, mucous membrane, renal, hepatic, hematologic, central nervous system.

General Considerations

Toxic shock syndrome was first described in children in 1978 but was quickly identified as an illness occurring primarily in menstruating women 12–24 years of age. An association with use of superabsorbent tampons was made by the CDC. The majority of cases have occurred in California, Minnesota, Wisconsin, Utah, and Iowa. Peak incidence was reported in August 1980. Whether the abrupt decline in incidence has been the result of changes in tampon use, improvements in manufacture, or reduction in disease severity due to early recognition is not known. Of the approximately 30 million menstruating women in the United States, it is estimated that 70% use tampons and more than 50% of those women use superabsorbent types. Almost 1 million women are at theoretic risk. The incidence in menstruating women is now 6–7:100,000 annually. Toxic shock syndrome has also been reported in women after delivery and in those using a diaphragm, in men and women following surgical procedures, or in patients with soft-tissue abscesses or osteomyelitis. The incidence of nonmenstrual disease has increased only slightly in the past 10 years.

The cause of toxic shock syndrome is preformed toxins produced by *Staphylococcus aureus* so that colonization or infection by this microorganism must occur. A pyrogenic toxin induces high fever and may enhance susceptibility to endotoxins that cause shock as well as liver, kidney, and myocardial damage. Other unrecognized toxins may play a role. How toxins gain access to the circulatory system is unknown. Tampon use has been associated with this syndrome, but evidence for the mechanism of toxin entry remains obscure. Insertion could cause mucosal damage. Vaginal ulcerations due to pressure changes usually are not observed, although vaginal erythema commonly is present. Superabsorbent tampons may obstruct the vagina, resulting in retrograde menstruation and peritoneal absorption of bacteria or toxin. Tampons may be associated with increased numbers of aerobic bacteria due to oxygen trapped in interfibrous spaces. The longer a tampon is left in place, the greater the risk for development of this syndrome.

Clinical Findings

SYMPTOMS AND SIGNS

Onset is usually sudden, with high fever, watery diarrhea, and vomiting—the triad often seen with viral gastroenteritis. Myalgia, headache, and sometimes sore throat may be present as well as erythroderma and conjunctivitis, as frequently seen with viral infections. Unlike most viral infections, however, this disorder may progress to hypotensive shock within several hours (usually < 48 hours). Timely diagnosis is critical, and the key is the fact that the woman is menstruating or using tampons. The patient will appear acutely ill, with a fever of 39 °C (102.2 °F) or higher. An erythematous, sunburnlike rash is seen over the face, proximal extremities, and trunk. Dehydration is evident, and the patient will have tachycardia and perhaps hypotension. The conjunctiva will be erythematous as will the pharynx, and usually muscle and abdominal tenderness is noted. A vaginal examination must be performed; if a tampon is present, it must be removed. Mucosal lesions should be sought, and a culture for *S aureus* performed. If nuchal rigidity, headache, or disorientation unexplained by hypotension or fever is present, a lumbar puncture must be performed to rule out meningitis. During convalescence, desquamation can be striking.

LABORATORY FINDINGS

Tests should include a CBC with differential, electrolyte measurements, urinalysis, urea nitrogen measurement, creatinine measurement, and hepatic function tests. Other tests are performed as indicated by clinical symptoms and signs. Cultures should be made of blood, throat secretions, and probably CSF. A vaginal culture will yield penicillinase-producing *S aureus*.

Differential Diagnosis

Other systemic diseases characterized by rash, fever, and systemic complications should be considered. Most patients will not have an obvious source of infection such as a recent incision, soft-tissue abscess, or osteomyelitis, but these should be sought. Kawasaki's disease of young children is similar but not as severe, as hypotension, renal failure, and thrombocytopenia do not occur and the incidence of myalgia, diarrhea, and hepatic damage is greatly decreased. Scarlet fever must be excluded. Rocky Mountain spotted fever, leptospirosis, and measles can be excluded by appropriate serologic tests. Gram-negative sepsis must be excluded by both blood and CSF cultures.

Complications

Approximately 30% of women who develop toxic shock syndrome have recurrences. The greatest risk for recurrence is during the first 3 menstrual periods following treatment, and the recurrent episode may be less or more severe than the initial one. The incidence is reduced to less than 5% if antistaphylococcal antibiotic therapy is given during therapy of the initial occurrence. Half of the women who developed this disease in Wisconsin during the infancy of its recognition have experienced 3 recurrences. Cervicovaginal and nasal cultures for *S aureus* should be negative twice, 4 weeks apart, prior to resumption of tampon use. Women can almost entirely eliminate the risk of this illness by not using tampons and may substantially reduce the risk by using tampons only intermittently during menstruation.

Treatment

Aggressive supportive therapy is imperative for a successful outcome. Appropriate initial management begins with fluid and electrolyte resuscitation—up to 12 L/d. Packed red blood cells and coagulation factors may be necessary. Central venous or pulmonary wedge pressures and urine output must be monitored to guide therapy. Laboratory studies and appropriate cultures must be obtained early. Dopamine infusion at 2–5 µg/kg/min may be necessary if fluid volume alone does not correct hypotension. Mechanical ventilation may be necessary if acute respiratory syndrome develops, and hemodialysis may be necessary if renal failure develops. Corticosteroid therapy (methylprednisolone 30 mg/kg or dexamethasone 3 mg/kg as a bolus and repeated every 4 hours as necessary), if instituted early, may reduce the severity of illness and duration of fever. Naloxone has resulted in reversal of hypotension in seriously compromised patients by antiendorphin activity. Although *S aureus* is not present in the blood, treatment with a β-lactamase-resistant antibiotic such as nafcillin or oxacillin (2 g IV every 4 hours) should be given. If penicillin allergy is present, vancomycin should be given. Dose reduction is necessary with renal impairment. Until gram-negative sepsis has been excluded, an aminoglycoside should be included with caution because of altered renal function. The mortality rate associated with toxic shock syndrome is 3–6%. The 3 major causes of death are acute respiratory distress syndrome, intractable hypotension, and hemorrhage secondary to disseminated intravascular coagulopathy.

Human Immunodeficiency Virus Infection

Essentials of Diagnosis

ASYMPTOMATIC INFECTION

- HIV antibody, antigen, or ribonucleic acid or culture.
- High-risk group member.

- Mononucleosis-like syndrome with weight loss, fever, night sweats.
- Neurologic involvement.
- Lymphadenopathy.
- Pharyngitis.
- Erythematous maculopapular rash.
- Extragenital lymphadenopathy.

ACQUIRED IMMUNODEFICIENCY SYNDROME (AIDS)

- HIV antibody, antigen, ribonucleic acid, or culture.
- Any of the above signs or symptoms of asymptomatic infection.
- Opportunistic infections.
- Cognitive difficulties or depression.
- Kaposi's sarcoma.
- CD4⁺ counts below 200 CD4 lymphocytes/mm³.
- Cervical neoplasia.

General Considerations

The World Health Organization (WHO) and The Joint United Nations Program on HIV/AIDS (UNAIDS) estimate that the total number of people living with HIV worldwide in 2005 is just over 40 million. Worldwide, women represent half of the people infected with HIV. Globally, fewer than 1 in 5 people at risk for becoming infected with HIV has access to basic prevention services. Only 1 in 10 people living with HIV has been tested and knows his or her HIV status. According to 2003 data, the CDC estimates that up to 1,185,000 persons in the United States were living with HIV/AIDS. In 2004, 25% of all AIDS diagnoses in the United States were made in women. The best estimates of the incidence of HIV infection in the United States are likely to come from ongoing serologic surveillance studies in sentinel areas and hospitals. In the general population, HIV infection is most prevalent in gay or bisexual men, intravenous drug abusers, and hemophiliacs. The high-risk groups of women are intravenous drug abusers, those with heterosexual contacts with men in high-risk groups, recipients of unscreened transfusions, and prostitutes.

Over 80% of the female AIDS cases occur in women of reproductive age, making heterosexual and perinatal transmission important concerns. Minorities are disproportionately represented in the reported AIDS cases. Most HIV infections in the United States are due to HIV-1. The prevalence of HIV-2 in this country is very low. HIV-2 is endemic in parts of West Africa and has been reported increasingly in Angola, Mozambique, Portugal, and France.

Modes of Transmission

Although there has been much speculation about the modes of HIV transmission, HIV infection can be acquired in only 3 ways.

First, HIV infection can be acquired by sexual contact. Transmission has been reported from male to male, male to female, female to male, and, recently, female to female. The risk appears to be greatest for the female sexual partners of men with AIDS, followed in decreasing order by intravenous drug abusers, bisexual men, transfusion recipients, and hemophiliacs. Other factors that increase the risk for

heterosexual acquisition of HIV infection are the number of exposures to high-risk sexual partners; anal-receptive intercourse; and infection with other STDs such as syphilis, genital herpes, chancroid, and condylomata acuminata.

The second means by which HIV transmission can occur is by parenteral exposure to blood or bodily fluids, such as with intravenous drug use or occupational exposure.

The third means by which HIV infection can occur is by transmission from an infected woman to her fetus or infant.

Course of Infection

The chance of acquiring HIV infection through sexual contact is unknown. In women in the United States, approximately 40% of the reported cases appear to be acquired through heterosexual contact; some of the cases without risk factors may be heterosexually acquired. The percentage of cases arising from heterosexual contact is significantly larger in women than in men, probably because transmission can occur more easily from male to female. This is due to 2 reasons: (1) the concentration of HIV in semen is high, and (2) coitus causes more breaks in the introital mucosa than in the penile skin. It is hypothesized that these breaks in the mucosa, similar to those that occur with anal-receptive intercourse, increase the chances for acquiring HIV through sexual contact. The presence of a genital ulcerative disease also increases the risk of infection in a similar fashion.

The natural course of HIV infection is becoming better understood. HIV is a single-stranded RNA-enveloped retrovirus that attaches to the CD4 receptor of the target cell and integrates into the host genome. Most patients who become infected develop anti-HIV antibody within 12 weeks and 95% within 6 months after exposure. As many as 45–90% of patients develop an acute HIV-induced retroviral infection in the first few months after infection. This is similar to mononucleosis, with symptoms of weight loss, fever, night sweats, pharyngitis, lymphadenopathy, erythematous maculopapular rash, and extragenital lymphadenopathy. Critical awareness of this acute syndrome is important because of improved prognoses associated with early antiretroviral treatment. This syndrome usually resolves within several weeks, and the patient becomes asymptomatic. HIV-infected individuals ultimately show evidence of progressive immune dysfunction, and the condition progresses to AIDS as immunosuppression continues and systemic involvement becomes more severe and diffuse. AIDS develops in the majority of untreated HIV-infected individuals within 17 years after contracting the virus. All women diagnosed with HIV require counseling, an extensive STD work-up, Pap smear, CBC, chemistry panel, toxoplasma antibody, hepatitis panel, purified protein derivative, and chest radiograph. All patients should be offered vaccinations for hepatitis B, influenza, and pneumococcus. The CDC case definition of AIDS is an HIV-infected person with a specific opportunistic infection (eg, *Pneumocystis carinii* pneumonia, central nervous system toxoplasmosis), neoplasia (eg, Kaposi's sarcoma), dementia, encephalopathy, wasting syndrome, rapid progression of cervical dysplasia to cancer, or CD4 lymphocyte count less than 200/mm³. A patient without laboratory evidence of infection may also be diagnosed with AIDS if one of the indicator diseases is present and there is no explanation for the immune dysfunction.

Unfortunately, the mortality rate for patients with established AIDS is high and at present does not appear to be altered by antiviral agents such as zidovudine. Further research in the development of antivirals and vaccines is in progress.

Prevention

"Safer sex" guidelines have been established to decrease the risk of acquiring HIV infection through sexual contact. These guidelines include a reduction in the number of sexual partners, especially those who are in high-risk groups, and use of condoms for all coital activity. Latex condoms are the most

effective. Condoms lubricated with spermicides such as nonoxynol 9 are no more effective than other lubricated condoms in protecting against transmission of HIV. In addition, recent data indicate that nonoxynol 9 may increase the risk for HIV transmission during vaginal intercourse, possibly via development of genital lesions that have been associated with nonoxynol 9 use.

Education and counseling for detection of HIV-infected patients and prevention of HIV infection are difficult tasks. HIV infection in women appears to be a disease of drug users and sexual partners of high-risk men. Groups to whom information must be targeted are intravenous drug users and ethnic minorities, particularly blacks and Hispanics. Counseling must not only stress behavior modification but also reinforce those behavioral changes through culturally significant and sensitive messages. In general, reduction of high-risk behavior and use of safer sex guidelines have been the two main areas of education and counseling.

The general preventive guidelines for seropositive women include the following:

- (1) Refraining from donating blood, plasma, organs, or tissue.
- (2) Being in a mutually monogamous sexual relationship.
- (3) Using condoms with spermicide.
- (4) Avoiding pregnancy.

HIV Infection during Pregnancy

Maternal transmission of HIV can occur transplacentally before birth, peripartum by exposure to blood and bodily fluids at delivery, or postpartum through breastfeeding. Hence, all pregnant women should be offered HIV testing. In the absence of any intervention, an estimated 15–30% of mothers with HIV infection will transmit the infection during pregnancy and delivery, and 10–20% will transmit the infection through breast milk. Vertical transmission of HIV-1 occurs mostly during the intrapartum period (50–70%) but also can occur in the antepartum period (15–30%), especially in untreated women who seroconvert during pregnancy. The risk appears to be higher in subsequent pregnancies if a patient has delivered 1 infected infant; in this setting the risk may be 37–65%. The mode of delivery may play a role in increasing or decreasing the risks of developing pediatric AIDS. It is recommended that membranes not be ruptured longer than 4 hours. Fetal scalp electrodes and scalp sampling are contraindicated.

Many of the concerns about the effect of pregnancy on HIV infection are unanswered. Does the altered immune status of pregnancy accelerate the progression of HIV infection? Clinically, progression from asymptomatic infection to AIDS is uncommon in pregnancy. However, 45–75% of women will develop symptomatic HIV infection within 2–3 years postpartum if their child was infected. Whether this represents an accelerated progression of HIV infection or demonstrates more effective perinatal transmission in women with longstanding infection is unknown. Diagnosis of acute HIV infection may be delayed because some of the symptoms of early HIV infection may mimic those of the first trimester of pregnancy.

Prenatal care must be individualized, with referral to support systems ideally occurring during the pregnancy rather than postpartum. Screening for other STDs (eg, syphilis, gonorrhea, and HSV infection) is important. Other specific HIV-related infections must be sought, including *P carinii* pneumonia, *Mycobacterium tuberculosis*, cytomegaloviral infection, toxoplasmosis, and candidiasis. At a minimum, HIV-infected patients should undergo shielded chest radiography, a tuberculin skin test with controls, and cytomegalovirus and toxoplasmosis baseline serologic tests. Susceptible patients should receive hepatitis B virus, pneumococcal, and influenza vaccines. CD4⁺ lymphocyte cell counts should be monitored each trimester. A CD4⁺ count less than 200/mm³ is an indication for prophylaxis against *P carinii* pneumonia.

Plasma viral load (HIV-1 RNA) is also monitored throughout pregnancy. HIV-1 RNA levels should be monitored every 3–4 months or every trimester. In addition, the levels should be evaluated at 34–36 weeks to determine mode of delivery.

Zidovudine (ZDV) administered during the second and third trimesters, during labor, and for 6 weeks to the newborn has been shown to decrease vertical transmission from 25–30% to 5–8%. Newer protocols that use a combination of drugs are now being used and compose what is referred to as highly active anti-retroviral therapy (HAART). HAART in patients has been shown to reduce the overall transmission to 1.2–1.3%. The 3 main classes of drugs used in HAART are nucleoside analogue reverse transcriptase inhibitors, non-nucleoside reverse transcriptase inhibitors (NNRTIs), and protease inhibitors. Perinatal transmission rates appear to have declined even further with use of HAART. Pregnant women should be treated according to standard guidelines for antiretroviral therapy in adults, with the goal being reduction of plasma viral load (plasma HIV-1 RNA). However, specific recommendations for antiretroviral treatment in pregnant patients continue to evolve, so all pregnant patients with HIV infection should be under the supervision of experts in the management of HIV in pregnancy. Although individual treatment regimens may vary, ZDV plus lamivudine (3TC) are the recommended dual nucleoside reverse transcriptase inhibitor (NRTI) backbone for pregnant women. Nevirapine is an NNRTI that should be initiated in pregnant women with CD4⁺ counts greater than 250 cells/mm³.

Data suggest that cesarean section prior to onset of labor and rupture of membranes further decreases the risk of vertical transmission. However, the bulk of these data were obtained prior to the routine use of viral load testing and combination antiretroviral therapy. More recent data suggest that the risk of vertical transmission is proportional to the viral load. In 2 separate analyses, when the viral load was less than 1000 copies per milliliter, the perinatal transmission rate was zero (upper limits of 95% confidence interval were 2.8% and 5.1%). Therefore, it is reasonable to offer scheduled cesarean section prior to onset of labor and rupture of membranes to HIV-infected women with viral loads greater than 1000 copies per milliliter. The American College of Obstetricians and Gynecologists (ACOG) recommends that a scheduled cesarean section be performed at 38 weeks' gestation in order to prevent HIV transmission. For patients receiving ZDV, adequate levels of the drug in the blood should be achieved if the infusion is begun 3 hours preoperatively. The increased maternal morbidity associated with cesarean section must be taken into account, however, when making decisions regarding mode of delivery. Whether cesarean section is beneficial when the mother has received HAART and/or has low to undetectable viral loads is unclear. Also unclear is whether cesarean section after rupture of membranes or onset of labor confers a decrease in HIV transmission.

Peripartum care should include universal application of infection control guidelines to prevent exposure to blood and bodily fluids. These measures include water-repellant gowns, double gloves, handwashing between patient contacts, goggles for significant splash exposures, and wall or bulb suction. Needles should not be recapped. A 1:10 sodium hypochlorite solution should be used to clean instruments. Fetal scalp sampling and scalp electrodes should be avoided because they could become portals of entry for infection.

Postpartum care should entail a continuance of blood and bodily fluids precautions with proscription of breastfeeding. Family planning and safer sex counseling can be continued in the postpartum period with consideration given to tubal ligation. Medical and support system referrals should be initiated prior to discharge from the hospital, if possible.

Pediatric HIV Infection

As of 2004, approximately 93% of pediatric AIDS cases in the United States were perinatally acquired, occurring in infants born to women in high-risk groups (intravenous drug users, partners of high-risk

men, and women with AIDS). The progression to infection appears to be faster than in adults, and pediatric AIDS carries a mortality rate similar to that in adults.

Identification of infected neonates is difficult because maternal anti-HIV IgG crosses the placenta. Thus, most infants are born with HIV seropositivity, which may persist up to 15 months by the enzyme immunoassay technique. Nucleic acid or antigen HIV studies are necessary to help identify fetal infection. An HIV embryopathy similar to the fetal alcohol syndrome has been described. Because many the high-risk mothers have multifactorial perinatal problems, assigning the cause of the syndrome to HIV is uncertain.

Infant care involves many of the same guidelines as for maternal peripartum care. Blood and bodily fluid precautions, as well as immunosuppression care guidelines, should be exercised. Consultation with a pediatric immunologist to plan neonatal and follow-up care should begin prior to discharge from the hospital. Circumcision should be discouraged. Prior to discharge, detailed home-care instruction regarding avoidance of bodily secretions should be given.

Guidelines for HIV Testing

HIV serologic testing should include pretest and posttest counseling about interpretation of test results. After obtaining informed consent from the patient, confidentiality must be maintained concerning the test results. Situations in which HIV testing should be offered include the following:

- (1) Women who have used intravenous drugs.
- (2) Women who have engaged in prostitution.
- (3) Women with sex partners who are HIV-infected or are at risk for HIV infection.
- (4) Women who have STDs.
- (5) Women who have lived in communities or were born in countries where the prevalence of HIV infection (especially heterosexually acquired HIV infection) among women is high.
- (6) Women who received blood transfusions between 1978 and 1985.
- (7) Women undergoing medical evaluation or treatment for clinical signs and symptoms of HIV infection.
- (8) Women who have been inmates in correctional systems.
- (9) Women who consider themselves at risk.
- (10) Pregnancy: In 2003, the CDC revised its guidelines to recommend the opt-out approach whereby pregnant women have the option of declining universal HIV testing as part of routine prenatal blood tests.

HIV Antibody Testing

The diagnosis of HIV infection is usually by HIV-1 antibody tests. Routine testing for HIV-2, other than at blood banks, is currently not recommended unless a patient is at risk for HIV-2 infection or has clinical findings of HIV disease and has had a negative HIV-1 antibody test. Refer to recent reviews cited in the references for details of the criteria for HIV antibody detection. In general, the ELISA functions as a screening test for exposure to HIV. Most patients exposed to HIV develop detectable levels of antibody against the virus by 12 weeks after exposure. The presence of antibody indicates current infection, although the patient may be asymptomatic for years. The sensitivity and specificity of the ELISA test is 99% when it is repeatedly reactive. Thus, the test for HIV antibody is considered negative if the ELISA is nonreactive, and it indicates a lack of HIV infection unless the period is too early for detection of antibody production.

The probability of a false-negative test in an uninfected woman is remote unless she is in the "window" before antibody is produced. A positive test result occurs when an ELISA is repeatedly reactive followed by a positive Western blot assay. The Western blot assay is reactive when a critical pattern of specific antibodies is detected against the 3 main gene products of HIV. The probability that an abnormal testing sequence will falsely identify a patient as HIV-infected is less than 1 in 100,000 to 5 in 100,000 persons. Individuals in high-risk groups should be retested in 3 months; they are likely to become positive. The status of those without associated risk factors is likely to remain indeterminate, but persistent indeterminate status is not diagnostic of HIV infection.

Rapid HIV testing can be used to identify HIV infection in women who arrive at labor and delivery with undocumented HIV status and to provide an opportunity to begin prophylaxis of previously undiagnosed infection before delivery. Test results are available within a few hours. Most rapid assays have a sensitivity and specificity comparable to ELISA.

Current OB/GYN > Chapter 42. Antimicrobial Chemotherapy >

ANTIMICROBIAL CHEMOTHERAPY

Although microbial infection has always been a threat to obstetric and gynecologic patients, gratifying developments in antimicrobial therapy have led to decreases in puerperal and postoperative morbidity and perinatal mortality.

PRINCIPLES OF SELECTION OF ANTIMICROBIAL DRUGS

Several special conditions are pertinent to most infections encountered in obstetric and gynecologic practice. First, patients (except for some elderly and some oncology patients) are generally healthy and free of debilitating illness. Second, most infections, such as postpartum or postoperative infection and pelvic inflammatory disease, are polymicrobial in origin, involving an array of aerobes, anaerobes, genital mycoplasmas, and, in some conditions, *Chlamydia trachomatis*. Third, when a clinical diagnosis of infection is made, empiric antibiotic therapy is usually indicated before culture results are available. Fourth, because of limitations in laboratory technique, culture results may not be available in a timely fashion, or tests may not even be performed at all.

To serve as a guide to antibiotic selection, 4 tables are provided. Table 42–1 provides the classification of β -lactam and related antibiotics. Table 42–2 provides a classification of antibiotics commonly used in obstetric and gynecologic practice and their main adverse effects, both in the adult and in the fetus. Table 42–3 shows recommended drugs and alternatives for suspected or proved etiologic microorganisms. Table 42–4 shows appropriate selections by clinical diagnosis.

Table 42–1. Classification of β -Lactam and Related Antibiotics.

Group	Selected Members
Natural penicillins	Penicillin G, penicillin V
Antistaphylococcal penicillins	Methicillin, nafcillin, oxacillin, dicloxacillin
Aminopenicillins	Ampicillin, amoxicillin
Antipseudomonas penicillins	Carbenicillin, ticarcillin
Extended-spectrum penicillins	Mezlocillin, piperacillin
Amidino penicillins	Mecillinam
Penicillin/ β -lactamase inhibitor combinations	Amoxicillin/clavulanic acid (Augmentin) Ticarcillin/clavulanic acid (Timentin) Ampicillin/sulbactam (Unasyn) Piperacillin/tazobactam (Zosyn)
First-generation cephalosporins	Cephalothin (Keflin)

Group	<p>Selected Members</p> <p>Cefazolin (Ancef, Kefzol)</p> <p>Cephalexin (Keflex)</p> <p>Cephradine (Velosef, Anspor)</p> <p>Cephapirin (Cefadyl)</p> <p>Cefadroxil (Duricef, Ultracef)</p>
Second-generation cephalosporins	<p>Cefamandole (Mandol)</p> <p>Cefoxitin (Mefoxin)</p> <p>Cefotetan (Cefotan)</p> <p>Cefuroxime (Zinacef)</p> <p>Cefaclor (Ceclor)</p> <p>Cefonacid (Monicid)</p> <p>Cefmetazole (Zefazone)</p>
Third-generation cephalosporins	<p>Cefotaxime (Claforan)</p> <p>Cefoperazone (Cefobid)</p> <p>Moxalactam (Moxam)</p> <p>Ceftizoxime (Ceftizox)</p> <p>Ceftriaxone (Rocephin)</p> <p>Ceftazadime (Fortaz)</p> <p>Cefixime (Suprax)</p>
Carbapenems	Imipenem
Monobactam	Aztreonam

Table 42–2. Classification of Antibiotics Commonly Used in Obstetric-Gynecologic Practice and Their Adverse Effects.

Main Adverse Effect		
Antibiotic	Adult	Fetus
Penicillins	Allergic reaction	None known
Cephalosporins	Allergic reaction	None known
Monobactams		
Aztreonam	Rash, abnormal serum transaminases	None known
Carbapenems		
Imipenem	Allergic reaction; seizures rarely	None known
Macrolides		
Erythromycins ¹	GI ²	None known
Clarithromycin (Biaxin)	Interaction with some antihistamines	
Azithromycin	GI	None known
Tetracyclines	GI, hepatotoxicity, renal failure (rarely)	Discoloration of teeth; abnormal bone growth
Clindamycin	GI pseudomembranous colitis ³	None known
Aminoglycoside		
Gentamicin	Oto- and nephrotoxicity, increased neuromuscular blockade	Ototoxicity reported with other aminoglycosides
Folate antagonists		
Trimethoprim-sulfamethoxazole	Rash, GI, allergic reaction	Possibly teratogenic due to inhibition of folate metabolism
Metronidazole	GI, alcohol intolerance, CNS at high doses	None known
Vancomycin	Allergic reaction; rare hearing loss; hypotension if given rapidly	None known
Quinolones	GI, headache, dizziness	Possible, due to inhibition of DNA gyrase

¹Erythromycin esolate may be hepatotoxic.

²GI = gastrointestinal side effects.

³Pseudomembranous colitis may result from use of any antibiotic.

Table 42–3. Recommended and Alternative Drugs Used to Treat Commonly Encountered Organisms in Obstetric-Gynecologic Practice.

Suspected or Proved Etiologic Agent	Recommended Drug(s)	Alternative Drug(s)
Gram-negative cocci		
Gonococci	Cefixime, ceftriaxone, ciprofloxacin, ofloxacin	Spectinomycin, other single-dose cephalosporins; other single-dose quinolones (also treat <i>C trachomatis</i>)
Gram-positive cocci		
Pneumococci (<i>Streptococcus pneumoniae</i>)	Penicillin ¹	Vancomycin, clindamycin, clarithromycin
<i>Streptococcus</i> , hemolytic, groups A, C, G	Penicillin ¹	Erythromycin, ² cephalosporin, clindamycin, vancomycin
Group B <i>Streptococcus</i>	Penicillin, ¹ ampicillin	Erythromycin, ² clindamycin, vancomycin, cephalosporins
<i>Streptococcus viridans</i>	Penicillin ¹ ± aminoglycosides	Cephalosporin, vancomycin
<i>Staphylococcus</i> , penicillinase-producing	Penicillinase-resistant penicillin	Vancomycin, cephalosporin
<i>Streptococcus faecalis</i>	Ampicillin + aminoglycoside	Vancomycin
Gram-negative rods		
<i>Acinetobacter</i> (Mima-Herellea)	Aminoglycoside ± imipenem	TMP-SMX ³
<i>Bacteroides</i> , oropharyngeal strains	Penicillin, ¹ clindamycin	Metronidazole, cephalosporin
<i>Bacteroides</i> , gastrointestinal and pelvic strains	Metronidazole, clindamycin	Cefoxitin, chloramphenicol, cefotetan
<i>Enterobacter</i>	Newer cephalosporins	Aminoglycoside, TMP-SMX ³
<i>Escherichia coli</i> (sepsis)	Aminoglycoside ± cephalosporin or extended spectrum penicillin	Some second- or third-generation cephalosporins, TMP-SMX ³
<i>Escherichia coli</i> (first urinary tract infection)	TMP-SMX, ³ TMP	Cephalosporin, nitrofurantoin
<i>Klebsiella</i>	Newer cephalosporins, aminoglycoside	TMP-SMX ³
<i>Proteus mirabilis</i>	Ampicillin, amoxicillin	Newer cephalosporins, aminoglycoside, TMP-SMX, ³ quinolones
<i>Proteus vulgaris</i> and other species	Newer cephalosporins	Aminoglycoside

Suspected or Proved Etiologic Agent	Recommended Drug(s)	Alternative Drug(s)
<i>Pseudomonas aeruginosa</i>	Aminoglycoside + ticarcillin	Newer cephalosporins ± aminoglycoside
<i>Serratia, Providencia</i>	Newer cephalosporins, aminoglycoside	TMP-SMX ³
Gram-positive rods		
<i>Actinomyces</i>	Penicillin ¹	Tetracycline ⁴
<i>Clostridium</i> , (eg, gas gangrene, tetanus)	Penicillin, ¹ clindamycin	Metronidazole
<i>Listeria</i>	Ampicillin ± aminoglycoside	TMP-SMX ³
Mycoplasma	Tetracycline ⁴	Erythromycin (for <i>U urealyticum</i>); Clindamycin (for <i>M hominis</i>)

± = alone or combined with.

¹Penicillin G is preferred for parenteral injection; penicillin V for oral administration, to be used only in treating infections due to highly sensitive organisms.

²Erythromycin estolate is best absorbed orally but should be avoided in pregnancy because of risk of hepatotoxicity.

³TMP-SMX is a mixture of 1 part trimethoprim and 5 parts sulfamethoxazole.

⁴All tetracyclines have similar activity against microorganisms. Dosage is determined by rates of absorption and excretion of various preparations. Tetracyclines should not be used in pregnancy.

Table 42–4. Drugs Used to Treat Suspected or Proved Infections.

Suspected or Proved Infection	Recommended Drug(s)	Alternative Drug(s)
Sexually Transmitted Infections		
Syphilis	Benzathine penicillin	A tetracycline
Genital herpes	Acyclovir, famciclovir, valacyclovir	
Gonorrhea	See Table 42–3	
<i>C trachomatis</i>	Azithromycin, tetracycline	Erythromycin, ofloxacin; amoxicillin or clindamycin in pregnancy
Pelvic inflammatory disease	Cefoxitin (or alternate) plus doxycycline OR clindamycin plus gentamicin for parenteral treatment; ofloxacin plus metronidazole OR ceftriaxone (or alternate) plus doxycycline for oral treatment.	See CDC Guidelines for multiple alternatives. ¹

Suspected or Proved Infection	Recommended Drug(s)	Alternative Drug(s)
Vaginitis		
Trichomonas vaginalis	Metronidazole	
Candidiasis	Topical imidazoles; fluconazole	
Bacterial vaginosis	Metronidazole, clindamycin	
Obstetric Infection		
Puerperal endometritis	Clindamycin plus gentamicin	Several including cefoxitin or cefotetan; ampicillin plus sulbactam
Clinical chorioamnionitis	Ampicillin plus gentamicin, plus clindamycin if cesarean delivery	As for endometritis
Sepsis	Clindamycin plus gentamicin, plus ampicillin	Metronidazole plus gentamicin, plus ampicillin
Pyelonephritis, first episode	Ceftriaxone, TMP-SMX, ² ofloxacin or ciprofloxacin	Third-generation cephalosporin
Urinary Tract Infection		
Recurrent	Ampicillin plus gentamicin	Same
Gynecologic Infection		
Posthysterectomy cuff infection	As for endometritis	As for endometritis
Abdominal wound infection	Drainage with or without antibiotics as for endometritis	

¹Reproduced, with permission, from Centers for Disease Control and Prevention: 1998 guidelines for treatment of sexually transmitted diseases. MMWR Recomm Rep 1998; 47: (RR-1).

²TMP-SMX is a mixture of 1 part trimethoprim and 5 parts sulfamethoxazole.

The following steps merit consideration in each patient.

ETIOLOGIC DIAGNOSIS

The physician must attempt to decide on clinical grounds (1) whether the patient has a microbial infection that might be influenced by antimicrobial drugs and (2) the most probable infectious agent causing the disorder ("best guess") (Table 42-4).

"BEST GUESS"

Based on a best guess about the probable cause of the patient's infection, the physician should choose a drug (or drug combination) that is likely to be effective against the suspected microorganism.

LABORATORY CONTROL

Before beginning antimicrobial drug treatment, obtain meaningful specimens, if available, for laboratory examination to determine the causative infectious organism and, if appropriate, its susceptibility to antimicrobial drugs.

CLINICAL RESPONSE

Based on the clinical response of the patient, evaluate the laboratory reports and consider the desirability of changing the antimicrobial drug regimen. Laboratory results should not automatically overrule clinical judgment.

DRUG SUSCEPTIBILITY TESTS

Some microorganisms are uniformly susceptible to certain drugs; if such organisms are isolated from the patient, they need not be tested for drug susceptibility. For example, group A and B streptococci and clostridia are uniformly susceptible to penicillin. On the other hand, enteric gram-negative rods are sufficiently variable in their response to warrant drug susceptibility testing when they are isolated from a significant specimen, and group B streptococci have variable susceptibility to erythromycin and clindamycin.

Antimicrobial drug susceptibility tests can be performed on solid media as "disk tests," in broth tubes, or in wells of microdilution plates. The latter method yields results usually expressed as minimal inhibitory concentration (MIC). In some infections, the MIC provides a better estimate of the amount of drug required for therapeutic effect in vivo. Disk tests usually indicate whether an isolate is susceptible or resistant to drug concentrations achieved in vivo with conventional dosage regimens, thus providing valuable guidance in selecting therapy.

When marked discrepancies are noted between in vitro test results and in vivo response, the following possibilities must be considered:

- (1) Presence of an abscess, hematoma, or foreign body.
- (2) Choice of inappropriate dose or route of administration.
- (3) Poor concentration of the drug at the site of infection (eg, central nervous system).
- (4) Emergence of drug-resistant or tolerant organisms.
- (5) Participation of 2 or more microorganisms in the infectious process, of which only 1 was originally detected and used for drug selection.

ADEQUATE DOSAGE

To determine whether the proper drug is being used in adequate dosage, a serum assay can be performed. However, in obstetric-gynecologic practice, testing antibiotic levels usually is unnecessary. However, with dosing of an aminoglycoside every 24 hours, determination of serum levels is standard. Determination of drug levels may also be useful in obese women, in women with renal insufficiency, in patients with longer courses (> 7 days), and in patients not responding to therapy.

ROUTE OF ADMINISTRATION

The absorption of oral penicillins, tetracyclines, and erythromycin is impaired by food. Therefore, these oral drugs should be given between meals.

DURATION OF ANTIMICROBIAL THERAPY

In general, effective antimicrobial treatment results in marked clinical improvement within a few days. However, continued treatment for varying periods may be necessary to effect cure. For most postoperative and postpartum infections, intravenous antibiotics can be discontinued after the patient has been afebrile for 24–48 hours. Furthermore, in most patients who respond promptly to intravenous treatment, oral antibiotic therapy is unnecessary.

ADVERSE REACTIONS

The administration of antimicrobial drugs is occasionally associated with untoward reactions (Table 42–2). These reactions can be divided into several groups.

Hypersensitivity

The most common reactions are fever and skin rashes. Hematologic or hepatic disorders and anaphylaxis are rare.

Direct Toxicity

Most common are nausea, vomiting, and diarrhea. More serious toxic reactions are impairment of renal, hepatic, or hematopoietic function or damage to the eighth nerve.

Suppression

Suppression of normal microbial flora and "superinfection" by drug-resistant microorganisms, or continued infection with the initial pathogen through the emergence of drug-resistant variants.

Oliguria, Impaired Renal Function, & Uremia

Oliguria, impaired renal function, and uremia have an important influence on antimicrobial drug dosage, because most of these drugs are excreted by the kidneys. Only minor adjustment in dosage or frequency of administration is necessary with renally excreted drugs when relatively nontoxic drugs (eg, penicillins) are used. On the other hand, the dosage or frequency of administration of aminoglycosides (gentamicin, tobramycin, and amikacin), tetracyclines, and vancomycin must be reduced if toxicity is to be avoided in the presence of nitrogen retention. Administration of such drugs during renal failure should be guided by assay of drug concentrations in serum.

ANTIMICROBIAL DRUGS

PENICILLINS

The penicillins are a large group of antimicrobial substances, all of which share a common chemical nucleus (6-aminopenicillanic acid) that contains a β -lactam ring essential to their biologic activity (Table 42-1). All β -lactam antibiotics inhibit formation of microbial cell walls. In particular, they block the final transpeptidation reaction in the synthesis of cell wall mucopeptide (peptidoglycan), and they activate autolytic enzymes in the cell wall. These reactions result in bacterial cell death.

One million units of penicillin G equals 0.6 g. Other penicillins are prescribed in grams or milligrams. A blood level of 0.01–1 μ g/mL of penicillin G or ampicillin is lethal for most susceptible gram-positive microorganisms. Most β -lactamase-resistant penicillins are 5–50 times less active against penicillin G-susceptible organisms.

Absorption, Distribution, & Excretion

After parenteral administration, absorption of most penicillins is complete and rapid. After oral administration, only a portion of the dose is absorbed (from 1/20 to 1/3, depending on acid stability, binding to foods, and presence of buffers). To minimize binding to foods, oral penicillins should not be preceded or followed by food for at least 1 hour.

After absorption, penicillins are widely distributed in body fluids and tissues. With parenteral doses of 3–6 g (5–10 million units) per 24 hours of any penicillin injected by continuous infusion or divided intramuscular injections, average serum levels of the drug reach 1–10 units (0.6–6 μ g) per milliliter.

In many tissues, penicillin concentrations are equal to those in serum. Lower levels are found in the central nervous system. However, with active inflammation of the meninges, as in bacterial meningitis, penicillin levels in the cerebrospinal fluid exceed 0.2 μ g/mL with a daily parenteral dose of 12 g.

Most of the absorbed penicillin is rapidly excreted by the kidneys into the urine—90% by tubular secretion. Tubular secretion can be partially blocked by probenecid 0.5 g every 6 hours by mouth, to achieve higher systemic levels.

Renal excretion of penicillin results in very high levels in the urine.

Indications, Dosages, & Routes of Administration

The penicillins have been among the most effective and the most widely used antimicrobial drugs.

PENICILLIN G

In obstetric-gynecologic practice, penicillin is the drug of choice for treatment of infections caused by group A and B streptococci, *Treponema pallidum*, aerobic gram-positive rods, clostridia, and *Actinomyces*.

Penicillin G has not been recommended to treat gonococci for more than 25 years because of widespread resistance. Enterococci are not susceptible to penicillin G alone, but they are susceptible to a synergistic combination of penicillin G and an aminoglycoside or, in milder infections (particularly in the urinary tract), to ampicillin alone.

Intramuscular or Intravenous

Although most of the infections respond to aqueous penicillin G in daily doses of 0.6–5 million units administered by intermittent intramuscular injection, larger amounts (6–50 g daily) given by intermittent intravenous infusion are usually used. Sites for intravenous administration are subject to thrombophlebitis and must be rotated every 2–3 days. In enterococcal infections, an aminoglycoside is given simultaneously with large doses of a penicillin.

Oral

Penicillin V is indicated in minor infections (eg, of the respiratory tract or its associated structures) in daily doses of 1–4 g (1.6–6.4 million units).

BENZATHINE PENICILLIN G

This penicillin is a salt with low water solubility. It is injected intramuscularly to establish a depot that yields low but prolonged drug levels. An injection of 2.4 million units intramuscularly once per week for 1 or 3 weeks is the recommended treatment for early and late syphilis, respectively.

AMPICILLIN, AMOXICILLIN, CARBENICILLIN, TICARCILLIN, PIPERACILLIN, MEZLOCILLIN, AZLOCILLIN

These drugs have greater activity against gram-negative aerobes than does penicillin G but are destroyed by penicillinases (β -lactamases).

Ampicillin can be given orally in divided doses, 2–3 g daily, to treat urinary tract infections with susceptible coliform bacteria, enterococci, or *Proteus mirabilis*. It is ineffective against *Enterobacter* and *Pseudomonas*. Amoxicillin, 500 mg every 8 hours, is similar to ampicillin but is better absorbed. Thus, it can be given at less frequent intervals. Because of widespread gram-negative bacterial resistance to ampicillin, susceptibility testing should be performed.

Carbenicillin is more active against *Pseudomonas* and *Proteus*, but resistance emerges rapidly. Ticarcillin resembles carbenicillin but gives higher tissue levels. Because carbenicillin and ticarcillin also possess moderate activity against the wide array of bacteria involved in pelvic infections, they have been used with fairly good success as single-agent therapy. Carbenicillin indanyl sodium can be given orally for some urinary tract infections. Piperacillin resembles ticarcillin but is somewhat more active against some gram-negative aerobes, especially *Pseudomonas*. Combinations of clavulanic acid with amoxicillin or ticarcillin are somewhat protected against destruction by β -lactamases and have been used for treatment of some lactamase producers, eg, *Haemophilus influenzae*.

β -LACTAMASE-RESISTANT PENICILLINS

Cloxacillin, nafcillin, and others are relatively resistant to destruction by β -lactamase. The main indication

for use of these drugs is infection by β -lactamase-producing staphylococci.

Oral

Oxacillin, cloxacillin, dicloxacillin, or nafcillin can be given in doses of 0.25–0.5 g every 4–6 hours in mild or localized staphylococcal infections. Food markedly interferes with absorption.

Intravenous

For serious systemic staphylococcal infections, nafcillin 6–12 g is given intravenously, by adding 1–2 g every 2 hours to a continuous infusion of 5% dextrose in water.

COMBINATIONS OF PENICILLINS PLUS β -LACTAMASE INHIBITORS

Because of their wide spectrum of activity against bacteria involved in pelvic infections, these combinations have been successful in many circumstances, particularly pelvic infections. For example, ampicillin plus sulbactam (Unasyn), 3 g every 6 hours, carbenicillin plus clavulanic acid (Timentin), 3.1 g every 6 hours, or piperacillin plus tazobactam (Zosyn), 4 g piperacillin plus 0.5 g tazobactam IV every 8 hours may be the regimen given in such polymicrobial infections (Table 42–1).

Adverse Effects

Most of the serious side effects of the penicillins are due to hypersensitivity.

ALLERGY

All penicillins are cross-sensitizing and cross-reacting. In general, sensitization occurs in direct proportion to the duration and total dose of penicillin received in the past. Skin tests with penicilloyl-polylysine, with alkaline hydrolysis products (minor antigen determinants), and with undegraded penicillin can identify many hypersensitive individuals. Among positive reactors to skin tests, the incidence of subsequent immediate (immunoglobulin [Ig]E-mediated) penicillin reactions is high. Although many persons develop IgG antibodies to antigenic determinants of penicillin, the presence of such antibodies is not correlated with allergic reactivity (except rare hemolytic anemia). A history of a penicillin reaction in the past is not reliable; however, in such cases the drug should be administered with caution. Allergic reactions may occur as anaphylactic shock, serum sickness-type reactions (urticaria, fever, joint swelling, angioneurotic edema, intense pruritus, and respiratory embarrassment occurring 7–12 days after exposure), skin rashes, oral lesions, fever, nephritis, eosinophilia, hemolytic anemia and other hematologic disturbances, and vasculitis. The incidence of hypersensitivity to penicillin is estimated to be 3–5% among adults.

Acute anaphylactic life-threatening reactions are rare (0.05%). Ampicillin produces skin rashes (mononucleosis-like) 3–5 times more frequently than do other penicillins, but some ampicillin rashes are not allergic. Methicillin and other penicillins can induce interstitial nephritis; nafcillin is less nephrotoxic than methicillin. In circumstances where penicillin is the clear drug of choice and where alternatives are likely to be less effective, an oral desensitization protocol may be used safely. One such indication is the treatment of a patient with syphilis. One widely used protocol is administration of penicillin V suspensions orally starting at 100 units and giving incremental doses over 4 hours.

TOXICITY

Because the action of penicillin is directed against a unique bacterial structure, the cell wall, penicillin has virtually no effect on animal cells. The toxic effects of penicillin G are due to the direct irritation caused by intramuscular or intravenous injection of exceedingly high concentrations (eg, 1 g/mL). A patient receiving more than 50 g of penicillin G daily parenterally may exhibit signs of cerebrocortical irritation as a result of the passage of large amounts of penicillin into the central nervous system. With doses of this magnitude, direct cation toxicity (Na^+ , K^+) can also occur. Potassium penicillin G contains 1.7 mEq of K^+ per million units (2.7 mEq/g), and potassium may accumulate in the presence of renal failure.

Carbenicillin contains 4.7 mEq of Na^+ per gram—a risk in heart failure.

Large doses of penicillins given orally may lead to gastrointestinal upset, particularly nausea and diarrhea. These symptoms are most marked with oral ampicillin or amoxicillin. Oral therapy may be accompanied by luxuriant overgrowth of staphylococci, *Pseudomonas*, *Proteus*, or yeasts, which may cause enteritis. Penicillins have caused pseudomembranous colitis. Superinfections in other organ systems may occur. Carbenicillin and ticarcillin may damage platelet function, cause bleeding, or result in hypokalemic alkalosis.

CEPHALOSPORINS

The cephalosporins are structurally related to the penicillins. They consist of a β -lactam ring attached to a dihydrothiazolidine ring. Substitutions of chemical groups at various positions on the basic structure have resulted in a proliferation of drugs with varying pharmacologic properties and antimicrobial activities.

The mechanism of action of cephalosporins is analogous to that of the penicillins: (1) binding to specific penicillin-binding proteins that serve as drug receptors on bacteria, (2) inhibition of cell wall synthesis, and (3) activation of autolytic enzymes in the cell wall that result in bacterial death.

Cephalosporins have been divided into 3 major groups or "generations," based mainly on their antibacterial activity (Table 42–1). First-generation cephalosporins have good activity against aerobic gram-positive organisms and many community-acquired gram-negative organisms. Second-generation drugs have a slightly extended spectrum against gram-negative bacteria, and some are active against anaerobes. Third-generation cephalosporins have less activity against gram-positives but are extremely active against most gram-negative bacteria. Not all cephalosporins fit neatly into this grouping, and there are exceptions to the general characterization of the drugs in the individual generations. However, the generational classification of cephalosporins is useful for discussion purposes.

First-Generation Cephalosporins

Antimicrobial Activity

These drugs are very active against gram-positive cocci, including pneumococci, viridans streptococci, group A and B streptococci, and *Staphylococcus aureus*. Like all cephalosporins, they are inactive against enterococci and methicillin-resistant staphylococci. Among gram-negative bacteria, *Escherichia coli*, *Klebsiella pneumoniae*, and *Proteus mirabilis* are usually sensitive except for some hospital-acquired strains. There is no activity against such gram-negatives as *Pseudomonas aeruginosa*, indole-positive *Proteus* spp., *Enterobacter* spp., *Serratia marcescens*, *Citrobacter* spp., and *Acinetobacter* spp. Anaerobic cocci are usually sensitive, but most *Bacteroides* species are not.

Pharmacokinetics & Administration

ORAL

Cephalexin, cephradine, and cefadroxil are absorbed from the gut to a variable extent. After a 500-mg oral dose, serum levels range from 15 to 20 $\mu\text{g/mL}$. Urine concentrations are usually very high, but in other tissues the levels are variable and usually lower than in the serum. Cephalexin and cephradine are given orally in doses of 0.25–0.5 g 4 times daily (15–30 mg/kg/d). Cefadroxil can be given in doses of 0.5–1 g twice daily.

Dosage should be reduced in marked renal insufficiency: for creatine clearance (Cl_{cr}) 20–50 mL/min, give half the normal dose; for Cl_{cr} less than 20 mL/min, give one-fourth the normal dose.

INTRAVENOUS

Cefazolin has a longer half-life than cephalothin or cephapirin. After an intravenous infusion of 1 g, the peak serum level of cefazolin is 90–120 $\mu\text{g/mL}$, whereas cephalothin and cephapirin levels reach 40–60 $\mu\text{g/mL}$. The usual dose of cefazolin for adults is 1–2 g intravenously every 8 hours (50–100 mg/kg/d) and

for cephalothin and cephapirin is 1–2 g every 4–6 hours (50–200 mg/kg/d). In patients with impaired renal function, dosage adjustment as for oral dosage is needed.

INTRAMUSCULAR

Both cephapirin and cefazolin can be given intramuscularly, and pain on injection is less than with cefazolin.

Clinical Uses

Although the first-generation cephalosporins have a broad spectrum of activity and are relatively nontoxic, they are rarely the drugs of choice. Oral drugs are indicated for treatment of urinary infections in patients who are allergic to trimethoprim-sulfamethoxazole (TMP-SMX) or penicillins, and they can be used for minor staphylococcal infections in penicillin-allergic patients. Oral cephalosporins may be preferred for minor polymicrobial infections (eg, cellulitis, soft-tissue abscess).

Cefazolin or an alternative cephalosporin is the drug of choice for group B streptococcal infection or for prophylaxis in patients who cannot take penicillin, but who are at low risk for anaphylaxis.

Intravenous first-generation cephalosporins penetrate most tissues well and are among the drugs of choice for gynecologic and cesarean section prophylaxis. More expensive second- and third-generation cephalosporins offer no advantage over the first-generation drugs for surgical prophylaxis and should not be used for that purpose.

Other major uses of intravenous first-generation cephalosporins include infections for which they are the least toxic drugs (eg, *Klebsiella* infections) and infections in persons with a history of mild penicillin allergy (not anaphylaxis).

Second-Generation Cephalosporins

Second-generation cephalosporins are a heterogeneous group with marked individual differences in activity, pharmacokinetics, and toxicity. In general, all of them are active against organisms also covered by first-generation drugs, but they have an extended gram-negative coverage. Indole-positive *Proteus* and *Klebsiella* spp. (including cephalothin-resistant strains) are usually sensitive. In addition, cefoxitin and cefotetan are active against *Bacteroides fragilis*, other gram-negative anaerobes, and some strains of *Serratia*, but they have poor activity against *Enterobacter* and *H influenzae*. Against gram-positive organisms, these drugs are less active than the first-generation cephalosporins. Like the latter, second-generation drugs have no activity against *P aeruginosa* or enterococci.

Pharmacokinetics & Administration

After an intravenous infusion of 1 g, serum levels range from 75–125 µg/mL. Because of differences in drug half-life and protein binding, intervals between doses vary greatly. For cefoxitin (short half-life), the interval is 4–6 hours; cefoxitin, 50–200 mg/kg/d.

Drugs with longer half-lives can be injected less frequently: cefotetan, 1–2 mg every 8–12 hours; and cefonicid or ceforanide, 1–2 g (15–30 mg/kg/d) once or twice daily. In renal failure, dosage adjustments are required.

Clinical Uses

Because of their activity against anaerobes, cefoxitin and cefotetan are widely used to treat polymicrobial obstetric and gynecologic infections. They are not more effective than first-generation cephalosporins for perioperative prophylaxis, and they are more expensive.

Third-Generation Cephalosporins

Antimicrobial Activity

These drugs are active against staphylococci (not methicillin-resistant strains) but less so than first-generation cephalosporins. They have no activity against enterococci but inhibit nonenterococcal streptococci. Most of these drugs are active against *N gonorrhoeae*. A major advantage of the new cephalosporins is their expanded gram-negative coverage. In addition to organisms inhibited by other cephalosporins, they are consistently active against *Enterobacter* spp., *Citrobacter freundii*, *S marcescens*, *Providencia* spp., *Haemophilus* spp., and *Neisseria* spp., including β -lactamase-producing strains. Two drugs—ceftazidime and cefoperazone—have good activity against *P aeruginosa*, whereas the others inhibit only 40–60% of strains. *Listeria* spp., *Acinetobacter* spp., and non-*aeruginosa* strains of *Pseudomonas* are variably sensitive to third-generation cephalosporins. Only ceftizoxime and moxalactam have good activity against *B fragilis*. Several of these drugs have relatively long half-lives.

Pharmacokinetics & Administration

After an intravenous infusion of 1 g, serum levels of these drugs range from 60–140 μ g/mL. They penetrate well into body fluids and tissues. The half-life of these drugs is variable: ceftriaxone, 7–8 hours; cefoperazone, 2 hours; the others, 1–1.7 hours. Consequently, ceftriaxone can be injected every 12–24 hours in a dose of 15–30 mg/kg/d (or 30–50 mg/kg every 12 hours in adult meningitis and 50 mg/kg every 12 hours in infants). Cefoperazone can be given every 8–12 hours in a dose of 25–100 mg/kg/d, and the other drugs of the group every 6–8 hours in doses ranging from 2–12 g/d depending on the severity of infection. Cefoperazone and ceftriaxone are eliminated primarily by biliary excretion, and no dosage adjustment is required in renal insufficiency. The other drugs in this generation are eliminated by the kidney and thus require dosage adjustments in renal insufficiency.

Clinical Uses

Ceftriaxone 250 mg intramuscularly and cefixime 400 mg orally are two recommended regimens for treating uncomplicated gonorrhea. They are combined with doxycycline or azithromycin for cotreatment of chlamydia.

In obstetric-gynecologic practice, these agents have been used to treat urinary infection.

ADVERSE EFFECTS OF CEPHALOSPORINS

Allergy

Cephalosporins are sensitizing, and a variety of hypersensitivity reactions occur, including anaphylaxis, fever, skin rashes, nephritis, granulocytopenia, and hemolytic anemia. The incidence of cross-allergy between cephalosporins and penicillins is estimated to be approximately 6–10%. Persons with a history of anaphylaxis to penicillins should not receive cephalosporins.

Toxicity

Local pain can occur after intramuscular injection, or thrombophlebitis can occur after intravenous injection. Hypoprothrombinemia is a potential adverse effect of cephalosporins that have a methylthiotetrazole group (eg, cefamandole, moxalactam, cefoperazone), but these are infrequently used in obstetric-gynecologic practice.

Superinfection

Many newer cephalosporins have little activity against gram-positive organisms, particularly staphylococci and enterococci. Superinfection with these organisms—as well as with fungi—may occur.

Pseudomembranous colitis has occurred with use of these antibiotics.

NEW β -LACTAM DRUGS

Monobactams

Monobactams are drugs with a monocyclic β -lactam ring, which are resistant to β -lactamases and are active against gram-negative organisms (including *Pseudomonas*) but not against gram-positive organisms or anaerobes. Aztreonam resembles aminoglycosides in activity. The usual dose is 1–2 g intravenously every 6–8 hours. Clinical uses of aztreonam alone are limited because of the availability of third-generation cephalosporins with a broader spectrum of activity and minimal toxicity. However, in combination with a drug such as clindamycin, aztreonam provides a regimen with broad activity and appears equivalent to clindamycin–gentamicin in efficacy. Although aztreonam has potentially less toxicity than gentamicin, gentamicin is much less expensive, and the majority of obstetric-gynecologic patients are at low risk for gentamicin toxicity. The place of aztreonam in obstetric-gynecologic practice remains limited.

Carbapenems

This class of drugs is structurally related to β -lactam antibiotics. Imipenem, the first drug of this type, has a wide spectrum with good activity against many gram-negative rods, gram-positive organisms, and anaerobes. It is resistant to β -lactamases but is inactivated by dipeptidases in renal tubules. Consequently, it must be combined with cilastatin, a dipeptidase inhibitor, for clinical use.

The half-life of imipenem is 1 hour. Penetration into body tissues and fluids, including the cerebrospinal fluid, is good. The usual dose is 0.5–1 g intravenously every 6 hours. Dosage adjustment is required in renal insufficiency. Because imipenem has an unusual spectrum, it should be reserved for special cases such as treatment of highly resistant organisms. It should not be used as a first-line treatment for pelvic infections.

The most common adverse effects of imipenem are nausea, vomiting, diarrhea, reactions at the infusion site, and skin rashes. Seizures can occur in patients with renal failure. Patients allergic to penicillins may be allergic to imipenem as well.

MACROLIDES (ERYTHROMYCIN, AZITHROMYCIN, CLARITHROMYCIN)

The erythromycins inhibit protein synthesis and are bacteriostatic or bactericidal against gram-positive organisms in concentrations of 0.02–2 μ g/mL. *Chlamydia*, *Ureaplasma urealyticum*, *Legionella*, and *Campylobacter* are also susceptible. Activity is enhanced at alkaline pH.

Erythromycins are the drugs of choice in pneumonia caused by mycoplasmas or *Legionella*. They are useful as substitutes for penicillin in persons who are allergic to penicillin and for tetracyclines in pregnancy for treatment of *Chlamydia* and *Ureaplasma*. Erythromycin preparations can be used parenterally for prophylaxis of group B streptococcal perinatal infection in patients with penicillin allergy. However, because the likelihood of erythromycin resistance to group B streptococci is up to 15%, erythromycin should not be used unless susceptibility has been established.

Dosages

ORAL

Erythromycin base, stearate, or estolate, 0.25–0.5 g every 6 hours (for children, 40 mg/kg/d), or erythromycin ethylsuccinate, 0.4–0.6 g every 6 hours. The estolate derivative should not be used during pregnancy because it elevates hepatic enzyme levels.

INTRAVENOUS

Erythromycin lactobionate, 0.5 g every 6 hours.

Adverse Effects

Nausea, vomiting, and diarrhea may occur after oral intake. Erythromycin estolate probably more than the other salts can produce acute cholestatic hepatitis (fever, jaundice, impaired liver function) because of hypersensitivity. Most patients recover completely.

AZITHROMYCIN

Azithromycin is the first of the azalide antibiotics that are chemically similar to the macrolides such as erythromycin. With excellent in vitro activity against *C. trachomatis* and with favorable kinetics including sustained high concentration in tissue (even though serum concentrations are low), azithromycin (1 g orally once) has been as effective as doxycycline (100 mg twice daily for 7 days), 97% versus 95%, respectively, in treating chlamydia urethritis and cervicitis. Side effects were similar, mainly gastrointestinal, and were mild to moderate. Accordingly, azithromycin has become one of the recommended regimens for treatment of chlamydial infection as a 1-g dose given orally. In pregnancy, the 1-g dose of azithromycin is an alternative regimen to the recommended regimens in pregnancy of erythromycin base or amoxicillin. Because this 1-g dose of azithromycin is not adequate for treating gonorrhea, cotreatment with single-dose ceftriaxone (250 mg intramuscularly) is necessary.

CLINDAMYCIN

Clindamycin resembles erythromycin and is active against gram-positive organisms (except enterococci). Clindamycin 0.15–0.3 g orally every 6 hours yields serum concentrations of 2–5 µg/mL. The drug is widely distributed in tissues. Excretion is through the bile and urine. Group B streptococcal resistance to clindamycin has become common. Thus, as with erythromycin, clindamycin should not be used for group B streptococcus prophylaxis unless susceptibility has been established. It is also effective against most strains of *Bacteroides* and is an excellent drug in polymicrobial aerobic-anaerobic infections, when used in combination with an aminoglycoside. Seriously ill patients are given clindamycin intravenously during a 1-hour period, 900 mg every 8 hours. Vaginal clindamycin cream (2%) when used nightly (5–7 mL) for 5–7 days is highly effective in treating bacterial vaginosis. A clindamycin ovule is indicated for treatment of bacterial vaginosis for 3 days.

Common side effects of systemic clindamycin are diarrhea, nausea, and skin rashes. Impaired liver function and neutropenia have been noted. If 3–4 g is given rapidly intravenously, cardiorespiratory arrest may occur. Pseudomembranous colitis has been associated with clindamycin administration. This is due to necrotizing toxin produced by *Clostridium difficile*, which is clindamycin-resistant and increases in the gut with the selection pressure exerted by administration of this drug. *C. difficile* is sensitive to vancomycin and metronidazole, and the colitis rapidly regresses during oral treatment with metronidazole, which is preferred to vancomycin because of its lower cost.

TETRACYCLINE GROUP

The tetracyclines have common basic chemical structures, antimicrobial activity, and pharmacologic properties. Microorganisms resistant to one tetracycline show cross-resistance to all tetracyclines.

Antimicrobial Activity

Tetracyclines are inhibitors of protein synthesis and are bacteriostatic for many gram-positive and gram-negative bacteria. They are strongly inhibitory for the growth of mycoplasmas, rickettsiae, chlamydiae, and some protozoa (eg, amoebas). Equal concentrations of all tetracyclines in blood or tissue have approximately equal antimicrobial activity. However, there are great differences in the susceptibility of different strains of a given species of microorganism, so laboratory tests are important. Because of the emergence of resistant strains, tetracyclines have lost some of their former usefulness against gram-negative and gram-positive bacteria, but they have ongoing usefulness in treating sexually transmitted organisms. Tetracyclines alone are no longer considered adequate therapy for gonorrhea, but they are

recommended for chlamydia.

Absorption, Distribution, & Excretion

Tetracyclines are absorbed somewhat irregularly from the gut. Absorption is limited by the low solubility of the drugs and by chelation with divalent cations, eg, Ca^{2+} or Fe^{2+} . A large proportion (80%) of orally administered tetracycline remains in the gut lumen, modifies intestinal flora, and is excreted in feces. With full systemic doses (2 g/d), levels of active drug in serum reach 2–10 $\mu\text{g}/\text{mL}$. Tetracyclines are specifically deposited in growing bones and teeth, bound to calcium.

Absorbed tetracyclines are excreted mainly in bile and urine. Up to 20% of oral doses may appear in the urine after glomerular filtration. With renal failure, doses of tetracyclines must be reduced or intervals between doses increased.

Minocycline and doxycycline are well absorbed from the gut but are excreted more slowly than others, leading to accumulation and prolonged blood levels. Doxycycline does not accumulate greatly in renal failure.

Indications, Dosages, & Routes of Administration

Tetracyclines are the drugs of choice in chlamydial and genital mycoplasmal infections in nonpregnant women.

ORAL

Tetracycline hydrochloride is dispensed in 250-mg capsules. Give 0.25–0.5 g orally every 6 hours. Doxycycline 100 mg twice daily is as effective as tetracycline hydrochloride 2 g/d.

INTRAVENOUS

Several tetracyclines are formulated for parenteral administration in individuals unable to take oral medication. The dose is generally similar to the oral dose (see manufacturer's instructions).

Adverse Effects

ALLERGY

Hypersensitivity reactions with fever or skin rashes are uncommon.

GASTROINTESTINAL SIDE EFFECTS

Gastrointestinal side effects are common. They can be diminished by reducing the dose or by administering tetracyclines with food. After a few days of oral use, the gut flora is modified so that drug-resistant bacteria and yeasts become prominent. This may cause functional gut disturbances, anal pruritus, and even enterocolitis.

BONES AND TEETH

Tetracyclines are bound to calcium deposited in growing bones and teeth, causing fluorescence, discoloration, enamel dysplasia, deformity, or growth inhibition. Tetracyclines are contraindicated in pregnant women.

LIVER DAMAGE

Tetracyclines can impair hepatic function or even cause liver necrosis, particularly during pregnancy, in the presence of preexisting liver damage, or with doses of more than 3 g intravenously.

KIDNEY DAMAGE

Outdated tetracycline preparations have been implicated in renal tubular acidosis and other renal damage. Tetracyclines may increase blood urea nitrogen when diuretics are administered.

OTHER

Tetracyclines may induce photosensitization, especially in fair-complected individuals. Intravenous

injection may cause thrombophlebitis, and intramuscular injection may induce local inflammation with pain. Minocycline causes vestibular reactions (dizziness, vertigo, nausea) in 30–60% of cases after doses of 200 mg daily.

AMINOGLYCOSIDES

This group includes widely used drugs such as gentamicin and tobramycin. These agents inhibit protein synthesis in bacteria by attaching to and inhibiting the function of the 30S subunit of the bacterial ribosome. Anaerobic bacteria are resistant to aminoglycosides because transport across the cell membrane is an oxygen-dependent, energy-requiring process.

All aminoglycosides are potentially ototoxic and nephrotoxic, although to different degrees. All can accumulate in renal failure; therefore, dosage adjustments must be made in uremia.

Aminoglycosides are used widely against presumed or established gram-negative enteric bacteria. In the treatment of bacteremia or endocarditis caused by fecal streptococci or by some gram-negative bacteria, the aminoglycoside is given together with penicillin to enhance permeability and facilitate the entry of the aminoglycoside.

General Properties of Aminoglycosides

PHYSICAL PROPERTIES

Aminoglycosides are water soluble and stable in solution. If they are mixed in solution with β -lactam antibiotics, they may form complexes and lose some activity. Aminoglycosides may be mixed with clindamycin in IV solutions.

ABSORPTION, DISTRIBUTION, METABOLISM, AND EXCRETION

Aminoglycosides are well absorbed after intramuscular or intravenous injection but are not absorbed from the gut. They are distributed widely in tissues and penetrate pleural, peritoneal, or joint fluid in the presence of inflammation. They accumulate in amniotic fluid, but not for 6 hours after maternal injection. They enter the central nervous system to only a slight extent after parenteral administration. There is no significant metabolic breakdown of aminoglycosides. The serum half-life is 2–3 hours; excretion is mainly by glomerular filtration. Urine levels are 10–50 times higher than serum levels.

DOSE AND EFFECT IN CASES OF IMPAIRED RENAL FUNCTION

In the past, the dose of gentamicin for a person with normal renal function was 3–7 mg/kg/d divided in 3 equal injections every 8 hours. In the past several years, dosing every 24 hours has become the usually recommended regimen. The usual initial dose of gentamicin is 4.0–5.0 mg/kg intravenously once daily, in an infusion given over a 30-minute period. Reasons for the once-daily administration of gentamicin are the potentially less toxicity, less cost, and equivalent clinical efficacy. In persons with impaired renal function, excretion is diminished and the dosing interval may be prolonged beyond 24 hours.

Because of the increased glomerular filtration rate in pregnancy and the subsequent rapid excretion of aminoglycosides in pregnancy, doses greater than 5 mg/kg every 24 hours may be necessary. When 24-hour dosing is used, gentamicin levels are usually determined and plotted on a nomogram to ascertain appropriateness of the dose. Studies of gentamicin in postpartum individuals have been performed, but there have been few studies of 24-hour dosing of gentamicin during pregnancy. Accordingly, some clinicians prefer to continue to use dosing at 8-hour intervals for gentamicin in the pregnant patient.

ADVERSE EFFECTS

All aminoglycosides can cause varying degrees of ototoxicity and nephrotoxicity. Ototoxicity can present either as hearing loss (cochlear damage) that is noted first as a deficiency in hearing high frequencies or as vestibular damage, as evidenced by vertigo, ataxia, and loss of balance.

In very high doses, aminoglycosides can be neurotoxic, producing a curarelike effect with neuromuscular blockage that results in respiratory paralysis. This has been most common in gynecologic surgery when solutions containing aminoglycosides have been used for peritoneal irrigation. Calcium gluconate or neostigmine can serve as antidote. Rarely, aminoglycosides cause hypersensitivity and local reactions.

Gentamicin

Gentamicin is the most widely used aminoglycoside antibiotic on obstetric-gynecologic services. In concentrations of 0.5–5 µg/mL, gentamicin is bactericidal not only for staphylococci and coliform organisms but also for many strains of *Pseudomonas*, *Proteus*, and *Serratia*. Enterococci are resistant to gentamicin alone, but they are susceptible to gentamicin plus penicillin. With doses of 3–7 mg/kg/d, serum levels reach 3–8 µg/mL. Gentamicin may be synergistic with ticarcillin against *Pseudomonas*. However, the 2 drugs should not be mixed in vitro.

Indications, Dosages, & Routes of Administration

Gentamicin is used for severe infections caused by gram-negative bacteria, including *Klebsiella-Enterobacter*, *Proteus*, *Pseudomonas*, and *Serratia*. The dosage is usually 4–5 mg/kg every 24 hours in a single IV infusion. It is necessary to monitor renal function by checking serum creatinine levels every few days and to reduce the dosage or lengthen the interval between doses if renal function declines. Approximately 2–3% of patients develop vestibular dysfunction and loss of hearing when peak serum levels exceed 10 µg/mL. Serum concentrations should be monitored in selected circumstances.

Tobramycin

Tobramycin is an aminoglycoside that closely resembles gentamicin in antibacterial activity and pharmacologic properties and exhibits partial cross-resistance. Tobramycin may be effective against some gentamicin-resistant gram-negative bacteria, especially *Pseudomonas*. Tobramycin may be less nephrotoxic than gentamicin; their ototoxicity is similar.

SPECTINOMYCIN

Spectinomycin is an aminocyclitol antibiotic, related to the aminoglycosides. Its sole indication is for treatment of β-lactamase-producing gonococci or gonorrhea in a penicillin-hypersensitive person. One injection of 2 g (40 mg/kg) is given. Pain at the injection site is usual, and nausea and fever may occur.

SULFONAMIDES-TRIMETHOPRIM

The combination of sulfonamides, particularly sulfamethoxazole with trimethoprim, offers a combination of 2 folic acid antagonists that is useful in a number of circumstances. The indications are as follows:

(1) Urinary tract infection: Many coliform organisms that are the most common causes of urinary tract infections are susceptible to the combination of TMP-SMX. For lower urinary tract infection, TMP-SMX 160/800 mg is often given every 12 hours for a 3-day regimen. For uncomplicated pyelonephritis in women who do not have evidence of sepsis, TMP-SMX 160/800 mg can be given orally every 12 hours for 10–14 days. Women who have pyelonephritis requiring hospitalization can be treated with TMP-SMX 160/800 mg intravenously every 12 hours until the patient is able to tolerate oral nourishment and oral therapy, which should be continued to complete a 10- to 14-day course.

(2) Parasitic diseases: The combination of trimethoprim with sulfamethoxazole is often effective for prophylaxis or treatment of *Pneumocystis carinii* pneumonia. The combination of pyrimethamine with sulfadiazine is used for treatment of toxoplasmosis. It should be given in combination with folic acid in pregnant women.

(3) Sexually transmitted diseases: Sulfonamides are no longer considered for treatment of infection by *C trachomatis*.

Because trimethoprim and sulfonamides both are folate antagonists, there is a hypothetical possibility of teratogenesis. Accordingly, this combination should be avoided in the first trimester of pregnancy. Sulfonamides may lead to hemolysis in persons with glucose-6-phosphate (G6PD) enzyme deficiency. Sulfonamides also compete with bilirubin for binding sites. Accordingly, long-acting sulfonamides should not be given at term in order to avoid the unusual complication of low-level kernicterus in the newborn infant. These infants do not develop hyperbilirubinemia, but they do develop kernicterus at low bilirubin levels because of displacement of bilirubin from its binding sites to free bilirubin.

Adverse Effects

Sulfonamides produce a wide variety of side effects—due partly to hypersensitivity and partly to direct toxicity—which must be considered whenever unexplained symptoms or signs occur in a patient who may have received these drugs. Except in the mildest reactions, fluids should be forced and, if symptoms and signs progressively increase, the drugs should be discontinued.

SYSTEMIC SIDE EFFECTS

Side effects may include fever, skin rashes, urticaria; nausea and vomiting or diarrhea; stomatitis, conjunctivitis, arthritis, exfoliative dermatitis; hematopoietic disturbances, including thrombocytopenia, hemolytic (in G6PD deficiency) or aplastic anemia, granulocytopenia, leukemoid reactions; hepatitis, polyarteritis nodosa, vasculitis, Stevens-Johnson syndrome; and psychosis.

URINARY TRACT DISTURBANCES

Sulfonamides may precipitate in urine, especially at neutral or acid pH, producing hematuria, crystalluria, or even obstruction. They have been implicated in various types of nephritis and nephrosis. Sulfonamides and methenamine salts should not be given together.

Precautions in the Use of Sulfonamides

(1) There is cross-allergenicity among all sulfonamides. Obtain a history of past administration or reaction. Observe for possible allergic responses.

(2) Keep the urine volume above 1500 mL/d by encouraging fluid intake. Check urine pH—it should be 7.5 or higher. Give alkali by mouth (sodium bicarbonate or equivalent, 5–15 g/d). Examine fresh urine for crystals and red cells every 5–7 days.

(3) Check hemoglobin, white blood cell count, and differential count once weekly to detect possible disturbances early in high-risk patients.

METRONIDAZOLE

Metronidazole is an antiprotozoal drug that also is active against most anaerobes, including *Bacteroides* species. Metronidazole is well absorbed after oral administration and is widely distributed. The drug is metabolized in the liver, and dosage reduction is required in the presence of hepatic insufficiency. Metronidazole can also be given intravenously or by rectal suppository, with serum levels equivalent for both routes. It is used to treat amebiasis and the following:

(1) *Trichomonas* vaginitis: The recommended dose is 2 g orally (single dose). The alternative is 500 mg twice daily for 7 days. Both sexual partners should be treated.

(2) Bacterial vaginosis: Recommended regimens for nonpregnant women are 500 mg orally 2 times daily for 7 days or vaginal gel 0.75%, 5 g vaginally twice daily for 5 days. In pregnant women, the CDC-recommended regimen is 250 mg orally 3 times daily. Topical treatment of BV is not recommended in pregnancy. Single-dose treatment is less effective, and treatment of sexual partners is not recommended because it does not decrease recurrences in the female.

(3) In anaerobic or mixed infections, metronidazole can be given intravenously, 500 mg 3 times daily.

(4) For pseudomembranous colitis, give 500 mg 3 times daily orally.

Adverse effects of metronidazole include stomatitis, nausea, diarrhea, and disulfiram-like reactions. With prolonged use, peripheral neuropathy may develop.

VANCOMYCIN

Vancomycin is bactericidal for most gram-positive organisms, particularly staphylococci. Resistant mutants had been rare, but development of vancomycin-resistant enterococci has become a major cause for concern since the late 1980s. In many institutions, policies for control of vancomycin use have been developed. Vancomycin is an alternative to metronidazole in the treatment of pseudomembranous colitis. For this indication, it is given 2 g/d orally, but metronidazole is preferred because it is less expensive and because of the concern that oral vancomycin may lead to increased selection pressure for vancomycin-resistant enterococci in the gut. For systemic effect, the drug must be administered intravenously. After intravenous infusion of 0.5 g over 20 minutes, blood levels of 10 µg/mL are maintained for 1–2 hours. Vancomycin is excreted mainly through the kidneys, but it may accumulate in the kidneys in patients with liver failure. In renal insufficiency, the half-life may be up to 8 days. Thus, only 1 dose of 0.5–1 g can be given every 4–8 days to a uremic individual undergoing hemodialysis.

The chief indications for parenteral vancomycin are serious staphylococcal infection and enterococcal endocarditis (in combination with an aminoglycoside). Vancomycin is the recommended drug for group B streptococcus prophylaxis in patients who are at high risk for a serious penicillin allergic reaction and when the group B streptococcus isolate is resistant to clindamycin or erythromycin or when the susceptibility is unknown. Vancomycin 0.5 g is infused intravenously over 20 minutes every 6–8 hours (for children, 20–40 mg/kg/d).

Vancomycin is irritating to tissues; chills, fever, and thrombophlebitis sometimes follow intravenous injection. Rapid infusion may result in diffuse hyperemia (red man syndrome); this can be avoided by giving infusions over 1 hour. Vancomycin is sometimes ototoxic and (perhaps) nephrotoxic.

LINEZOLID

Linezolid (Zyvox) is an antibiotic of the new class providing clinical use in the treatment of aerobic gram-positive infections, especially those resistant to more common antibiotics. The potential use of linezolid is for treatment of resistant enterococcal, staphylococcal, and other streptococcal infections. Linezolid is available in preparations for both intravenous and oral administration. Its use in obstetric and gynecologic practice currently is limited.

QUINOLONES

Quinolones are synthetic analogues of nalidixic acid and are active against many gram-positive and gram-negative bacteria. All quinolones inhibit bacterial DNA synthesis by blocking the enzyme DNA gyrase. The earlier quinolones (nalidixic acid, oxolinic acid, cinoxacin) did not achieve systemic antibacterial levels and thus were useful only as urinary antiseptics. The newer fluoroquinolones (eg, norfloxacin, ciprofloxacin, enoxacin, oxofloxacin, pefloxacin, levofloxacin, and trovafloxacin) have greater antibacterial activity, achieve clinically useful levels in blood and tissues, and have low toxicity. They are active against a wide variety of aerobic bacteria, and some members of this group are active against clinically important anaerobes. After oral administration, these newer fluoroquinolones are well absorbed and widely distributed, with a serum half-life of 3–8 hours. They are excreted mainly by tubular renal secretion or glomerular filtration. Up to 20% of the dose is metabolized by the liver.

Indications for fluoroquinolones have been developed over the last few years and are as follows:

(1) Urinary tract infection: Use of quinolones should be reserved for infection due to organisms resistant

to first-line treatment with nitrofurantoin, trimethoprim, and TMP-SMX. Quinolones should be used when resistant organisms are suspected (eg, for treatment of documented resistant strains), treatment failures, recurrent infection, or infection in patients with allergy to preferred drugs of choice. For complicated pyelonephritis, an oral quinolone can be used. For women with evidence of sepsis requiring hospitalization, a regimen including a fluoroquinolone can be used. For example, ofloxacin or ciprofloxacin in a dose of 200–400 mg IV every 12 hours can be used until the patient's course improves. Thereafter, when the patient can take oral nourishment, oral therapy should be started and continued to complete a 10- to 14-day course.

(2) Fluoroquinolones are widely used for treatment of sexually transmitted diseases. For example, for treatment of pelvic inflammatory disease, quinolones fit among the alternative parenteral regimens such as ofloxacin 400 mg IV every 12 hours with or without other antibiotics such as IV metronidazole, plus doxycycline. Another alternative regimen is levofloxacin 500 mg IV every 24 hours with or without the other combinations. Fluoroquinolones are also recommended in combination with other agents for treatment of pelvic inflammatory disease on an ambulatory basis. One recommended regimen is ofloxacin 400 mg orally twice daily or levofloxacin 500 mg once daily for 14 days plus metronidazole 500 mg orally twice daily for 14 days.

For treatment of chlamydial infections in adolescents and adults, ofloxacin 300 mg twice daily for 7 days is an alternative regimen.

Several fluoroquinolones are listed as recommended regimens for treatment of uncomplicated gonococcal infection of the cervix, urethra, and rectum. For example, 1 regimen is ciprofloxacin 500 mg orally in a single dose or ofloxacin 400 mg orally in a single dose. Either of these regimens should be combined with either azithromycin or doxycycline if chlamydial infection is not ruled out. Because they inhibit DNA gyrase, quinolones should be avoided in pregnancy.

The most pronounced adverse effects are nausea, vomiting, diarrhea, headache, dizziness, insomnia, occasional skin rashes, impairment of liver function, seizures, and anaphylaxis.

NITROFURANTOIN

Nitrofurantoin is bacteriostatic and bactericidal for both gram-positive and gram-negative bacteria in urine. The drug has no systemic antimicrobial activity. Its activity in urine is enhanced at pH 5.5 or below. Microbial resistance does not emerge rapidly.

The usual daily dose for treatment of urinary tract infections is 100 mg orally twice daily for 3 days, taken with food. Nitrofurantoin is also useful for continuous or postcoital suppression of urinary infection.

Oral nitrofurantoin may cause nausea and vomiting. Hemolytic anemia occurs in G6PD deficiency. Hypersensitivity may produce skin rashes and pulmonary infiltration. In uremia, there is virtually no excretion of nitrofurantoin into the urine and no therapeutic effect.

ANTI FUNGAL DRUGS

Most antibacterial drugs have no effect on yeasts and fungi. Others (eg, amphotericin B) are relatively effective in some systemic mycotic infections but are difficult to administer because of toxicity. New imidazoles are fairly effective and relatively nontoxic. Many topical preparations, such as 2% miconazole, 1% clotrimazole, 2% butoconazole, and 0.4% terconazole, all have been used effectively for treatment of vaginal candidiasis. Ketoconazole can be given orally, 200–600 mg once daily, preferably with food. It is well absorbed, reaches serum levels of 2–4 µg/mL, and is degraded in tissues, thus requiring no renal or biliary excretion. It has a dramatic therapeutic effect on chronic vaginal candidiasis. Ketoconazole blocks the synthesis of adrenal steroids and can cause gynecomastia. Adverse effects are mild, with nausea, headache, skin rashes, and occasional elevations in transaminase levels. If evidence of liver dysfunction persists, the drug should be discontinued.

Fluconazole (Diflucan) is an effective single-dose treatment of uncomplicated yeast infection. The dose is 150–200 mg orally as a single dose. The drug is also effective for treatment of recurrent or refractory vulvovaginal candidiasis and is less hepatotoxic than ketoconazole. One regimen for recurrent or refractory yeast infection is fluconazole 150 or 200 mg taken on days 1, 4, and 8. Because of its unusually long half-life, it does not need to be given more frequently. One prophylactic regimen for patients with frequent recurrent yeast infections (ie, > 4–6 per year) is fluconazole 150 mg taken once weekly for up to 6 months.

ANTI MICROBIAL CHEMOPROPHYLAXIS IN SURGERY

A major portion of all antimicrobial drugs used in hospitals are used on surgical services with the stated intent of "prophylaxis." Several general features of "surgical prophylaxis" are applicable.

- (1) Prophylactic administration of antibiotics should generally be considered only if the expected rate of infectious complications is high or where a possible infection would have a catastrophic effect.
- (2) If prophylactic antimicrobials are to be effective, a sufficient concentration of drug must be present at the operative site to inhibit or kill bacteria that might settle there. Thus, it is essential that drug administration begin immediately before (or in cesarean section just after) operation begins.
- (3) Prolonged administration of antimicrobial drugs tends to alter the normal flora of organ systems, suppressing the susceptible microorganisms and favoring the implantation of drug-resistant ones. Thus, antimicrobial prophylaxis should last only 1–3 doses.
- (4) Systemic antimicrobial levels usually do not prevent wound infection, pneumonia, or urinary tract infection if physiologic abnormalities or foreign bodies are present.

In hysterectomy and nonelective cesarean section, administration of a broad-spectrum bactericidal drug from just before until 1 day after the procedure has been found effective. Thus, for example, cefazolin 1 g intravenously given before pelvic operations and again for 1–2 doses after the end of the operation results in a demonstrable lowering of the risk of deep infections at the operative site.

Other forms of surgical prophylaxis are used to reduce normal flora or existing bacterial contamination at the site. Thus, the colon is routinely prepared not only by mechanical cleansing through cathartics and enemas but also by oral administration of poorly absorbed drugs (eg, neomycin 1 g, plus erythromycin base 0.5 g, every 6 hours) for 1–2 days before operation.

In all situations in which antimicrobials are administered with the hope that they may have a prophylactic effect, the risk from these same drugs (eg, allergy, toxicity, selection of superinfecting microorganisms) must be evaluated daily, and the course of prophylaxis must be kept as brief as possible.

ANTIVIRAL CHEMOPROPHYLAXIS & THERAPY

Several compounds can suppress development of viral diseases. Of these, acyclovir is important in gynecologic practice.

Acyclovir (acycloguanosine [Zovirax]) inhibits replication of herpesviruses in infected cells. When given intravenously (15 mg/kg/d), acyclovir is effective in controlling disseminating herpesvirus infections in immunocompromised patients. It can also markedly reduce pain and the extent of lesions in primary genital herpes infections of women. In herpetic encephalitis and neonatal herpetic dissemination, acyclovir is more effective than vidarabine. Acyclovir has no effect on cytomegalovirus or Epstein-Barr virus infections, but acyclovir can arrest the progression of varicella and herpes zoster, especially in immunocompromised patients.

Oral acyclovir, 200 mg 5 times daily for adults, has therapeutic effects similar to those of intravenous acyclovir, particularly in primary genital herpes simplex infections. When taken prophylactically in patients with frequent (> 6 per year) episodes, it can reduce the frequency of recurrent lesions for up to 3 years. However, no regimen of acyclovir can block the establishment of latency or permanently eliminate recurrences.

Two additional antiviral drugs have become available: famciclovir and valacyclovir. The advantage of these preparations is that they have longer half-lives, and they can be given at less frequent dosing intervals than acyclovir. However, they appear to be no more effective. Valacyclovir, famciclovir, and acyclovir are all recommended for first-episode genital herpes, for recurrent episodes of genital herpes, and for daily suppressive therapy of frequent recurrences. Their use in pregnancy has not been extensive, but available data are reassuring for no side effects peculiar to the pregnant woman or the fetus. Valacyclovir has also been established as a means of preventing herpes simplex virus HSV-2 transmission from 1 sexual partner to the other when the HSV-2-infected partner has taken daily valacyclovir (500 mg) for 8 months.

Current OB/GYN > Chapter 43. Endometriosis >

Endometriosis: Introduction

Endometriosis is a disorder in which abnormal growths of tissue, histologically resembling the endometrium, are present in locations other than the uterine lining. Although endometriosis can occur very rarely in postmenopausal women, it is found almost exclusively in women of reproductive age. All other manifestations of endometriosis exhibit a wide spectrum of expression. The lesions are usually found on the peritoneal surfaces of the reproductive organs and adjacent structures of the pelvis, but they can occur anywhere in the body (Fig 43–1). The size of the individual lesions varies from microscopic to large invasive masses that erode into underlying organs and cause extensive adhesion formation. Similarly, women with endometriosis can be completely asymptomatic, or may be crippled by pelvic pain and infertility.

Common sites of endometrial implants (endometriosis).

(Reproduced, with permission, from Way LW [editor]: *Current Surgical Diagnosis & Treatment*, 7th ed. Lange, 1985.)

Epidemiology

Endometriosis is a common and important health problem of women. Its exact prevalence is unknown because surgery is required for its diagnosis, but it is estimated to be present in 3–10% of women in the reproductive age group and 25–35% of infertile women. It is seen in 1–2% of women undergoing sterilization or sterilization reversal, in 10% of hysterectomy surgeries, in 16–31% of laparoscopies, and in 53% of adolescents with pelvic pain severe enough to warrant surgical evaluation. Endometriosis is the most common single gynecologic diagnosis responsible for hospitalization of females 15–44 years old, being found in over 6% of patients.

Pathogenesis

The cause of endometriosis is unknown. The leading theories include retrograde menstruation with transport of endometrial cells, metaplasia of coelomic epithelium, hematogenous or lymphatic spread, and direct transplantation of endometrial cells. A combination of these theories likely is responsible.

A theory of retrograde menstruation was proposed during the 1920s. It was postulated that endometriosis occurred because viable fragments of endometrium were shed at the time of menstruation and passed through the uterine tubes. Once in the pelvic cavity, the tissue became implanted on peritoneal surfaces and grew into endometriotic lesions. Subsequent observations have confirmed that some degree of retrograde menstruation normally occurs in women with patent tubes, that outflow tract obstructions (cervical stenosis, transverse vaginal septa) increase the incidence of endometriosis, and that intentional deposition of endometrium onto peritoneum can initiate endometriosis. Also, the risk of developing the disease is higher in women with prolonged menstrual flow and in those with short menstrual cycle lengths (more menses per year). This theory is simple, attractive, and easily explains why endometriosis is most commonly found on the peritoneal surfaces of the ovaries, cul-de-sac, and bladder and why lesions may develop in episiotomies and other incisions. However, it does not explain why all women do not develop endometriosis, nor does it explain the rare cases of endometriosis in the lung, brain, or other soft tissues or in nonmenstruating subjects (women with Turner's syndrome or with absent uteri).

Evidence indicates that altered humoral and cell-mediated immunity plays a role in the pathogenesis of endometriosis. The activity of natural killer cells may be reduced, and deficient cellular immunity may cause an inability to recognize endometrial tissue in abnormal locations. Endometriosis may occur when the deficiency in cellular immunity allows menstrual tissue to implant and grow on the peritoneum. Some evidence also indicates increased concentration of leukocytes and macrophages in the ectopic endometrium and the peritoneal cavity, which secrete growth factors and cytokines into the peritoneal fluid. These cytokines and growth factors are postulated to lead to proliferation of the endometriotic implants and the inflammatory reaction, of which oxidative stress may be another component. Patients with endometriosis have been described as having a higher rate of autoimmune inflammatory disorders compared to the general population. Genetic influences in the development of endometriosis also have been described. Studies have found that 7–9% of first-degree female relatives of patients with endometriosis are diagnosed with the disease; this rate is significantly greater than the control rate of 1–2%. Further investigation has revealed a possible role for the HLA-B7 allele. Expression of HLA-B7 has been shown to inhibit the cytotoxic activity of natural killer-like T lymphocytes, suggesting that growth of ectopic endometrial cells might be under genetic control.

Pathology

The gross appearance of endometriosis at operation is usually quite characteristic and, to an experienced surgeon, is sufficient for diagnosis. The smallest (and presumably earliest) implants are red, petechial lesions on the peritoneal surface. With further growth, menstrual-like detritus accumulates within the

lesion, giving it a cystic, dark brown, dark blue, or black appearance. The surrounding peritoneal surface becomes thickened and scarred. These "powder burn" implants typically attain a diameter of 5–10 mm. With progression of disease, the number and size of lesions increase, and extensive adhesions may develop. When present on the ovary, cysts may enlarge to several centimeters in size and are called "endometriomas" or "chocolate cysts." Severe disease can erode into underlying tissues and distort the remaining organs with extensive adhesions. In addition to these traditional presentations, endometriosis lesions can have a variety of nonclassical appearances: clear vesicles, white or yellow spots or nodules, circular folds of peritoneum ("pockets"), and visually normal peritoneum (lesions so small they can only be detected microscopically).

The distribution of lesions also exhibits a characteristic pattern. Solitary lesions are possible, but multiple implantations are the rule. The most common site of disease is the ovary (approximately half of all cases), followed by the uterine cul-de-sac, posterior broad ligament, uterosacral ligaments, uterus, fallopian tubes, sigmoid colon, appendix and round ligaments. Implants may occur over the bowel, bladder, and ureters; rarely, they erode into underlying tissue and cause blood in the stool or urine, or their associated adhesions result in stricture and obstruction of these organs. Implants can occur deep in tissue, especially on the cervix, posterior vaginal fornix, or within wounds contaminated by endometrial tissue (see Fig 43–1). Very rarely, endometriosis is found distant from the pelvis, in such sites as the lung, brain, and kidney. Pleural implantations are associated with recurrent right pneumothoraces at the time of menses, termed "catamenial pneumothorax." Similarly, lesions in the central nervous system can cause catamenial seizures.

The microscopic finding that these lesions are composed of tissue histologically resembling endometrial glands and stroma gives endometriosis its name (Fig 43–2). The normal endometrial appearance is best seen in small, early lesions. With advanced disease, cyst formation, and fibrosis, the wall of the implant is lined by a monolayer of cells, if at all. Blood is present inside the cyst, and hemosiderin-laden macrophages are found in the cyst wall.

Pathologic Physiology

It is generally agreed that pelvic pain occurs premenstrually in endometriosis patients. Because of this, pain from endometriosis is thought to be due to stimulation from estrogen and progesterone during the menstrual cycle; the tissue of the implant is stimulated to grow in much the same way as is the endometrium. The implants enlarge and may undergo secretory change and bleeding; however, the fibrotic tissues surrounding the implants prevent the expansion and escape of hemorrhagic fluid that occurs in the uterus. With subsequent cycles, this process repeats itself. Pain is produced by pressure and inflammation within and around the lesion, by traction on adhesions associated with the lesions, by the number of implants and their proximity to nerves and other sensitive structures, and by the mass effect of large lesions. Although this sequence of events explains why premenstrual pelvic pain can occur in endometriosis, it is incomplete, because many patients with extensive endometriosis have no pain. It is a common observation that the occurrence and severity of pain from endometriosis bear little relationship to the amount and distribution of the disease. Severe pain in patients with endometriosis is associated with deeply infiltrating lesions, and it is thought that the degree of pain is perhaps determined by the depth of invasion.

The relationship between endometriosis and infertility has been more extensively investigated. Moderate and severe endometriosis is associated with pelvic adhesions that distort pelvic anatomy, prevent normal tubo-ovarian apposition, and encase the ovary. Implants can destroy ovarian and tubal tissue, although occlusion of uterine tubes is rare.

It is not difficult to understand how advanced disease can result in infertility, but minimal or mild endometriosis, in which pelvic anatomy is entirely normal except for a few peritoneal surface lesions, can

also cause infertility. The mechanism by which this occurs is unknown. Various theories explaining this phenomenon have been proposed.

Several investigators have examined peritoneal fluid abnormalities. The peritoneal fluid is an ultrafiltrate of plasma, with less than 5 mL normally present in the pelvis. After ovulation, a transient rise to approximately 20 mL occurs. The volume of peritoneal fluid and the concentrations of various hormones and other substances in it affect the processes of ovulation, ovum pickup, tubal function, and so on. The normal role of the peritoneal fluid and its constituents in these processes, and how it is altered by endometriosis, are largely unknown. Peritoneal fluid volume has been reported to be altered in endometriosis patients, but studies have led to inconsistent results.

Similarly, reports are contradictory as to whether endometriosis patients have elevations in peritoneal fluid prostaglandins F_2 and E_2 . Prostaglandins are normally secreted by the endometrium and by endometriosis lesions; an increase in peritoneal fluid prostaglandin levels could theoretically decrease fertility by altering ovulation, tubal motility, nidation, and luteal phase adequacy. The conflicting reports may result from fluctuations that normally occur across the cycle in prostanoid production, as well as variations in the lesions' synthesis of prostaglandins; small red petechial implants have been found to secrete more prostaglandins than larger, powder burnlike ones.

Several disorders of menstrual cyclicity and ovulation have been suggested as a basis for the infertility caused by mild endometriosis. The rate of ovulation among endometriosis patients is 11–27%. Nearly half of patients become pregnant when this problem is also treated. More subtle problems in folliculogenesis in endometriosis patients have been reported, including lower serum estradiol levels, smaller follicle size during follicular growth, and lower oocyte fertilization rates and pregnancy rates in assisted reproduction. Problems with ovum pickup by the fallopian tube and embryo implantation in the endometrium have also been suggested.

Clinical Findings

Endometriosis is common among women of reproductive age, and its prevalence increases to 30–40% among infertile women. Clinical findings vary greatly depending on the number, size, and extent of the lesions and on the patient population being examined.

The diagnosis of endometriosis is often strongly suspected from a patient's initial history. Infertility, dysmenorrhea, and dyspareunia are the main presenting complaints. Most patients complain of constant pelvic pain or a low sacral backache that occurs premenstrually and subsides after menses begins. Dyspareunia is often present, particularly with deep penetration. Lesions involving the urinary tract or bowel may result in bloody urine or stool in the perimenstrual interval. Implantations on or near the external surfaces of the cervix, vagina, vulva, rectum, or urethra may cause pain or bleeding with defecation, urination, or intercourse at any time in the menstrual cycle. Adhesions from endometriosis may cause discomfort at any time during the cycle, and a sensation of pelvic pressure may result if large masses are present. Premenstrual spotting may occur and is more likely to be associated with endometriosis than with luteal phase inadequacy. It must be emphasized, however, that many patients either have no symptoms or have infertility as their only symptom and that the extent of disease often has little correlation with the severity of symptoms.

The physical examination may be helpful in discerning whether endometriosis is present. Classically, pelvic examination reveals tender nodules in the posterior vaginal fornix and pain upon uterine motion. The uterus may be fixed and retroverted due to cul-de-sac adhesions, and tender adnexal masses may be felt because of the presence of endometriomas. Careful inspection may reveal implants in healed wounds, especially episiotomy and cesarean section incisions, in the vaginal fornix, or on the cervix.

Biopsy may be required to prove that the lesions are due to endometriosis. However, many patients have no abnormal findings on physical examination.

For the vast majority of patients, endometriosis is included in the differential diagnosis of infertility or pelvic pain. Endometriosis should be suspected in any patient of reproductive age complaining of pain or infertility. Medical treatment can be given for pelvic pain thought to be due to endometriosis, but the specific diagnosis of endometriosis should not be made unless documented by direct visualization. The final diagnosis of endometriosis can only be made at laparoscopy or laparotomy, by direct observation of the implants. Occasionally, an isolated endometrioma is removed, and the diagnosis must be made histologically by the demonstration of "endometrial" glands and stroma or of hemosiderin-laden macrophages in the cyst wall.

Except for special circumstances, such as urography or sigmoidoscopy for suspected bowel or urinary involvement, ancillary diagnostic studies (ultrasound, x-ray films, computed tomographic scans) are of little help in diagnosis. Cancer antigen-125 (CA-125) is often elevated in women with endometriosis. However, it has been shown that this marker is elevated in many other pelvic diseases and therefore has little specificity in the diagnosis of endometriosis. Elevated CA-125 levels that return to normal after medical or surgical treatment can be helpful in the evaluation for recurrences.

Complications

True complications of endometriosis are few. Implants over the bowel or ureters may cause obstruction and silent impairment of renal function. The erosive nature of the lesions in advanced aggressive disease can cause a myriad of symptoms, depending on the tissue damaged. Endometriomas can cause ovarian torsion, or they can rupture and spill their irritating contents into the peritoneal cavity, resulting in a chemical peritonitis. Excision of endometriosis causing catamenial seizures or pneumothorax may be necessary.

Differential Diagnosis

The varied presentations of endometriosis mandate that its consideration in the differential diagnosis of virtually all pelvic disease. In particular, the pain, infertility, and adhesions associated with endometriosis must be distinguished from similar symptoms accompanying pelvic inflammatory disease and pelvic tumors. Usually this requires operative evaluation. A patient with a persistent adnexal mass larger than 5 cm should never be presumed to have an endometrioma even if endometriosis has been diagnosed previously. Such masses require surgical diagnosis.

Prevention

Prevention of endometriosis is not currently possible. Traditionally, women with relatives affected by endometriosis—or in whom the diagnosis has recently been made—are advised not to postpone childbearing. The merits of this advice have not been proved. A more thorough understanding of the pathophysiology of endometriosis is required before preventive strategies can be devised.

Classification

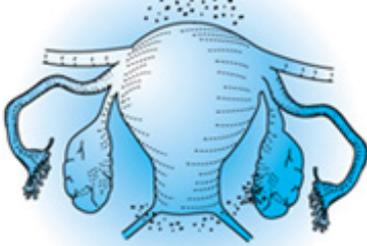

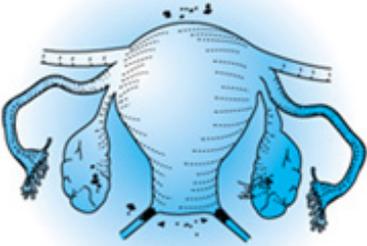

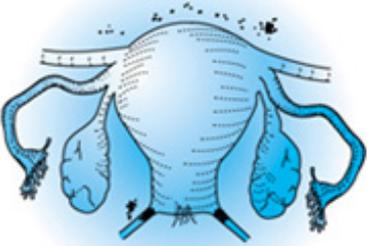

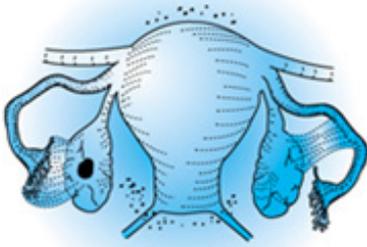

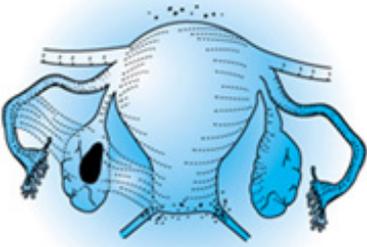

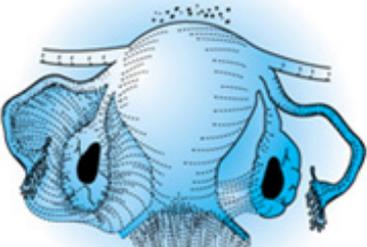

Several classification schemes to assist in describing the anatomic location and severity of endometriosis at operation have been created. Although none is entirely satisfactory, the scoring systems are useful for reporting operative findings and for comparing the results of various treatment protocols. The revised American Society for Reproductive Medicine classification is given in Table 43–1 and Fig 43–3. Note that this system does not correlate with the severity of pain but is mainly designed to predict the chance of pregnancy.

Table 43–1. American Society for Reproductive Medicine Revised Classification of Endometriosis.

Peritoneum	Endometriosis		< 1 cm	1–3 cm	> 3 cm
		Superficial	1	2	4
		Deep	2	4	6
Ovary	R	Superficial	1	2	4

Staging of endometriosis. Determination of stage or degree of endometrial involvement is based on a weighted point system (see Table 43–1 for point values). Distribution of points has been arbitrarily determined and may require further revision or refinement as knowledge of the stage of the disease increases. To ensure complete evaluation, inspection of the pelvis in a clockwise or counterclockwise fashion is encouraged. Number, size, and location of endometrial implants, plaques, endometriomas, and/or adhesions are noted. For example, 5 separate 0.5-cm superficial implants on the peritoneum (2.5 cm total) would be assigned 2 points. (The surface of the uterus should be considered peritoneum.) The severity of the endometriosis or adhesions should be assigned the highest score only for peritoneum, ovary, tube, or cul-de-sac. For example, a 4-cm superficial and a 2-cm deep implant of the peritoneum should be given a score of 6 (not 8). A 4-cm deep endometrioma of the ovary associated with more than 3 cm of superficial disease should be scored 20 (not 24). In patients with only 1 set of adnexa, points applied to disease of the remaining tube and ovary should be multiplied by 2. Points assigned may be circled and totaled. Aggregation of points indicates stage of disease (minimal, mild, moderate, or severe). The presence of endometriosis of the bowel, urinary tract, fallopian tube, vagina, cervix,

and skin should be documented under "additional endometriosis." Other pathology, such as tubal occlusion, leiomyomata, and uterine anomaly, should be documented under "additional pathology." All pathology should be depicted as specifically as possible on the sketch of pelvic organs, and the means of observation (laparoscopy or laparotomy) should be noted.

Treatment

Treatment options are dictated by the patient's desire for future fertility, her symptoms, the stage of her disease, and to some extent her age. It must be emphasized that therapy for endometriosis requires operative inspection of the lesions for correct diagnosis and staging and to ensure that the patient's symptoms are attributable to endometriosis only.

EXPECTANT MANAGEMENT

In asymptomatic patients, those with mild discomfort, or infertile women with minimal or mild endometriosis, expectant management may be appropriate. Although endometriosis is generally believed to be a progressive disease, no evidence indicates that treating an asymptomatic patient will prevent or ameliorate the onset of symptoms later. Many reports have found expectant management of infertile women with minimal or mild endometriosis to be as successful as medical or surgical therapies.

ANALGESIC THERAPY

Analgesic treatments include nonsteroidal anti-inflammatory drugs. These drugs are appropriate sole therapy for endometriosis when the patient has mild premenstrual pain from minimal endometriosis, no abnormalities on pelvic examination, and no desire for immediate fertility.

HORMONAL THERAPY

The goal of treatment with hormonal therapy is to interrupt the cycles of stimulation and bleeding of endometriotic tissue. This can be achieved with various agents.

Oral Contraceptive Pills

Oral contraceptive pills (OCPs) are a good choice for patients with minimal or mild symptoms. In general, monophasic products are prescribed either cyclically or continuously for 6–12 months. The continuous exposure to combination OCPs results in decidual changes in the endometrial glands. Continuous use of OCPs has been shown to be effective in decreasing dysmenorrhea and may retard progression of endometriosis.

Progestins

These agents work via a mechanism similar to that of the OCPs, causing decidualization in the endometriotic tissue. Oral medroxyprogesterone acetate can be prescribed as a 10- to 30-mg daily dose. An alternative regimen is norethindrone acetate 5 mg daily or megestrol acetate prescribed as a 40-mg daily dose. Depot medroxyprogesterone acetate 150 mg IM can also be given as a single injection every 3 months.

In a few small studies, the levonorgestrel-releasing intrauterine device has been shown to relieve dysmenorrheal and pelvic pain. Eighty percent of women treated with progestins have a partial or complete relief of pain.

Danazol

Danazol is a 19-nortestosterone derivative with progestinlike effects. Danazol acts via several mechanisms to treat endometriosis. It acts at the hypothalamic level to inhibit gonadotropin release, inhibiting the midcycle surge of luteinizing hormone and follicle-stimulating hormone. Danazol also inhibits steroidogenic enzymes in the ovary responsible for estrogen production. As a result, a

hypoestrogenic environment is created. This, in addition to the androgenic effects of danazol, prevents the growth of endometriotic tissue.

The dosage of danazol is 400 to 800 mg/d in divided doses for 6 months.

Side effects of danazol include acne, oily skin, deepening of the voice, weight gain, edema, and adverse plasma lipoprotein changes. Most changes are reversible upon cessation of therapy, but some (such as deepening of the voice) may not be.

Pain relief is achieved in up to 90% of patients taking danazol.

GnRH Agonists

Gonadotropin-releasing hormone (GnRH) agonists are analogues of the 10-amino-acid peptide hormone GnRH. With continuous administration of GnRH analogues, suppression of gonadotropin secretion occurs, resulting in elimination of ovarian steroidogenesis and suppression of endometrial implants. Pain related to endometriosis is relieved in most cases by the second or third month of therapy. GnRH agonists can be administered intramuscularly as leuprolide acetate 3.75 mg once per month, intranasally as nafarelin 400 to 800 mg daily, or subcutaneously as goserelin 3.6 mg once per month.

Use of these agents is generally limited to 6 months because of the adverse effects associated with a hypoestrogenic state, particularly loss of bone mineral density. Other side effects include vasomotor symptoms, vaginal dryness, and mood changes.

Many side effects can be minimized by providing add-back therapy in addition to the GnRH agonists in the treatment of endometriosis. The addition of 2.5 mg of norethindrone or 0.625 mg of conjugated estrogens with 5 mg/d of medroxyprogesterone acetate seems to relieve vasomotor symptoms and decrease bone mineral density loss in a 6-month treatment period. The addition of 5 mg daily of norethindrone acetate alone or in conjunction with low-dose conjugated equine estrogen seems to eliminate the loss of bone mineral density effectively as well.

Aromatase Inhibitors

Anastrozole 1 mg daily or letrozole 2.5 mg daily are the most commonly used aromatase inhibitors. They act by inhibiting the enzyme aromatase, which converts androgens to estrogens. Endometriosis lesions may contain aromatase and be deficient in the enzymes that degrade estrogen, which promotes their own growth by creating an estrogen-rich microenvironment within the lesions. This may explain why some patients continue to have symptoms on therapies that lower systemic estrogen levels. Aromatase inhibitors have not been studied extensively in endometriosis; they can be used singly or as an adjunct to other therapies. Adverse effects on bone mass limit their use.

Surgical Treatment

In women with complaints of infertility who have severe disease or adhesions or who are older, conservative surgical therapy is the treatment of choice. This surgery attempts to excise or destroy all endometriotic tissue, remove all adhesions, and restore pelvic anatomy to the best possible condition. Conservative surgery has traditionally been performed at laparotomy, but a laparoscopic approach is associated with a shorter hospital stay and less morbidity, and it may be more cost effective. This is particularly true in contemporary practice, where this therapy is usually performed at the time of the initial diagnostic laparoscopy. Reported pregnancy rates following conservative surgery are inversely proportional to the severity of disease and vary greatly. In counseling patients, approximate pregnancy rates of 75% for mild disease, 50–60% for moderate disease, and 30–40% for severe disease should be quoted; however, individualization of therapy is stressed.

Presacral neurectomy to relieve pain should be performed only in selected cases, such as women with

recurrent endometriosis, severe incapacitating dysmenorrhea, or disease that did not respond to initial treatment, because the efficacy of this treatment is controversial.

If the patient does not desire future childbearing and has severe disease or symptoms, definitive surgery is appropriate and often curative. This entails total abdominal hysterectomy, bilateral salpingo-oophorectomy, and excision of remaining adhesions or implants. If endometriosis remains after excision, postoperative medical therapy may be indicated. After this or after complete excision, hormone replacement therapy is indicated. Estrogen–progestin therapy can be used without reactivating the endometriosis, but individualization of therapy is required.

Assisted Reproduction

Infertile women with endometriosis who are older, or who have not responded to other therapies for infertility, can undergo assisted reproduction, such as ovulation induction with intrauterine insemination or in vitro fertilization (IVF). However, women with endometriosis undergoing IVF were found to have significantly lower pregnancy rates, fertilization rates, implantation rates, mean number of oocytes retrieved, and peak estradiol concentrations compared to women with tubal factor infertility. The need to treat women surgically or medically prior to starting an IVF cycle remains unclear.

Prognosis

Proper counseling of patients with endometriosis requires attention to several aspects of the disorder. Of primary importance is the initial operative staging of the disease to obtain adequate information on which to base future decisions about therapy. The patient's symptoms and desire for childbearing dictate appropriate therapy. Most patients can be told that they will be able to obtain significant relief from pelvic pain and that treatment will assist them in achieving pregnancy.

Long-term concerns must be more guarded because all current therapies offer relief but not cure. Even after definitive surgery, endometriosis may recur, but the risk is very low (approximately 3%). Estrogen replacement therapy does not significantly increase the risk of recurrence. After conservative surgery, reported recurrence rates vary greatly but usually exceed 10% in 3 years and 35% in 5 years. Pregnancy delays but does not preclude recurrence. Recurrence rates after medical treatment vary and are similar to or higher than those reported following surgical treatment.

Although many patients are concerned that endometriosis will progress inexorably, experience has been that conservative surgery prevents the necessity for hysterectomy in the great majority of cases. The course of endometriosis in any individual cannot be predicted at present, and future treatment options should greatly improve upon what is offered now.

Current OB/GYN >Chapter 44. Pelvic Organ Prolapse>

Pelvic Organ Prolapse: Introduction

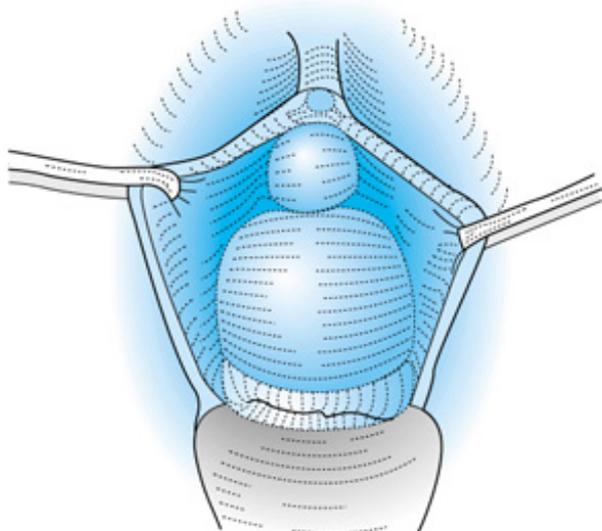

Pelvic organ prolapse (POP) is a common group of clinical conditions affecting women. The prevalence rates increase with age and POP currently affects millions of women. In the United States, POP is responsible for more than 200,000 surgeries per year. The lifetime risk that a woman will undergo surgery for prolapse or urinary incontinence is 1 in 3, with a third of surgeries representing repeat procedures. The risk of requiring a repeat procedure for POP may be as high as 29%. As our population ages, quality-of-life-altering conditions such as POP will demand more attention from our health care services. The ability to screen, diagnose and treat these entities will become increasingly important for clinicians.

Defects in the pelvic supporting structures result in a variety of clinically evident pelvic relaxation abnormalities. Support defects can be classified by their anatomic location.

Anterior Vaginal Wall Defects

- *Anterior vaginal prolapse* describes an anterior vaginal wall defect where the bladder is associated with the prolapse. It is also known as a cystocele (Fig 44–1).
- *Urethrocele* describes a distal anterior vaginal wall defect where the urethra is associated with the prolapse, essentially a very distal anterior wall defect.
- *Paravaginal/midline/transverse prolapse* indicate the location of anterior vaginal wall defect (Fig 44–2)

Four areas in which pubocervical fascia can break or separate—four defects.

Apical Prolapse

- *Uterine prolapse* (Fig 44–3)
- *Vaginal vault prolapse* (posthysterectomy)
- *Enterocoele* describes an apical vaginal wall defect in which bowel is contained within the prolapsed segment (44–4). Generally occurs in posthysterectomy women, but can occur with the uterus in situ.

Description and Staging of Pelvic Organ Prolapse

Two general classifications are used to describe and document the severity of pelvic organ prolapse.

The most current system employs objective measurements from fixed anatomic points. The Pelvic Organ Prolapse Quantification (POP-Q) system standardizes terminology of female pelvic organ prolapse. This is accepted as the objective method for quantifying prolapse as it provides a more precise description of the anatomy. This descriptive system contains series of site-specific measurements of vaginal and perineal anatomy. Prolapse in each segment is evaluated and measured relative to the hymen, which is a fixed anatomic landmark that can be consistently identified. The anatomic position of the six defined points for measurement should be in centimeters above the hymen (negative number) or centimeters beyond the hymen (positive number). The plane at the level of the hymen is defined as

(Fig 44–7 and Table 44–1). Stages are assigned according to the most severe portion of the prolapse when the extent of the protrusion has been demonstrated. An ordinal system is utilized for measurements of different points along the vaginal canal that facilitates communication among clinicians and enables objective tracking of surgical results. The POP-Q system has generally replaced the "1/2 way" system designed by Baden and Walker.

Figure 44–7.

Six sites (points *Aa*, *Ba*, *C*, *D*, *Bp*, and *Ap*), genital hiatus (*gh*), perineal body (*pb*), and total vaginal length (*TVL*) used for pelvic organ quantitation.

(Reproduced with permission from Bump RC et al: The standardization of terminology of female pelvic organ prolapse and pelvic floor dysfunction. *Am J Obstet Gynecol* 1996;175:10.)

Table 44–1. Staging of Pelvic Organ Prolapse.

Stage 0

No prolapse is demonstrated. Points *Aa*, *Ap*, *Ba*, and *Bp* are all at -3 cm and either point *C* or *D* is between $-TVL$ vaginal length) cm and $-(TVL-2)$ cm (ie, the quantitation value for point *C* or *D* is $\leq -(TVL-2)$ cm).

Stage I

The criteria for stage 0 are not met, but the most distal portion of the prolapse is > 1 cm above the level of the hymen (ie, its quantitation value is < -1 cm).

Stage II

The most distal portion of the prolapse is ≤ 1 cm proximal to or distal to the plane of the hymen (ie, its quantitation value is ≥ -1 cm but $\leq +1$ cm).

Stage III

The most distal portion of the prolapse is > 1 cm below the plane of the hymen but protrudes no further than 2 cm than the total vaginal length in centimeters (ie, its quantitation value is $> +1$ cm but $< +(TVL-2)$ cm).

Stage IV

Essentially, complete eversion of the total length of the lower genital tract is demonstrated. The distal portion of prolapse protrudes to at least $(TVL-2)$ cm (ie, its quantitation value is $\geq +(TVL-2)$ cm). In most instances, the leading edge of stage IV prolapse is the cervix or vaginal cuff scar.

Reproduced, with permission, from Bump RC et al: The standardization of terminology of female pelvic organ prolapse and pelvic floor dysfunction, *Am J Obstet Gynecol* 1996;175:10.

A better understanding of the pathophysiology of the pelvic supportive defects, their causes, and clinical presentation allows the individualization of the therapy most likely to successfully affect long-term therapy for each patient. As POP is a disease impacting the quality of life, obtaining a detailed symptom history is an essential starting point.

General Considerations

The cause of POP is most assuredly caused by multiple factors. This is the clearest model to explain the vast discrepancies in the incidence of POP and variety of anatomic findings despite shared risk factors. Proven risk factors include age, increasing parity, obesity, and history of pelvic surgery, specifically hysterectomy. Additionally, certain lifestyle or disease conditions can promote the development of POP. Chronic coughing from lung disease and straining from chronic constipation for example, may increase the pressures on the pelvic floor. Acting as a constant pistoning driving forces exerted onto the pelvic support tissues can cause herniation of the vaginal walls. In a similar manner occupational activity requiring repetitive heavy lifting (e.g. environmental service workers or care providers of the elderly) may promote the development of POP with this daily insult of frequent pelvic pressure.

Furthermore, menopausal status, physical debilitation and even neurologic decline can contribute to the development of POP. Yet even with a multitude of risk factors, certain women are predisposed to developing POP. As demonstrated in women with no identifiable risk factors, the inherent quality of a woman's connective tissue plays a large role in the susceptibility to the development of prolapse and related conditions. Investigating the consistent composition of the endopelvic "fascial" tissues and the interplay of enzymatic remodeling is an area of intense interest and current research.

Parity has long been recognized as a prime risk factor for the development of POP. Not surprisingly, it is also strongly associated with anal and urinary incontinence as well. Parity is clearly associated with POP, as case-controlled studies show vaginal parity as an independent risk factor with a threefold increased risk for POP amongst parous women compared to nullipara controls. This risk increases up to 4.5-fold with more than two vaginal deliveries. The question to whether it is the pregnancy, the size of the baby, or the mode of delivery that plays the largest role in the development of POP is still not clear. During labor, as the vertex descends through the vagina, the physical forces on the pelvic tissues can be severe. The muscles, viscera, connective tissue, and nerves are all potentially susceptible to injury. Forces of compression and stretching combine to injure pelvic-floor nerves, leading to ischemia and neuropathy. Myofascial fibers can be disrupted or torn because of distention of the fetal head and body. When tissues are injured the body will repair them. Factors impairing adequate tissue repair and wound healing may also play an as yet undetermined role in the development of POP.

The principal components of the basin-like pelvic floor are the pelvic bones (including the coccyx), the endopelvic fascia, and the levator and perineal muscles. These structures normally support and maintain the position of the viscera despite great increments in intra-abdominal pressure that occur with straining, coughing, and heavy lifting when the patient is in the erect position. The urogenital hiatus ("anterior levator muscle gap"), which permits the urethra, vagina, and anus to emerge from the pelvis, is a site of potential weakness. Attenuation of the pubococcygeus and puborectal portions of the levator muscles, whether as the result of a traumatic delivery or of involutional changes, widens the levator gap and converts this potential weakness to an actual defect. If there has been a concomitant or attenuation of the endopelvic fascia (uterosacral and cardinal ligaments, rectovaginal and pubocervical fascia), heightened intra-abdominal pressure gradually leads to uterine prolapse along with anterior vaginal prolapse, rectocele, and enterocele. If the integrity of the endopelvic fascia and its condensations has been maintained, the incompetence of the genital hiatus and levator muscles may be associated only with elongation of the cervix.

Anterior and posterior vaginal relaxation, as well as incompetence of the perineum, often accompanies prolapse of the uterus. Large anterior vaginal prolapse is more common than posterior vaginal prolapse because the bladder is relatively

easily carried downward than is the rectum. Prior to the menopause, the prolapsed uterus hypertrophies and is engorged and flaccid. After the menopause, the uterus atrophies. In procidentia, the vaginal mucosa thickens and cornifies, coming to resemble skin.

Essentials of Diagnosis

SYMPTOMS

The symptoms of POP are in general not unique to any particular vaginal defect. Often the symptoms are a reflex only the most prominent point of prolapse. Most women become symptomatic only when the prolapse nears the opening. A critical concept is that the functional complaints may not always relate to the anatomic findings.

Symptoms of POP include:

- Sensation of vaginal fullness, pressure, "something falling out," or "heaviness."
- Sensation of "sitting on a ball."
- Discomfort in the vaginal area.
- Presence of a soft, reducible mass bulging into the vagina and distending through vaginal introitus.
- With straining or coughing, increased bulging and descent of the vaginal wall.
- Back pain and pelvic pain are often also associated with POP. It is important in women with these complaints to investigate other causes, as a direct link in mild to moderate prolapse is unproven.
- Urinary symptoms are also common.
 - Feeling of incomplete emptying of the bladder
 - Stress incontinence
 - Urinary frequency
 - Urinary hesitancy
 - Perhaps a need to push the bladder up in order to void (splinting)
 - Patients with advanced prolapse may have "potential" stress urinary incontinence. A condition in which underlying urinary incontinence is masked by kinking of the urethra and causing functional continence

Defecatory symptoms may also occur, more commonly in posterior vaginal prolapse. The sense of incomplete emptying, need to strain or manually splint in the vagina or on the perineal body (space between vagina and anus) in order to defecate. The history may include prolonged, excessive use of laxatives, or frequent enemas. Other notable symptoms such as low back pain, dyspareunia, or even fecal and gas incontinence may be reported.

Symptoms of sexual function may also be elicited. Coital laxity or a sense of feeling "loose" may be reported. Avoidance of intercourse as a consequence of embarrassment may occur. Attention to this aspect of a woman's symptoms is especially critical if any surgical intervention is considered.

Clinical Findings

PHYSICAL EXAMINATION

Examination for pelvic organ prolapse should begin in the dorsal lithotomy position. Inspection of the vulva and perineum should focus on evaluation of vulvar architecture, the presence of pressure ulceration or erosions or other skin lesions. Epithelial skin lesions, particularly in the elderly should be biopsied.

At first with the patient at rest the labia should be separated and any prolapse noted (Figs 44-1 and 44-6).

Examination of the patient with vaginal prolapse reveals a relaxed and open genital hiatus with a thin-walled, rather smooth, bulging mass. Vaginal rugae are normally present. A loss of rugation denotes disruption of the connective

tissue attachment below the epithelium.

During evaluation for urinary incontinence, a stress test is performed at this initial portion of the examination. The patient should be asked to cough forcefully and any loss of urine noted.

For prolapse assessment, when using the POP-Q system, the genital hiatus, perineal body, and vaginal length are recorded. (Use of a wooden PAP spatula and tape measure can be helpful.) Vaginal support can then be assessed with strain (cough or Valsalva) and the point of maximal protrusion should be noted in centimeters relative to the hymen and recorded. A speculum can also be used to "usher" the prolapse out during straining. This is also the most effective way to evaluate uterocervical support. In posthysterectomy patients, the cuff can often be visualized by the presence of "dimples" in the vaginal epithelium at the apex. Discriminate examination of the vaginal walls using the posterior of a Graves speculum or similar retractor should then be used to evaluate the anterior and posterior walls separately, again noting the point of maximal prolapse during strain. For evaluation of the anterior wall compress the posterior wall and have the patient strain. For evaluation of the posterior wall, elevate the anterior wall and have the patient strain. Complete examination should also include a rectovaginal palpation. In this way, one can evaluate for the presence of concurrent enterocele in addition to a rectocele. The septal defect may involve only the lower third of the posterior vaginal wall, but it often happens that the entire length of the rectovaginal septum is thinned out. The finger in the rectum confirms sacculation into the vagina. A deep pocket into the perineal body may be noted, so that on application of the finger in the rectum and the thumb on the outside, the perineal body seems to consist of nothing but skin and rectal wall.

Assessment of anal sphincter tone should also be performed both at rest and with squeeze contraction. The presence of perianal lesions or hemorrhoids should be noted.

If during examination the prolapse is not able to be reproduced based on symptoms, examination with the woman in the standing position should be performed. With the patient facing the seated examiner, knees slightly bent, and on strain, prolapse not demonstrable in the supine position because of poor Valsalva, can often be confirmed in the standing position.

Assessment of the pelvic floor strength is accomplished by vaginal or rectovaginal palpation of the levator ani musculature. Within 2 to 3 cm from the hymen, the bulk of the pubococcygeus component of the levator ani muscle can be palpated. The patient should be asked to contract the muscle and the tone, symmetry, and duration should be recorded. This portion of the examination is often a valuable time to provide feedback to the patient about the woman's ability to contract the pelvic floor muscles. If the patient's ability to identify and contract the muscles is inadequate, the examiner may facilitate isolation of the proper muscles using verbal cues and manual feedback.

Evaluation of urinary function is also important in patients with POP. This is most germane in patients with large anterior vaginal defects. With prolapse of the anterior vagina, the bladder and urethra may herniate into the vagina. The urethra can bend and kink as it is fixed distally at the level of the pubourethral ligament. This "kinking" can impact normal voiding function in two fundamental ways. One, it will increase outflow resistance and impair normal emptying of the bladder. After voiding, simple catheterization should be performed and the residual volume measured. The specimen should then be sent for routine urinalysis and culture. Although not standardized, postvoid residual volumes over 100 mL are considered elevated and may indicate abnormal voiding, and require referral for more sophisticated testing.

The second way urethral kinking can impact voiding, is by masking underlying stress urinary incontinence. With increased outflow resistance functional continence is created. Reduction of the prolapse during examination can be performed (elevation of anterior segment with a pessary, ring forceps, or speculum). The patient strains/coughs and the presence of urinary loss confirms the condition of stress urinary incontinence. This is commonly referred to as "potential" stress urinary incontinence and should be addressed with an anti-incontinence procedure at the same time surgery is offered for POP.

IMAGING STUDIES

In general, a complete discriminative gynecologic examination is all that is necessary to accurately assess pelvic prolapse. In certain cases, further diagnostic studies can be employed.

Recent advances in radiologic medicine have allowed assessment of the pelvic floor with sonography, computed tomography (CT), and magnetic resonance imaging (MRI).

Despite newer techniques, intravenous pyelogram (IVP) still holds great value, as it is a simple and safe method to visualize the urinary tract. It can be used to evaluate the bladder and ureters. The course of the ureters can be identified preoperatively if obstruction caused by pelvic mass or scarring is suspected. IVP can be used to evaluate fistulae, congenital anomalies, or suspected damage as a result of operative injury. However, it lacks sensitivity in imaging the pelvic floor and its associated defects, and does not yield much information regarding vaginal support, pelvic floor musculature, and lacks dynamic capabilities.

Ultrasound techniques can be an important tool to the urogynecologist. Compared to other radiologic techniques, ultrasound is noninvasive and inexpensive, and does not require contrast media. Its main disadvantage is that the quality of the study depends heavily on the skill of the operator. When performed transabdominally, transvaginally, transperineally, and combined with Doppler or endoluminal transducers, the bladder, urethra, and surrounding structures can be visualized.

Videocystourethrography (VCUG)

VCUG combines a fluoroscopic voiding cystourethrogram with simultaneous recording of intravesical, intraurethral, intra-abdominal pressure and urine flow rate. The contrast in the bladder allows dynamic evaluation of the bladder and bladder support.

Computed Tomography (CT)

CT can be used in the evaluation of ureteral obstruction, urolithiasis, and the kidneys. It has poor resolution of soft tissues and has limited value in imaging the pelvic floor and associated defects.

Magnetic Resonance Imaging (MRI)

MRI has evolved into an important tool for the evaluation of the pelvic floor. It is an ideal modality because its resolution of soft tissues is superior to that of other radiologic techniques. The capability to image in multiple planes is also an advantage, particularly when visualizing the complex three-dimensional relationships of the pelvic floor. As this modality becomes less costly and techniques evolve to allow evaluation of patients in the upright position, the information provided by MRI will be invaluable in increasing our knowledge and understanding of functional pelvic support.

Differential Diagnosis

Prolapse of the vagina is generally a straightforward diagnosis. However, less common disease entities may present as vaginal bulges in the vagina. Tumors of the urethra and bladder are much more indurated and fixed than is anterior vaginal prolapse.

A large urethral diverticulum may look and feel like an anterior vaginal prolapse but usually is more focal, and is often painful. With urethral diverticulum, compression may express some purulent material from the urethral meatus. Anterolateral defects can represent embryologic remnants such as a Gartner's duct cyst. Skene's and Bartholin's glands can become obstructed and enlarge to form cysts or abscesses. Rarely, hemangiomas will present as vaginal bulges, although they will often have characteristic purple discoloration on the overlying epithelium.

Soft tumors (lipoma, leiomyoma, sarcoma) of the vagina are more fixed and are nonreducible.

Cervical tumors—as well as endometrial tumors (pedunculated myoma or endometrial polyps)—if prolapsed through a dilated cervix and presenting in the lower third of the vagina, may be confused with mild or moderate uterine prolapse. Myomas or polyps may coexist with prolapse of the uterus and cause unusual symptoms.

Despite the variety of possibilities, the history and physical findings in uterine prolapse are so characteristic that diagnosis is usually not a problem.

Prevention

Prevention of genital prolapse is the focus of much debate. Antepartum and intrapartum and postpartum exercises especially those designed to strengthen the levator and perineal muscle groups (Kegel), often help improve or restore pelvic support. Obesity, chronic cough, straining, and traumatic deliveries must be corrected or avoided. Estrogen therapy following the menopause may help to maintain the tone and vitality of pelvic musculofascial tissues and thereby prevent or postpone the appearance of anterior vaginal prolapse and other forms of relaxation.

Treatment

Pelvic organ prolapse, except in rare situations, is a condition that impacts only the quality of life. Consequently, extent and type of treatment should reflect and be commensurate with the degree of negative impact on the quality of life the patient experiences. Patient perception is also a critical component, and self-image and conceptual distortions are relevant to any discussion of therapy. Common reasons to intervene are when function is impaired because of prolapse. Anterior prolapse can contribute to urinary incontinence or, when severe, urinary obstruction. Bulging epithelium can come into contact with undergarments and clothing and over time develop pressure sores and eventually leading to cellulitis. A posterior vaginal defect can become so large that fecal evacuation is difficult, or the patient may find it necessary to manually reduce the posterior vaginal wall into the vagina to expedite expulsion of feces. Mobility may be impaired by a large prolapse. All of the above complaints are reasons to discuss surgical repair.

Chronic decubitus ulceration of the vaginal epithelium may develop in procidentia. Urinary tract infection may occur with prolapse because of anterior vaginal prolapse; and partial ureteral obstruction with hydronephrosis may occur in procidentia. Hemorrhoids result from straining to overcome constipation. Small-bowel obstruction from a deep enterocele is rare.

CONSERVATIVE MEASURES

The patient with a small or moderate-sized POP requires reassurance that the pressure symptoms are not the result of a serious condition and that, in the absence of urinary retention or severe skin pressure ulceration, no serious illness will result. The natural history of POP is such that it either will stay the same or progress. There is some evidence that a small subset of patients may experience regression of the prolapse after the menopause or postpartum if the prolapse is noted shortly after delivery. Reassurance and observation of prolapse should be encouraged in the absence of symptoms.

If prolapse presents in the reproductive years, surgical correction of POP is rarely indicated in women who may still wish to have children. If the young woman does present with significant symptoms related to POP or with a distinct degree of urinary incontinence—temporary medical measures may provide adequate relief until she has completed childbearing, whereupon a definitive operative procedure can be accomplished.

Pessary

Pessary use in selected patients may provide adequate relief of symptoms. There are a variety of available pessary types and sizes that allow for individualization of therapy (Fig 44–8). For the most common type of POP of the anterior or apical segment, a ring pessary is usually a sensible starting point for treatment. For the patient with complicating medical factors who is a poor operative risk, the temporary use of a vaginal pessary may provide relief of symptoms until her general condition has improved.

Types of pessaries.

Prolonged use of pessaries, if improperly managed, may lead to pressure necrosis and vaginal ulceration.

The vaginal pessary is a prosthesis of ancient lineage, now made of rubber, plastics, and silicone-based material with a metal band or spring frame. Many types have been devised, but fewer than a dozen are basically unique ; specifically helpful.

Pessaries are principally used to support the uterus and vaginal walls. They are effective because they reduce vaginal prolapse and increase the tautness of the pelvic floor structures. Little or no leverage is involved. Either by placement behind the pubic bone and perineal body or by filling the vaginal vault, pessaries remain in place to hold up the prolapsing vaginal walls or uterus. In most cases, adequate support anteriorly and a reasonably good perineal body are required; otherwise, the pessary may slip from behind the symphysis and extrude from the vagina.

Pessaries are contraindicated in acute genital tract infections and in adherent retroversion of the uterus.

Several pessary types are available:

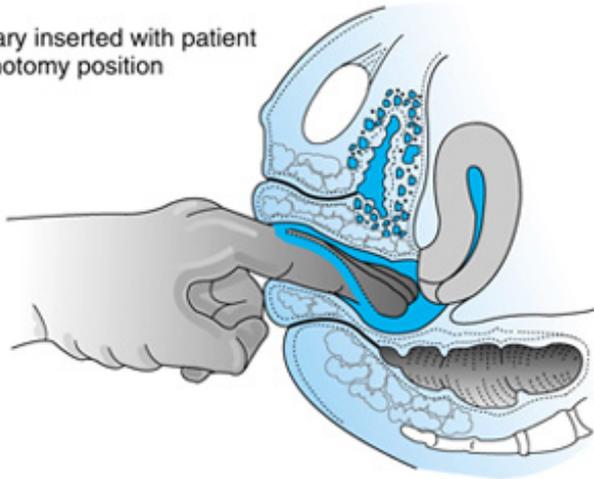

- Ring Pessary A ring pessary with or without support provides relief of uterine prolapse or anterior vaginal prolapse.
- Gellhorn Pessaries These types are uniquely shaped like a collar button and provide a ringlike platform for the cervix or apex. The pessary is stabilized by a stem that rests on the perineum. These pessaries are used to correct marked prolapse when the perineal body is reasonably adequate.
- Doughnut The doughnut is made of soft rubber or silicone, and this type of pessary provides support for severe uterine prolapse or vault prolapse.
- Gehrung Pessary The Gehrung pessary resembles two firm letter Us attached by crossbars. It rests in the vagina with the cervix cradled between the long arms; this arches the anterior or posterior vaginal wall and reduces the vaginal prolapse.
- Hodge Pessary (Smith-Hodge, or Smith and Other Variations) This is an elongated, curved ovoid. One is placed behind the symphysis and the other in the posterior vaginal fornix. The anterior bow is curved toward the urethra; the cervix rests within the larger, posterior bow. This type of pessary is used to hold the uterus in place after it has been repositioned.
- Inflatable Pessary The inflatable pessary functions much like a doughnut pessary. The ball valve is movable and can be moved up and down; when the ball is in the down position, air inflates the pessary; when in the up position, the air is sealed in and inflation is maintained.
- Cube This is a flexible rubber cube, with suction cups on each of its six sides that adhere to the vaginal wall. This is useful in women with severe prolapse. However, vaginal erosions are common and can be severe. Frequent monitoring initially to identify pressure ulcers is critical.

FITTING OF PESSARIES

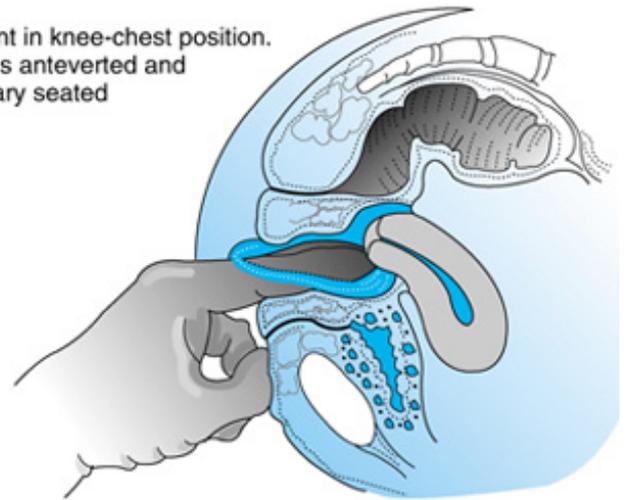

Medicine is known as both an art and a science. Pessary fitting (Fig. 44–9) falls into the art category. Pessaries that are too large cause irritation and ulceration; those that are too small may not stay in place and may protrude.

Figure 44–9.

Insertion of Hodge-type pessary.

In general, fitting a pessary is very much a trial-and-error endeavor. Once a type is selected based on the defect of the vaginal anatomy and on symptoms, sizing is best done with an office sizing set. This task is somewhat complex as each pessary has its own measurement system, but familiarity with each pessary over time simplifies this task. Each pessary should be lubricated and inserted with its widest dimension in the oblique diameter of the vagina to avoid painful distention at the introitus. With a finger of the opposite hand, depress the perineum to widen the introitus. The Hodge-type pessary has an optimal method for insertion.

Once a pessary is in place, the forefinger should pass easily between the sides of the frame and the vaginal wall. If it cannot, the pessary is too large. After the pessary has been fitted, the patient should be asked to stand, walk, and squat to determine whether pain occurs or whether the pessary becomes displaced. The patient should be shown how to withdraw the pessary if it becomes displaced or is uncomfortable, and cautioned that a contraceptive vaginal diaphragm cannot be used while a vaginal pessary is in place.

During the initial period of pessary wear, any discomfort, bleeding, or disturbance in defecation or urinary function should be reported immediately. The patient should be examined 1–2 weeks after insertion to inspect for the presence of pressure and inflammatory or allergic reactions. A repeat exam in 4 weeks can be done, then visits should be at 3- to 6-month intervals to assess for continued proper fit and to evaluate for vaginal erosion and inflammation as a result of pessary use. For women who are unable to remove and clean the pessary themselves, the pessary should

changed about every 2–3 months.

The pessary should be maintained with an acidic pH gel such as Trimo-San (Milex Products, Inc., Chicago, Illinois) in postmenopausal patients, topical estrogen can vitalize the vaginal mucosa and reduce ulceration. An estrogen-containing ring can also be used in conjunction by "piggybacking" the ring with the pessary and then changing it every 3 months.

Vaginal pessaries are not curative of prolapse, but they may be used for months or years for palliation with proper supervision.

A neglected pessary may cause fistulas or promote genital infections, but there is no clear evidence that cancer is a result of wearing a modern pessary.

Pelvic Floor Muscle Exercises

In some patients, improvement of pressure symptoms and of urinary control may be obtained by using pelvic floor muscle exercises, also referred to as Kegel exercises. These exercises are aimed to tighten and strengthen the pubococcygeus muscles. Evidence strongly supports use of Kegel exercises as first-line management in the treatment of urinary and fecal incontinence; however, they may also have some benefit in the relief of POP symptoms. Kegel exercises work best after specific instruction on how to perform them as most women do not perform them either correctly or in optimal fashion without supervised instruction and feedback.

Estrogens

In postmenopausal women, local estrogen therapy for a number of months may improve the tone, quality, and vascularity of the musculofascial supports. It is available in cream, parvule, and ring insert forms. With counseling, estrogen can be offered to all postmenopausal women to reduce urogenital atrophy. For postmenopausal patients with exposed prolapse, who are awaiting surgery, or using a pessary, local therapy should be recommended to promote healthy epithelium.

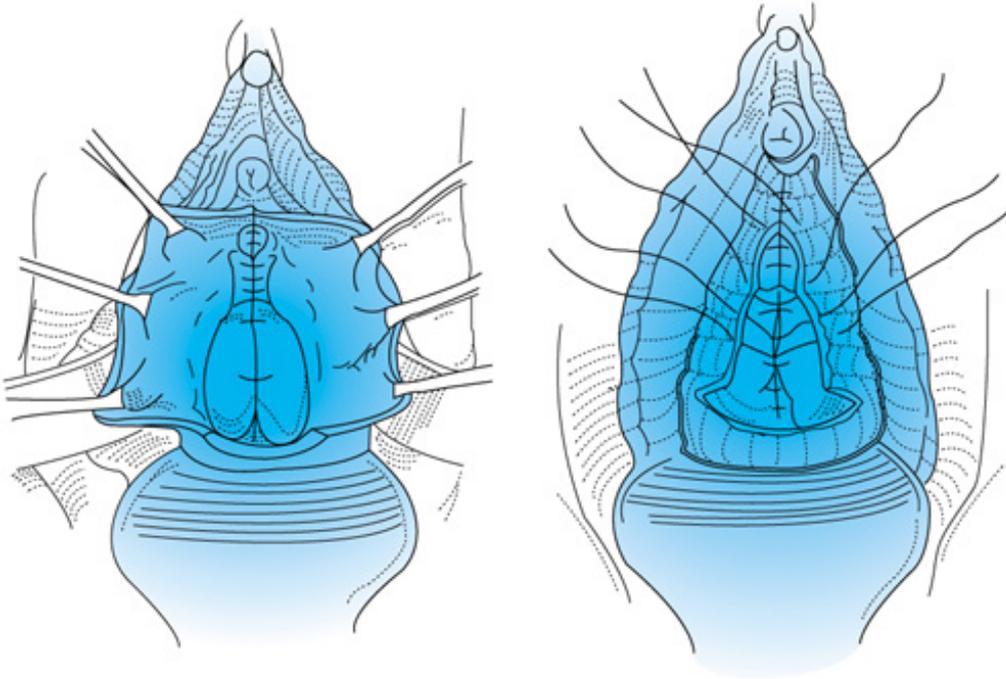

SURGICAL MEASURES

Anterior Vaginal Prolapse

ANTERIOR VAGINAL COLPORRHAPHY

Anterior vaginal colporrhaphy is the most common surgical treatment for anterior vaginal prolapse (Fig 44–10). Traditional anterior colporrhaphy (anterior repair) is a vaginal approach that involves dissecting the vaginal epithelium from the underlying fibromuscular connective tissue and bladder, then plicating the vaginal muscularis across the midline. Excess vaginal epithelium is excised and the wound closed. Recurrence of anterior prolapse as high as 50% has been reported and has always been a limitation of all reparative procedures. Modifications involving permanent suture material and most recently graft materials have been introduced in the hope of increasing durability.

Repair of anterior vaginal prolapse.

PARAVAGINAL REPAIR

The etiology of the anterior vaginal prolapse has been much debated, beginning with White in 1912. The repair of defects in the anterior vaginal segment has traditionally been done by midline plication. An alternative method based on the anatomic observations by Richardson and colleagues advocates identification of the specific defect in the pubocervical fascia underlying the anterior vaginal epithelium and repairing the discrete breaks. These breaks are described as paravaginal, midline (central), distal, and transverse (superior) (Fig 44–2). This relationship may help explain why no single operative repair should be universally applied to patients with anterior vaginal wall defects why traditional repair has resulted in high recurrence rates.

Paravaginal repair is performed for anterior vaginal prolapse that is confirmed to be a result of detachment of the pubocervical fascia from its lateral attachment at the arcus tendineus fascia pelvis (white line). This defect can be unilateral or bilateral. It can be confirmed preoperatively by noting loss of the lateral sulci and lack of rugation of epithelium along the base of the bladder and elongation to the anterior vaginal wall. Clinically, vaginal examination using a speculum reveals a preponderance of the prolapse lateralized to one side as the speculum is withdrawn. In addition, a ring forceps can be used by gently exerting anterior traction along the vaginal sulci. If the defect is reduced then the defect is consistent with a paravaginal defect and can be approached with a paravaginal repair technique.

The surgery can be performed either abdominally or vaginally. Both require identification of the white line and placement of serial sutures from the medial portion of the pubocervical fascia to the lateral sidewall at the level of the white line as it runs from the ischial spine over the obturator internus muscle to the posterior and inferior aspect of the pubic bone on the ipsilateral side. Reapproximation of the detached pubocervical fascia should reduce the anterior vaginal prolapse. This procedure can be done with other reconstructive procedures in the vagina as well as surgery to alleviate incontinence. Short-term surgical studies have shown good results but no long-term or comparative data for this repair.

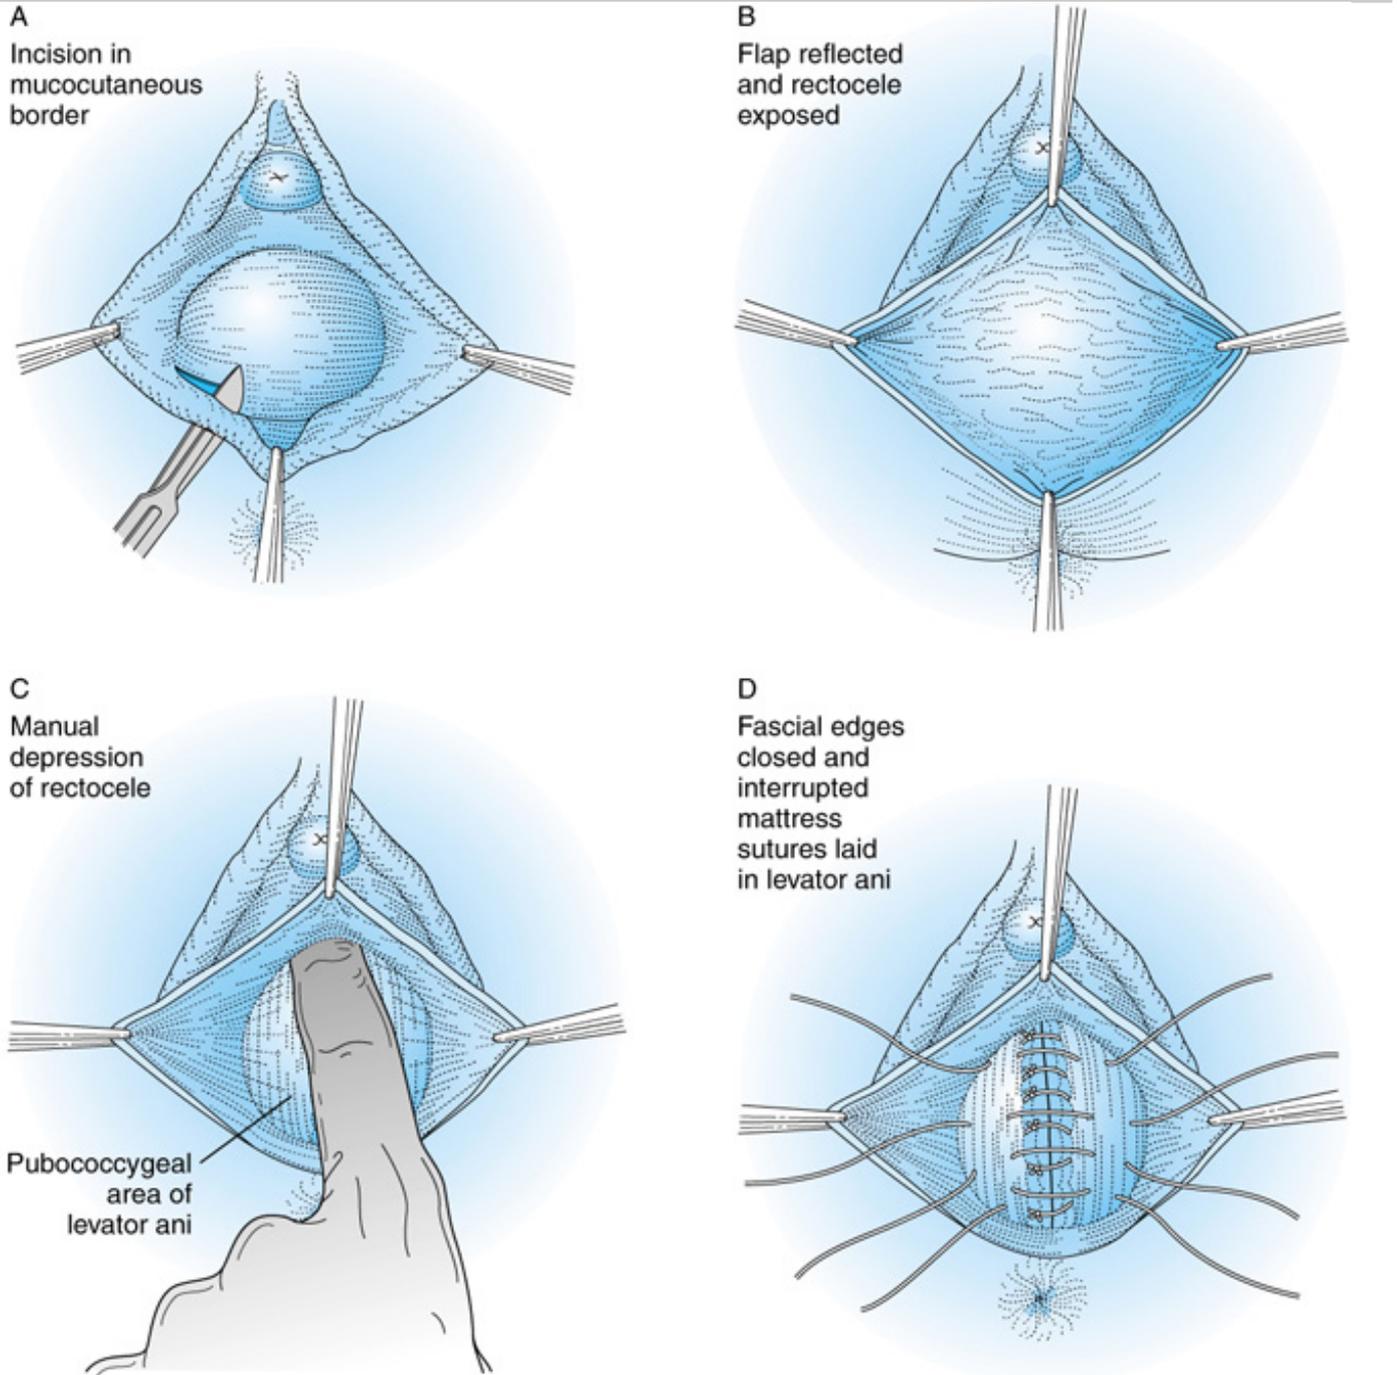

Transabdominal approach to the paravaginal repair may be elected to correct the anterior vaginal prolapse when an abdominal approach is necessary for other pelvic conditions such as abdominal hysterectomy, adnexal surgery, or

most commonly, with sacral colpopexy for apical prolapse repair.

Posterior Vaginal Prolapse

There are two main surgical methods of a posterior vaginal defect (rectocele) repair. The traditional repair (Fig. for colpoperineorrhaphy is the one described in most texts and involves posterior midline incision, often high, to level of the posterior fornix. The vaginal epithelium is separated off the underlying fibromuscular layer and endofascia. Repair often includes plication of the levator ani muscles and bulk lateral plication of tissue oversewing th rectovaginal fascia. No attempt at identifying specific fascial defects is made.

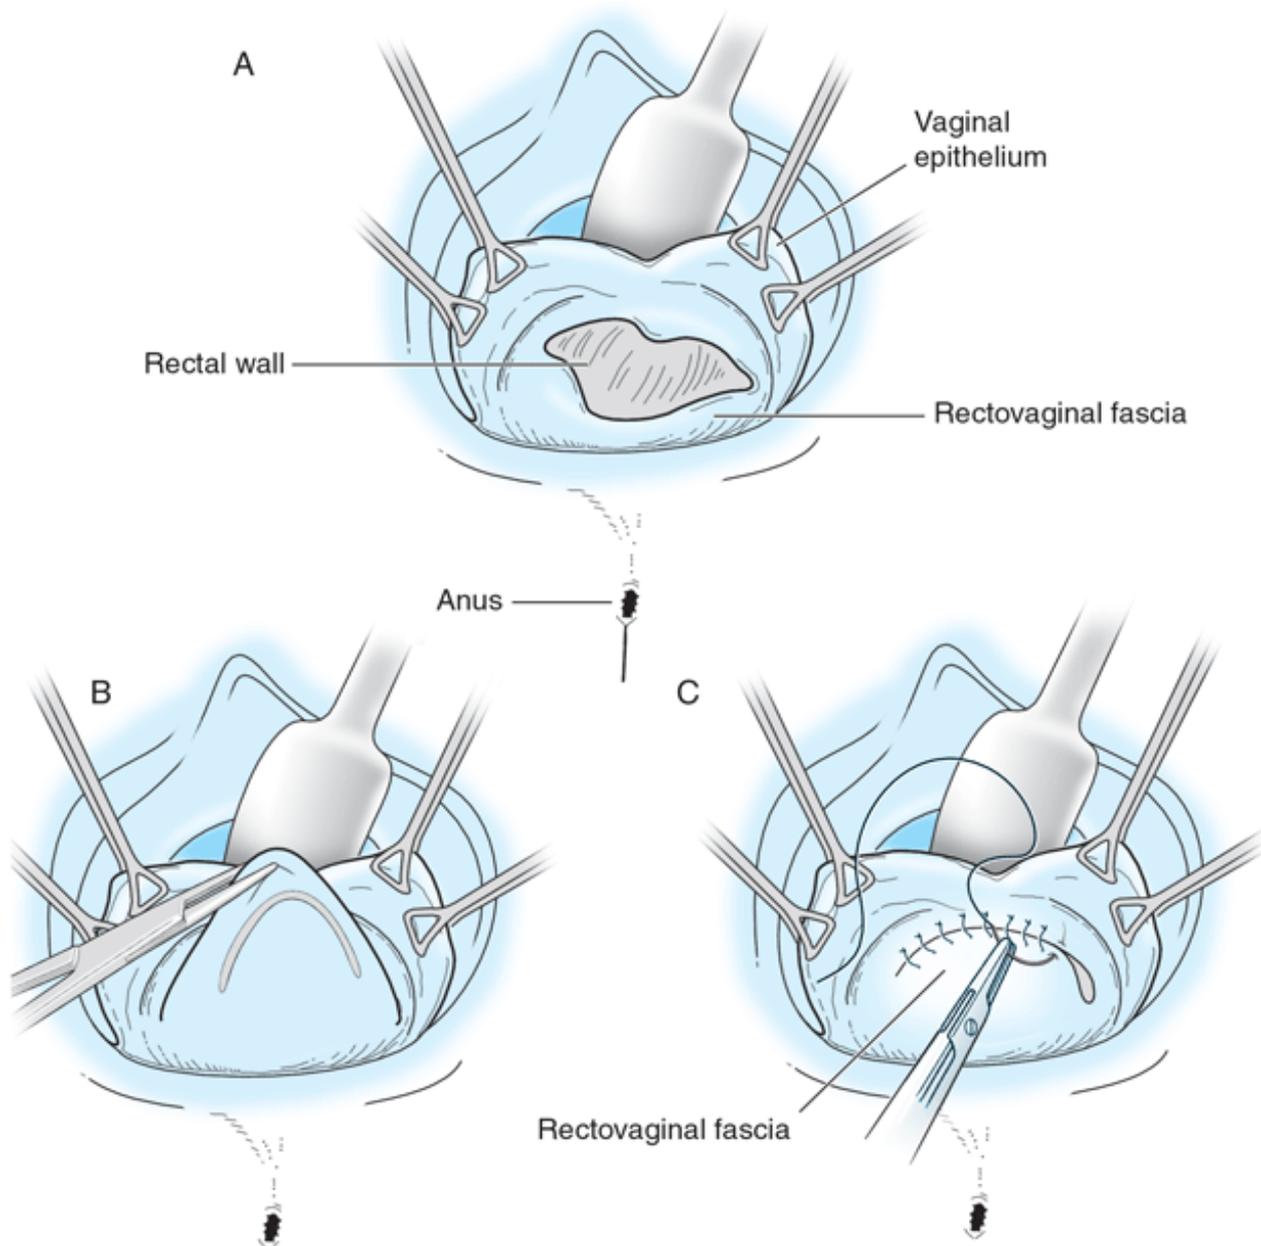

Figure 44-11.

Repair of rectocele.

An alternate method of posterior vaginal defect (rectocele) repair relies on the identification of discrete defects in the rectovaginal fascia (Fig 44–12). This anatomic description was first introduced by gynecologists advocating that rectoceles were caused by a variety of breaks in the rectovaginal fascia and that repairing these defects primarily was critical to anatomic restoration and lasting cure. This surgical technique included separating the vaginal epithelium from the underlying rectovaginal fascia as in a traditional colpoperineorrhaphy. Efforts are made to leave as much fascia over the rectum as possible. The surgeon inserts a finger of the nondominant hand into the rectum to inspect the rectovaginal fascia for defects. The rectal wall is brought forward to distinguish the uncovered muscularis (fascia defect) from the muscularis that was covered by the smooth semitransparent rectal vaginal septum. The defects are then repaired with interrupted sutures to plicate over the rectal wall. In this manner, the isolated defects are repaired and the functional anatomy is optimally restored. Notably absent is any effort to plicate the levator ani musculature, which often results in a bandlike stricture over the posterior wall—a likely cause of dyspareunia.

Figure 44–12.

Site-specific repair of posterior vaginal prolapse. A: Dissection below vaginal epithelium exposes defect in rectov (RV) fascia. B: Reflection of detached RV fascia. C: Restoration of the continuity of RV fascia by reapproximation delayed absorbable suture.

Perineorrhaphy is generally combined with posterior vaginal repairs. This procedure is principally aimed at restor perineal body, and reducing the vaginal outlet (genital hiatus) to more normal caliber. Reapproximation of the superficial transverse perinei muscle and the bulbocavernosus muscle rebuilds the perineum, and lengthens the distance between vaginal opening and anal verge.

Postoperative factors—The prognosis after vaginal repair is excellent in the absence of a subsequent pregnancy comparable factors (eg, constipation, obesity, large pelvic tumors, bronchitis, bronchiectasis, heavy manual labo increase intra-abdominal pressure. The recurrence of the POP is probable when a specific defect of pelvic suppor been overlooked or ignored; in such cases, subsequent progression of the overlooked site may itself lead to new symptoms, or even to disruption of the previously repaired segment.

Postoperative avoidance of straining, coughing, and strenuous activity is advisable. Careful instruction about diet to avoid constipation, about intake of fluids, and about the use of stool-softening laxatives and lubricating suppositories is necessary to ensure durable integrity of the rectocele repair.

Apical Vaginal Repair

Prolapse of the vaginal apex includes:

Uterine prolapse

Posthysterectomy vaginal cuff prolapse

Enterocoele

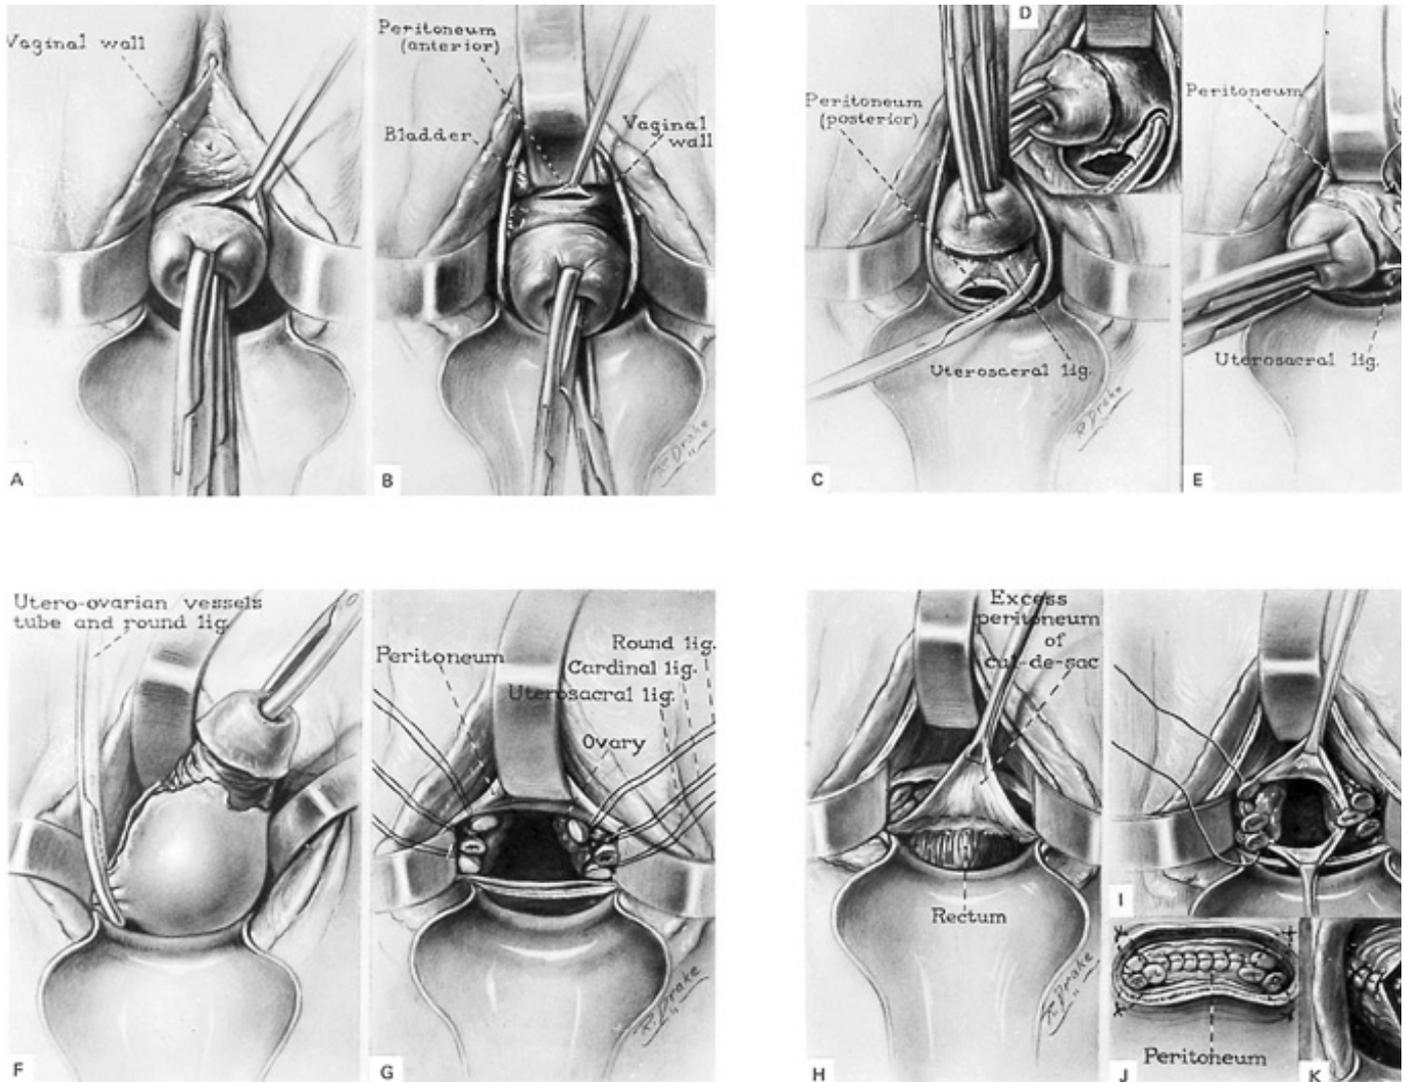

All of the clinical conditions above indicate a failure of apical support. The procedures used to address surgical repair requires a knowledge of the specific support structures available to reestablish normal anatomy.

Apical prolapse may be congenital or acquired; the latter is much more common. The congenital form rarely causes symptoms. The acquired form of enterocoele occurs in multiparous premenopausal or postmenopausal women and almost invariably is associated with other manifestations of pelvic organ prolapse. The trauma of many pregnancies and vaginal deliveries (particularly operative deliveries), large pelvic tumors, marked obesity, ascites, chronic bronchitis, and other factors that increase intra-abdominal pressure are of etiologic importance.

Uterine prolapse is almost always accompanied by some degree of enterocoele, and, as the degree of uterine descent progresses, the size of the hernial sac increases. Similarly, posthysterectomy prolapse of the vaginal vault is usually the result of an enterocoele that was overlooked (not repaired) at the time of hysterectomy or develops as a result of inadequate repair and identification of cuff support structures. Consequently, it is critical to always address apical cuff support at the time of surgery if a hysterectomy is being performed because of prolapse. Rarely, after hysterectomy, the enterocoele is located anterior to the vaginal vault, where it may be easily confused with ordinary anterior vaginal prolapse.

Apical vaginal repair may be accomplished transabdominally or transvaginally. A review of vaginal operations includes, among others, sacrospinous ligament suspension, iliococcygeal fixation, and high uterosacral ligament suspensives (e.g., McCall culdoplasty; Fig 44–13).

Figure 44–13.

Vaginal hysterectomy for uterine prolapse.

Because the normal vaginal axis is directed some distance posteriorly (almost horizontally when the patient is in erect position) over the levator plate, operative correction by any means, whether by the vaginal or the abdominal route, should restore a normal vaginal axis. This is accomplished by suspension of the vaginal apex far back on uterosacral ligaments, the presacral fascia, or the sacrospinous ligaments.

SACROSPINOUS LIGAMENT FIXATION

A popular method of vaginal vault suspension is that of unilateral fixation to the sacrospinous ligament. In this technique, the vaginal mucosa is separated from the rectovaginal tissues, and the associated enterocele is identified and repaired (as previously described). Perforation through the right or left rectal pillar is usually easily accomplished by directing blunt dissection toward the ischial spine through the loose areolar tissue. After an appropriate location the sacrospinous ligament is identified (usually 2–3 cm medial to the ischial spine), one of several techniques may be used to safely pass 2 or more permanent (or delayed absorbable) ligatures through the ligament to the submucosal apex of the vagina. Tying the sutures brings the vaginal apex to that sacrospinous ligament, and a posterior colporrhaphy is then performed (as noted previously). Closing the dead space by intermittently suturing the vaginal mucosa to the underlying reconstituted rectovaginal septum may be useful. Patients who have concomitant stress urinary incontinence should have a corrective procedure at this time.

Bilateral vaginal connection to both sacrospinous ligaments has been described, but may result in excessive lateral stretching of the vaginal apex or posterior impingement on the distal sigmoid colon. Vaginal vault suspension to both sacrospinous ligaments has the potential of injury to the pudendal nerve or pudendal vessels and is often technically difficult. Because gluteal and posterior leg pain is a potential complication of this procedure, it requires a skilled surgeon and should be undertaken only by those familiar with the technique.

ILIOCOCCYGEAL VAGINAL SUSPENSION

First described in 1962, this procedure uses the fascia overlying the iliococcygeal muscle. Although not as commonly used as other procedures, this point of attachment allows reliable apical fixation without the need to gain peritoneal access. It is generally a safe procedure requiring a posterior vaginal incision in the midline with wide dissection of the overlying epithelium. Bilateral placement of permanent or delayed absorbable suture can be used.

BILATERAL UTEROSACRAL LIGAMENT SUSPENSION

The use of the uterosacral ligaments to attach the vaginal cuff has become a reappreciated technique in apical prolapse. Several modifications of the procedure have been described since its introduction in 1938. This technique, as with other vaginal procedures, can be done at the time of vaginal hysterectomy or to correct posthysterectomy apical prolapse. After entrance into the peritoneum is complete, traction on the ipsilateral posterior vaginal wall with a digital examination will facilitate transperitoneal identification of the uterosacral ligament. Placement of a pair of permanent sutures in a lateral-to-medial fashion, one at the level of the ischial spine and another placed more cephalad, can be performed bilaterally. These sutures are then brought to the ipsilateral vaginal apices. Fixation of the cuff at this level reproduces cuff placement to the normal position of the cervicovaginal junction. Anterior vaginoplasty should be performed prior to tying down the vaginal cuff.

A risk of this procedure is medial displacement and kinking of the ureters, which has been reported to occur in up to 11% of patients undergoing this procedure. Cystoscopic assessment of ureteral function without and with tension of the fixation sutures, prior to tying down the vaginal apices, is critical. If ureteral flow compromise is identified, removal of the sutures on the affected side will often restore normal function.

ABDOMINAL SACROCOLPOPEXY

Vaginal vault suspension can also be performed abdominally by attaching the vaginal cuff to the sacral promontory. Abdominal sacrocolpopexy is an excellent primary procedure for apical vaginal prolapse and enterocele, and is the procedure of choice for those who are already having an abdominal approach for hysterectomy or for another indication. In this procedure, a laparotomy is performed, and the cul-de-sac and peritoneum overlying the sacrum are visualized. A window in the peritoneum over the sacral promontory is created and two permanent sutures are placed through the anterior longitudinal ligament, approximately at the level of S1. The vaginal cuff is then exposed by dissecting off the overlying peritoneum. Fixation of a graft over the anterior and posterior vagina is then performed, fashioning a Y-shape. This Y graft is then brought posteriorly along the hollow of the sacrum and affixed to the anterior longitudinal ligament sutures overriding the sacral promontory. Avoidance of undue tension is critical.

Many different graft types have been described, as well as different methods of attaching these grafts to the vagina. Synthetic grafts have higher erosion complication rates than biologic grafts. Biologic grafts, however, have high erosion rates when placed at the apex. As graft technologies evolve, identification of the optimal graft material that maximizes durability and compatibility may materialize. Numerous studies demonstrate this technique to be curative (Table 44–2. Follow-Up and Cure Rate after Abdominal Sacral Colpopexy).

In addition to concerns about graft complications, operative hemorrhage is a significant risk. Specifically, during placement of the sacral sutures, the nearby fragile sacral veins may be lacerated. Bleeding from these veins is difficult to control if the veins retract into the bone. Use of sterile thumbtacks to occlude these veins has been an operative technique used to stem potentially life-threatening hemorrhage.

OBLITERATIVE VAGINAL OPERATIONS (COLPOCLEISIS AND LE FORT'S OPERATION)

These are used primarily for severe uterovaginal prolapse in elderly patients and chronically ill patients who no longer desire coital function. It has the advantage of being done with either regional or local anesthesia. These procedures are highly effective and generally well tolerated. Traction produced by the obliterating scar tissue under the bladder and the urethra that may actually cause or aggravate stress incontinence is associated with these operations. Closure of the genital hiatus may reduce the chance of recurrence and can be achieved by performing an "extended" perineorrhaphy concomitantly.

Current OB/GYN >Chapter 45. Urinary Incontinence>

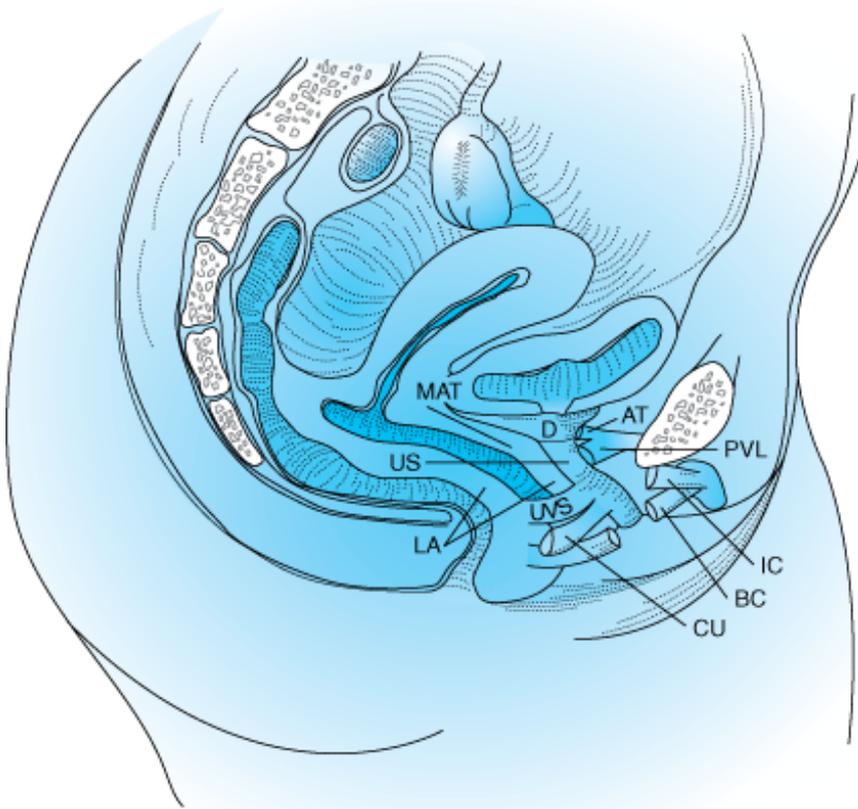

URINARY INCONTINENCE: INTRODUCTION

Urinary incontinence affects well over 13 million adult women in the United States. It is estimated to affect 30–40% of American women during their lifetime. Despite its prevalence and estimated costs in excess of \$19.5 billion annually, up to 70% of women do not seek help for incontinence, primarily because of social embarrassment or because they are unaware that help is available. Because of increasing awareness by both patients and physicians, the societal concept that incontinence is part of the "normal" aging process is no longer acceptable. Advances in modern medicine during the last 80 years have increased the life expectancy of women well into the eighth and ninth decades. We are caring for patients longer and better than ever, effectively managing chronic medical problems such as hypertension, cardiovascular disease, and diabetes, enabling women to enjoy longer and more productive lives. This results in a large population of women living up to one-third of their life after menopause, thereby introducing a whole host of medical issues and health concerns. A prime example of this is the problem of urinary incontinence, which has become more prevalent as the population of aging women grows. In this chapter we focus on the evaluation and treatment of women with urinary incontinence.

ANATOMY

The urinary and reproductive tracts are intimately associated during embryologic development. The lower urinary tract can be divided into 3 parts: the bladder, the vesical neck, and the urethra (Fig 45–1). The bladder is a hollow muscular organ lined with transitional epithelium designed for urine storage. The bladder musculature consists of 3 layers of smooth muscle, which are densely intertwined and constitute the detrusor muscle. The bladder stays relaxed to facilitate urine storage and contracts periodically to completely evacuate its contents when appropriate and acceptable. At the bladder base is the trigone, which is embryologically distinct from the bladder.

Figure 45–1.

Interrelationships and approximate location of paraurethral structures. Levator ani muscles are shown as light lines running deep to the pelvic viscera. AT, arcus tendineus fasciae pelvis; BC, bulbocavernosus muscle; CU, compressor urethrae; D, detrusor loop; IC, ischiocavernosus muscle; LA, levator ani muscles; MAT, muscular attachment of the urethral supports; PVL, pubovesical ligament (muscle); US, urethral sphincter; UVS, urethrovaginal sphincter.

The 2 ureteral orifices and the internal urethral meatus form the boundaries of the trigone. The trigone has 2 distinct muscular layers: superficial and deep. The deep layer shares a similar cholinergic autonomic innervation as the detrusor muscle, whereas the superficial layer is densely innervated by noradrenergic nerves. This distinct difference in receptor distribution is important, as it provides opportunities to target more specific sites for pharmacotherapeutic intervention. The superficial detrusor layer extends muscular fibers that contribute to the distal urethra and posterior to the proximal urethra. The urethral "sphincter" itself is not a well-delineated structure; rather, it is a complex and intricate meshwork of intertwining smooth and striated muscle fibers that functionally responds neurophysiologically to variable degrees of vesicle pressures and facilitates urine storage and voiding.

The female urethra is approximately 3–4 cm long. The composition and support of the urethra and bladder neck play key roles in the function and maintenance of urinary continence. Together the striated urethral and periurethral muscles compose the extrinsic urethral sphincter mechanism. The urethral sphincter, along with the levator ani, function in the reflex contraction. The urethra is surrounded by dense vasculature that contributes to the urethral mucosal seal and urethral closure pressure. An abundance of submucosal glands are found along the dorsal surface. Most of the urethral diverticula arise from this area. The uroepithelium is stratified squamous (Fig 45–2).

Urethral anatomy. The submucosal vascular plexus matures after puberty but undergoes great changes after menopause. The amount of smooth and especially striated muscles decreases with age, and the striated components become almost rudimentary.

Neuroanatomy

Neuronal innervation of the lower urinary tract is considered part of the autonomic and somatic nervous systems. The autonomic system (ie, the parasympathetic and sympathetic components) receives visceral sensation and regulates smooth muscle actively during conscious and involuntary lower urinary tract functions. The autonomic nervous system constitutes the bulk of neural control of the lower urinary tract. Sympathetic contributions from T1–L2 and parasympathetic contributions from S2–4 compose the neuronal control system (Fig 45–3). Voluntary control of micturition is controlled by the central nervous system. Cortical control of the detrusor muscle rests in the supramedial portion of the frontal lobes and in the genu of the corpus callosum. Receiving both sensory afferent and modulating motor efferent nerves, the net effect is that the brain provides tonic inhibition of detrusor contraction. Lesions in the frontal lobe chiefly cause loss of voluntary control of micturition and thus loss of suppression of the detrusor reflex, resulting in uncontrolled voiding or urge urinary incontinence. The pons and mesencephalic reticular formation in the brainstem constitute the micturition center. A reflex activation in the central brainstem and peripheral spinal cord mediate a coordinated series of events, consisting of relaxation of the striated urethral musculature and detrusor contraction that result in opening of the bladder neck and urethra. Lesions that interrupt these pathways have various effects depending on the level of interruption, essentially resulting in dyscoordination or dyssynergia of detrusor function.

URINARY INCONTINENCE—OVERVIEW

Definition

Urinary incontinence as defined by the International Continence Society (ICS) is the complaint of any involuntary leakage of urine. Incontinence can be a sign, a symptom (patient complaint), or a condition diagnosed by an examiner. There are many types and causes of urinary incontinence (Table 45–1). The reported incidence of urinary incontinence varies widely, ranging from 8–41% in women over 65 years. Incontinence becomes more common as women age, particularly after menopause. In light of projections that the percentage of postmenopausal women in the population will increase from 23% in 1995 to 33% in 2050, it is apparent that the problem of urinary incontinence will be a major health and quality-of-life issue well into the future.

Table 45–1. Classification and Causes of Urinary Incontinence.

Genuine stress incontinence
Bladder neck displacement

Intrinsic sphincter dysfunction (ISD)

Detrusor instability/urge incontinence
Idiopathic

Neurologic detrusor hyperreflexia

Mixed incontinence (genuine stress and detrusor instability combined)

Overflow incontinence with urinary retention
Obstruction

Bladder hyporeflexia

Bypass incontinence
Genitourinary fistulas

Urethral diverticulum

Congenital urethral abnormalities (eg, epispadias, bladder exstrophy, ectopic ureter)

Functional and transient incontinence
Infection

Pharmacologic

Restricted mobility

Dementia/delirium

Excessive urine production (diabetes mellitus, diabetes insipidus, resorption of extravascular fluid as with lower extremity edema)

Stool impaction

Etiology

Numerous factors play a role in maintaining urinary continence; therefore, the development of incontinence is frequently not attributable to any single cause. Gender, age, hormonal status, birthing trauma, and genetic differences in connective tissue all contribute to the development of incontinence. Urinary incontinence is 2–3 times more common in women than in men because of women's shorter urethral length and the risk of connective tissue, muscle, and nerve injury associated with childbirth. Observational studies have consistently noted a high incidence of incontinence in the elderly population, with 1 study finding a 30% higher prevalence

for each 5-year increase in age. The association of childbirth with urinary incontinence has long been suspected and has generated new interest in identifying the causes. In 1 study of over 15,000 women, the risk of developing urinary incontinence was 2.3 times higher in women who had a vaginal delivery compared to nulliparous women. Damage to the pelvic floor neuromusculature during vaginal delivery may lead to loss of pelvic muscle strength and nerve function, resulting in both stress urinary incontinence (SUI) and pelvic floor support defects. Although muscle strength may be regained over time or with the help of pelvic floor muscle exercises, dysfunction may be permanent.

Aging and incontinence are closely associated. The prevalence of incontinence increases as women age, but the specific cause is unclear. Global decrease in the storage capacity, reduced receptor response, general loss in muscle tone, or latent manifestation from denervation during parturition may all be important factors. The state of hypoestrogenism as a woman transitions to the menopause may also contribute to urinary incontinence. Although estrogen reduces urinary urgency, results from studies specifically examining menopausal status have been equivocal, with some studies showing a positive association and others showing no association.

Abnormalities in the muscular components and innervation of the pelvic floor and the connective tissue to this region likely contribute to the multifactorial etiology of incontinence. Initial observations that the prevalence of abdominal hernias, lower leg varices, and uterine prolapse was higher in women with SUI suggested that connective tissue weakness may identify women at risk for developing incontinence. Subsequent studies have supported a connection between relative collagen deficiencies in the connective tissues of incontinent patients versus continent controls.

Incontinence affects a woman's quality of life, and it is an uncomfortable and embarrassing problem. The psychosocial impact on the patient as well as her family is enormous. Women with urinary incontinence are reported to be more depressed, to have lower self-esteem, and to be ashamed about their appearance and the odor. Urinary incontinence impacts sexual desire and reduces sexual activity. This can curb social interactions to the point where individuals become isolated and even entirely homebound.

History

The first step in evaluating an incontinent patient is a thorough history. The nature and extent of the patient's lower urinary tract symptoms (LUTS) should be elucidated. Knowledge of the duration, frequency, and severity of the urinary incontinence is essential to understanding the social implications and its impact on the patient's life and aids the clinician in determining the direction and extent of diagnostic and therapeutic measures (Table 45–2). A multitude of diagnostic and imaging studies are available, but taking a thorough but focused urogynecologic history can isolate many of the easily reversible causes of incontinence (Table 45–3). Knowledge of the use of protective items, such as sanitary napkins, panty liners, absorbent pads, or adult diapers, is useful in quantitating urinary loss. Including questions about menopausal status and use of hormone treatment, history of urinary tract infections, previous surgery to remedy incontinence, and the patient's mental and functional status are essential.

Table 45–2. Lower Urinary Tract Symptoms (LUTS).

Urinary incontinence: the complaint of any involuntary leakage

Stress urinary incontinence: the complaint of involuntary leakage on effort or exertion, or on sneezing or coughing

Urge urinary incontinence: the complaint of involuntary leakage accompanied by or immediately preceded by urgency

Mixed urinary incontinence: the complaint of involuntary leakage associated with urgency and also with exertion, effort, sneezing or coughing

Increased daytime frequency: the complaint by the patient who considers she voids too often by day

Nocturia: the complaint that the individual has to wake one or more times to void

Urgency: the complaint of a sudden compelling desire to pass urine

Nocturnal enuresis: complaint of loss of urine occurring during sleep

Table 45–3. Helpful Questions When Taking History of Incontinence.

- Do you leak urine when you cough, sneeze, or laugh?
 - Do you ever have such an uncomfortably strong need to urinate that if you don't reach the toilet you leak?
 - How many times during the day do you urinate?
 - How many times do you get up to void during the night after going to bed?
 - Have you ever wet the bed?
 - Do you leak during sexual intercourse?
 - Do you wear a pad to protect your clothing?
 - If yes, how often do you change the pad: when it has only a few drops, when it is damp, or when it is totally wet?
 - After you urinate do you have dribbling or still feel the presence of urine in your bladder?
 - Does it hurt when you urinate?
 - Do you lose urine without the urge to go?
-

Patient Questionnaires

Survey instruments can be valuable in helping to identify and determine the severity of patient symptoms. Although initially designed for clinical research, short forms of longer questionnaires exist and can be used for clinical care. Surveys such as the Urinary Distress Inventory (UDI-6) and Incontinence Impact Questionnaire (IIQ-7) can be easily filled out by a patient to facilitate diagnosis and to follow treatment interventions.

Voiding Diary

A voiding diary, or urolog, that quantitates frequency and volume is a helpful tool. For a 24- to 48-hour period the patient records all fluid intake, and measures and records all urine output, including frequency and episodes of leakage (Fig 45–4). Numerous studies have validated the voiding diary as a reliable tool in the diagnosis and management of urinary urgency or urge incontinence. These data are beneficial to the physician because they clarify home voiding patterns, particularly in the elderly. They are often useful to patients as well because they provide a focus on the problem and can serve as a baseline for treatment interventions such as behavioral training, bladder drills, and pharmacologic management.

Figure 45–4.

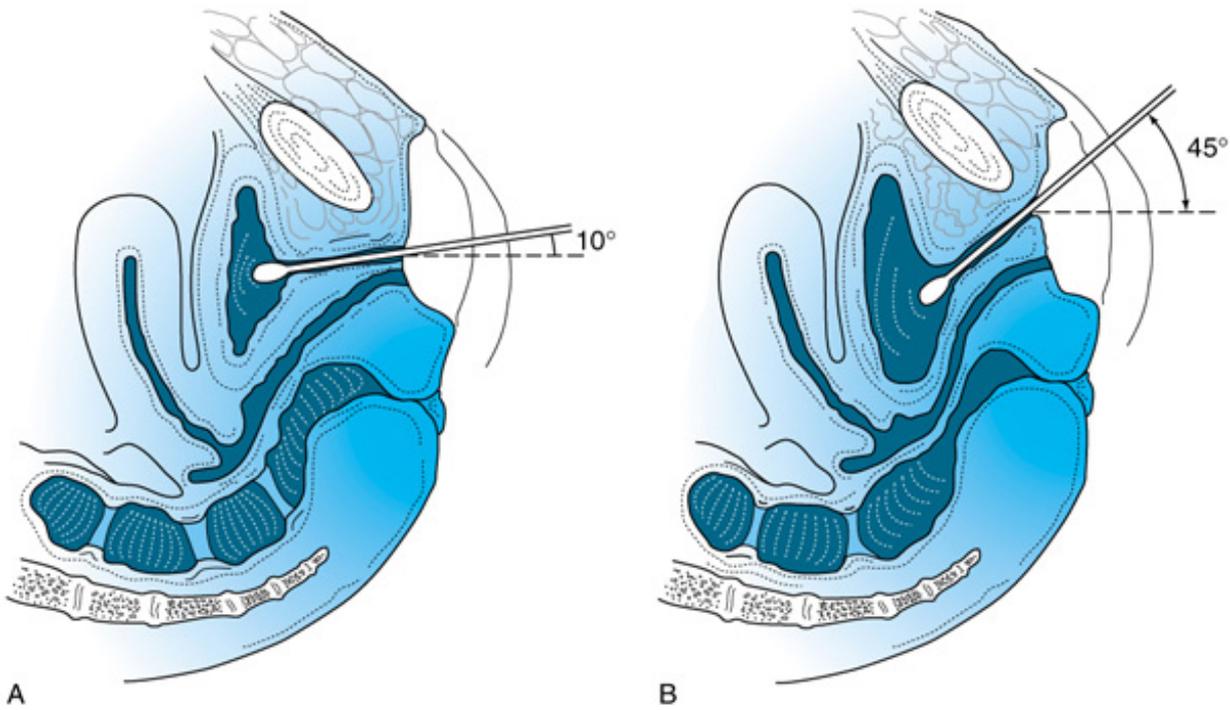

A general gynecologic and neurologic examination should be performed on all patients, with a focus on the vaginal walls and pelvic floor. The patient should come to the clinic with a comfortably full bladder for spontaneous uroflowmetry and postvoid residual assessment. An examination should be performed with the patient in the lithotomy position. The examination should begin with an assessment of the vulvar area. In postmenopausal patients, atrophy and change in labial architecture may be due to estrogen deficiency. Vulvar dermatoses may be coexistent with vulvar complaints ascribed to incontinence. The presence of inflammation or irritation from chronic moisture or pad usage should be noted. The presence of discharge should be noted because this may mimic urinary incontinence. Examination of the urethra with palpation of the anterior vaginal wall under the urethra for fluctuance, masses, or discharge may reveal signs of urethral diverticulum, infection of the urethra, or rarely carcinoma. Tenderness may point to urethral pain syndrome, a condition marked by episodic urethral pain usually with voiding, and by daytime frequency and nocturia.

Vaginal wall integrity must be assessed. Vaginal rugae, or the folds in the epithelium, are normal and tend to be absent if the underlying supportive endopelvic fascia is detached. The presence of anterior wall defects (cystoceles), posterior vaginal wall defects (rectoceles), and apical defects (enteroceles) can be quantified. The uterocervical position, or, if the woman has had a hysterectomy, the cuff position and its descent should be recorded. The position of the vaginal walls should be noted in the lithotomy position at rest and with Valsalva/straining maneuver. A Sims' speculum or the lower blade of a Graves' speculum allows easy visualization of either the anterior or posterior vaginal wall. The severity of vaginal laxity, which may be masked in the supine position, can often best be elicited by repeating the examination in the standing position while the patient places 1 foot on the step of the examination table or on a small portable step.

Cotton Swab Test

Mobility at the level of the bladder neck can be quantified with the use of a sterile cotton-tipped swab (Q-tip) test. The Q-tip test is 1 of the most commonly used tests to evaluate women with urinary problems because it effectively quantifies the degree of anatomic rotation of the support of the urethra and bladder neck. With the patient in the dorsolithotomy position, the labia are separated and urethral meatus swabbed with antiseptic. A sterile Q-tip lubricated with 1–2% lidocaine (Xylocaine) jelly is inserted transurethrally into the bladder and then withdrawn slowly until definite resistance is felt. This places the tip of the Q-tip at the level of the bladder neck just distal to the internal urethral meatus. Using a standard protractor, resting angle is measured. The patient is then asked to perform a Valsalva maneuver or to cough, and the maximum straining angle is noted. Net deflection is equal to the change from resting to maximum straining position (Fig 45–5). An angle greater than 30 degrees is considered abnormal. Urethral hypermobility must be interpreted with caution because it may be present in women without incontinence. The utility of this simple test is that an angle greater than 30 degrees is certainly present in the majority of women with genuine stress incontinence. In the absence of hypermobility, the physician must question the diagnosis of anatomic stress incontinence and entertain the possibility of a fixed and damaged urethral sphincter (also called *intrinsic sphincteric deficiency*) to explain stress-related urinary loss.

Figure 45–5.

The cotton-tipped swab (Q-tip) test for assessment of urethral and bladder support. A: Angle of the Q-tip at rest. B: Angle of the Q-tip with Valsalva maneuver or cough (straining). The urethrovesical junction descends, causing upward deflection of the Q-tip.

Urinary Cough Stress Test

Having the patient perform a Valsalva maneuver or to cough forcefully multiple times to reproduce urine loss at the beginning of the examination may reveal the presence of incontinence. Observation of urine lost immediately with the cough or Valsalva maneuver may obviate the need for more complex urodynamic testing if the complaint is minor. If no urine loss is exhibited, the patient is asked to stand with legs shoulder width apart and asked to cough. Immediate loss of urine suggests a diagnosis of SUI.

Bimanual examination to evaluate the uterine size, position, and descent within the vaginal canal and palpation of the ovaries should be performed. A rectovaginal examination permits adequate assessment of the posterior vaginal wall. Anal sphincter tone can be assessed at rest and with anal tightening. The presence of fecal impaction must be ruled out because this condition has been shown to be a contributing factor to urinary incontinence, particularly in the elderly population.

The description of pelvic organ prolapse is critical. (For details see Chapter 44 and Table 44–1.)

Neurologic Examination

The control of micturition is complex and multitiered, with both autonomic and voluntary control. In addition to a complete history and screening for neurologic symptoms, a thorough physical examination is important because many neurologic diseases may present with voiding dysfunction in the absence of overt neurologic findings.

Mental status, cranial nerves, motor strength, sensory function, deep tendon reflexes, and sacral spinal cord integrity should all be assessed. Testing the patient's orientation to place and time and assessing speech and comprehension skills will help to ascertain her mental status. Motor control may be diminished in focal brain or cord lesions, most commonly Parkinson's disease, multiple sclerosis, and cerebrovascular accident. Motor

strength is tested in the lower extremities by assessing hip, knee, and ankle flexion, as well as ankle eversion and inversion. Deep tendon reflexes are tested at the patella, ankle, and foot planus. Sensation can be tested at the dermatomes using light touch and pinprick over the perineum and thigh area. Deficits should be noted, but it should be kept in mind that there is considerable overlap in sensory innervation in the sensory nerve roots. The sacral spinal cord nerve roots 2–4 contain vital neurons controlling micturition. The anal wink reflex and the bulbocavernosus reflex can confirm integrity of neurovisceral and urethral reflex functions. These reflexes can be evoked by stroking the perianal area and looking for an external anal sphincter contraction, and by tapping or gently squeezing the clitoris and watching for contraction of the bulbocavernosus muscle, respectively. These reflexes are often easier to elicit at the beginning of the examination, but their absence is not always indicative of neurologic deficit. Clinically observed neurologic deficits should lead to a neurologic consultation.

Urodynamics

A urodynamic study is any test that provides objective dynamic information about lower urinary tract function. Many methods and tests are available (Table 45–4). Some methods are simple, such as diaries that track frequency and volume of urination, and some methods are more complex, requiring special equipment and training. A cystometrogram is necessary to rule out unstable bladder, overflow incontinence, reduced bladder capacity, or abnormalities of bladder sensation. A cystometrogram can be performed using water manometry or more advanced methods. Complex urodynamic testing increases the diagnostic accuracy and may often identify the reason for failure of previous therapy. Uroflowmetry can be performed to measure detrusor pressure and flow rate to evaluate for voiding dysfunction. If a poorly functioning urethra, such as intrinsic sphincter deficiency (ISD), is suspected, urethral pressure profile (UPP) or abdominal leak point pressure (ALPP) can be measured to evaluate urethral closure pressures. Such testing is particularly helpful in difficult or complex cases.

Table 45–4. Urodynamic Testing Methods.

Simple cystometry

Measures bladder pressure and volume

Useful in patients with clear-cut symptoms

Complex cystometry

Multiple parameters: bladder volume, filling rate, bladder pressure, abdominal pressure, and subtracted detrusor pressure

More accurate information on bladder function; most common type of urodynamics test

Uroflowmetry

Measures flow rate with special electronic flow-meters

Useful for general impression of voiding function

Pressure-flow

Combines complex cystometry and uroflowmetry. Measures bladder pressure, abdominal pressure, subtracted detrusor pressure, and uroflow

Provides accurate means of differentiating detrusor contraction, straining, and pelvic relaxation as mechanisms of urination

Leak point pressure

Using abdominal or bladder pressures, urethral resistance to abdominal strain is measured

Used in assessing urethral sphincter function

Urethral pressure profilometry

Using a dual transducer catheter, simultaneous bladder and urethral pressure can be recorded

Electromyography

Surface or needle electrodes to determine striated muscle activity of the pelvic floor or the anal or urethral sphincters

Test	Purpose	Indications
Test	Purpose	Indications

The indications for more complex testing in the form of multichannel urodynamics are not standardized, and each patient must be assessed individually (Table 45–5). However, some basic criteria, if met, indicate a need for urodynamic evaluation, which can aid in more accurate diagnosis and thus appropriate medical or surgical management.

Table 45–5. Indications for Multichannel Urodynamic Testing.

- Complicated symptoms and history
- Use when considering surgery for correction of incontinence or pelvic organ prolapse
- Underlying neurologic disease
- Urge incontinence refractive to initial conservative therapies
- Continuous leakage
- Previous anti-incontinence surgery
- Clinical findings do not correlate with symptoms
- Elderly patients > 65 years old

Cystourethroscopy

Endoscopic evaluation is an invaluable adjunct for the diagnosis and management of the urogynecologic patient. It is a simple office procedure that can yield important data when performed by experienced operators. Cystourethroscopy is indicated for hematuria, irritative voiding symptoms, obstructive voiding, suspicion of diverticula or fistula, persistent incontinence, and as a preoperative evaluation prior to reconstructive pelvic surgery.

Imaging Tests

Radiologic studies can be an integral component of the evaluation of lower urinary tract dysfunction and abnormalities. However, these modalities are of limited use in the evaluation of all but the most complex of incontinent patients. Magnetic resonance imaging (MRI) has become more extensively used in patients with pelvic floor dysfunctions and prolapse. As the technique becomes less costly, applications for the uses of MRI to aid in the urogynecological work-up will expand.

STRESS URINARY INCONTINENCE

The International Continence Society (ICS) defines SUI as the complaint of involuntary leakage on effort or exertion, or on coughing or sneezing.

Normally, at rest the intraurethral pressure is greater than the intravesical pressure. The pressure difference between the bladder and the urethra is known as the *urethral closure pressure*. If intra-abdominal pressure increases as it does with a cough, sneeze, or strain, and if this pressure is not equally transmitted to the urethra, then continence is not maintained and leakage of urine occurs. What is thought to cause this inequity of pressure transmission is not universally accepted, and the discussion of the proposed mechanisms are beyond the scope of this chapter.

Treatment of Stress Urinary Incontinence

NONSURGICAL MEASURES

For most patients with SUI, consideration of the simplest, least invasive, and least costly interventions is appropriate (Table 45–6). Dietary measures can be instituted, with identification of items that can be modified. Reduction in consumption of caffeinated beverages and alcoholic drinks should be encouraged. Fluid restriction in patients without chronic medical problems, such as cardiovascular, renal, or endocrinologic disease, can be attempted. Timed voiding to prevent filling the bladder to a capacity that causes urine loss should be undertaken with the use of a urine diary. The diary can also facilitate discussion between patient and clinician as therapy progresses.

Table 45–6. Nonsurgical Management of Urinary Incontinence.

Behavioral therapy
Fluid management
Bladder training
Pelvic floor muscle training

- Biofeedback
- Vaginal cones

Functional electrical stimulation
Anti-incontinence pessary
Pharmacotherapy

Pelvic floor muscle exercises or Kegel exercises have been found to be extremely helpful in patients with mild to moderate forms of incontinence. Focused repetitive voluntary contractions of the levator ani muscles (pubococcygeus, coccygeus, and iliococcygeus) created by having the patient contract or "squeeze" the muscle as if to prevent the passage of rectal gas is an effective therapy. The contractions exert a closing force on the urethra and increase muscle support to the pelvic organs. The patient should be provided written and verbal instructions on performing the exercises. Repetitions, with each contraction held for 3–5 seconds alternated with periods of relaxation, should be begun at 45–100 repetitions daily. In settings in which the patient is motivated and has individual instruction and thorough follow-up and support, results for cure or improvement of bladder control (reduction in urine loss) can be up to 75%.

Biofeedback

Biofeedback is an adjunct to pelvic floor exercises that is used to facilitate the patient's comprehension of the proper muscles to contract. By using a pressure catheter and myographic monitoring, a visual or auditory signal of the physiologic response can be provided to the patient to help refine exercise skills. Using surface electromyography on the perineum to measure levator contraction and a pressure monitor in the vagina or rectum to indicate abdominal pressure, the patient can be instructed to preferentially contract the pelvic floor without concomitant abdominal contraction. Studies using a variety of techniques demonstrate a 54–95% cure rate or improvement in SUI. The efficacy of this modality is highly dependent on patient motivation and compliance. Pelvic floor muscle exercises with or without biofeedback require continued implementation and practice or effectiveness will wane.

Electrical Stimulation

As an alternative to active patient contraction of the levator muscles, electrical stimulation of the muscles via small electrical currents can be used to help both SUI and mixed incontinence. Using intravaginal or transrectal electrodes with stimulators, the pelvic muscles automatically contract and are thereby artificially "trained." When used long term, weakened muscles are strengthened and innervation re-established during activation. Experiences with the devices are variable, but they generally show a positive impact on incontinence and acceptable patient tolerance.

Pessaries

Intravaginal devices or pessaries to correct the anatomic deficits associated with stress incontinence have long been used to address this vexing problem. Many devices have been proffered, but long-term solutions to incontinence have yet to be proven in the general population. Pessaries, traditionally used for treatment of genital prolapse, have also been shown to have a potential role in supporting the bladder neck and urethra and preventing stress incontinence. Many pessary devices designed to fit within the vagina and elevate the bladder neck are available. Continence can often be achieved because many devices adequately obstruct the bladder neck and urethra. As with all intravaginal devices, maintenance is essential to avoid urinary obstruction and vaginal erosion if the pessary is too compressive.

Occlusive devices are commercially available. External devices, such as urethral plugs that are placed over the external urethral meatus or internal occlusive devices placed transurethraly with an internal balloon, are available and have been shown to be partially helpful in reducing wetting episodes.

SURGICAL MANAGEMENT

Surgical treatment should be offered for moderate to severe incontinence. Urinary incontinence is not a life-threatening condition, and the decision to operate must be based on the patient's symptoms and the impact on daily life. Many patients are able to tolerate slight urine loss, and what often provokes a desire for treatment is an increase in loss above a tolerable threshold. If medical management to improve bladder control is possible and symptoms are reduced to below this threshold, then medical management is most desirable. If not, surgery should be considered.

At least 130 operative procedures have been described for treatment of female urinary stress incontinence. It is therefore not surprising that many of these procedures have not resulted in long-term success. For patients who desire surgical correction, the options can be categorized by method of surgical approach (Table 45–7). Common to most surgical procedures is restoration of bladder neck support by elevation of the urethrovesical junction. Some procedures reconstruct bladder neck supports and provide a stable suburethral layer.

Table 45–7. Surgical Treatment of SUI .

Retropubic urethropexy
Burch
Marshall-Marchetti-Krantz (MMK)
Needle urethropexy
Suburethral sling
Midurethral sling
Retropubic (TVT, Uretex, SPARC, Advantage)
Transobturator
Urethral bulking agents

Assessment of the cure rate of any surgical treatment for genuine stress incontinence must take into account the selection of patients, accuracy of the preoperative diagnosis, length of postoperative follow-up, and criteria for cure. Reported cure rates for abdominal procedures range from 60–100%, with 75–90% being the generally accepted rate. Most failures appear to result from incorrect preoperative diagnosis, poor surgical technique, and healing failures.

Anterior Repair

Anterior colporrhaphy with Kelly plication is one of the oldest methods of surgical correction, introduced in 1914. Used for anterior vaginal defects (cystocele), the technique involves vaginal dissection of the epithelium below the bladder and bladder neck, identifying the perivesical fascia and pubocervical fascia, and plicating each side over the midline. The Kelly plication involves specific support at the bladder. Numerous studies have evaluated this approach, and long-term analysis does not support this method as an effective cure for stress

incontinence, with greater than 60% failure rates over 5 years.

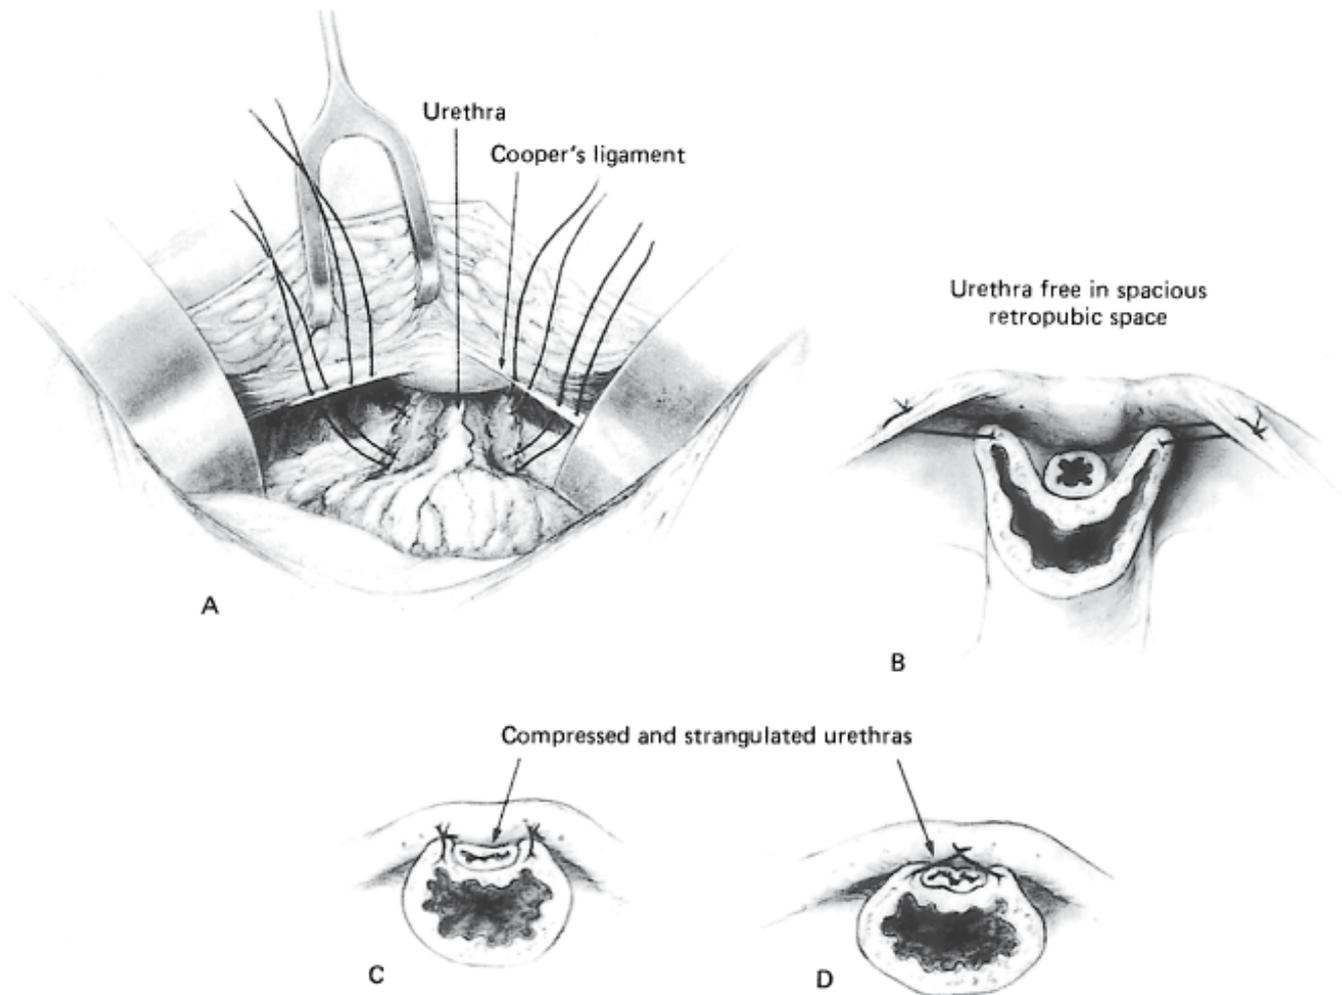

Needle Urethropexy

Since the introduction of this procedure in 1957 by Armand Pereyra and its modifications with contributions by Thomas Leberherz, needle urethropexy has become a fixture in anti-incontinence surgery. Numerous authors have published alterations of this technique (eg, Raz, Stamey, Gittes, and Musznai). All rely on vaginal incision, dissection and mobilization of periurethral tissues, entry into the space of Retzius (retropubic space), and passage of a needle ligature carrier from a small abdominal incision into the vaginal incision. The periurethral tissues and fascia are identified, secured with delayed absorbable suture, and brought through retropubically and secured above the abdominal rectus fascia. In this manner the bladder neck is elevated and continence restored. The heterogeneity of procedure and technique make generalized statements about this procedure difficult, but prospective long-term studies for individual procedures are available. The procedures appear to be effective initially, with cure rates of approximately 80–85% with variable follow-up. When examining some studies (including 1 large prospective study) with at least 2 years of follow-up, the cure rates drop dramatically to less than 65%.

Abdominal Retropubic Colpopexy

The Marshall-Marchetti-Krantz (MMK) and Burch colposuspension are the two classic retropubic surgeries for incontinence. They share the same mechanism of correction. First, both suspend the periurethral and paravaginal tissue at the level of the urethrovesical junction, and second, both use a firm point of attachment for fixation of these suspension sutures. In the MMK procedure, the sutures are fixed to the periosteum of the pubic bone, and in the Burch procedure, the iliopectineal ligament (Cooper's ligament) (Fig 45–6). The Burch colposuspension has become the first choice for treatment of patients with hypermobility of the bladder neck and genuine SUI. In both longitudinal studies and randomized comparative trials against other procedures, the Burch procedure maintains the highest objective and subjective cure rates of 80% after 5 years and 68% after 10 years of follow-up.

Figure 45–6.

Abdominal surgical procedure to correct stress incontinence. A: Anterior vaginal wall has been mobilized. Two sutures have been placed on either side and far lateral from the midline. Distal sutures are opposite the midurethra. Proximal sutures are at the end of the vesicourethral junction. Sutures are attached to Cooper's ligament. B: Cross-section shows urethra free in the retropubic space, with anterior vaginal wall lifting and supporting it. C and D: Urethra is compressed and strangulated against pubic bone when vaginal sutures are applied close to the urethra and then fixed to the pubic symphysis.

(Reproduced, with permission, from Tanagho EA: Colpocystourethropexy. *J Urol* 1876;116:751. Copyright 1976 by The Williams and Wilkins Co.)

A laparoscopic approach to Burch colposuspension offers the benefit of minimally invasive surgery with the same level of efficacy. With the laparoscopic approach, hospital stay and postoperative recovery are minimized. Using the transperitoneal or preperitoneal approach, this method has demonstrated cure rates comparable to the open procedure. Success rates with variable follow-up range between 87% and 97%, with 85% at 5 years of follow-up reported by 1 prospective study. The procedure requires advanced laparoscopic skills, and the results are highly dependent on the skill of the operator. Accordingly, some reports report lower cure rates and higher complications compared with the open procedure.

Suburethral Slings

The suburethral sling was one of the original surgical procedures developed for correction of SUI. The SUI concept of restoring continence by encircling the urethra with supportive tissue, either from the patient or

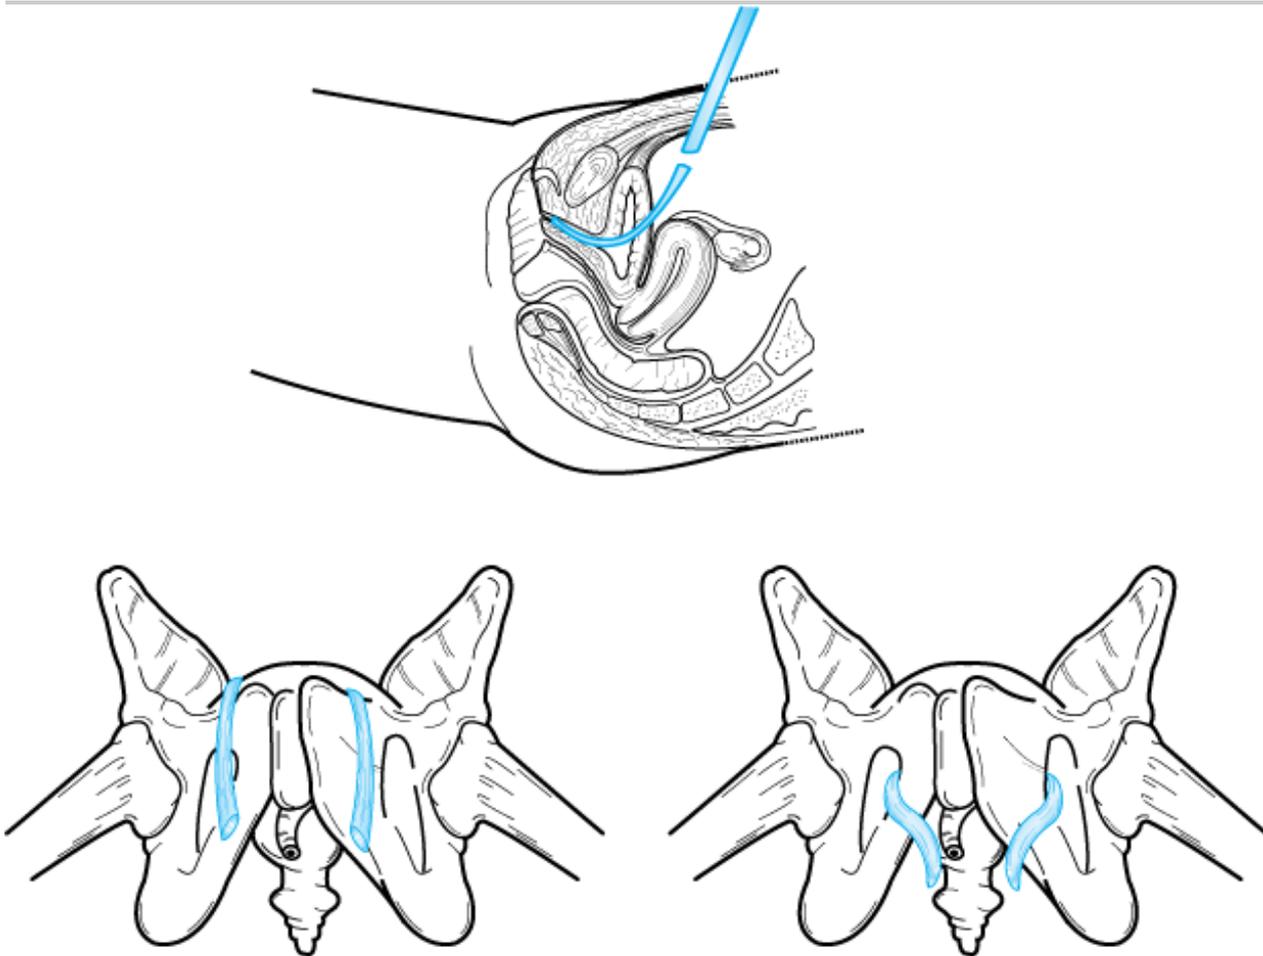

foreign material, was introduced at the beginning of the 20th century. Contemporary techniques have used a patient's own fascia harvested from the leg or rectus fascia, or donor fascia in the form of cadaveric fascia lata. Cure rates of suburethral sling procedures for genuine stress incontinence vary from 70–95%. Reported rates vary because of the heterogeneity of patients, and many are previous surgical failures. Variations in sling material and technique have made cure rates among sling techniques difficult to interpret. Furthermore, most studies vary in the definition of cure and may not distinguish between cure and improvement.

In a large review study summarizing cure rates of surgical treatments for SUI, 16 studies comparing sling procedures to colposuspension were reviewed. Of the 4 that were randomized controlled trials comprising 150 patients, none reported a difference in cure. The remaining 12 were retrospective studies, with only 1 demonstrating a difference in outcome between procedures, 79% versus 95% cure for sling and colposuspension, respectively.

Midurethral Slings

The latest modification of the sling is the use of tension-free vaginal mesh made of polypropylene placed at the level of the midurethra. This pioneering technique, developed in Sweden, was introduced to the United States in the late 1990s. Use of tension-free vaginal tape (TVT) (Fig 45–7) was developed as a minimally invasive technique for surgical correction of genuine SUI. The initial study had an 84% cure rate in 75 women with 2-year follow-up. Considerable data now support a high subjective cure of 85–93% and objective cure rate of 75–85% with up to 7-year follow-up.

Figure 45–7.

A: Placement of midurethral sling in the sagittal view. B: Retropubic passage of midurethral sling. C: Transobturator passage of midurethral sling.

Because of the success of TVT, numerous other devices using the same principles and technique have been introduced. All use a polypropylene mesh but have different designs of delivery needle/trocar, mesh construction, and sheath type. Comparative data between devices are scanty.

The newest variation of the midurethral sling is the transobturator approach. Rather than retropubic passage, the sling is passed through the obturator foramen laterally. This creates a more lateral point of fixation. The purported advantage is reduction in bladder, bowel, or major vascular injury because this method avoids the space of Retzius and does not traverse the peritoneal space. Early data suggest similar short-term cure rates to retropubic passage (94%). Long-term comparative studies will determine the role of the transobturator approach as a viable alternative to retropubic midurethral slings (Fig 45–7).

PERIURETHRAL AND TRANSURETHRAL INJECTION

Periurethral or transurethral injection of a bulking agent into the submucosal space of the bladder neck causes narrowing or coaptation of the proximal urethra and bladder neck opening. This increases urethral resistance to involuntary urine loss without changing resting urethral closure pressure. Currently glutaraldehyde cross-linked bovine collagen is the most commonly used material. This procedure is generally reserved for genuine SUI caused by intrinsic sphincteric deficiency. The injections can be performed with the patient under sedation with local anesthetic in an outpatient or office setting. The bovine collagen degrades over 9–19 months, and repeat "booster" injections are often required. Improvement and cure rates are very high in the short term, and complications are minimal. Pyrolytic carbon beads (Durasphere) is a permanent and hypoallergenic bulking agent that may obviate the need for repeat injections, but long-term cure rates are equally disappointing. Newer formulations are being introduced. Inert gel formulations that become firm after injection are being studied in clinical trials.

ARTIFICIAL SPHINCTERS

The artificial urethral sphincter is an effective option for patients with incontinence not amenable to standard surgical treatment because of urethral scarring or atony. The artificial urinary sphincter is best used in patients with incontinence due to poor urethral sphincter function. The sphincter obstructs the urethra by compressing the bladder neck via a pressure-regulated balloon and releases the compression when the patient desires to void. Reported success rates are up to 91%, but complication rates are high, with 21% of patients requiring surgical replacement of parts or the entire sphincter.

URGE URINARY INCONTINENCE

Definition

Urge urinary incontinence is the complaint of involuntary leakage accompanied by or immediately preceded by urgency. Urge urinary incontinence is usually associated with involuntary contractions of the bladder or detrusor contractions. Strictly speaking, detrusor instability (DI) is an urodynamic definition and term. Recent questions about the relevance and reproducibility of the role of involuntary contractions in the clinical presentation of incontinence have been raised. The literature is at times confusing concerning the methodology (catheter type, bladder filling rate, provocative maneuvers, etc) for data acquisition. The literature is filled with many different terms describing DI, such as overactive bladder (OAB), bladder dyssynergia, uninhibited detrusor, and unstable bladder. In addition, when the cause of involuntary detrusor contractions is due to an underlying neurologic lesion, DI is called detrusor hyperreflexia. OAB is a term that lends itself to encompassing all conditions related to bladder urgency, frequency with and without incontinence. Overactive bladder has become a preferred term because it comprises symptoms of urgency, urge urinary incontinence, frequency, and nocturia.

Etiology

The incidence of OAB varies depending on the population studied and the definition applied. Consequently, the reported prevalence varies widely from 8–50% in the general population, and in women over 65 years it is estimated to be at least 38%. An important concept is that involuntary detrusor contractions for bladder emptying are normally overridden by cortical inhibition of reflex bladder activity. In the majority of cases the cause of OAB symptoms is unknown. Patients with underlying neurologic disease may manifest with urinary incontinence. Although neurologic disease is not a common cause of OAB, multiple sclerosis, cerebrovascular disease, Parkinson's disease, and Alzheimer's disease are most often associated with involuntary bladder contractions.

Diagnosis

Diagnosis of OAB is suggested by urinary frequency often associated with a strong urge or a sense of impending urine loss. Incontinence often occurs prior to reaching the toilet. Loss of urine may occur seconds after stress, such as a cough or strain. Physical or environmental stimuli, such as running water, cold weather, or hand washing, may elicit an urge. Patients often describe "key in lock" syndrome. This is typically characterized by an uncontrollable urge to void when unlocking the door after returning from a trip out of the house. The first thing done upon return is to immediately rush to the toilet or risk losing urine.

Treatment

Adequate therapy depends greatly on accuracy of diagnosis of OAB. History is most often suggestive, and the diagnosis can be confirmed with office cystometry or more precisely with multichannel urodynamics.

Patients with OAB first should be offered simple treatments. Behavioral modifications and medical treatment are the standard first-line therapy for urge urinary incontinence.

BEHAVIORAL THERAPY

Behavioral therapy includes bladder training, timed voiding, and pelvic floor muscle exercises. Bladder training is an educational program that combines written and verbal instruction to educate patients about the mechanisms of normal bladder control with the teaching of relaxation and distraction skills to resist premature signals to urinate. Creating a voiding schedule for which the patient urinates at preset intervals while attempting to ignore the urge to urinate may progressively lead to re-establishment of cortical voluntary control over the micturition reflex.

Timed voiding is a form of bladder retraining that again mandates regularly scheduled voiding and attempts to match the person's natural voiding schedule. No effort is made to motivate the patient to delay voiding by resisting the urge. This method is geared more toward elderly patients with more challenging problems who have skilled help available.

Pelvic floor exercises may aid in the treatment of OAB. Evidence supports the utility of this modality in all types of incontinence. Particularly when augmented with biofeedback, pelvic floor exercises can greatly reduce symptoms of urinary frequency and urge incontinence, by up to 54–85%.

PHARMACOLOGIC THERAPY

One of the most effective and popular treatments for urge urinary incontinence and OAB is drug therapy. Numerous agents for the treatment of these patients have been tried over the years, but only a few have demonstrated substantial impact on reduction of symptoms in controlled trials. One of the main difficulties in treating OAB is that the cause of OAB is still under investigation. The drugs available can be divided into classes by mechanism of action (Table 45–8).

Table 45–8. Pharmacologic Treatment of Urge Incontinence.

Oxybutynin chloride

Ditropan

Anticholinergic (antimuscarinic)/smooth muscle relaxant; tertiary amine

15–30 mg daily

Dry mouth, blurry vision, constipation, tachycardia, drowsiness, dizziness

Oxybutynin chloride (OROS)

Ditropan XL

See above

5–30 mg daily

See above, less CNS side effects

Transdermal oxybutynin

Oxytrol

See above

3.9 mg/day patch

See above

Tolterodine

Detrol

Antimuscarinic/smooth muscle relaxant

1–2 mg BID

See above

Tolterodine (long acting)

Detrol LA

See above

2–4 mg Q day

See above

Tropium chloride

Sanctura

Antimuscarinic; quaternary amine

20 mg BID

Dry mouth, constipation, headache

Darifenacin

Enablex

Antimuscarinic selective; tertiary amine

7.5–15 mg Q day

Dry mouth, constipation, blurred vision

No CNS effects

Imipramine hydrochloride

Tofranil

Tricyclic antidepressant: anticholinergic, alpha-adrenergic, antihistamine

25–100 mg daily

Drowsiness, orthostatic hypotension, hepatic dysfunction, xerostomia

Drug Name	Trade Name	Drug Type	Dosage	Potential Side Effects
-----------	------------	-----------	--------	------------------------

Antimuscarinics, or anticholinergics, have become the mainstay of drug treatment of OAB. Acetylcholine is the primary neurotransmitter involved with bladder contraction. The detrusor muscle of the bladder is heavily populated with cholinergic receptors. Anticholinergic activity, therefore, is a property of most drugs used to treat OAB. The prototype medicine is propantheline. Used for many years, it has excellent results in uncontrolled case series but only modest efficacy in controlled trials, providing benefit in up to 53% of patients.

The mainstays of drug therapy for OAB include oxybutynin chloride and tolterodine. Oxybutynin chloride has been shown in randomized placebo-controlled trials to be effective in increasing bladder capacity, decreasing the frequency of detrusor contractions, and improving symptoms of urinary urgency in approximately 70% of

patients. It is effective for both idiopathic and neuropathic etiologies of DI.

Tolterodine is a medication designed specifically for OAB. It also has anticholinergic activity with specificity for the bladder, and it acts through muscarinic receptors as well as smooth muscle relaxation. In a multicenter randomized controlled trial, the medication compared favorably with oxybutynin in terms of reducing the number of micturitions in 24 hours and the number of incontinent episodes. Because of its bladder specificity, tolterodine has a more favorable side effect profile than oxybutynin. It is also dosed less frequently and improves patient compliance. Both are available in immediate-release and long-acting formulations. Oxybutynin is also available for delivery in a transdermal patch. Recently, a third antimuscarinic, trospium, has become available in the United States for treatment of OAB.

A large randomized comparative trial evaluating the performance of the long-acting formulations of oxybutynin and tolterodine demonstrated similar efficacy. Both reduced weekly urge incontinence episodes, but patients randomized to oxybutynin had a significant reduction in micturition frequency compared with patients receiving tolterodine, and significantly more patients taking oxybutynin became totally dry (23% vs 16%). Adverse events were similar, but the occurrence of dry mouth was higher in the oxybutynin group.

Two new antimuscarinics are solifenacin and darifenacin. Both significantly improve OAB symptoms compared to placebo. Evidence suggests that their side effects will be similar or lower than those of currently available antimuscarinics.

Imipramine hydrochloride is a tricyclic antidepressant that acts through its anticholinergic properties to increase bladder storage. The drug improves bladder compliance rather than counteracting uninhibited detrusor contractions. It is given in doses greatly reduced from those recommended for use as an antidepressant. It also has pharmacologic activity in the blockade of postsynaptic noradrenaline uptake and thereby increases bladder outlet resistance. With its dual action, imipramine may be effective in patients with both stress incontinence and DI (mixed incontinence). It has a low rate of discontinuation because of the main side effects of tremor and fatigue, but it should be dosed in the evening because it may have a sedative effect, and it should be used with caution in elderly patients because of potential orthostatic hypotension.

Surgical measures are methods of last resort for severe intractable DI. Recently, the InterStim surgically implantable device has been found to be effective in patients with intractable urinary urgency and voiding dysfunction.

MIXED INCONTINENCE

Mixed incontinence occurs when both stress incontinence and DI occur simultaneously. Patients may present with symptoms of both types of incontinence. These patients present both a diagnostic and therapeutic dilemma. The prevalence of mixed incontinence is more common than most practitioners realize. A detailed history will reveal symptoms of SUI with urine loss associated with cough, sneeze, or other increase in Valsalva pressure, as well as urinary urgency, frequency, and concomitant incontinence. The coexistence of these 2 conditions may be brought about by many causes. Patients with stress incontinence often preemptively urinate to avoid a full bladder and subsequent urine loss, thereby conditioning the bladder to habituate to a low functional capacity. This may promote premature signaling of bladder fullness and result in frequent urge symptoms. Patients may have DI that is precipitated by coughing or laughing. Patients may have indolent involuntary bladder contractions that only manifest with the additional pressure of a cough, sneeze, or laugh. The cause is often difficult to ascertain, but the diagnosis should be confirmed with urodynamic studies that can assist in identifying the cause of urine loss.

Treatment

For mixed incontinence, treatment should be based on the patient's worst symptoms. Often patients can

prioritize their symptoms, stating that one component impacts their life more than the other. By having the patient separate the symptoms, a practical management plan with realistic expectations can be devised. A great disservice can be done by operating on a patient to restore bladder neck support and remove stress symptoms, when the patient's main concern is daily urge incontinence while she is at work. Conservative measures should be tried first, and if symptoms do not improve surgical measures can be entertained to target alleviation of the stress component. However, there is a 50–60% chance that urge symptoms may resolve after a midurethral sling is performed. Occasionally the involuntary contractions are alleviated by restoration of bladder support and vaginal anatomy.

OVERFLOW INCONTINENCE

Definition

Overflow incontinence is defined as the involuntary loss of urine associated with bladder overdistention in the absence of detrusor contraction. This condition classically occurs in men who have outlet obstruction secondary to prostatic enlargement that progresses to urinary retention. In women this is a relatively uncommon cause of urinary incontinence. When it does occur, it can be from increased outlet resistance from advanced vaginal prolapse causing a "kink" in the urethra or after an anti-incontinence procedure which has overcorrected the problem. Additionally, it can result from bladder hyporeflexia from a variety of neurologic causes (Table 45–9).

Table 45–9. Causes of Overflow Incontinence.

- Spinal cord trauma
- Extrinsic compression
- Surgery
- Cerebral cortical lesions
- Urethral mass
- Obstetric
- Diabetes mellitus
- Anesthetic
- Multiple sclerosis
- Infectious
- Pharmacologic
- Cystitis
- Anticholinergics
- Urethritis
- α-Adrenergics

Neurologic	Anatomic	Iatrogenic

Etiology

Overflow incontinence most often occurs due to postoperative obstruction if the bladder neck is overcorrected, or with a hyporeflexic bladder due to neurologic disease or spinal cord injury. The normal act of voiding is controlled centrally by sacral and pontine micturition centers. Impaired emptying can be the result of disruption of either central or peripheral neurons mediating detrusor function. Failure to identify the cause early may lead to permanent dysfunction and may lead to injury to the detrusor muscle or compromise in the parasympathetic ganglia in the bladder wall.

Diagnosis

Usually symptoms are loss of urine without awareness or intermittent dribbling and constant wetness. Suprapubic pressure or pain may be associated. Patients will often note a sensation of a full bladder and the need to strain in order to empty or apply suprapubic pressure to void. Patients are at risk for urinary tract

infection secondary to persistent residual urine in the bladder, which acts as a medium for bacterial growth. It is commonly seen after a bladder neck suspension. Complaints of poor urinary stream and sense of incomplete emptying combined with having to strain or apply hand pressure to void are likely.

Evaluation should always include a postvoid residual and, if the diagnosis is questionable, voiding pressure flow studies. An imaging study of the upper urinary tract to evaluate the ureters and kidney should follow, because persistent high-volume retention can lead to reflux and hydroureter or hydronephrosis and renal injury if left unchecked.

Treatment

Bladder drainage to relieve retention is the first priority. Self-intermittent or prolonged catheterization may be necessary, depending on resolution of the inciting cause. In cases of postoperative urinary retention, bladder function can be evaluated by serial postvoid residual urine determinations. Although no normal volume for residual urine is universally accepted, it less than 100 mL is generally considered to be within normal limits and greater than 150 mL is considered abnormal. More than one value is needed because persistently high residual volumes will require prolonged catheterization.

When urinary retention occurs in the setting of neurologic disease, diabetes, or stroke, correction of the underlying cause is often impossible; therefore, the goal is to prevent injury or damage to the upper urinary tract. Intermittent self-catheterization is preferable to an indwelling catheter, which may predispose to infection, bladder spasms, or erosion.

Medical therapy may assist in the care of these patients. Acetylcholine agonists can stimulate detrusor contractions in patients that have vesical areflexia. α -Adrenergic blockers can facilitate bladder emptying by relaxing tone at the bladder neck.

Behavior modification in the form of timed voiding on a preset schedule to empty regardless of urge will prevent accumulation of excess urine. Usually a voiding pattern of every 2–3 hours is preferable. In bladder areflexia, manual pressure or abdominal splinting may facilitate emptying.

BYPASS INCONTINENCE

Urinary loss due to abnormal anatomic variations is uncommon but extremely important to consider in the evaluation of the incontinent woman. Bypass incontinence may often mimic other forms of urinary incontinence but usually presents as constant dribbling or dampness. Patients may complain of positional loss of urine without urge or forewarning. Diagnosing this type of incontinence requires a high level of suspicion and an understanding of the underlying anatomic deviation in the lower urinary tract. Genitourinary fistulas (vesicovaginal or ureterovaginal) can be a debilitating cause of incontinence and are formed because of poor wound healing after a traumatic insult (eg, obstetric laceration, pelvic surgery, perineal trauma, or radiation exposure). Leakage due to fistulas is generally continuous, although it may be elicited by position change or stress-inducing activities. Evaluation should include a careful examination of the vaginal walls for fistulas. This can be facilitated by filling the bladder with milk or dilute indigo carmine dye and looking for pooling in the vaginal canal. Pad testing can be performed by having the patient ingest 200 mg of oral phenazopyridine hydrochloride (Pyridium) several hours before a subsequent examination. By placing a tampon in the vagina and on the perineum, the diagnosis may be confirmed by inspection of the pads after a period of time. Further imaging (intravenous urography) and cystoscopy can identify the exact location of the aberrant communication. If diagnosis is made early, the fistulous tract may heal with prolonged catheterization. However, if this procedure is unsuccessful or if diagnosis is made late, surgical correction is generally the only hope for cure.

DIVERTICULUM

Another important but uncommon cause of involuntary urine loss is urethral diverticula. Diverticula are

essentially weaknesses or "hernias" in the supportive fascial layer of the bladder or urethra. Urethral diverticulum is most likely to cause symptoms of urinary loss. It has an incidence of 0.3–3% in women and is thought to be largely an acquired condition resulting from obstruction and expansion of the paraurethral Skene's glands. The symptoms of constant small amounts of leakage or urethral discharge are often described. A suburethral mass is visible and palpable on physical examination. Urine or discharge may often be "milked" by palpation of the suburethral mass. Treatment is usually surgical excision of the diverticulum.

FUNCTIONAL AND TRANSIENT INCONTINENCE

Incontinence may be caused by factors outside the lower urinary tract and is particularly significant in the geriatric population, because often a multitude of special circumstances affect the health of the elderly. Physical impairment, cognitive function, medication, systemic illness, and bowel function are all factors that may contribute to incontinence. Many immobile patients are incontinent because of the inability to toilet. Cognitive disturbances limit a patient's ability to respond normally to the sensation to void. Numerous medications have effects on the bladder that may reduce capacity, inhibit bladder function, increase diuresis and bladder load, or relax the urinary sphincter. Additionally, stool impaction and constipation both have been associated with increased prevalence of urinary incontinence. Treatments should first identify the etiologic factors of the incontinence and then reduce or remove the cause.

Current OB/GYN >Chapter 46. Perioperative Considerations in Gynecologic Surgery>

PERIOPERATIVE CONSIDERATIONS IN GYNECOLOGIC SURGERY: INTRODUCTION

The gynecologic surgeon focuses on the normal and pathologic anatomy and function of the female reproductive system. However, because no organ system functions independently, the gynecologist must also be familiar with many pathologic conditions not directly related to the reproductive system. At no time is this more crucial than during the perioperative period, i.e., just before, during, and immediately after gynecologic surgery.

The differential diagnosis of abdominopelvic pain and dysfunction not directly related to the reproductive system must be fully understood by the gynecologist because many of these entities can present with symptoms suggestive of uterine or adnexal origin. Conversely, the first evidence of nongynecologic disease may be an alteration in the function of the female reproductive system.

This chapter covers the perioperative period: the decision to operate (emergently or electively), and the pre- and immediate postoperative management of these patients. Selected medical and surgical disorders of importance to the gynecologist are reviewed as they relate to management of the surgical patient.

ACUTE ABDOMEN

Essentials of Diagnosis

ESSENTIAL ELEMENTS:

- Acute onset of severe abdominal pain.
- Signs of peritoneal irritation with guarding and rebound tenderness.

FREQUENTLY SEEN:

- Anemia or hypovolemic shock if intraperitoneal hemorrhage exists.
- Varying degrees of gastrointestinal irritation, nausea, and vomiting.
- Elevated white blood cell count (if cause is inflammatory or infectious).
- Fever (occasionally).
- Possible complication of pregnancy.

General Considerations

The diagnosis of acute abdomen has traditionally been based on signs and symptoms of peritonitis, which can be caused by a diverse array of disease processes. Although the acute abdomen always requires an immediate surgical or medical decision, some patients suffer from a major intra-abdominal pathologic process not associated with peritonitis and should not be considered to have an acute abdomen. An example is the patient with acute gastrointestinal bleeding who requires emergency care but does not have an acute abdomen in the

strictest sense. Although the acute abdomen is not precisely defined, a number of signs and symptoms generally accompany this diagnosis (Table 46–1).

Table 46–1. Differential Diagnosis of Acute Gynecologic Intra-Abdominal Disease.

Ruptured ectopic pregnancy

Hematocrit low after treatment of hypovolemia.

Red blood cells rare.

Positive. β -hCG low for gestational age.

Possible adnexal mass.

Possible sac-like decidual reaction in uterus.

Possible increased free fluid in cul-de-sac.

High hematocrit.

Defibrinated, non-clotting sample with no platelets. Crenated red blood cells.

No.

Unusual.

Salpingitis

Rising white blood cell count.

White blood cells occasionally present.

Generally negative.

Negative unless pyosalpinx or tubo-ovarian abscess present.

Yellow, turbid fluid with many white blood cells and some bacteria.

Progressively worsening. Spiking.

Gradual onset with ileus.

Ruptured ovarian cyst (hemorrhagic)

Hematocrit may be low after treatment of hypovolemia.

Normal.

Usually negative.

No masses. Increase free fluid in cul-de-sac.

Hematocrit generally less than 10%.

No.

Rare.

Ruptured ovarian cyst (non-hemorrhagic)

Normal.

Normal.

Generally negative

No masses. Increased free fluid in cul-de-sac.

Increased clear fluid.

No.

Rare.

Torsion of adnexa

Normal or elevated white blood cell count with necrosis.

Normal.

Generally negative.

Adnexal mass common. Decreased flow on Doppler study.

Minimal clear fluid if obtained early.

Possibly with necrosis.

Possibly.

Degenerating leiomyoma

Normal or elevated white blood cell count.

Normal.

Generally negative.

Pedunculated or uterine mass often with central fluid areas.

Normal clear fluid.

Possibly.

Rare.

Clinical and Laboratory Findings							
Disease	CBC	Urinalysis	Pregnancy Test	Ultrasound	Culdocentesis	Fever	Nausea and Vomiting

It is important to note that although many physicians perceive the acute abdomen as a problem always requiring surgical intervention, in many instances medical management is more appropriate. The presence of an acute abdomen does not dictate the type of management, only the need to come to a rapid decision and implement appropriate therapy as expeditiously as possible.

Finally, it should be stated that an abdomen with generalized peritonitis in all four quadrants is commonly termed a "surgical abdomen." If the patient has a rigid abdomen with guarding and rebound tenderness in all four quadrants, a clear diagnosis usually cannot be achieved except in the operating room. Ultrasonography, computed tomography (CT), culdocentesis, and other routine tests can often establish whether the process is hemorrhagic or inflammatory, but the specific diagnosis can typically be determined only during laparotomy or laparoscopy.

The patient with a surgical abdomen should never be delayed. The operating room should be notified, large-bore intravenous access obtained, and blood work, including a complete blood count (CBC) and blood for cross-matching, should be sent as the patient is being moved to the operating room. This is the exceptional case that demands the gynecologic surgeon's total attention and skills. For most patients with localized peritonitis, however, a diagnosis can be made outside the operating room, allowing more time for consideration of therapeutic options.

Etiology and Pathogenesis

The acute abdomen can be caused by a wide variety of problems. Their similar clinical presentation reflects the stimulation of pain receptors in the peritoneum by leakage of purulent matter into the peritoneal cavity, intraperitoneal bleeding, necrosis of an intra-abdominal structure, or inflammation because of infection. Stomach acid, bile, and pancreatic secretions cause intense peritoneal irritation when released into the peritoneal cavity, but urine and ascitic fluid generally do not.

Clinical Findings

SYMPTOMS AND SIGNS

The most common symptom of a patient with acute abdomen is pain. It can be generalized or have a maximum intensity in a specific area. The presence of guarding, rebound tenderness, or referred tenderness on abdominal examination can be helpful in localizing the area of greatest peritoneal irritation. On pelvic examination, the patient may exhibit uterine motion tenderness. Although commonly associated with pelvic inflammatory disease, this sign is nonspecific and is likely to be present with a number of irritative pelvic processes.

The irritated peritoneum is most sensitive to stretching and movement, so patients often minimize motion to reduce these stimuli. The patient's position may provide a useful clue to the site of greatest irritation. Patients with pelvic peritonitis are frequently most comfortable with one or both hips flexed, depending on the site and extent of the peritonitis.

The quality of the patient's pain is important. Patients with intermittent torsion of the adnexa or ruptured ovarian cyst may have had such pain before. The temporal relationship of the onset of pain to the patient's last

menstrual period may give valuable clues, especially regarding possible complications of early pregnancy.

Gastrointestinal symptoms that often accompany the acute abdomen are anorexia, nausea, vomiting, and/or diarrhea. The extent of bowel involvement depends on the severity of the peritonitis. Patients with mild bowel irritation note decreased appetite. Nausea and vomiting may develop as the bowel becomes more directly involved in the inflammatory process. Further progression leads to inhibition of peristalsis with associated abdominal distention secondary to gas- and fluid-filled loops of bowel. As peristalsis decreases, bowel sounds may be decreased, and eventually may be absent. High-pitched bowel sounds and rushes may be heard if obstruction is present.

If the peritoneum covering the bladder or rectosigmoid is irritated first, the patient's initial complaint may be of painful bladder or bowel function. It can be a mistake to assume that a patient complaining of painful bladder filling and emptying merely has cystitis. For example, it is not unusual for a patient to note an episode of urinary or bowel urgency at the time of initial rupture of an ectopic pregnancy or an ovarian cyst.

When taking the history, keep in mind the progression and timing of the appearance of the patient's symptoms. When performing the physical examination, it is necessary to realize that the patient has an evolving process occurring, and a single examination only assesses one stage of that process. Several serial examinations may be necessary to guide clinical decision making.

LABORATORY FINDINGS

Routine laboratory studies for all women with pelvic peritonitis should include CBC, urinalysis, and rapid pregnancy test. The CBC may demonstrate either acute blood loss or, if the white blood cell count is elevated, an infectious process.

A rapid, reliable pregnancy test should always be performed immediately in the female patient with pelvic pain. A patient whose history suggests salpingitis may actually have a ruptured ectopic pregnancy. In addition, a pregnancy may coexist with an independent pathologic process, in which case the pregnancy may influence management. For example, elective surgery for a degenerating leiomyoma in a pregnant patient should be deferred until the second trimester if possible.

Urinalysis may demonstrate urinary tract infection, but pyuria may also result from an abscess adjacent to the ureter, as occurs in ruptured retrocecal appendicitis. Gross or microscopic hematuria can reflect the passage of a stone, or perhaps exacerbation of an underlying pathologic process such as interstitial cystitis.

Patients with diabetic ketoacidosis may present with severe acute abdominal pain, making testing the blood and urine for glucose and ketones essential. It is also possible for the stress of an acute abdomen from other causes to initiate or aggravate ketoacidosis in a normally well-controlled diabetic patient. Prior to operating on such patients every effort must be made to fully correct their fluid, glucose, electrolyte, and acidotic status.

Cervical cultures for *Neisseria gonorrhoeae* and *Chlamydia trachomatis* should also be obtained. Although not useful for immediate management decisions, they may aid in guiding antibiotic therapy if the patient is determined to have a pelvic infection. The erythrocyte sedimentation rate is a nonspecific test for the presence of inflammation and is not very useful in the initial evaluation of the acute abdomen.

SPECIAL EXAMINATIONS

Culdocentesis

Culdocentesis is an easily performed and important diagnostic procedure that is often overlooked in the modern era of high-resolution imaging studies, but it may be useful when those studies are not available. The contents of the peritoneal cavity can be evaluated by means of culdocentesis in any patient with pelvic peritonitis or pain during uterine and adnexal movement.

Clear, straw-colored peritoneal fluid represents a negative culdocentesis, indicating no intraperitoneal bleeding.

An unruptured ectopic gestation could still be present. Large amounts of fluid of this type can indicate a ruptured, nonhemorrhagic ovarian cyst or ascites. Turbid peritoneal fluid containing white blood cells on Gram-stained smear suggests an intrapelvic inflammatory process.

A bloody, nonclotting peritoneal fluid sample with a hematocrit in the range of 15–40% reflects recent hemorrhage into the peritoneal cavity, possibly from ruptured ectopic pregnancy or a bleeding ovarian cyst. In this case, prior clotting of blood in the peritoneal cavity results in crenated red blood cells, defibrination, absence of platelets, and lack of clotting factors in the hemorrhagic fluid aspirated from the cul-de-sac. A bloody aspirate that forms a clot may represent blood inadvertently drawn from vaginal or uterine vessels. An attempted culdocentesis that returns no fluid at all is termed "nondiagnostic."

Given the increasing availability of transvaginal ultrasonography, the role of culdocentesis for the detection of hemoperitoneum is currently being reassessed. A review of 252 consecutive cases, in which patients underwent culdocentesis and subsequent surgery for presumed ectopic pregnancy revealed that 86% of the patients with a positive culdocentesis had a hemoperitoneum. However, 25 of the 42 patients with a negative result from culdocentesis were found to have a hemoperitoneum, a false-negative rate of 54%.

More recently, another study compared the sensitivity and specificity of culdocentesis and transvaginal ultrasound to identify hemoperitoneum. Among 46 patients who underwent surgery for the treatment of suspected ectopic pregnancy, the presence of "echogenic fluid" on transvaginal ultrasound had a sensitivity of 95% and a specificity of 100% for the detection of hemoperitoneum. A positive culdocentesis was found to have a sensitivity of 62% and a specificity of 89% for the detection of hemoperitoneum. Because culdocentesis is an invasive procedure whose sensitivity may be lower than previously thought, it should be primarily used when transvaginal ultrasound is not available.

Radiographic Studies

Transvaginal and transabdominal ultrasound studies have become extremely useful over the past decade for diagnosis of the acute abdomen. In the pelvis, ultrasonography is useful for characterizing the location and gestational age of early pregnancies, identifying adnexal or uterine masses, and determining the presence or absence of pelvic abscesses or excessive free fluid in the cul-de-sac. Outside the pelvis, ultrasonography is often the initial diagnostic modality used to investigate possible cholecystitis, choledocholithiasis, and appendicitis. In patients too uncomfortable to allow adequate abdominal or bimanual pelvic examination, ultrasound examination plays an even more important role. A number of CT techniques have also proved useful in the evaluation of the acute abdomen.

Plain radiograph films of the abdomen are less helpful in diagnosing gynecologic causes of acute abdomen, but may be helpful in detecting bowel obstruction or paralytic ileus if dilated loops of bowel with air-fluid levels are seen. Free air under the diaphragm on an upright film indicates perforation of a viscus organ and requires immediate intervention. An upright film that does not show the diaphragms should be considered inadequate in the work-up of the acute abdomen. Occasionally, loss of the psoas shadow on the right side is seen, supporting a diagnosis of appendicitis. In addition, renal calculi may be seen on plain films.

Microbiologic Studies

In the acute patient, Gram stains and cultures assume a role of lesser importance. Cervical cultures for *N. gonorrhoeae* should be done; however, because this organism can be found on the cervix of asymptomatic as well as symptomatic patients, Gram-stained smears of cervical secretions to detect gram-negative diplococci may be unreliable. Finding *N. gonorrhoeae* on the cervix does not prove that peritonitis is caused by salpingitis. Conversely, many patients with laparoscopically proven pelvic infections have negative cervical cultures. In the patient who proves to have salpingitis, cervical cultures or cultures of washings done at laparoscopy may help to sharpen the focus of subsequent antibiotic therapy. Cervical material should be submitted for culture in all patients suspected of having gonococcal salpingitis, if only to determine the need for treatment of the sexual

partner. Chlamydial culture or enzymatic assay is frequently done as well.

GYNECOLOGIC CAUSES OF ACUTE ABDOMEN

Ruptured ectopic pregnancy, salpingitis, and hemorrhagic ovarian cyst are the three most commonly diagnosed gynecologic conditions presenting as acute abdomen in the emergency room. Degenerating leiomyomas occur less frequently. Table 46–1 lists typical clinical and laboratory findings for these conditions. These gynecologic entities are discussed fully in their respective chapters.

Torsion, or twisting, of the ovary or both the ovary and tube is an unusual cause of acute abdomen. The most common etiology is ovarian enlargement by a benign mass. Patients present with acute, severe abdominal, pelvic pain which may be accompanied by nausea and vomiting. With progressive torsion venous and lymphatic obstruction occurs. Interruption of the arterial supply may follow, resulting in hypoxia, necrosis, fever and leukocytosis. Diagnosis is aided by ultrasound, where an adnexal mass is usually seen. Management is surgical. In a patient of reproductive age with a benign mass, it is acceptable to untwist the ovary and if the ovary is viable, remove the mass and stabilize the remaining ovary with sutures.

The challenge of the acute abdomen is expeditious arrival at an accurate diagnosis and the rapid implementation of a treatment plan. The gynecologist may be the only physician to evaluate the patient and must be capable of entertaining all possible diagnoses in the differential—both gynecologic and nongynecologic. The next section and Table 46–2 review the most common nongynecologic entities that need to be considered by the gynecologist evaluating the patient with an acute abdomen.

Table 46–2. Differential Diagnosis of Acute Nongynecologic Intra-Abdominal Disease.

Appendicitis

Normal early; high white blood cell count later.

Normal.

If patient is pregnant, presentation of disease is atypical.

Yellow, turbid fluid with many white blood cells and no bacteria.

Not early in course.

Yes.

Retrocecal appendicitis

Normal early; high white blood cell count later.

Many white blood cells if abscess forms.

Not helpful.

May be normal.

Yes in advanced diseases.

Variable.

Regional enteritis (Crohn's disease)

High white blood cell count.

Normal.

Not helpful.

Yellow, turbid fluid with many white blood cells.

Yes if severe.

Yes if severe. Recent history of diarrhea.

Colonic diverticulitis

High white blood cell count.

Normal.

Not helpful.

Yellow, turbid fluid with many white blood cells and no bacteria.

Yes if severe.

Variable.

Bowel obstruction

High if ischemic bowel damage is present.

Normal.

Not helpful.

Increased amount of fluid with many white blood cells if bowel is ischemic.

Only if bowel is ischemic.

Yes.

	Clinical and Laboratory Findings

NONGYNECOLOGIC CAUSES OF ACUTE ABDOMEN

Appendicitis

More than 10% of the general population will develop appendicitis at some time in their lives. Appendicitis is widely recognized as a disease of childhood and is the most common reason for laparotomy in infants and children. In the older patient, however, appendicitis can manifest later and in a more subtle fashion. This can be of great clinical significance in these patients, who often have other significant underlying diseases. It is wise to consider the possibility of appendicitis in every patient—regardless of age—who presents in the emergency room with an acute abdomen.

In pregnancy the need to consider appendicitis is of paramount importance. One researcher found in a 10-year experience at a large teaching hospital a perinatal mortality rate of less than 3% for uncomplicated appendicitis as well as for negative laparotomy. When perforation occurred before surgery, the perinatal mortality rate rose to 20%. As the researcher put it, "the maxim regarding acute appendicitis—if in doubt, take it out—is never more true than in pregnancy."

Clinical Findings

SYMPTOMS AND SIGNS

It is prudent for the gynecologist to remember that the patient may not present with the "classic" symptoms of appendicitis, but may present with many variations that closely mimic other diagnostic entities.

The patient's first symptom may be nausea and loss of appetite. Pain typically begins in the periumbilical area and then gradually shifts to the right lower quadrant. Fever is usually not significant unless the appendix has ruptured. Bowel sounds are reduced, and often no bowel movement will have occurred since the onset of pain. After the patient's pain migrates to the right lower quadrant, tenderness to palpation is most severe at McBurney's point, approximately 5 cm medial to the right anterior superior iliac spine on a line between the anterior superior iliac spine and the umbilicus. As inflammation increases, guarding and rebound tenderness appear at this location. Palpation in the left lower quadrant may produce referred pain in the right lower quadrant.

Some patients note marked discomfort upon uterine motion, as well as right adnexal tenderness on pelvic examination. These symptoms develop because the inflamed appendix irritates the peritoneum adjacent to the uterus and oviduct, and they may be improperly interpreted as signs of salpingitis. The patient is generally most comfortable in the supine position with the right hip flexed to minimize tension on the peritoneum adjacent to the appendix.

LABORATORY FINDINGS

The CBC may be normal, but an elevated white blood cell count may develop, especially after rupture of the appendix. Urinalysis results are usually normal unless the inflamed appendix rests adjacent to the ureter, or unless an abscess has formed near the ureter, producing pyuria. If the pregnancy test is positive, the presentation of appendicitis may be significantly altered.

RADIOLOGIC FINDINGS

High-resolution ultrasonography with graded compression has proven useful in the diagnosis of acute appendicitis. In one study, researchers claimed a diagnostic sensitivity varying from 80–95%, a specificity of 95–100%, and an accuracy rate of 91–95%. Ultrasonography also allows some differentiation between the acute appendix and the gangrenous and perforated appendix.

X-ray films of the abdomen may demonstrate an oval calcified fecalith up to 1–2 cm in diameter in the right lower quadrant. A dilated, gas-filled "sentinel loop" of the bowel may also be seen as a result of localized inflammation near the cecum on plain films.

SPECIAL EXAMINATIONS

Culdocentesis may demonstrate straw-colored, turbid peritoneal fluid containing numerous white blood cells. This finding is not diagnostic for appendicitis but merely reflects the existence of an intraperitoneal inflammatory process; similar findings may be seen in salpingitis and acute regional enteritis.

Laparoscopy may be appropriate in young, nulligravid patients in whom a missed diagnosis may have an adverse effect on future fertility. Considerable technical skill may be required to establish or rule out a diagnosis of appendicitis, depending on the location of the appendix and other intra-abdominal conditions. Removal of the appendix through the laparoscope may then also be possible as well.

Differential Diagnosis

On the basis of physical examination alone, it may be difficult to distinguish acute salpingitis from appendicitis. The irritation associated with pelvic inflammatory disease usually extends to both lower quadrants unless unilateral salpingitis (possibly associated with an intrauterine device) is suspected. In contrast to the patient with appendicitis, the patient with salpingitis is more likely to have a fever with an elevated white blood cell count at an earlier stage of her disease. The woman with salpingitis usually develops gastrointestinal symptoms later, as pelvic inflammation spreads from the oviducts to secondarily involve the bowel in the pelvic cavity.

A history of early gastrointestinal symptoms, decreased appetite, and nausea and vomiting are often the most reliable factors in establishing a diagnosis of appendicitis rather than early pelvic inflammatory disease. The possibility of a ruptured right ovarian cyst must be entertained as well.

In the emergency setting, it is occasionally impossible to differentiate appendicitis from acute regional enteritis (Crohn's disease) with involvement of the terminal ileum. At laparotomy for suspected appendicitis in the patient with regional enteritis, the appendix is normal but the terminal ileum is inflamed. In contrast to the patient with appendicitis, a patient with regional enteritis usually has a history of recent diarrhea (Table 46–2).

Ruptured retrocecal appendicitis may be misdiagnosed as pyelonephritis. The fever, nausea, right-sided back pain, and pyuria from a retrocecal abscess may be mistakenly assumed to be of renal origin.

In the pregnant patient, the enlarging uterus displaces the appendix upward, thereby changing the site of the pain of appendicitis. Pregnant patients with appendicitis also demonstrate less dramatic gastrointestinal symptoms and may even continue to have an appetite. For these reasons, the diagnosis of appendicitis in the pregnant patient is much more likely to be made after appendiceal rupture and abscess formation have occurred than in the nonpregnant patient. This most often leads to premature labor. The risk of early surgical intervention in the gravid patient must be weighed against the considerable risk of premature delivery if appendicitis is indeed present and rupture occurs.

Treatment

The diagnosis of acute appendicitis requires immediate surgical removal of the appendix either by laparotomy or laparoscopy.

Complications

Early diagnosis and surgery are essential to prevent rupture of the appendix and the possible complications of recurrent pelvic abscess, wound infection, pelvic adhesions, and occasionally, infertility.

Acute Bowel Obstruction

Bowel obstruction may result from an intrinsic or extrinsic expanding neoplasm, compression of a segment of bowel by a hernia, constriction of the lumen by extrinsic bowel adhesions, or volvulus or intussusception of a segment of bowel. Because of the wide range of causes, all age groups or populations should be considered at risk for development of bowel obstruction. The cause is often not clear until laparotomy is performed.

Obstruction caused by adhesions is always a possibility if the patient has undergone previous abdominal surgery, especially if the previous surgery was complicated by peritonitis.

Clinical Findings

SYMPTOMS AND SIGNS

Nausea and vomiting associated with abdominal distention and severe abdominal pain are the hallmarks of bowel obstruction. Bowel sounds may be absent if obstruction is total, or high-pitched if it is partial. The patient may complain of constipation and usually ceases to have bowel movements. A hernia or abdominal mass may be evident on physical examination. Abdominal palpation produces guarding and rebound tenderness.

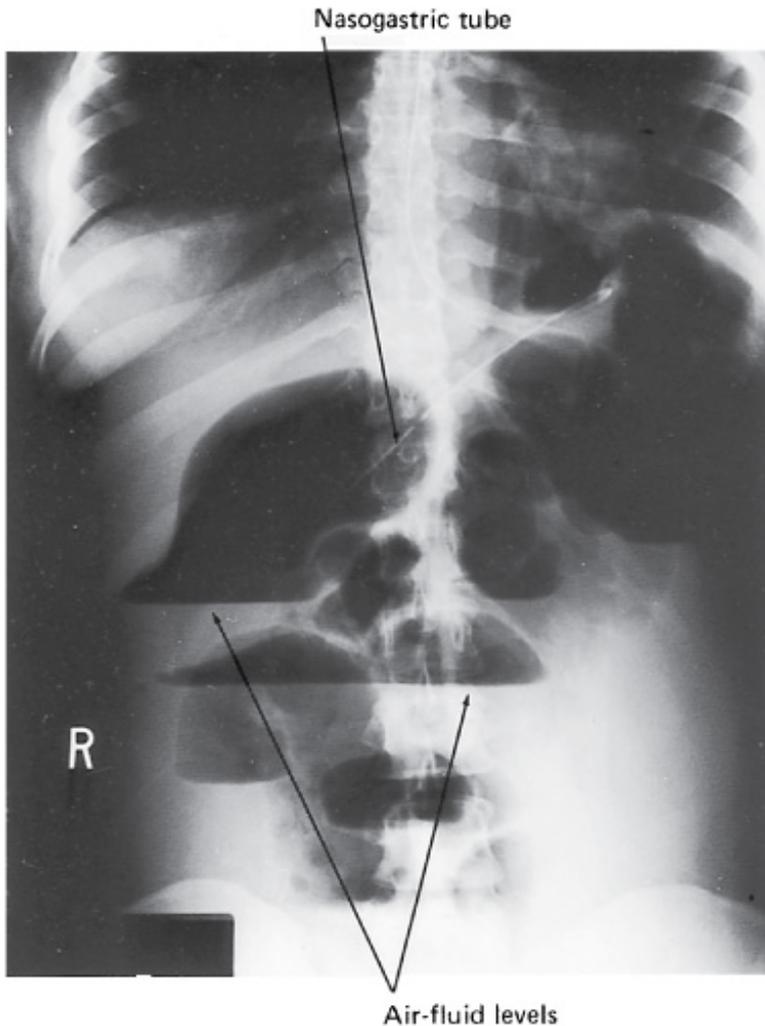

LABORATORY FINDINGS

Loss of hydrochloric acid through protracted vomiting results in alkalosis with respiratory compensation. Serum bicarbonate levels may be high. Serum potassium levels may be low, indicating general depletion of electrolytes.

X-RAY FINDINGS

A supine x-ray view of the abdomen demonstrates one or more loops of gas-filled bowel. Air-fluid levels are evident in these loops in upright films (Fig 46–1).

Figure 46–1.

Upright abdominal film demonstrating air-fluid levels in a patient subsequently found to have small-bowel obstruction.

Differential Diagnosis

Peritonitis with secondary inhibition of peristalsis, generally termed paralytic ileus, must be distinguished from bowel obstruction. The patient with paralytic ileus usually experiences constant abdominal pain rather than the cramping abdominal pain associated with bowel obstruction. Treatment of the condition causing peritonitis also results in gradual resolution of paralytic ileus.

Complications

Marked distention of a segment of bowel may result in vascular compromise, strangulation, and, eventually, bowel perforation with spillage of toxic bowel contents into the abdominal cavity. Dehydration and loss of electrolytes are associated with accumulation of fluid within the bowel lumen. Hypokalemia may produce electrocardiographic abnormalities if the serum potassium level is lower than 3 mEq/L.

Treatment

Nasogastric suction may be effective in decompressing the distended bowel and may relieve the persistent vomiting and cramping pain associated with bowel obstruction. Surgical correction of the structural abnormality responsible for obstruction is the only definitive treatment. Partial bowel obstruction caused by adhesions occasionally subsides while the patient is undergoing nasogastric or long-tube suction. Fluid or electrolyte imbalance must also be corrected, and losses must be compensated for during prolonged suction drainage.

Evidence of a perforated viscus organ requires immediate surgical intervention.

Inflammatory Bowel Disease (Ulcerative Colitis & Regional Enteritis [Crohn's Disease])

Ulcerative colitis and regional enteritis represent two distinct forms of inflammatory bowel disease.

Inflammation restricted to the colon is termed ulcerative colitis. Regional enteritis (Crohn's disease, terminal ileitis) is characterized by multiple sites of small bowel or colonic inflammation, especially in the terminal ileum.

Women are twice as likely to develop regional enteritis but carry the same risk as men for ulcerative colitis.

Inflammatory bowel disease is most likely to develop during the reproductive years.

Clinical Findings

SYMPTOMS AND SIGNS

Patients suffering from inflammatory bowel disease generally complain of episodic bloody diarrhea and abdominal pain. Abdominal guarding and rebound tenderness are noted on palpation of the localized area of peritonitis associated with the inflamed segment of bowel. The severity of recurrent episodes of abdominal pain and diarrhea varies widely. Acute regional enteritis with terminal ileitis may mimic appendicitis, although the patient with acute regional enteritis is far more likely to give a history of recent diarrhea.

LABORATORY FINDINGS

The CBC generally shows an elevated white blood cell count with an increased number of polymorphonuclear leukocytes. Culdacentesis should be avoided if inflammatory bowel disease is suspected. If done, however, it would yield turbid fluid containing numerous white cells—largely a result of inflammatory transudate from the inflamed bowel.

X-RAY FINDINGS

Barium enema and an upper gastrointestinal study with small-bowel follow-through may demonstrate either mucosal changes of the bowel consistent with acute inflammation, or induration and narrowing of bowel segments, suggesting chronic disease. Involvement of only one segment of colon suggests a diagnosis of ulcerative colitis; multiple sites of involvement, often including the terminal ileum, suggest regional enteritis. X-ray studies may be normal in patients with early or inactive inflammatory bowel disease.

SPECIAL EXAMINATIONS

Endoscopic evaluation with biopsy of areas of inflamed bowel mucosa is the most direct method of diagnosis.

Differential Diagnosis

Appendicitis, diverticulitis, torsion of the adnexa, and salpingitis may produce physical findings similar to those of acute terminal ileitis. Because of the great difference in appropriate therapy for each of these conditions and because of the serious results of inappropriate treatment, each disease must be ruled out whenever the diagnosis of acute inflammatory bowel disease is suspected.

Complications

Perforation of the colon and small bowel fistulas are serious inflammatory complications. Appendectomy in a patient with terminal ileitis carries an additional risk of poor healing, abscess formation, and fistula development, especially if the cecum and base of the appendix are involved in the inflammatory process.

Treatment

Acute inflammatory bowel disease generally responds to administration of corticosteroids. Intravenous metronidazole has been effective in some patients with acute illness. Recurrence may be prevented by long-term administration of sulfasalazine. Therapy is complex, however, and should be directed by a gastroenterologist. Surgical excision of segments of inflamed bowel may be appropriate in cases of stricture

with obstruction, perforation, or massive hemorrhage, or in severe cases unresponsive to corticosteroids. Reanastomosis of bowel after resection for inflammatory bowel disease is often unsuccessful, and resection fails to prevent recurrence, which often occurs just proximal to the anastomotic site. Supportive care, including intravenous fluids, electrolytes, transfusion, antibiotics if sepsis is present, and nutritional replacement for patients with malabsorption, are essential general measures.

Colonic Diverticulitis

Diverticula of the distal colon are uncommon in women during the reproductive years, but as many as one-third of postmenopausal women have colonic diverticula demonstrable by barium enema or colonoscopy. Colonic diverticula appear to result from herniation of the bowel mucosa at a site of weakness of the colonic muscularis. The mucosa may be disrupted as the diverticulum enlarges, with resulting bleeding or localized infection. Bleeding may require partial colonic resection. Superficial infection may be self-limiting and associated with mild left lower quadrant pain, which spontaneously subsides as the bowel mucosa heals over a period of 2 or 3 days. Broad-spectrum antibiotics may be necessary if the patient with diverticulitis develops severe left lower quadrant pain, guarding, rebound tenderness, fever, and leukocytosis. Patients not responding to antibiotics or patients with associated pelvic abscess formation require surgical management, including drainage of the pelvic abscess, temporary colostomy, and possible resection of the segment of inflamed or obstructed colon. The surgeon must also rule out carcinoma of the colon, especially in the case of bowel obstruction.

Meckel's Diverticulitis

Meckel's diverticulum, a remnant of the vitelline duct, is found in 2–3% of the general population but is three times more common in men than in women. The diverticulum is generally found on the antimesenteric surface of the small bowel, about 8 cm from the ileocecal valve, although the exact distance from the cecum varies greatly. Ectopic secretory gastric mucosa may be found in 20% of patients with Meckel's diverticulum.

If secretory gastric mucosa is present in the diverticulum, ulceration of adjacent bowel mucosa may result in bleeding. Bleeding is an indication for laparotomy in 50% of patients subjected to surgery for complications arising from Meckel's diverticulum. Intestinal obstruction from intussusception of Meckel's diverticulum or obstruction due to volvulus around a vestigial band from the diverticulum to the umbilicus is the reason for an additional 25% of surgical procedures, and Meckel's diverticulitis is the reason for the remaining 25% of surgical cases.

Meckel's diverticulitis is associated with symptoms similar to those of appendicitis, except that abdominal pain is located more medially. Inflamed Meckel's diverticulum may rupture earlier than an inflamed appendix. If the cause of inflammatory peritonitis is unclear at the time of laparotomy, it is important to inspect the entire length of the small bowel for a possible inflamed Meckel's diverticulum. An inflamed Meckel's diverticulum should be resected. The base of the diverticulum may be broader than the base of the appendix, so simple ligation may not be possible.

Nephrolithiasis

Various metabolic factors, in combination with dehydration, may frequently produce supersaturated solutions of relatively insoluble substances that subsequently crystallize in the urine. Men are two to three times more likely than women to develop calcium renal stone disease. The less-frequently detected struvite (magnesium-ammonium-phosphate), uric acid, and cystine stones are associated with chronic *Proteus* infection of the urinary tract, gout, and cystinuria, respectively.

Clinical Findings

SYMPTOMS AND SIGNS

Renal stones may be discovered in any portion of the urinary tract but are most likely to be symptomatic in the ureter. A renal stone passing from the ureteropelvic junction to the bladder usually causes severe ureteral spasm. Ureteral colic generally radiates from the flank on the affected side to the labia or bladder and may occur episodically over several hours or days until the stone passes into the bladder. Although the pain is usually prostrating, the patient experiences no peritonitis and may sometimes be able to remain mobile during the attack. A renal stone may remain lodged at the ureterovesical junction for a long time. In a patient with partial ureteral obstruction, symptoms caused by a renal stone at the ureterovesical junction may mimic the urinary frequency, urgency, bladder discomfort, and hematuria of hemorrhagic cystitis.

Abdominal and pelvic examinations remain normal during an acute attack of ureteral colic, but gentle flank percussion worsens ureteral pain.

LABORATORY FINDINGS

The most helpful initial laboratory test is evaluation for hematuria; blood is found in the urine sample of every patient with a renal stone unless total ureteral obstruction exists. Abdominal x-rays are helpful in locating calcium- and magnesium-containing stones. An intravenous pyelogram is useful in assessing ureteral obstruction and secondary renal structural damage. Intravenous pyelogram may also be necessary to locate stones not containing calcium or magnesium (< 10% of all stones), as these are not visible on x-rays. Renal ultrasonography will reveal hydronephrosis or hydroureter if distal obstruction is present.

SPECIAL EXAMINATIONS

After acute pain has subsided, efforts should be directed toward establishing the cause of renal stone disease. All urine should be filtered to collect stones for analysis of their mineral content. Appropriate metabolic studies to detect hyperuricosuria, hypercalciuria, hyperoxaluria, etc, are dictated by the composition of the stones.

Treatment

Treatment to prevent recurrent stone formation includes correction of any metabolic abnormalities in the minority of patients who demonstrate such disorders. The most helpful therapy for most patients appears to be conscientious efforts to maintain adequate hydration; consumption of more than 2 L of water daily is advised. Efforts to maintain hydration are especially important after meals and during the night. The pain caused by passage of a stone can be excruciating; adequate pain control is very important.

Obstructing stones lodged in the ureter must occasionally be removed surgically, either by laparotomy or through a cystoscope with the aid of a wire snare attached to a ureteral catheter. Large stones in the renal pelvis or proximal ureter may be pulverized by high-energy shockwave therapy (extracorporeal shockwave lithotripsy) to facilitate passage through the ureter.

Other Nongynecologic Causes

Other causes of acute onset of abdominopelvic pain in the female must also be entertained. Perforation of a peptic ulcer will allow entry of gastric secretions into the peritoneal cavity with resultant severe peritonitis. Acute cholecystitis is most often associated with right upper quadrant pain subsequent to a fatty ingestion. Always keep in mind the remote possibility of a nongynecologic intra-abdominal hemorrhage—either spontaneous or secondary to trauma. Trauma to the left upper quadrant can lead to intraperitoneal splenic hemorrhage that is delayed significantly from the event secondary to capsular containment. Sick cell crisis can present with severe abdominal pain, as interstitial cystitis does occasionally.

THE DECISION TO OPERATE: SCHEDULED GYNECOLOGIC SURGERY

Emergent operations represent a small fraction of all the gynecologic surgical procedures performed. Most operations are planned in an elective fashion with varying degrees of urgency. The patient with a gynecologic malignancy does not have to be rushed to the operating room in the middle of the night, but will need to have

her procedure planned within a reasonable period of time. On the other hand, the patient who is having a uterovaginal prolapse repaired has much more leeway to fit her operation into her life rather than having to fit her life around her operation.

Scheduled surgery allows a patient time to get mentally prepared for the procedure. Patients should be encouraged to assemble support and assistance to help with their recovery, to help cover their responsibilities at work, and to help with child care during the postoperative period. The date for an elective gynecologic procedure should always be selected by the patient for the time that is most convenient in her life.

Patients should be encouraged to optimize their physical and emotional conditions prior to scheduled surgery. There is time to attempt to stop smoking, to donate autologous blood for surgery, to lose weight, to take preoperative estrogen or iron, and to take care of any concurrent medical problems before their surgery. In addition, the option exists to postpone a patient's surgery if a respiratory infection or other medical problem develops as the date for surgery approaches.

The indications, work-ups, and operations for benign and malignant gynecologic conditions are well documented elsewhere in this text. Hysterectomy, laparoscopy, hysteroscopy, and dilatation and curettage; surgery for pelvic floor relaxation (Chapter 44); infertility surgery (Chapter 55); and surgery for urinary incontinence (Chapter 45) make up a large portion of procedures done for benign disease or dysfunction. Surgeries for gynecologic malignancies are well covered in Chapters 49, 50, 51, and 52.

PREOPERATIVE CARE

GENERAL CONSIDERATIONS IN PREOPERATIVE EVALUATION

Preoperative evaluation should include a general medical and surgical history, a complete physical examination, and appropriate laboratory tests. An anesthesiologist routinely sees patients preoperatively; however, a patient's medical status may warrant earlier consultation with an anesthesiologist and possibly with physicians in other specialties as well. The medical evaluation must be carried out in such a way as to identify all disorders that might complicate the operative procedure or convalescence. Although "diagnostic overkill" should be avoided, the responsibility of the operating gynecologist is to adequately assess—and take steps to minimize—a given patient's operative risk.

Records of prior hospitalizations should be obtained. Past records may be essential to the interpretation of present findings and may significantly influence the management plan. Patients' ability to recall illnesses and the details of previous surgeries is notoriously inaccurate.

Laboratory Studies

Although the efficacy of various preoperative testing regimens has not been established in a prospective, randomized fashion, most gynecologists would agree that preoperative laboratory studies should include, at a minimum, a CBC, a blood typing and antibody screen, and a urinalysis and culture. Further laboratory tests should be performed only when indicated by the patient's medical condition or by the type of surgery to be performed. A Papanicolaou smear should also be obtained.

A routine chest x-ray and electrocardiogram for all preoperative patients should be discouraged. One set of researchers found an overall positive yield for routine chest x-ray of 6%: 17% in patients older than 60 years of age, and 2% in patients younger than 60 years of age. Routine electrocardiograms showed an overall positive yield of 7%: 7.4% in those older than 40 years of age and 4.5% in those younger than 40 years of age. Finally, they found that investigations prompted by history or physical findings yielded a high positive rate (34% for chest x-ray and 31% for electrocardiograms) and included most of the younger patients who would be missed by an age-only criterion for preoperative testing. It seems reasonable to obtain a preoperative chest x-ray and electrocardiogram on all patients older than 45 years of age, as well as on all patients whose medical

history or physical findings are matters of concern, regardless of their age.

Blood should be drawn for typing and cross-matching if a need for transfusion is anticipated, especially in patients with abnormal antibodies that would make intraoperative cross-matching time-consuming. If the patient's preoperative hematocrit and physical status permit, and if there is an appropriate interval before the anticipated surgery, the possibility of autologous blood donation should be discussed. Directed donor programs can be discussed as well.

Patients scheduled for surgery for menorrhagia with low hematocrit can often be allowed the time to build up their own blood supply through the use of a gonadotropin-releasing hormone (GnRH) agonist and iron supplementation. This can significantly lower the patient's risk for requiring transfusion by starting with a larger red blood cell mass. A GnRH agonist-induced reduction in the size of fibroids, if present, may also help reduce intraoperative blood loss or enable the patient to have a vaginal hysterectomy.

More extensive testing tailored to the individual patient's needs can improve the safety of surgical procedures. Fasting and 2-hour postprandial plasma glucose determinations are helpful to exclude diabetes. Platelet count, bleeding time, prothrombin time, and partial thromboplastin time evaluate the adequacy of the clotting system. Liver, renal, and endocrine function testing should be obtained as indicated. A patient with poor pulmonary function might benefit from a baseline arterial blood gas determination. If prolonged parenteral dependency is anticipated, a preoperative laboratory assessment of the patient's nutritional status would be useful. Liver function tests and tumor markers are often obtained in the gynecologic cancer patient (see Chapters 49, 50, 51, and 52). Finally, testing for human immunodeficiency virus (HIV) antibodies and hepatitis B surface antigen, and a serologic test for syphilis, although controversial, may also be appropriate.

Further imaging studies should be obtained only as indicated. Ultrasonography is particularly useful for characterization of pelvic masses. Important morphologic characteristics most often associated with cancer include thick septation, solid tumors and papillary projections. Ascites has been found to have a positive predictive value (95%) for ovarian cancer. Hysterosonography can be used to differentiate between endometrial polyps, focal hyperplasia, and submucosal leiomyomata, and to determine if leiomyomata can be approached hysteroscopically. CT is more commonly used to estimate the extent of ovarian cancer, and can also provide information regarding the course of the ureters and an assessment of retroperitoneal adenopathy. Intravenous pyelogram demonstrates renal function and architecture and provides information on the course of the ureters and presence of urinary tract abnormalities. Magnetic resonance imaging, with its superb soft-tissue differentiation, can give much information regarding uterine, adnexal, and retroperitoneal architecture. Its use is mainly reserved for situations with nondiagnostic ultrasound studies. It is also helpful for evaluation of colorectal endometriosis and anterior vaginal wall cysts. Double-contrast barium enema can be useful in identifying bowel lesions or colonic involvement with pelvic masses.

Imaging studies as well as functional studies (eg, pulmonary function tests, stress electrocardiograms, multichannel urodynamics, and anal manometry) are informative but costly. They should be obtained on an individualized basis when the information they yield would decrease the patient's perioperative risk, influence the choice of the surgical procedure to be performed, or increase the chances for a successful surgical outcome for the patient. See the following section on Assessment and Minimization of Surgical Risk for further discussion of the extended preoperative evaluation.

Consultations

Patients should be seen well in advance of their surgical date by a member of the anesthesia team. This allows for the optimal selection of the type of anesthesia by considering the patient's physical status, prior anesthesia history, proposed surgery, and personal preferences. Consultation also gives the anesthesia team an opportunity to allay the patient's anxieties.

Consultations with other physicians should be requested if the surgeon desires advice or assistance with a particularly high-risk surgical candidate or if the proposed procedure involves high risk. Medical preoperative consultation is of particular importance for the older surgery patient as well as the younger patient with known cardiovascular, pulmonary, renal, hematologic, or endocrinologic problems.

Preoperative urogynecologic consultation, individualized as noted in Chapter 45, can be considered in many cases requiring surgery for urinary incontinence. Consultation with a gynecologic oncologist should be considered preoperatively when the index of suspicion for malignancy is high.

Patient–Physician Communication

INFORMED CONSENT

It is imperative for every patient to have a complete understanding of exactly what her procedure will involve, why it is proposed, what alternatives are available, what the chances are for success, and what all the possible complications of the proposed procedure might mean to her in terms of further surgery, disability, or even death. It is important that this dialogue be carried out in lay terms in the patient's native language and that the patient have ample opportunity to ask any questions that she may have.

To document that this important interaction took place to the satisfaction of the patient, she or her legal guardian should sign a consent form or note. All major points covered in the preoperative discussion should be written on the consent form or within the consent note before it is signed by the patient and the physician. If an interpreter was used, the interpreter should sign this document as well. Permission should be considered as being granted only for the procedures discussed in the preoperative conversation and designated in the consent form or note. This includes optional procedures such as appendectomy.

PATIENT EDUCATION

In view of the increasing complexity of operative procedures and the associated short- and long-term risks, audiovisual aids may be helpful in the patient counseling process. These aids can supplement, but should never replace, the actual communication between the gynecologic surgeon and the patient as outlined above.

A well-prepared videotape with simple diagrams can provide a consistent, in-depth presentation. Patient education pamphlets can serve a similar function. The patient should have an opportunity to ask questions about the videotape or pamphlet, and any modifications pertinent to her particular case should be explained. As documentation that this patient education was accomplished, it is appropriate to have the patient sign a form indicating that she has viewed the videotape, discussed it with the physician, and understands its content. If necessary, the videotape and signed form may serve as evidence that adequate preoperative counseling has been provided.

DOCUMENTATION

All details of the history, physical examination, and diagnostic and therapeutic formulations and conclusions of all preoperative consultations must be entered in the patient's chart. This history and physical, or preoperative note, must include a problem-oriented assessment and a clearly delineated plan to address each problem. A note, or consent form as just described, documenting the scope of preoperative counseling must also be entered in the admission record. A carefully completed record is important for health care team communication and continuity of the patient's care, as well as for hospital quality assurance.

ASSESSMENT AND MINIMIZATION OF SURGICAL RISK

Cardiovascular System

Cardiac Disease

The perioperative period is associated with significant cardiovascular stress. Annually, it has been estimated that 1 million patients undergoing noncardiac surgery have a perioperative cardiac complication, and 50,000 of

these have a myocardial infarction. Therefore, any patient with heart disease should be considered a high-risk surgical candidate and must be fully evaluated preoperatively. The goal of the preoperative cardiac evaluation is to evaluate the patient's current medical status and identify the most appropriate testing and treatment strategies to optimize care of the patient, identify short- and long-term cardiac risk, minimize cardiac risk from surgery, and yet avoid unnecessary testing and intervention in this era of cost containment. In patients with known cardiac disease, this evaluation should take place in consultation with the patient's internist or a cardiologist.

Goldman's 1977 landmark study identified patients most at risk for a perioperative cardiac ischemic event. Since then, other models have been developed to stratify perioperative cardiac risk. In 2002, the American College of Cardiology and the American Heart Association (ACC/AHA) issued a practice guideline update regarding perioperative cardiovascular evaluation in the noncardiac surgical patient. The guideline offers an algorithm for deciding which patients are candidates for preoperative cardiac testing. The algorithm takes into account clinical markers, functional capacity, and surgery-specific risk. Patients most at risk are those with a recent unstable coronary syndrome such as acute myocardial infarction (MI) less than 7 days previously, a recent MI less than 1 month previously, unstable or severe angina, evidence of a large ischemic burden, decompensated heart failure (HF), significant arrhythmias (eg, high-grade atrioventricular block, supraventricular tachycardia with uncontrolled rate), and severe valvular disease. Intermediate predictors of increased risk are mild angina, MI more than 1 month previously, compensated HF, preoperative serum creatinine ≥ 2 mg/dL, and diabetes mellitus (DM). Minor predictors of risk are advanced age, abnormal electrocardiogram (ECG), nonsinus rhythm, low functional capacity, history of stroke, and uncontrolled systemic hypertension.

Functional capacity is expressed in metabolic equivalent (MET) levels. Perioperative cardiac risk is increased in patients unable to meet a 4-MET demand. The Duke Activity Status Index is a useful scale to help determine a patient's functional status. For instance, asking a patient if she can climb a flight of stairs demonstrates at least 4-MET tolerance.

Surgery-specific cardiac risk is related to the type of surgery itself and the associated hemodynamic stress it produces intraoperatively and in the immediate postoperative period. Most benign gynecologic surgeries are considered intermediate or low-risk procedures from a cardiac standpoint, with a cardiac risk of less than 5%. Many factors may adversely affect cardiovascular function during and after surgery; for example, fluid shifts, hypotension, electrolyte imbalance, infection, severe pain, apprehension, and tachycardia. Perioperative monitoring, anesthesia induction, maintenance techniques, and postoperative care can be tailored to the specific cardiovascular disease, thus improving the patient's chances for a good surgical outcome. *If a recent stress test does not indicate residual myocardium at risk, the likelihood of reinfarction after noncardiac surgery is low. Although there are no adequate clinical trials on which to base firm recommendations, it appears reasonable to wait at least 4–6 weeks after MI to perform elective surgery.*

Special Studies

ELECTROCARDIOGRAPHY

The need for a preoperative ECG in an asymptomatic patient without a history of cardiac disease is controversial, as the literature to support this practice is lacking. In 2002, the American Society of Anesthesiologists Task Force on Preanesthesia Evaluation did not reach consensus on a specific minimum age in those patients without specific risk factors, and recognized that age alone may not be an indication for an electrocardiogram. The aforementioned ACC/AHA practice guideline also concluded that evidence supporting routine preoperative ECG on asymptomatic patients is not well established. Nonetheless, a common practice is to obtain a preoperative ECG on all patients older than 50 years of age. It should also be obtained on younger patients with a history of symptoms of cardiovascular disease or diabetes mellitus. The ECG is of value in

identifying the patient with coronary artery disease, ventricular hypertrophy, electrolyte disturbance, arrhythmia, and digitalis or other drug effect. Comparison with older ECGs is important when significant changes do exist. The preoperative ECG should serve as a baseline for subsequent studies if postoperative complications develop. In patients with important abnormalities on their resting ECG (eg, left bundle-branch block, left ventricular hypertrophy with strain), other techniques such as exercise ECG or exercise myocardial perfusion imaging should be considered.

ECHOCARDIOGRAPHY

Echocardiography demonstrates any valvular or ventricular wall motion abnormalities resulting from coronary artery insufficiencies or cardiomyopathy. Left ventricular ejection fraction can also be estimated from an echocardiogram. Resting left ventricular function has not been a consistent predictor of perioperative ischemic events. Echocardiography may be of value in patients with current or poorly controlled heart failure, or dyspnea of unknown etiology.

DIPYRIDAMOLE/THALLIUM STRESS TEST

Patients with a significant cardiac history or an abnormal ECG should have a preoperative stress ECG under the direction of the patient's cardiologist. Dipyridamole or thallium stress-tolerance scanning demonstrates older, fibrosed, fixed lesions, or areas subject to ischemia and potential infarct. This test identifies ischemia under stress before the patient is subjected to the stress of surgery. The result will guide the gynecologist and anesthesiologist in their invasive monitoring and surgical anesthesia maintenance decisions.

INTRAOPERATIVE CENTRAL MONITORING

Invasive catheter measurements of intracardiac pressures can often provide useful information regarding cardiovascular dynamics. In most cases, the need for this intraoperative information can be evaluated simply by careful attention to aspects of the physical examination such as blood pressure, pulse, pulse pressure, heart rate, status of neck veins when supine, auscultation and percussion of the chest, presence or absence of edema, and size of the liver. If the preoperative evaluation raises a significant question, direct central venous pressure monitoring should be considered. A Swan-Ganz pulmonary artery catheter is particularly useful when surgery is likely to be prolonged, and the history, physical examination, and cardiology testing indicate depressed myocardial function or pulmonary artery hypertension. In patients at high risk for heart failure, the information provided by a pulmonary artery catheter can help optimize stroke volume without excessive hydration. However, use of a pulmonary artery catheter is not without risk. Moreover, the 2002 ACC/AHA Guidelines Update confirms that there is no general agreement that the pulmonary artery catheter monitoring is effective and useful for noncardiac surgery. The decision to use a pulmonary artery catheter should be made in consultation with the anesthesiologist and a critical care specialist, taking into account the patient's underlying disease, the planned surgery, and expected fluid shifts.

Prophylaxis for Venous Thromboembolism

Venous thromboembolism (VTE) is a relatively common postoperative complication. Because of the clinically silent nature of the disease in the majority of patients, the morbidity, and potential mortality associated with unprevented thrombi, perioperative prophylaxis against the development of this condition is always an important consideration. The major risk factors that have been identified for the development of VTE include increasing age; prolonged immobility, stroke, or paralysis; previous VTE; cancer and its treatment; major surgery (particularly operations involving the abdomen, pelvis, and lower extremities); trauma (especially fractures of the pelvis, hip, or leg); obesity; varicose veins; cardiac dysfunction; indwelling central venous catheters; inflammatory bowel disease; nephrotic syndrome; and pregnancy or estrogen use. Without prophylaxis, the patients considered to be at highest risk after major surgery, eg, patients older than the age of 40 years with VTE, cancer, or hypercoagulable state, are estimated to have a risk of calf deep venous thrombosis (DVT) between 40% and 80% and a risk of fatal DVT between 0.2% and 5%. Among patients

younger than age 40 years without other risk factors, the risk of calf DVT is estimated to be as high as 10–20%, with a risk of fatal DVT estimated to be between 0.1% and 0.4%. One researcher reviewed 2 meta-analyses of more than 70 published trials of deep venous thrombosis prophylaxis in general surgical patients. Both studies concluded that prophylaxis significantly reduced the rates of deep venous thrombosis and fatal pulmonary embolism and resulted in improved overall survival. Physical methods such as compression stockings and intermittent pneumatic compression were shown to be as effective as pharmacologic prophylaxis with heparin. Surgeons in the United States tend to avoid pharmacologic prophylaxis because of concerns of bleeding complications. The disadvantages to their routine administration of heparinoids include prolonged lymph leak, lymphocele, and hematoma formation, and epidural hematoma when epidural analgesia is employed.

Prophylactic administration of unfractionated heparin, 5000 units subcutaneously initiated just before surgery and every 8–12 hours thereafter until full ambulatory status is achieved, may be used to prevent thromboembolization in high-risk cases. With this standardized approach, it is unnecessary to check the partial thromboplastin or activated partial thromboplastin times. Low-molecular weight heparin is an alternative to unfractionated heparin. The benefit of these agents is that they are dosed less often than unfractionated heparin, typically once a day rather than every 8 or 12 hours. Also, there is some data that indicates that low-molecular-weight heparin is less likely to cause heparin-induced thrombocytopenia. In a large multicenter, double-blind trial, 936 patients undergoing resection of part or all of the colon or rectum were randomized to receive, by subcutaneous injection, 5000 units of unfractionated heparin or 4000 units of low-molecular-weight heparin once daily (plus two additional saline injections so that the dosing regimens would be equal). Treatment was initiated 2 hours prior to surgery. Deep vein thrombosis was assessed by routine bilateral contrast venography performed between postoperative days 5 and 9, or earlier if clinically suspected. The venous thromboembolism rates were the same in both groups. There were no deaths from pulmonary embolism or bleeding complications. Although the proportion of all bleeding events in the low-molecular-weight heparin group was significantly greater than in the unfractionated heparin group, the rates of major bleeding and reoperation for bleeding were not significantly different. Because unfractionated heparin is considerably less expensive than low-molecular-weight heparin, many authors deem unfractionated heparin to be the agent of choice.

Given the variety of thromboprophylaxis regimens available, how should the gynecologic surgeon choose which approach to employ. In their exhaustive review article on the subject, Geerts et al. conclude that the decision as to which option(s) to choose should be tailored to the risk of VTE for each individual patient. For example, for patients younger than 40 years of age who are undergoing procedures that are shorter than 1 hour in duration, early ambulation may be all that is required. In contrast, an elderly patient with a gynecologic malignancy may warrant dual therapy in which a heparinoid and a mechanical antithrombotic device is employed.

Varicose Veins and History of Deep Vein Thrombosis

Patients with large, extensive varicosities or a history of thrombophlebitis or thromboembolic events are at risk for developing lower-extremity thrombophlebitis or thromboembolic phenomena. This risk may be minimized by prevention of dehydration, early ambulation, and prompt and adequate treatment of cardiac disorders. Discontinuation of oral contraceptives 3 to 4 weeks preoperatively should be considered.

Before the operation, the patient should wear support stockings from toe to thigh. After surgery, these stockings should be worn continuously and discarded only after full ambulation is restored. Pressure on the calf or thigh should be avoided during a long operative procedure. Postoperative leg exercises should be initiated as soon as possible to prevent phlebitis. These may be begun even before ambulation by having the patient press against a footboard whenever supine. When discharged the patient should be advised to avoid prolonged sitting

(eg, auto, train, or air travel) during the first month after surgery. Similarly, the use of sequential compression boots intraoperatively and postoperatively or the use of subcutaneous heparinoids until the patient is fully ambulatory may help to prevent thrombosis in high-risk patients.

Valvular Heart Disease

Patients with a history of valvular heart disease or a heart murmur should have echocardiography performed to determine the severity of the valvular lesion. Antibiotic prophylaxis should be administered according to the American Heart Association (AHA) guidelines. The most recent AHA guidelines (1997) regarding endocarditis prophylaxis stratify valvular lesions by risk and recommend a treatment regimen based on the type of proposed surgery. Most gynecologic surgeries, in contrast to dental, respiratory, or urinary tract procedures, do not represent a high risk for development of endocarditis.

Pulmonary System

Elective surgery should be postponed if acute upper or lower respiratory tract infection is present. Even mild upper airway infection is associated with an irritable airway, which predisposes to laryngospasm or severe coughing on induction or emergence from anesthesia. Pulmonary infection causes poor ciliary motility, which predisposes to postoperative bronchitis and pneumonia. If emergency surgery is necessary in the presence of a respiratory tract infection, regional anesthesia should be used if possible and aggressive measures should be taken to avoid postoperative atelectasis or pneumonia. If the infection is severe, appropriate antibiotic therapy should be initiated promptly and modified as necessary when the results of cultures become available. The patient should be free from respiratory infection for at least 1–2 weeks, and preferably for 1 month, before elective surgery.

Chronic obstructive pulmonary disease, including chronic bronchitis, and emphysema, puts the patient at increased risk in the perioperative period. Optimizing the patient's pulmonary status with chest physical therapy, breathing exercises such as incentive spirometry, and appropriate antibiotic prophylaxis decreases the potential for prolonged postoperative ventilation and suture line strain from coughing. Bronchiectasis, relatively uncommon at present, requires the patient to have rigorous chest physiotherapy and antibiotics before surgery. Preoperative pulmonary function tests should be performed to assess the severity and type of disease and to have as a baseline for reference in the postoperative period.

Those who smoke are at particular risk of developing pulmonary complications during or after surgery. These complications include increased airway reactivity that can result in coughing, bronchospasm, increased sputum production, atelectasis, and an increased risk of postoperative pulmonary infection. Furthermore, up to 15% of smokers' hemoglobin is combined with carbon monoxide to form carboxyhemoglobin, thus diminishing oxygen-carrying capacity. Patients who smoke and for whom general anesthesia by endotracheal intubation is planned should be encouraged to stop smoking for as long as possible before their surgery. Prolonged operations involving general anesthesia increases the risk of postoperative hypoventilation. Careful evaluation, including chest x-rays and pulmonary function tests, enable the surgeon and the surgeon's consultant to decide when the operation may be safely undertaken, and may influence the mode of anesthesia selected.

Asthmatics typically have intermittent symptoms of expiratory airflow obstruction. The preoperative medical history should include frequency of attacks, any hospitalizations or intubations, steroid use, and regular medication use. In patients with a significant asthma history, preoperative pulmonary function tests help gauge the severity of the disease, and assess the benefit of bronchodilators. A forced vital capacity in 1 second (FEV₁) of less than 50% normal indicates moderate to severe disease. After recent exacerbation, patients should be given adequate time to return to baseline before proceeding with elective surgery.

Renal System

Renal function should be appraised if there is a history of kidney disease, diabetes mellitus, or hypertension; if

the patient is older than 60 years of age; or if routine urinalysis reveals proteinuria, casts, or red cells.

Functional examination of renal function include measurement of creatinine clearance, blood urea nitrogen, and plasma electrolytes. Radiographic examinations, such as intravenous pyelogram or CT scan, may sometimes be indicated for functional or anatomic evaluation, especially in patients with a history of prior reconstructive urologic surgery.

Most patients with chronic renal failure are anemic, and many have hypertension. Hypertension should be controlled, and any electrolyte imbalances corrected prior to surgery. In dialysis patients, the optimum time for elective surgery is 24 hours after dialysis. Care should be taken not use the arm with the arteriovenous fistula for intravenous access.

Hematologic System

Anemia

Anemia diagnosed in the preoperative obstetric or gynecologic patient usually is of the iron-deficiency type caused by inadequate diet, chronic blood loss, or chronic disease. Care must be taken to differentiate iron-deficiency anemia from other anemias such as sickle cell anemia. Iron-deficiency anemia is the only type of anemia in which stained iron deposits cannot be identified in the bone marrow. Megaloblastic, hemolytic, and aplastic anemias usually are easily differentiated from iron-deficiency anemia on the basis of the history and simple laboratory examinations. The diagnosis of obscure anemias may require the help of a hematologic consultation.

Anemia mainly impacts surgery and anesthesia by decreasing oxygen-carrying capacity. Chronically anemic patients can partially compensate by expanding plasma volume, however this mechanism fails when hemoglobin falls below 10 g/dL. Although, traditionally, a hemoglobin of at least 10 mg/dL was a prerequisite for elective surgery, some authorities now accept a hemoglobin as low as 7–8 g/dL in young, healthy patients. Patients with iron-deficiency anemia respond to oral or parenteral iron therapy. Before elective surgery for menorrhagia, the patient's blood loss might be stopped with a GnRH agonist long enough to allow reversal of the anemia. In emergencies or urgent cases, preoperative blood transfusions, preferably with packed red cells, may be given.

von Willebrand's Disease

von Willebrand's disease is a family of congenital bleeding disorders characterized by altered factor VIII activity and deficient platelet function. Inheritance is generally autosomal dominant, although more rare autosomal recessive forms have been identified. Clinical manifestations include epistaxis, easy bruising, hypermenorrhea, and postpartum hemorrhage. von Willebrand's disease is reported to be the most common congenital cause of hypermenorrhea. Menstrual abnormalities are generally persistent and severe but may be intermittent or moderate, so that milder cases are less likely to be diagnosed. Hypermenorrhea may develop in affected persons at menarche and persist until the menopause or may not develop until after the second or third decade of life. von Willebrand's disease is diagnosed in 10 persons per 100,000, but the true prevalence may be as high as 1–2% of the general population. It is possible that the true cause of menstrual abnormalities is undetected in some women with undiagnosed von Willebrand's disease who undergo hysterectomy for hypermenorrhea.

The diagnosis of von Willebrand's disease is confirmed by a prolonged bleeding time, decreased factor VIII activity, and abnormal platelet function. The platelet count is normal. All patients should avoid aspirin and nonsteroidal anti-inflammatory medications preoperatively, but this is especially true of the patient with von Willebrand's disease. For patients with the most common types of von Willebrand's disease, types 1 and 2a, treatment with desmopressin, or desmopressin acetate (DDAVP), 0.3 µg/kg intravenously immediately before surgery may help to improve platelet function. This should only be done in patients known to respond to

DDAVP. DDAVP is a synthetic analogue of antidiuretic hormone, and must be used judiciously, as fluid overload and hyponatremia may result. Patients with more severe forms of this disease, or who have not responded to DDAVP, should be given factor VIII concentrates or cryoprecipitate intraoperatively, if needed. Preoperative consultation with a hematologist is helpful.

Thrombocytopenia

The normal platelet count ranges from 150,000–350,000/mm³. In the patient with thrombocytopenia but normal capillary function, platelet deficiency begins to manifest itself clinically as the count falls below 100,000/mm³. Typical manifestations include petechiae on easily traumatized areas of the body, epistaxis, and menorrhagia. Epistaxis and hypermenorrhea may be severe enough to require transfusion. Bleeding into deep muscle and hemarthroses usually does not result spontaneously from thrombocytopenia, but intracranial hemorrhage is a serious risk if the platelet count is very low. The thrombocytopenic patient may require transfusion of platelets before surgery if the platelet count falls too low.

If thrombocytopenia is severe, the deficiency of platelet-produced factors involved in the coagulation cascade may result in some prolongation of clotting time. Transfusion of fresh-frozen plasma or cryoprecipitate may be useful in the acute patient with a prothrombin time and partial thromboplastin time greater than 1.5 times normal. The most sensitive early clinical measure of platelet deficiency was thought to be the bleeding time. More recent literature suggests that bleeding time may not be a reliable indicator of platelet function and no study has established that bleeding time will predict the risk of hemorrhage in individual patients. Spontaneous hemostasis is not expected if the platelet count falls to 10,000/mm³ or less, and the patient may begin to bleed from all old puncture wounds as the platelet count approaches this threshold.

Bone marrow suppression, autoimmune disease, and platelet consumption are the chief causes of thrombocytopenia. Treatment revolves around treating the underlying cause and support with platelet transfusion and clotting factors as necessary.

Patients Receiving Oral Anticoagulation

Dunn and Turpie performed a systematic review of the 31 English-language reports regarding the perioperative management and outcomes of patients receiving long-term oral anticoagulant therapy. The available literature supports the continuation of oral anticoagulants without increasing the risk of major bleeding for single and multiple dental extractions, joint and soft-tissue injections, cataract surgery, and upper endoscopy or colonoscopy with or without biopsy. However, if oral anticoagulants are continued for one of these procedures, the international normalized ratio should not be beyond the therapeutic range at the time of the procedure.

For invasive surgical procedures, oral anticoagulation should be withheld. The surgeon faces the decision as to how to manage perioperative anticoagulation. There are three options: (a) Hold the oral anticoagulant until after the patient is determined to be a low risk for postoperative hemorrhage. (b) Pursue an aggressive strategy of therapeutic anticoagulation with perioperative intravenous heparin or subcutaneous low-molecular-weight heparin and re-initiate anticoagulation as soon as possible after surgery. (c) Employ subcutaneous unfractionated or low-molecular-weight heparin to achieve partial, but not therapeutic, anticoagulation. The decision as to which management strategy to employ should be individualized and should result as a compromise between the risk of arterial and venous thrombosis as a result of the condition that warrants anticoagulation and the potential consequences of postoperative hemorrhage.

Endocrine System

Diabetes Mellitus

Diabetes is the most common disease of disordered metabolism, arising largely from altered pancreatic islet cell function. The incidence increases with age, and occurs in up to 4% of the general population. The American

Diabetes Association adopted new criteria for diagnosis in 1997. Diabetes is diagnosed by a fasting plasma glucose of greater than or equal to 126 mg/dL, or a random plasma glucose above 200 mg/dL. The oral glucose tolerance test (OGTT) is no longer required for diagnosis, but it may still be of some value in identifying at-risk patients with nondiabetic fasting plasma glucose values. Fifty percent of diabetics are treated by diet alone, with the remaining 50% evenly divided between oral hypoglycemic use and insulin use.

Diabetes can lead to the long-term complications of both large and small vessels. Conditions such as atherosclerosis, neuropathy, and nephropathy, may negatively impact the diabetic patient during the perioperative period. Control of diabetes is made especially difficult by the stress of operation, acute infection, anesthesia, and electrolyte imbalance. The operative diabetic patient must be carefully observed and promptly treated before fluid and electrolyte abnormalities, ketosis, hyperglycemia, and infection develop. Diabetics whose disease is out of control are especially susceptible to postoperative sepsis. Preoperative consultation with an internist may be considered to ensure control of insulin-requiring diabetics before, during, and after surgery.

Type I diabetes accounts for approximately 90% of cases and is seen in the older, usually more obese, patient population. Insulin production is close to or at normal values, but not appropriate for the blood sugar level. There is also peripheral insulin resistance. These patients develop neither ketoacidoses nor hyperosmolar states. The blood sugar is controlled by diet or oral medication. The oral medications most commonly used are the sulfonylurea derivatives, glyburide or glipizide. Their duration of action can be greater than 24 hours, and chlorpropamide may be effective for up to 50 hours. Consequently, it is important to avoid hypoglycemia by closely monitoring blood sugar on the day of surgery, and possibly by not using the longer-acting agents for up to 2 days preoperatively.

Type I diabetics tend to be younger, are less likely to be obese, and have little or no insulin production. They require insulin to avoid development of ketoacidoses, nonketotic hyperosmolar states, and hyperglycemia. Insulin-dependent diabetics with good control should be given half of their total morning insulin dose as regular insulin on the morning of surgery. This is preceded or immediately followed by the initiation of a 5% dextrose solution intravenously to prevent hypoglycemia in a fasting patient. Regular insulin should then be given by continuous infusion at a rate dictated by plasma glucose or fingerstick determinations.

If the diabetes is severe, it may be necessary to admit the patient to the hospital before the operation for glycemic control. Regular insulin may be substituted for long-acting insulin to achieve tighter control. Serum electrolyte determinations should be recorded as points of reference for postoperative management. Fasting plasma glucose should be determined prior to surgery. The insulin/dextrose infusion is continued postoperatively until the patient is eating.

Some controversy exists regarding how tightly the blood sugar should be controlled perioperatively. It is generally accepted that keeping the blood sugar in the 100–250 mg/dL range in the perioperative period is adequate for most types of surgery. Impaired neutrophil phagocytic activity has been reported when blood glucose is above 200–250 mg/dL. Cardiopulmonary bypass surgery, procedures in pregnancy or after a cerebral ischemic episode, and neurosurgical operations in which maintenance of cerebral autoregulation is important, have better results if the blood sugar is more tightly controlled at about 80–130 mg/dL. Tight control is achieved by using an intravenous insulin infusion based on frequent blood sugar estimations.

Occasionally, surgery is required emergently in a patient who presents in a hyperglycemic ketoacidotic state. It is important to first correct the fluid and electrolyte status, particularly the potassium levels, but it is not necessary to hold off surgery until complete resolution has occurred. The surgical condition may be the precipitating factor, and final correction may not be possible until surgery is completed. The hyperglycemic ketoacidotic state is treated by giving 10 U of regular insulin intravenously followed by an infusion of insulin based on the formula of the blood sugar level divided by 150 U/h. Normal saline solution is given to correct dehydration. Potassium must be supplemented because the insulin drives it into the cells. Total-body

potassium, despite its initial elevated serum level, may be significantly depleted. Because there are a fixed number of insulin receptors, there is nothing to gain by using higher doses of insulin. Blood glucose levels usually fall at a maximum rate of 100 mg/dL/h, except during the initial rehydration period, when the fall is more precipitous.

Chronic medical conditions associated with diabetes may also complicate the perioperative period, eg, hypertension and coronary artery disease. Myocardial ischemia may often be silent in the diabetic with autonomic neuropathy. Autonomic neuropathy is also associated with gastric paresis and increased risk of aspiration. These patients should have an extended cardiac work-up and receive metoclopramide as well as a nonparticulate antacid before surgery. Intubation in some patients may be difficult because the atlantooccipital joint may be involved with the diabetic process.

Thyroid Disease

Elective surgery should be postponed when thyroid function is suspected of being either excessive or inadequate. Hyperthyroidism is suspected clinically when the patient has a history of weight loss, muscle weakness, a persistently rapid pulse, agitation, tremor, heat intolerance, nervousness, or warm skin. The gland either may be diffusely enlarged, as in Graves' disease, or may have only an unobtrusive adenoma. Exophthalmos may be evident. Cardiac signs may be the only clue in the elderly patient (apathetic hyperthyroidism) and may include an unexplained atrial fibrillation or other tachyarrhythmia or dysrhythmia. A varying level of ventricular dysfunction is present in all patients with hyperthyroidism.

The patient should be rendered euthyroid before surgery if possible. This may take up to 2 months if antithyroid medications are used in combination with potassium iodide (Lugol's solution). The combination of a blocker, usually propranolol, and potassium iodide allows surgery in about 14 days. Propranolol blocks the peripheral effects of hyperthyroidism (ie, nervousness, sweating, tachycardia) and may slow the response to atrial fibrillation. It also impairs the conversion of thyroxine (T_4) to triiodothyronine (T_3) peripherally. Care must be exercised in the use of propranolol in patients with asthma or congestive heart failure. If surgery is immediately required, propranolol is titrated slowly intravenously in 0.5-mg aliquots until the peripheral signs of thyrotoxicosis are brought under control. Regional or local anesthesia is preferable. If general anesthesia is required, the airway should be adequately assessed clinically and by x-ray or CT scan for severe tracheal compression or any deviation that might interfere with placement of an intratracheal airway.

Severe stress, such as that provided by surgery and anesthesia, can precipitate a thyroid storm in a person with hyperthyroidism. Thyroid storm is a life-threatening event that manifests itself as hyperpyrexia, tachycardia, and cardiovascular instability, and it may be mistaken for malignant hyperthermia.

Hypothyroidism is relatively common in the elderly. It is usually of insidious onset; 95% of cases are caused by primary failure of the thyroid to produce adequate T_4 and T_3 . Goiter may be present, and a history of surgery or radioactive iodine treatment may be elicited. There is a slowing down of the metabolism that affects both mental and physical abilities, including a slowing of the heart rate and diminished ventricular contractility in response to catecholamines. Patients are very sensitive to respiratory-depressant medications. There is blunting of the stress response, and corticosteroid supplementation may be needed.

In mild to moderate hypothyroidism, surgery and anesthesia need not be delayed before treatment is started. If the disease is severe, treatment should be started before surgery, if possible. In all cases, treatment must be started with a very low dose of thyroid-replacement therapy to avoid sudden large demands on the myocardium, which may not yet be able to respond appropriately. The usual tests of thyroid function include total T_4 and T_3 levels, free T_4 , T_3 resin uptake, and thyroid-stimulating hormone (TSH) levels. Preoperative consultation regarding the management of patients with thyroid dysfunction should be sought before major surgery.

Recent or Current Corticosteroid Use

It has been a long-held medical tenet that patients taking corticosteroids require supraphysiologic stress-dose steroids perioperatively. The origin of this belief stems from a case report in 1952 in which a steroid-dependent patient died postoperatively of intractable hypotension. Autopsy revealed bilateral adrenal cortical atrophy. Other case reports and biochemical studies confirming suppression of the hypothalamic–pituitary–adrenal (HPA) axis in steroid-dependent patients have reinforced the practice of administering perioperative stress-dose steroids. However, high-dose steroids, even if given for only a relatively short period of time, can potentially cause harm and are not without risk. Risks of high-dose steroid regimens can include immunosuppression, poor wound healing, and acute psychiatric disturbances. Brown and Buie reviewed the available literature and concluded that there is little evidence to support the practice of administering high-dose perioperative steroids to patients that have been on long-term steroids preoperatively. Hypotensive crisis can occur, but the literature supports a rate of only 1–2%, and these patients generally do well with a rescue dose of steroid when needed. The authors concluded that the current literature supports continuing patients on their normal daily dose of steroids through the perioperative period, instead of traditional high-dose regimens. An exception is critically ill patients who require pressors preoperatively—they should be given supraphysiologic dosing. As with other serious medical conditions preoperative consultation with the anesthesia team regarding perioperative medical management is always prudent.

Other Conditions Affecting Operative Risk

Pregnancy

The diagnosis of early pregnancy must be considered in the decision to do elective major surgery in the female. Elective surgery generally should be postponed until after delivery. Scheduled surgery that cannot be delayed, such as exploration for an adnexal mass, is best performed in the second trimester whenever possible.

Diagnostic or evaluative procedures necessary in the proper work-up for urgently needed surgery override theoretical fetal hazards in the pregnant patient. Appropriate protective measures should be taken to minimize these dangers, such as shielding the uterus from radiation during x-ray studies, using tocolytic agents to prevent premature labor, and considering possible fetal effects when pharmacologic and anesthetic agents are to be used. Hypotension and hypoxia must be meticulously avoided during anesthetic administration or surgical manipulation. Surgery should be performed in the left lateral decubitus position to optimize uterine perfusion. If the surgery is being performed after fetal viability, intraoperative fetal heart rate monitoring should be performed.

The new and more sensitive radioreceptor assay and radioimmunoassay for pregnancy are positive within 10 days of conception, ie, before the anticipated menstrual period. This capability may be important in scheduling elective surgery, especially in gynecologic procedures such as tubal ligation and hysterectomy.

Age

The 65-year-old and older segment of the population is currently undergoing the most rapid expansion of any demographic group in the United States. This expansion is projected to continue and accelerate. The majority of individuals in this age group are women. It has been estimated that more than 50% of this older population will at some point undergo some surgical intervention. In the future, the gynecologic surgeon will be caring increasingly for older patients requiring or desiring surgical procedures.

Care of the older patient can present a significant challenge. These women often have multiple medical problems against a background of a general decline of their physiologic reserve. However, if care is taken during preoperative evaluation and perioperative management, these patients can do quite well. Age itself is not an independent predictor of surgical risk. Neither the healthy elderly patient nor the carefully evaluated and managed elderly patient with medical problems should not be discouraged from pursuing a beneficial elective

procedure.

A careful history and review of systems must be taken and may require the assistance of family members or caretakers. A review of past medical records is crucial. A thorough physical examination must be performed. Appropriate preoperative consultation and extended preoperative evaluation as previously described should be obtained. The results should be reviewed with, and the patient seen by, the anesthesiologist well before the operative date so that an intraoperative management plan can be developed. Care should be taken when positioning older women to reduce the risk of postoperative complications. Finally, meticulous and expeditious technique must be used during surgery to limit blood loss, hypothermia, operative time, and fluid shifts.

The principles and general considerations of good surgical practice become critically important when operating on the older patient. Serum electrolytes must be determined preoperatively and any imbalances corrected by appropriate parenteral solutions. Care should be taken not to overload the elderly patient's circulation when administering intravenous fluids, as cardiac, pulmonary, and renal reserves are often diminished. Nutritional deficiencies should be corrected before elective surgery is undertaken if possible. In older patients who are found to be significantly nutritionally deprived, total parenteral nutrition (TPN) may be required before and after surgery.

Fluid intake and urinary output should be monitored carefully and the patient's weight recorded daily. Early ambulation of the patient is very important. Care must be taken that items the patient uses at home, such as glasses, hearing aids, walkers, or canes, are brought to or available in the hospital. The older patient, or one who has been bedridden, requires frequent change of position to prevent the development of decubitus ulcers. Early ambulation and aggressive active and passive physical therapy may prevent many vascular and pulmonary complications.

The elderly patient often requires smaller dosages of medications such as narcotics and anesthetic agents; however, optimum pain relief must be ensured. Use of nonsteroidal anti-inflammatories can help reduce narcotic requirements. Barbiturates should especially be prescribed with caution, as even small doses can cause mental confusion.

In addition, the woman and her family should be prepared for postoperative recovery. It is often helpful to have a family member stay with the patient in the hospital to assist with orientation. This might involve arranging for postdischarge care in the patient's home or a skilled nursing facility. All arrangements should be made prior to surgery.

Obesity

Obesity puts the patient and every member of the hospital team at a disadvantage. Obese surgical patients are at increased risk of mortality and morbidity. Every system in the body is affected by this disease. Obese patients have an increased potential for cardiovascular disease, diabetes, and deep venous thrombosis.

Risk factors that may affect the perioperative course must be ascertained during the preoperative assessment. Recommendations for preoperative testing in the obese patient include a complete blood cell count, chemistry panel, liver function test, coagulation studies, and urinalysis; a chest radiograph and electrocardiograph are required. Additionally, prior to surgery the weight capacity of the operating table should be determined.

When treating the obese patient, the anesthesiologist is often challenged by difficult intravenous access. Occasionally, preoperative central access must be obtained by interventional radiologists. These patients have markedly decreased functional residual capacity, making hypoxia a major concern, particularly in a supine or Trendelenburg position. Increased volume and acidity of gastric secretions, along with poor gastroesophageal sphincter tone, increases the risk of pulmonary aspiration. Poor neck extension makes intubation more difficult.

The gynecologic surgeon should arrange for extra assistants and long instruments. To reduce the risk of trauma

to adjacent organs, the surgeon must ensure adequate exposure through appropriate incisions. Care must be taken to avoid incisions below the pannus. In selected women, a panniculectomy may be performed in conjunction with the planned surgery. A mass closure technique with a delayed absorbable or permanent suture should be considered. Wound healing is inhibited, and there is an increased risk of postoperative wound seroma and infection.

Postoperatively, nursing personnel are also at a serious disadvantage. Attempts to achieve ambulation and to prevent respiratory and thromboembolic complications are much more difficult. Again, planning beforehand and extra personnel may be the key to a successful postoperative course.

Drug Allergies & Sensitivities

The obstetric or gynecologic patient who is being evaluated and prepared for a major operation may receive a variety of medications. Drug allergies, sensitivities, incompatibilities, and other adverse effects must be anticipated and prevented if possible. A history of serious reaction or sickness after injection, oral administration, or other use of any of the following substances should be noted and the medication avoided: antibiotic medications; narcotics; anesthetics; analgesics; sedatives; antitoxins or antisera; and antiseptics. Untoward reactions to other medications, foods (eg, milk, chocolate), adhesive tape, and antiseptic solutions, especially iodine, should also be noted.

Latex allergy is increasingly prevalent. The two main categories of latex sensitivity are type I and type IV. Type I reactions involve immediate urticaria, airway obstruction, systemic symptoms, or anaphylaxis; type IV reactions are generally limited to the skin that has come into contact with the latex and are delayed in onset. Patients with a history of atopy and/or allergies to avocado, kiwi, banana, or chestnuts have a higher incidence of latex allergy. Preoperative evaluation by an allergist is advisable in women with a history of latex sensitivity. Latex allergy is confirmed by a positive test of sensitization in a symptomatic individual. Sensitization can be identified by an in vitro assay for serum-specific immunoglobulin (Ig) E; positive skin-prick test reaction to latex antigen; or a provocative test, such as glove use or inhalation tests. Premedication with steroids and antihistamines has not proven effective. Consequently, surgery in latex-allergic individuals should take place in a latex-free environment. Most hospitals have latex-free packs or carts available for patients with latex allergy. These patients should also be scheduled as the first case of the day in the operating room.

Immunologic Compromise

A patient may be considered an immunologically compromised or altered host if her capacity to respond normally to infection or trauma has been significantly impaired by disease or therapy. Obviously, preoperative recognition and special evaluation of these patients are important.

INCREASED SUSCEPTIBILITY TO INFECTION

Certain drugs may reduce a patient's resistance to infection by interfering with host defense mechanisms. Corticosteroids, immunosuppressive agents, cytotoxic drugs, and prolonged antibiotic therapy are associated with an increased incidence of superinfection by fungi or other resistant organisms. It is possible that the synergistic combination of radiation, corticosteroids, and serious underlying disease may set the stage for clinical fungal infection.

A high rate of wound, pulmonary, and other infections is seen in renal failure, presumably as a result of decreased host resistance. Granulocytopenia and diseases associated with immunologic deficiency (eg, lymphomas, leukemias, and hypogammaglobulinemia) are frequently complicated by sepsis. The uncontrolled diabetic is also observed clinically to be more susceptible to infection. The acquired immunodeficiency syndrome (AIDS) is associated with increased susceptibility to infection.

DELAYED WOUND HEALING

This problem can be anticipated in certain categories of patients whose tissue repair process may be

compromised. Many systemic factors have been alleged to influence wound healing; however, only the following are of clinical significance: protein depletion, ascorbic acid deficiency, marked dehydration or edema, and severe anemia. It has been shown experimentally that hypovolemia, vasoconstriction, increased blood viscosity, and increased intravascular aggregation and erythrocytosis caused by remote trauma interfere with wound healing, probably by reducing oxygen tension and diffusion within the wound.

Large doses of corticosteroids depress wound healing. This effect apparently is increased by starvation and protein depletion. Wounds of patients who have received large doses of corticosteroids preoperatively should be closed with special care to prevent disruption that might delay healing.

Patients who have received anticancer chemotherapeutic agents are just as apt to require surgery as any other population group. Cytotoxic drugs may interfere with cell proliferation and may decrease the tensile strength of the surgical wound. It is wise to assume that healing may be delayed in patients receiving antitumor drugs.

Poor control of blood sugar in diabetic patients is associated with slow healing, poor scar formation, and an increased rate of wound infection. Slow healing sometimes is observed in debilitated patients, ie, those with advanced cancer, renal failure, gastrointestinal fistulas, or chronic infection. Protein and other nutritional deficiencies may be major causes of poor wound repair. Decreased vascularity and other local changes occur after a few weeks or months in tissues that have been heavily irradiated. These are potential deterrents to wound healing as well.

OTHER PREOPERATIVE CONSIDERATIONS

Autologous Blood Donation & Ovarian Preservation

Women undergoing hysterectomy must choose whether or not to undergo prophylactic oophorectomy. Specific groups of women whom will benefit from prophylactic oophorectomy have been identified. Women with the *BRCA1* or *BRCA2* mutation are at increased risk of ovarian cancer and prophylactic oophorectomy allows early ovarian cancer diagnosis and reduces the risk of ovarian and breast cancer. Women with endometriosis who are undergoing a hysterectomy without oophorectomy are at increased risk of requiring further surgery and recurrence of pain compared with women with an oophorectomy at the time of hysterectomy.

For most women however, this is a complex decision that must be fully discussed with the gynecologic surgeon. The advantage of oophorectomy is reduction of ovarian cancer risk (1 in 70 women); the disadvantage is loss of estrogen. This dilemma is compounded by the Women's Health Initiative findings. Risk factors for ovarian cancer, the potential for further surgery without performing a prophylactic oophorectomy, and a patient's age, must be considered when assisting the patient in decision making.

Supracervical Hysterectomy

The popularity and patient demand for supracervical hysterectomy has fluctuated over time. Recent randomized, controlled studies have compared supracervical with total hysterectomy. These studies found no significant differences in complication rate, symptom improvement, sexual function, bowel function, or urinary incontinence.

Preoperative Orders

Most patients are admitted to the hospital on the day of their surgery, or they have their surgery as outpatients. Much of the preoperative preparation of the patient that was formerly done in the hospital is now done at home by the patient and her family, as only a small percentage of gynecologic surgical patients are admitted before their surgical date. The following discussion reviews several areas of surgical concern that were formerly addressed in a patient's inpatient, night-before-surgery, preoperative orders.

SKIN PREPARATION

Many gynecologic surgeons choose to have patients wash the skin over the operative site with povidone-iodine

or hexachlorophene the night before the procedure is to be performed, and follow with a povidone-iodine preparation just before surgery. In addition, a povidone-iodine vaginal preparation is performed in the operating suite. Twenty milliliters of povidone-iodine gel placed at the vaginal apex after vaginal preparation reduces the risk of pelvic abscess formation after abdominal hysterectomy.

Wound infection incidence is decreased by shaving the operative site in surgery rather than the night before the procedure. The wound infection rate is lower still with the use of clippers in the operating room or with no hair removal at all.

DIET

The patient should receive nothing by mouth for at least 8 hours before the operation so the stomach will be empty at the time of anesthesia.

PREPARATION OF THE GASTROINTESTINAL TRACT

Although there is relatively little data to support its routine use prior to gynecologic surgery, bowel preparation is currently an established practice before abdominal surgery. In the literature there is scant evidence to support the use of mechanical bowel preparation before elective colorectal surgery. In fact, there is evidence based on randomized trials and a meta-analysis report, that a significantly higher incidence of wound infection in patients receiving mechanical bowel preparation versus no bowel preparation. As to gynecologic surgery, data are minimal. There is a single, randomized trial that demonstrated a lack of efficacy of mechanical bowel preparation when compared to no bowel preparation at the time of laparoscopy. Based on this evidence, the routine use of mechanical bowel preparation should be reconsidered both in general and gynecologic surgery. However, gynecologic surgeons need to be aware of the local customs of their colleagues who practice general surgery. Currently, the majority of colorectal surgeons currently employ mechanical bowel preparations before elective anastomotic surgery. If the gynecologic surgeon is performing a procedure in which there is a strong possibility of intraoperative consultation, the surgeon should consider the preferences of the available general surgical consultants. On the other hand, many gynecologic surgeons recommend that a patient use a cleansing enema the night before surgery to make certain that the examination under anesthesia will be accurate and to reduce the need for straining with a bowel movement during the early postoperative period.

If mechanical bowel preparation is deemed necessary, sodium phosphate preparation is better tolerated than polyethylene glycol. In 1997, Oliveira et al. compared sodium phosphate and polyethylene glycol in a prospective, randomized study involving 200 patients who underwent elective colorectal surgery. Sodium phosphate was better tolerated and judged equally effective by the operative surgeon. Wound complication rates were equal. Cohen et al. studied the safety, efficacy and tolerability of sodium phosphate compared to polyethylene glycol for precolonoscopy bowel preparation. Four hundred fifty patients were prospectively randomized to receive either 4 L of a polyethylene glycol solution or a 90-mL oral sodium phosphate preparation. The mean age of the participants was 71 years. Ninety-one percent of patients who had previously used polyethylene glycol preferred the sodium phosphate preparation. Mild hyperphosphatemia occurred in the sodium phosphate group but it was without clinical sequelae. Electrolyte imbalance, however, may be valid concern in the frail elderly.

SEDATION

A sedative-hypnotic can be prescribed to ensure restful sleep the night before the operation.

PREANESTHETIC MEDICATION

Preanesthesia medication is not administered until after an intravenous line has been started on the day of surgery. It generally consists of a sedative such as midazolam, titrated to effect.

OTHER MEDICATIONS

At least 25% of surgical patients take regularly scheduled medications, and this figure undoubtedly is much

higher in the older patient populations. The most common medications are cardiovascular drugs, central nervous system (CNS) agents, and gastrointestinal medications. The patient is generally advised to take all of her regular medications on the morning of surgery with sips of water sufficient to swallow them unless there are specific contraindications.

Most cardiovascular medications can and should be continued through the morning of surgery. In particular, β blockers are protective in the perioperative period. An exception is the angiotensin-converting enzyme (ACE) inhibitor/angiotensin-receptor blocker (ARB) class. Conflicting data indicate that this class of antihypertensive has the potential to intensify the hypotensive effect of anesthesia. It is therefore recommended that ACE inhibitors and ARBs be discontinued 24 hours prior to surgery, or for at least one scheduled dose. Diuretics are also typically withheld the morning of surgery.

Oral anticoagulants should be stopped 3–5 days prior to major gynecologic surgery. If necessary, such patients can be "bridged" before and after surgery with low molecular weight or unfractionated heparin. Surgery is generally considered safe when the preoperative international normalized ratio (INR) is below 1.5. The warfarin is then restarted on postoperative days 3–5, with the heparin bridge, if used, continued until the patient's INR is again within the therapeutic range. A general rule is to discontinue the heparin bridge 12 hours prior to surgery, and restart it 12 hours after surgery. It should be noted that regional block in patients receiving preoperative anticoagulation is generally contraindicated. Discontinuing warfarin is probably not needed for minor gynecologic surgery; the ophthalmology and dermatology literature shows that continuing warfarin preoperatively is not detrimental.

Antiplatelet medications with irreversible binding, such as aspirin and ticlopidine, should be discontinued 7–10 days prior to surgery. Other nonsteroidal anti-inflammatory drugs (NSAIDs), which bind platelets reversibly, can be continued until within 24–72 hours of surgery. Although the newer cyclooxygenase-2 (COX-2) inhibitor NSAIDs, such as celecoxib, theoretically have no adverse effect on platelet function, they, too, should be discontinued 72 hours prior to surgery because of concerns about renal function perioperatively.

The biggest concern regarding CNS agents is the development of withdrawal symptoms when the medication is withheld. This is especially true of benzodiazepines. Tricyclic antidepressants (TCAs) and serotonin reuptake inhibitors (SSRIs) are generally safe to take up to the day of surgery, although there are reports linking TCAs with intraoperative hypotension.

Asthma, antiepileptic, endocrine, and gastrointestinal medications are typically continued through the morning of surgery, and restarted as soon as practical postoperatively. Oral hypoglycemic agents are routinely withheld the morning of surgery. Metformin is withheld for up to 48 hours preoperatively because of the small but significant risk of lactic acidosis. Insulin, as noted above, is dosed differently on the morning of surgery.

The clinician should specifically ask the patient preoperatively about intake of herbal medicines. Some of these, such as ephedra (ma huang), ginseng, ginkgo, kava kava, St. John's wort, and even garlic and ginger, are reported to have cardiovascular, coagulation or sedative effects in the perioperative period. To be safe, patients should discontinue all herbal medications at least 2 weeks prior to surgery.

ANTIBIOTICS

Preoperative or prophylactic antibiotics are of value, especially in cases of expected bowel surgery, abdominal hysterectomy, all major vaginal surgery, and certain cesarean section deliveries. In contrast to mechanical bowel preparation, the positive effects of prophylactic antibiotics in case of bowel surgery is undisputed. The first- and second-generation cephalosporins have been particularly effective in decreasing postoperative febrile morbidity. Recent experience indicates that single-dose prophylaxis may be as effective as multiple doses.

BLOOD TRANSFUSIONS

In circumstances in which transfusions are not usually required, a type and screen is satisfactory and cost-

effective. If major blood loss is anticipated, a full cross-match should be performed. Keep in mind that more blood can be prepared as you are transfusing the units you already ordered.

Because of concerns about the risk of transmitting AIDS via transfusion, elective gynecologic surgery patients should be offered the option of autologous blood donation preoperatively. In addition, acute intraoperative autotransfusion should be considered if excessive intraperitoneal blood loss occurs either preoperatively, as in the case of ruptured ectopic pregnancy, or intraoperatively, as in the case of certain radical surgical procedures. Use of a cell-saver device, which processes blood aspirated from the surgical field and allows return of the patient's own red blood cells after washing in normal saline, is useful in these large-blood-loss situations and significantly cuts down on blood bank demand. The device is contraindicated in certain patients, such as those with infection near the operative site or those undergoing cesarean section or cesarean hysterectomy, because thromboplastins from decidual or amniotic fluid may become mixed with the blood.

BLADDER PREPARATIONS

For minor procedures, the patient voids prior to being moved to the operating room. If major pelvic surgery is planned, an indwelling Foley catheter should be placed when the vaginal preparation is done in the operating room. For prolonged bladder drainage, a suprapubic catheter provides a lower urinary tract infection rate along with the ability to allow voiding trials without multiple urethral catheterizations. Intermittent, clean self-catheterization is another bladder drainage modality that can be taught preoperatively and offers a low postoperative infection rate.

DAY OF SURGERY

Positioning the Patient

Care must be taken to ensure adequate access to the surgical sites during positioning. Many gynecologic procedures are performed in lithotomy position for vaginal access. The risk of neurologic injury can be reduced through proper positioning. The coccyx should be well supported on the operative table (and not hanging off) to avoid hyperextension of the back. The lateral calf should not come into contact with the candy cane stirrup post to reduce the risk of compression injury of the common peroneal nerve. To reduce sciatic nerve stretch, exaggerated hip flexion, knee extension, and hip abduction should be avoided. The femoral nerve can become compressed under the inguinal ligament with excessive thigh flexion. When using universal boot stirrups, the surgeon must ensure that the weight of the leg rests upon the heel, with no pressure on the lateral or posterior calf. A prospective study found patients in dorsal lithotomy position for longer than 2 hours were at increased risk of neurologic injury; consequently, steps should be taken to minimize operative time when feasible.

POSTOPERATIVE CARE

IMMEDIATE POSTOPERATIVE CARE

During the immediate postoperative period, maintenance of normal pulmonary and circulatory function should be emphasized. Vital signs and fluid balance should be monitored frequently to facilitate the early diagnosis of shock or pulmonary problems. Bleeding from the surgical site and persisting pulmonary or cardiovascular effects from anesthesia are risks that mandate careful surveillance of all patients in the immediate postoperative period.

Postoperative Orders

The postsurgical patient is taken to the recovery room, accompanied by the anesthesiologist and the surgeon or other qualified attendant, as soon as she responds. Patients with medical problems may require postoperative admission to an intensive care unit for prolonged ventilation or central monitoring. The nurse receiving the patient should be given a verbal report of her condition, as well as an operative summary and postoperative orders. The postoperative orders should include the following elements.

VITAL SIGNS

Record the blood pressure, pulse, and respiratory rate every 15–30 minutes until the patient is stable and hourly thereafter for at least 4–6 hours. Any significant change must be reported immediately. These measurements, including the oral temperature, should then be recorded 4 times a day for the remainder of the postoperative course.

WOUND CARE

Watch for excessive bleeding (inspect abdominal dressing or perineal pads). Determine the hematocrit the day after major surgery and, if there is a question of continued bleeding, repeat as indicated. An abdominal wound should be inspected daily. Skin sutures or clips generally are removed 3–5 days postoperatively and replaced with Steri-Strips.

MEDICATIONS

Following major surgery, give narcotic analgesics as needed (eg, meperidine, 75–100 mg intramuscularly every 4 hours, or morphine, 10 mg intramuscularly every 4 hours) to control pain. Injectable nonsteroidal anti-inflammatory drugs are available for postoperative pain control as well. Antiemetics such as promethazine or hydroxyzine may be helpful to suppress nausea, as well as to potentiate analgesics.

Patient-controlled analgesia (PCA) is widely available. With PCA, patients are able to give themselves intravenous pain medication as they need it within the parameters set by the physician. Many patients prefer PCA because it allows them to avoid the "peak and valley" effect of scheduled or on-demand pain injections.

Many centers are now using intrathecal or epidural opiate injection for relief of postoperative pain. This technique is particularly appropriate for patients who have been given regional anesthesia. A minimal dosage of less than 5 mg of morphine may allow several hours of complete pain relief without compromise of motor activity (ambulation, coughing). Respiratory depression is a hazard, however, and close monitoring of the patient is necessary. Patient-controlled epidural analgesia is becoming available in many centers as an alternative to single-dose spinal analgesics. Following minor surgery, give mild analgesics as needed. Other medications required by the patient that were taken prior to surgery (insulin, digitalis, cortisone, or others) should be resumed as required.

POSITION IN BED

The patient is usually placed on her side to reduce the risk of inhalation of vomitus or mucus. Other positions desired by the surgeon should be clearly stated, eg, flat with foot of bed elevated.

DRAINAGE TUBES

Connect the bladder catheter to the gravity drainage system. Written orders for other postoperative drainage and suction catheters should be specific and clear, setting forth the degree of negative pressure desired and the intervals for measurement of drainage volume.

INTAKE AND OUTPUT

The total fluid intake and output as well as daily weights are important clinical measures postoperatively.

FLUID REPLACEMENT

Administer fluids orally or intravenously as needed. When deciding how to replace a particular patient's fluid needs, always take into account factors such as intraoperative blood loss and urine output, operating time, intraoperative fluid replacement, and the amount of fluid received in the recovery area. Although each patient and operation are different, an average healthy young patient who has been appropriately replaced intraoperatively will do well with 2400 mL to 3 L of a balanced crystalloid and glucose solution, such as 5% dextrose in half-normal saline over the first 24 hours. The rate of intravenous hydration must always be individualized, as many patients require less volume and may become fluid overloaded at a faster rate. In the patient with normal renal function, adequate fluid replacement should result in a urine output of at least 30

mL/h.

DIET

Following minor surgery, offer food as desired and tolerated, when the patient is fully awake. Disagreement exists on how fast to advance a patient's diet after major surgery. This again must be individualized to the patient and depends on many factors.

One possible regimen is to allow the patient only sips of tap water on the day of surgery. Do not give ice water, because it may decrease bowel motility significantly. Give clear liquids on the first postoperative day if good bowel sounds are noted and until intestinal gas is passed. Change the diet thereafter to full regular. The time needed to progress to a full diet depends on the extent of the procedure, the duration of anesthesia, and individual variation among patients. Two randomized, controlled trials support the safety and efficacy of early oral feeding on postoperative day 1 following intra-abdominal gynecologic surgery in selected patients.

RESPIRATORY CARE

Encourage deep breathing every hour for the first 12 hours and every 2–3 hours for the next 12 hours. Incentive spirometry and the assistance of a respiratory therapist may be of great value, particularly in elderly, obese, or otherwise compromised or immobilized patients.

AMBULATION

Encourage early ambulation and bathroom privileges. If possible, require ambulation on the day of the operation after major surgery.

RECOVERY FROM MAJOR SURGERY

Even with the trend toward shorter hospital stays, the patient generally remains hospitalized until recovery of all bodily functions. Normal pulmonary function usually returns after resolution of inhalation anesthesia but may be influenced to some extent by surgical pain during the early postoperative period. Two or 3 days may pass before return of normal bowel function after laparotomy. The patient with febrile complications generally will not be discharged until she has remained asymptomatic and afebrile for 24 hours.

OUTPATIENT SURGERY

With the increasing number of outpatient procedures, the observation period following minor surgery becomes more critical. Following outpatient surgery, patients generally remain hospitalized until mental status and pulmonary and bladder functions return to normal. Occasionally, admission to the hospital becomes necessary for overnight observation or for further therapy. Although "ambulatory surgery" is designed for the healthy patient who is scheduled for less-extensive surgery, to become casual in preparation is to court disaster.

Because these patients play a more active role in the preparation and management of their surgery, the following additional elements must be considered: (a) Preoperative counseling should encompass the same information given the inpatient, but another responsible adult who will provide transportation and postoperative care for the patient should also be present at the session. (b) Emphasis should be placed on the importance of the "nothing by mouth" requirement and on the avoidance of any medications that the surgeon has not prescribed or approved. (c) A hospital must be available for backup if the facility is not hospital-based, and the patient must know where to report if problems arise; this entails establishing 24-hour telephone service for access to medical advice and care. (d) A follow-up call from the physician within 24 hours is often beneficial for picking up early postoperative problems as well as for emotional support for the patient. (e) All postoperative instructions should be reviewed with the patient before her surgery.

POSTOPERATIVE COUNSELING & RELEASE FROM THE HOSPITAL

Following operation, the patient should receive a careful explanation (both oral and written) of the surgical procedure performed, the findings at surgery, and any postoperative procedures or findings. The postoperative

course may be negatively influenced by the patient's anxiety regarding lack of information or unanswered questions. It may be helpful for the physician to refer to preoperative audiovisual aids during the postoperative counseling session.

Every postoperative patient should have a complete physical examination (including a pelvic assessment) before release from the hospital. Findings can be used as a baseline for subsequent follow-up examinations.

The patient should receive oral and written instructions regarding postoperative care at home, including which physical activities she may perform. Appointments should be made for outpatient or office follow-up examinations.

Current OB/GYN > Chapter 47. Intraoperative & Postoperative Complications of Gynecologic Surgery > Intraoperative Complications >

Intraoperative Complications: Introduction

The intimate anatomic relationship of the genital tract with urologic, gastrointestinal, vascular, and neurologic structures makes occasional injury during gynecologic surgery almost inevitable. The surgeon must do everything possible to prevent such complications and, if they do occur, recognize and treat them in an organized and timely fashion. The keys to avoiding surgical misadventure, and to recognizing it when it has occurred, are understanding pelvic anatomy, using methodical meticulous surgical technique, handling tissues gently, and maintaining constant vigilance. A detailed description of the management of every possible complication of gynecologic surgery is beyond the scope of this text. For this, the reader is referred to the many excellent references at the end of this chapter.

URINARY TRACT INJURY

Ureteral Damage

Ureteral injury occurs in association with most major gynecologic surgical procedures including hysterectomy for benign indications, pelvic cancer surgery, oophorectomy, and suspension of both the vaginal apex and of the bladder neck. The incidence of ureteral injury is reported to be 0.5% for simple hysterectomies for benign disease, up to 1.6% for laparoscopically assisted hysterectomies, and as high as 30% in some older series of Wertheim radical hysterectomies. Isolated statistics such as these have little clinical significance; rather, the knowledge, skill, and diligence of the surgeon, as well as the difficulty of the surgical procedure, determine the risk for any given patient.

The ureter may be accidentally ligated, kinked, transected, crushed, burned, or devascularized. In gynecologic surgery, injury to the ureter most often occurs at the level of the infundibulopelvic ligament, the uterine artery, the uterosacral ligament, or the anterolateral fornix of the vagina as the ureter crosses it to enter the trigone of the bladder. Early recognition of ureteral injury is crucial for preservation of function of the associated kidney. Repair is also more likely to be successful if performed at the time of injury.

The best defense against injury to the ureter is knowledge of its anatomic relations and use of the avascular spaces of the pelvis to identify it intraoperatively (see Chapter 2). This requires good exposure, proper lighting and definitive visualization or palpation.

Despite this careful attention, the need to confirm ureteral integrity may still arise. This can be done at the end of the procedure with a cystoscope or other endoscope. While the patient is being given 5 mL of indigo carmine intravenously, the bladder should be filled with 300 mL of normal saline. If vaginal surgery is being performed, a 70-degree endoscope can be introduced transurethrally. If an abdominal procedure is being performed, patency can be demonstrated by introducing an endoscope through a purposeful cystotomy. To do this, the extraperitoneal dome of the bladder is dissected away from the symphysis pubis and a pursestring suture is placed and small purposeful cystotomy made within it. A 0-degree or 30-degree endoscope is placed in the bladder and the pursestring suture cinched tightly. The

ureteral orifices are visualized and a blue effluent can be seen emanating from the orifices if the ureters are patent. The rest of the bladder should also be examined for gross abnormality or evidence of operative trauma. If cystotomy was performed, the pursestring suture is tied and imbricated after the endoscope is removed. Postoperative catheter management is unchanged.

If cystoscopy is not diagnostic, or if injury is strongly suspected, the dome of the bladder can be opened and a stent placed retrograde through each ureteral orifice. If ureteral patency cannot be demonstrated by any of these techniques, further steps, such as retrograde pyelography and transurethral stenting, can be initiated while the patient is still under anesthesia and the injury is fresh.

Patients who develop flank pain in the postoperative period should be strongly suspected of having a ureteral injury. However, a patient with an obstructed ureter may not experience any flank pain at all. Urinary tract injury can be detected postoperatively by intravenous pyelogram (IVP) or retrograde x-ray studies. Renal ultrasonography may reveal hydronephrosis or hydroureter. A continuous postoperative watery vaginal discharge is suggestive of vesicovaginal or ureterovaginal fistula. A urinary fistula should also be suspected if fluid draining from a surgical wound or drain demonstrates much higher creatinine concentration than the patient's blood.

URETERAL LIGATION

Ureters may be directly ligated during surgery. They can also be kinked by suture placement and functionally obstructed without actually being ligated. As soon as pressure within the renal pelvis builds to > 40 cm H₂O, renal function will begin to be lost. If renal function is to recover, ureteral ligation or obstruction must be discovered within a few weeks at the latest. Postoperative signs of ureteral obstruction can include flank or pelvic pain, pyelonephritis and sepsis, abdominal swelling secondary to collection of urine (urinoma), or development of a ureterocutaneous fistula. Again, ureteral obstruction and subsequent kidney failure can occur without associated warning signs.

TRANSECTION

Transection of the ureter may be detected intraoperatively if urine is noted to be leaking into the operative field. Hematuria may occur after transection but cannot be considered a reliable sign. If not repaired, ureteral transection can result in either a pelvic urinoma or ureterocutaneous fistula. Postoperatively such patients may present with ileus and distention. A ureteroneocystostomy should be performed if the transection occurs within 5 cm of the bladder. Otherwise, the transected ureter above the pelvic brim may be repaired with an end-to-end anastomosis over a ureteral stent.

CRUSH INJURY

There is a significant risk of segmental ureteral necrosis following a surgical clamp crush injury to the ureter. The smaller the amount of other tissue involved in the clamp along with the ureter, the greater the chance that the ureter has been seriously compromised. Resection of the crushed ureteral segment and reanastomosis, or performance of ureteroneocystostomy, depending on the site of injury, should be considered unless (a) the ureter was clamped for only a brief time as part of a larger pedicle, (b) there is no visible damage, and (c) peristalsis persists at the site of injury. In such a case, a double-J ureteral stent can be placed and removed after 4–6 weeks with outpatient cystoscopy. An intravenous pyelogram should be obtained after removal to rule out extravasation and evaluate ureteral patency.

DEVASCULARIZATION

Extensive retroperitoneal dissection of the ureter may injure its adventitial vascular supply with subsequent necrosis of the devitalized segment. This risk is greatest in cancer surgery. In the 1950s, Viennese physician Dr. A. H. Palmrich anatomically defined the complex of vessels and nerves that supply the ureter. Later series of radical hysterectomies that preserved this complex by avoiding skeletonization of the ureter resulted in a dramatic decline in ureteral complications.

Bladder Injury

Laceration of the bladder can be confirmed by filling the bladder with sterile milk or methylene blue through a urethral catheter and observing leakage of fluid. Milk has the advantage of not staining the operative field if an injury is present. All edges of the cystotomy must be visualized and mobilized as necessary. The bladder defect can then be repaired with two layers of absorbable suture after which the bladder is again filled to test for leakage. Uncomplicated recovery is generally the rule. Five to 10 days of catheter drainage, depending on the site and extent of injury, helps to promote healing by preventing bladder distention.

Very small bladder injuries caused by Veress needle insertion or small trocar insertion during laparoscopy or bladder neck suspension procedures can sometimes be managed conservatively with dependent drainage with a transurethral catheter. Although small extraperitoneal defects may respond to drainage, intraperitoneal injuries require closure as described above.

GASTROINTESTINAL TRACT INJURY

Bowel is highly susceptible to injury during laparotomy, laparoscopy, and vaginal surgery. The moment of entry into the peritoneal cavity is a crucial step and should be approached cautiously. Patients with adhesions caused by previous surgery, endometriosis, or salpingitis are at high risk for bowel injury as adherent bowel is dissected away from the operative site. The risk of bowel laceration is even greater during the acute phase of pelvic infection because of the increased friability of the secondarily inflamed bowel. These factors should be taken into account when deciding on the operative approach: transvaginal versus laparotomy versus open or closed laparoscopy.

Tight abdominal packing, exposure of the bowel serosa with subsequent dehydration, indiscriminate use of unipolar electrocautery and superficial abrasions from manipulation may be associated with apparently minimal trauma, yet ultimately result in postoperative bowel adhesions. Bowel exposure and manipulation should be minimized during laparotomy.

Complications associated with accidental penetration of bowel arise from bacterial and chemical peritonitis from spillage of bowel contents into the peritoneal cavity. Postoperative fever, abdominal distention, paralytic ileus, and diffuse peritonitis can develop within 24 hours after unrecognized bowel injury. Fecal contamination from colonic injury can prevent successful primary repair. Copious irrigation of the abdomen followed by placement of a closed drainage system at the repair site decreases the risk of generalized postoperative peritonitis. If unprepared colon is entered, or if the injury is extensive, a temporary diverting colostomy proximal to the site of injury may be necessary to allow healing. Abdominal abscess formation, wound infection, enterocutaneous fistula, and extensive bowel adhesions may follow fecal contamination of the abdominal cavity. The risk of bacterial peritonitis is clearly greater if the colon is the site of injury.

Small-bowel injury may produce chemical peritonitis from leakage of secretions from the stomach, gallbladder, and pancreas. Injury to the small bowel or stomach can be successfully repaired with two layers of interrupted suture. It may be necessary to convert a longitudinal small bowel laceration into a transverse repair to avoid constriction of the bowel lumen. Larger injuries and thermal injuries may require segmental resection using suture techniques or stapling devices.

Unrecognized covert injury, such as thermal-bowel injury from electrocoagulation, is particularly dangerous. A patient with such an injury may appear well in the immediate postoperative period. The delayed onset of symptoms of perforation may be misinterpreted or even overlooked. Such unrecognized injuries can prove lethal. Whether operating transvaginally, by laparotomy, or laparoscopically, keep in mind the possibility of unrecognized overt or covert intraoperative bowel injury as the patient moves

through the postoperative period.

NEUROLOGIC INJURY

Damage from Patient Positioning

Unnatural positioning of the patient while under anesthesia can cause significant sensory and motor defects in the extremities. Hyperextension or hyperabduction of an extremity may stretch the corresponding major nerve trunk as it exits the thorax or pelvis. The upper roots of the brachial plexus are especially vulnerable to injury, and transient shoulder pain may occur postoperatively if the shoulder has remained hyperextended during surgery. Femoral neuropathy occasionally follows procedures carried out in the lithotomy position when the hip has been hyperflexed and hyperabducted, stretching and compromising the nerve as it travels under the inguinal ligament.

Nerves in the extremities are also vulnerable to injury where they cross over a skeletal prominence. External pressure on these sites during surgery may produce prolonged sensory and motor defects. A common nerve injury results from compression of the common peroneal nerve at the head of the fibula when the lateral aspect of the leg below the knee rests against a hard leg brace with the patient in lithotomy position. The result is loss of sensation in the dorsum of the ankle often associated with footdrop as a result of loss of motor function of the peroneus longus and brevis muscles. Proper positioning and the use of sequential compression boots may help to avoid this complication.

Prolonged pressure transmitted through the gluteal muscles may injure the sciatic nerves. Compression of the ulnar nerve against the medial epicondyle of the humerus occurs if the elbow is extended with the wrist pronated and results in nerve injury if the patient's arm remains in this position for prolonged periods.

Damage during Surgery

The tips of the blades of an improperly placed self-retaining retractor may rest on the psoas muscles. Prolonged pressure may be transmitted to the femoral, ilioinguinal, iliohypogastric, or genitofemoral nerve with resulting painful neuropathy, sensory loss, and muscle weakness. The risk is especially great in the thin patient. To prevent this, the external part of the retractor can be bolstered with folded sterile towels to relieve this pressure. Alternatively, shorter lateral blades could be used if possible.

The sciatic or obturator nerves may be at significant risk during radical pelvic cancer surgery, and the long thoracic nerve can be easily damaged during surgery for breast cancer. Careful dissection and a strong anatomic background are the best defenses against these injuries.

VASCULAR INJURY

Major Vessel Injury

Incidental injury of major pelvic blood vessels is a rare but potentially catastrophic complication of pelvic surgery. The arteries, with their thick, muscular walls are less often damaged than the thin-walled veins. The inferior vena cava and iliac veins are delicate and are easily injured during lymphadenectomy and other procedures for invasive disease, whereas injury during procedures for benign disease is much less common.

Bleeding from even small injuries to these major vessels can be extremely heavy. If injury occurs, direct pressure should be applied to the injured vessel or the blood supply should be temporarily cut off by applying pressure proximal to the site of injury. This allows the surgeon time to obtain adequate exposure for repair, to carefully assess the nature and extent of the injury, to consult if necessary, and to have blood products delivered to the operating room while limiting the patient's blood loss. Keeping up with replacement of blood volume with packed red blood cells and blood products is essential.

If the injury occurs during laparoscopy with penetration of a vessel by a Veress needle or trocar, the instrument should not be removed while the laparoscopy is being converted to a laparotomy. This allows the instrument to provide some tamponade while aiding subsequent identification of the site of penetration. A midline incision, which can be easily extended as necessary, should be made to provide adequate exposure.

Small injuries often can be repaired with carefully placed, very fine sutures after adequate exposure is obtained and the patient is stabilized. Larger injuries might require emergent consultation with a vascular surgeon about the need for vessel grafts. In the pregnant patient, many vessels are engorged, making them behave like major vessels. The uterine vessels carry 500 mL/min of blood at term. Laceration of these vessels during cesarean delivery or cesarean hysterectomy can cause massive bleeding.

Hemorrhage

Even if major vessels are not injured, unexpected and hard-to-control bleeding from other sources can occur during any gynecologic surgery. The gynecologic surgeon should be comfortable with the technique of hypogastric artery ligation, which will frequently control such bleeding (see Fig 31–1). This technique involves dissection of the hypogastric artery distal to the bifurcation of the common iliac artery. Two silk ties are then passed under the internal iliac artery from lateral to medial and tied approximately 1 cm apart. The artery itself should not be cut. Great care must be taken not to damage the delicate internal iliac vein located immediately posterior and lateral to the hypogastric artery. This ligation acts by decreasing the pulse pressure at the distal bleeding site sufficiently to allow clot formation. Rich collateral circulation exists distal to the ligation, especially from the lumbar and middle sacral circulations. Enough perfusion to the pelvis remains so that not only will the pelvic organs remain viable, but also the potential for future pregnancy is preserved.

Another technique often employed to control massive hemorrhage after a cesarean section is uterine artery ligation. It involves taking large purchases with a stitch through the uterine wall at the level of the cervical isthmus to ligate the uterine artery. One must remain ever mindful of the course of the ureter during this procedure.

Angiographically guided arterial embolization is another technique that may be useful for lesser degrees of bleeding. This technique can be used either intraoperatively or postoperatively in an attempt to avoid a subsequent return to the operating room. Arterial catheters are placed using fluoroscopic guidance, the bleeding sites identified, and embolization done by a variety of techniques. If hypogastric ligation has already been performed, angiographic catheters may not be able to reach the bleeding site and angiographic embolization may not be possible.

Massive hemorrhage, defined as bleeding requiring transfusion of more than 10 units of blood, may occur in extensive pelvic and abdominal surgery such as tumor debulking, lymph node dissections, and pelvic exenteration. This heavy bleeding can occur any time the deep pelvic venous plexus are encountered. When other measures are unsuccessful, packing of the pelvis at the site of hemorrhage with long packs or with gauze rolls inside a bowel bag has been described. The abdomen is closed after it has been packed, and the patient brought back to the operating room 48–72 hours later for removal of the packing.

ANESTHETIC COMPLICATIONS

Malignant Hyperthermia

One surgical patient in 14,000 has a congenital defect of calcium metabolism that presents as life-threatening hyperthermia during general anesthesia. In these patients, the administration of

succinylcholine or the volatile anesthetic agents can prevent the reuptake of calcium by the sarcoplasmic reticulum in skeletal muscle cells. Massive calcium levels stimulate a dramatic increase in cell metabolism, causing the characteristic symptoms of elevated body temperature, generalized skeletal muscle rigidity, and metabolic acidosis. Fatal cardiac arrhythmias may occur as hyperkalemia develops in association with acidosis.

If malignant hyperthermia develops, all anesthetic agents should be immediately discontinued and intravenous dantrolene given promptly. Dantrolene exerts its effects by interfering with the release of calcium from the sarcoplasmic reticulum. The dose should be repeated until symptoms subside or until a maximum of 10 mg/kg has been given. Dantrolene should be continued postoperatively. Treatment should also be directed toward stabilization of the patient through correction of cardiac arrhythmias, metabolic acidosis, hyperkalemia, and hyperthermia.

Bronchospasm

Bronchospasm is caused by increased airway reactivity and is detected by wheezing and increased difficulty in ventilating the patient. Patients with known asthma and cardiopulmonary disease are at increased risk for bronchospasm with general anesthesia. However, bronchospasm can also occur in patients without a known history of pulmonary disease. In patients with known disease, consideration is often given to performing procedures under regional anesthesia whenever possible. When bronchospasm does occur intraoperatively, pharmacologic measures such as inhaled beta-mimetics and intravenous corticosteroids should be instituted immediately.

Hypothermia

Prolonged exposure of the lightly covered, anesthetized patient with an open abdomen to the relatively cool operating room environment can result in a drop of several degrees in core body temperature. Severe hypothermia is unusual, but even minor hypothermia has important implications. The return to normal body temperature, which often involves shivering, can cause a large increase in oxygen requirements, which, in turn, can cause cardiovascular stress, particularly for patients with underlying cardiac or pulmonary disease. These problems can be reduced with careful attention to patient temperature, including covering the patient and using warmed intravenous fluids and warmed, humidified ventilation.

Regional Anesthesia

Regional anesthetic techniques are being used with increasing frequency for primary anesthesia, as well as for relief of postoperative pain. Both epidural and spinal anesthetics are being used with increasing frequency in gynecologic surgery. The most common and worrisome problem is respiratory depression. This occurs when the anesthetic level reaches to C3-C5, the level of innervation of the diaphragm. Whenever regional anesthesia is planned, equipment for intubation and mechanical ventilation must be readily available in the event of respiratory depression. These patients must be closely observed both during the procedure and afterward, until the anesthetic agents have been completely metabolized and the anesthetic block resolved, because delayed respiratory depression can occur.

The most common and aggravating postoperative problem with regional anesthesia is spinal headache, caused by persistent leakage of cerebrospinal fluid through the hole made by the spinal or epidural needle. In most instances, headache can be avoided by the use of very-small-caliber needles and adequate hydration before, during, and after the procedure. Use of an epidural blood patch often gives immediate relief.

Other Complications

Teeth can be broken or chipped during intubation. Careful technique with the laryngoscope is always required. Some patients, particularly obese patients and patients with short necks, can be very difficult to intubate, resulting in laryngeal damage, laryngospasm, or abandonment of the procedure because of an inability to intubate the patient. Esophageal intubation can be catastrophic if unrecognized, but can be avoided by careful attention to laryngeal visualization, CO₂ monitoring of exhalation, and careful auscultation. Pneumothorax and aspiration pneumonia, two other common complications, are discussed at length in the section on pulmonary complications. It is thought that death caused by anesthetic complication occurs in approximately 1 in 1500–2000 surgical procedures.

COMPLICATIONS OF ENDOSCOPIC PROCEDURES

Laparoscopy and hysteroscopy are among the most frequently performed gynecologic procedures. These procedures are perceived as less invasive, with faster recovery times, and are frequently performed in an outpatient setting. It is clear, however, that despite being termed minimally invasive, major complications do occur with endoscopic surgery. Recognized complications include bowel, bladder, and ureteral injuries; hernias at the trocar sites; catastrophic major vessel injury at the time of trocar insertion; and CO₂ embolism. In addition to complications specific to endoscopy, any of the complications associated with traditional gynecologic surgery can occur.

Great care is necessary to minimize complications from endoscopic procedures. When inserting the Veress needle, careful attention should be paid to keeping the tip in the midline. The needle should be directed downward at approximately 45 degrees to avoid the bifurcations of the aorta and inferior vena cava, usually located 1–3 cm below the umbilicus. The umbilicus provides the shortest distance between skin and peritoneum because anatomic layers fuse there. Veress needle insertion at this site helps avoid the complication of extraperitoneal insufflation which can, in some cases, lead to respiratory acidosis, pneumothorax, and pneumomediastinum.

Many of the most serious complications occur at the time of trocar insertion. In patients with a high risk of bowel adhesions to the anterior abdominal wall, some surgeons advocate using an open trocar placement technique, although no published evidence exists to support this. All subsequent trocars should be placed under direct visualization, with careful attention paid to avoiding the inferior epigastric vessels. When performing laparoscopic procedures the same attention must be paid to identification of the ureters and other anatomy as in open procedures. Bowel, bladder, and ureter, as well as major vessels, can be injured just as easily during endoscopic procedures as during laparotomy.

Hysteroscopy has some unique complications in addition to the risks of uterine perforation, visceral damage, and hemorrhage. The uterine distention medium may cause life-threatening electrolyte imbalances as well as introduce air emboli into the uterine venous sinuses. Air emboli arise from bubbles in the distention media, room air introduced into the uterine cavity when the hysteroscope is placed, or from bubbles generated from vaporization or coagulation procedures within the distention media. Air emboli can cause pulmonary hypertension and hypoxic vasoconstriction, and result in pulmonary edema and respiratory distress. During the procedure, a drop in both oxygen saturation and end-tidal CO₂ should be recognized as a hallmark of air embolization.

Hyponatremia, hypokalemia, hypoosmolality, and fluid overload develop when electrolyte-free distention media such as glycine and sorbitol enter into the venous circulation. The patient can present with headache, nausea, vomiting, arrhythmias, and altered mental status secondary to hyponatremic encephalopathy. The most effective means to avoid these complications is to closely record hysteroscopic fluid inputs and outputs. When a deficit of 1000–2000 mL of fluid is noted, the procedure should be abandoned. Serum sodium will decrease by 10 mmol/L per 1000 mL of hypotonic solution retained. Complications from fluid overload occur at a rate of 1–4% of all hysteroscopies.

CARDIOVASCULAR COMPLICATIONS

Myocardial Infarction

Myocardial infarction is an infrequent but severe perioperative complication with significant risk of mortality. It usually occurs within the first 4 days after surgery. Its diagnosis should be considered whenever a postoperative patient demonstrates:

Chest pain

Hypotension refractory to fluid administration

Acute pulmonary edema

New-onset cardiac dysrhythmia

It is important to note that many postoperative myocardial infarctions are pain free.

The primary approach is risk stratification and prevention. The American College of Cardiology and American Heart Association have guidelines for the perioperative cardiology assessment. Patients at risk should have preoperative evaluation by their primary care provider, and high-risk patients may need consultation with a cardiologist. In at-risk patients, perioperative β blocker administration at a dose that keeps the patient's heart rate at 50–60 bpm decreases risk.

Patients suspected of having myocardial infarction need immediate evaluation with electrocardiogram and cardiac enzymes, including the myocardial band (MB) fraction of creatine phosphokinase (CPK) and troponin. The American College of Cardiology has revised the definition of myocardial infarction and outlines use of the electrocardiogram (ECG) and enzymes for making the diagnosis. Early diagnosis and treatment are important for decreasing the amount of infarcted myocardium, thereby decreasing the risk of sequelae and mortality. Immediate treatment usually includes oxygen, nitroglycerin, and morphine. Other treatments include angiographic revascularization procedures such as balloon angioplasty and stent placement. The use of thrombolytic therapy is limited in immediate postoperative patients by the risk of surgical site bleeding.

THROMBOEMBOLIC COMPLICATIONS

Superficial Thrombophlebitis

Postoperative superficial thrombophlebitis is the most common complication of peripheral intravenous catheters and can also occur in the lower extremities of women with varicosities. The affected vein becomes inflamed, with erythema, localized heat, swelling, and tenderness. This disorder is generally limited to the superficial veins, and concomitant deep vein involvement or pulmonary embolism is very unusual. When superficial thrombophlebitis is diagnosed, treatment includes moving the intravenous access site, application of warm, moist packs, elevation of the extremity, and analgesics. Anticoagulants are rarely indicated when only the superficial vessels are involved. Tagalakis reviews the epidemiology of peripheral vein infusion thrombophlebitis and summarizes the Centers for Disease Control and Prevention (CDC) recommendations for prevention.

Deep Vein Thrombosis

Thrombosis of the deep veins occurs most often in the calf but may also occur in the thigh or pelvis. It may be primary or an extension of more peripheral disease. Age older than 40 years, obesity, cancer, pregnancy, estrogen use, diabetes, prior thromboembolism, prolonged surgery, prolonged immobilization, and thrombophilias (eg, antithrombin III deficiency, protein C and S deficiencies, factor V Leiden and prothrombin mutations, and the lupus anticoagulant) are predisposing factors, but the

disease frequently occurs in otherwise healthy patients. The major complication of deep thrombophlebitis is pulmonary embolism. Chronic venous insufficiency of the affected extremity may also develop as a long-term consequence. As noted in Chapter 46, there are a number of proven prophylactic strategies that should be routinely used perioperatively to minimize the risk of deep vein thrombosis (DVT) and pulmonary embolism (PE).

CLINICAL FINDINGS

Symptoms may be localized to the involved extremity, or the thrombus may be asymptomatic. Pulmonary embolism may be the first sign. The patient may complain of a dull ache or more significant pain in the leg or calf. There may be tenderness or spasm in the calf muscle. Examination may reveal swelling of the calf, which may require measurement of the circumference of both calves at the same level to detect. Dorsiflexion of the foot may elicit pain in the calf (Homans' sign). Although a positive Homans' sign is specific, the test is not very sensitive (approximately 25%). Slight elevation of temperature and pulse is frequently noted. If the clot is in the femoral vein or in the pelvis, swelling of the extremity may be more severe. It is a difficult diagnosis to make clinically, with most episodes of suspected DVT unconfirmed, and a large fraction of DVTs asymptomatic.

DIAGNOSIS

Compression ultrasonography or impedance plethysmography usually provide a definite diagnosis. Both are noninvasive and are sensitive and specific. D-dimers have also been studied as a diagnostic test because the test is noninvasive. A normal D-dimer level is strongly predictive of the absence of thromboembolism. Unfortunately it is nonspecific, and can be elevated by recent surgery. If these tests are not diagnostic, contrast venography is the gold standard and should be performed. Chunilal and Ginsberg extensively review these tests and their use in combination in general, and Davis specifically reviews their use in gynecologic surgical patients.

TREATMENT

Medical Treatment

Once the diagnosis of a deep vein thrombosis extending into the veins proximal to the calf has been made, anticoagulant therapy should be started immediately. Bates and Ginsberg extensively review therapeutic options. Traditionally, intravenous unfractionated heparin has been the first-line therapy. Recently, subcutaneous low-molecular-weight heparin has gained acceptance. Coagulation studies, including international normalized ratio (INR) and partial thromboplastin time (PTT), should be measured before anticoagulant therapy is started; these tests provide a basis for interpreting the degree of anticoagulation achieved. When using unfractionated heparin, the PTT should be kept to 1.5–2.5 times the control value. The more predictable bioavailability, clearance, and activity of low-molecular-weight heparins obviates the need for laboratory monitoring except in unusual circumstances. Unfortunately, they are quite expensive despite costs savings from decreased need for laboratory monitoring. Heparin should be continued until effective long-term therapy is established.

Oral anticoagulants, particularly warfarin, are often started at the same time as heparin. The therapeutic effect of these agents is measured by the INR. Whereas heparin prolongs the clotting time almost immediately, the oral anticoagulants do not exert their full effect for 48–72 hours. Heparin is usually started for its immediate short-term effect, then replaced with oral anticoagulants for long-term treatment. Low-molecular-weight heparin can be used long-term in patients for whom bleeding is a particular risk or laboratory monitoring is problematic. If using warfarin, the INR should be determined daily until equilibrium levels of 2.0–3.0 are attained. Anticoagulation is usually continued empirically for 3–6 months.

Anticoagulation presents significant risks, and anticoagulated patients must be thoroughly counseled to

recognize possible complications of therapy, including hematuria, hemoptysis, hematemesis, melena, and easy bruisability. These patients should be provided with a means of identification indicating that they are receiving anticoagulant therapy, in case of an accident in which they become unconscious. Patients should also be given a list of over-the-counter medications to avoid, including nonsteroidal anti-inflammatory drugs, aspirin, and antibiotics, which may affect their anticoagulation.

Management of calf vein thromboses is somewhat controversial. They are often viewed as not being a problem unless they extend into the proximal veins. When suspected or confirmed, serial compression ultrasound can be performed with reservation of anticoagulation for the approximately 10% of patients whose clots eventually extend into the proximal circulation.

Local Measures

Local measures include elevation of the legs to provide good venous drainage and the application of full-leg gradient-pressure elastic hose. Full activities may be permitted when inflammation has subsided, usually within 1–2 weeks of starting therapy. The patient should be encouraged to continue to elevate her legs whenever she can. Prolonged sitting and the use of constrictive garments, especially knee-high support stockings or hosiery, should be avoided.

Surgical Treatment

Thrombectomy occasionally may be considered for persistent severe swelling of the extremity. An inferior vena cava filter or vena cava ligation may be considered for repeated episodes of pulmonary embolism that occur in spite of adequate anticoagulation or when anticoagulation is absolutely contraindicated.

Septic Pelvic Thrombophlebitis

Septic pelvic thrombophlebitis is a complication that is almost unique to pelvic surgery. It occurs most frequently related to cesarean delivery and is discussed in detail in Chapter 23.

Pulmonary Embolism

Pulmonary embolism is a critical complication of pelvic surgery. This diagnosis should be suspected if cardiac or pulmonary symptoms occur abruptly. Risk factors are the same as noted above for DVT. It is a complication of pelvic or proximal lower-extremity deep vein thromboembolism; nonetheless, pulmonary embolism may precede the diagnosis of peripheral disease. Pulmonary embolism may occur at any time. With the reduction in length of hospital stay, it is being noted more frequently after discharge. The differential diagnosis includes atelectasis, pneumonia, myocardial infarction, and pneumothorax.

Clinical Findings

SYMPTOMS AND SIGNS

The diagnosis of pulmonary embolism is suggested by pleuritic chest pain, dyspnea, tachypnea, and tachycardia. Unfortunately, these symptoms are neither specific nor consistent. Patients with large emboli can have chest pain, severe dyspnea, cyanosis, tachycardia, hypotension or shock, restlessness, and anxiety. If the embolus is massive, sudden death may result from acute cor pulmonale. The combination of risk factors and symptoms will prompt an evaluation. Fedullo and Tapson extensively review the diagnostic approach.

DIAGNOSIS

In the patient suspected of having a pulmonary embolus, an arterial blood gas, 12-lead ECG, and chest radiograph should be obtained. Chest film and ECG can show signs of pulmonary embolism, but are predominantly performed to eliminate other diagnostic possibilities, particularly myocardial infarction and pneumonia. Spiral chest computerized tomography (CT) is now the diagnostic procedure of choice. Lower-extremity studies, as discussed above, can also be performed. In a symptomatic patient, the

diagnosis is also confirmed by the confirmation of thrombus in a proximal lower-extremity vein.

LABORATORY FINDINGS

A low arterial P_{O_2} should raise suspicion of pulmonary embolus. D-Dimer assays have high negative predictive value for ruling out deep venous thrombosis and pulmonary embolism; their role in the postoperative setting needs further clarification as recent surgery can also elevate the D-dimer level, and false positives are likely.

RADIOGRAPH FINDINGS

Chest radiography frequently shows no abnormality, and changes may be delayed 24–48 hours. Its primary role is to rule out pneumonia. In approximately 15% of patients, a pulmonary density is present, which is in the periphery of the lung and roughly in the shape of a triangle with its base at the lung surface. Other possible findings are enlargement of the main pulmonary artery, small pleural effusion, and elevated diaphragm.

ELECTROCARDIOGRAPHY

The ECG may show characteristic changes of pulmonary embolism in one-third of cases. These changes include $S_1Q_3T_3$ patterns, right bundle-branch block, and T-wave inversion in leads V_1 through V_4 . The ECG is principally of use in ruling out myocardial infarction.

LUNG SCAN

The ventilation-perfusion (V/Q) scan was, until recently, the study of choice. Its use has largely been supplanted by spiral chest CT. The V/Q scan's main limitation is that it is frequently equivocal, although it still is useful in patients with allergy or a contraindication to contrast agents.

SPIRAL CHEST CT

Thin-section CT imaging of the chest with third-generation scanners has become the modality of choice for diagnosing pulmonary embolism. It frequently can visualize the emboli, as well as eliminate other diagnostic possibilities like pneumonia. High sensitivities and specificities have been reported.

ANGIOGRAPHY

Pulmonary angiography should be done in the rare instances when lower-extremity studies and spiral CT are nondiagnostic in a patient with high clinical suspicion. It is considered the "gold standard." It is invasive, with risks of catheter and contrast complications, and its use should be reserved for when noninvasive studies have been inadequate.

Treatment

Cardiopulmonary resuscitation measures should be instituted as necessary. Close monitoring is essential, as is treatment of acid–base abnormalities and shock. Because of the high mortality, patients with strong clinical suspicion of pulmonary embolism should be started immediately on heparin, and the heparin continued until the appropriate studies rule out the diagnosis. Management of anticoagulation follows the same procedure as for deep vein thrombosis. Goldhaber reviews current treatment in detail, as well as developing new alternatives.

Prevention

As discussed in Chapter 46, effective prophylactic measures exist, and should be routinely used. International consensus recommendations exist for prevention of venous thromboembolism and include specific recommendations for gynecologic surgery. Patients undergoing minor gynecologic surgery without risk factors may or may not receive prophylaxis. Patients at moderate and high risk (major surgery, age older than 40 years, use of oral contraceptives) should receive prophylaxis with intermittent pneumatic compression stockings or heparin.

PULMONARY COMPLICATIONS

Pulmonary Edema

Pulmonary edema is a serious complication that if improperly managed can be fatal. In general, it can be categorized as noncardiogenic and cardiogenic in origin. Noncardiogenic causes include diffuse pulmonary infection, aspiration, and shock, and can lead to the adult respiratory distress syndrome (ARDS). These etiologies are discussed elsewhere throughout this chapter and in other chapters.

Most postoperative pulmonary edema is cardiogenic in origin, resulting from congestive heart failure. This can be caused by fluid overload, as well as cardiac dysfunction from myocardial infarction or valvular disease such as mitral regurgitation. In many instances, it is likely a preventable complication resulting from less than full attention to fluid administration.

Pulmonary edema usually initially presents as mild tachypnea. An arterial blood gas will usually show decreased PO_2 and Pco_2 and increased alveolar–arterial gradient. These changes occur before physical or radiologic findings can be detected. If untreated, and the fluid content of the lungs further increases, symptoms worsen, blood gas parameters worsen, and the patient will develop physical findings of rales and chest radiograph findings of Kerley-B lines, development of a butterfly pattern, and opacities. At its worst, patients may have pink froth emerge from their mouth.

Strict monitoring of fluid balance may help prevent pulmonary edema. Patients suspected of having pulmonary edema should be diuresed, usually with furosemide. Patients being treated with furosemide also need careful monitoring of their potassium, and frequently need potassium supplementation. Patients with definitive signs of rales and radiographic findings should receive diuresis. Consideration should be given to diuretics in patients where there is a strong suspicion of pulmonary edema even in the absence of these findings, as patients can have early pulmonary edema prior to the development of these findings. Patients who have gone into pulmonary edema in the absence of volume overload, or who respond poorly to diuretics should be ruled out for myocardial infarction, and consideration given to echocardiography to check for valvular dysfunction.

Atelectasis

Atelectasis is largely an intraoperative problem, but can also occur during the postoperative period. It consists of areas of airway collapse and occurs because of diminished functional residual capacity in the supine position and splinting caused by pain from abdominal surgery. The blood that traverses the areas with atelectasis is not oxygenated, resulting in shunting and hypoxia. Massive atelectasis may occur when a mucus plug or aspirated vomitus occludes a large bronchus. Predisposing factors include chronic obstructive pulmonary disease, obesity, smoking, and general anesthesia. In the postoperative period, atelectasis can result in hypoxemia, and more importantly, prevention may decrease the incidence of other postoperative pulmonary complications, particularly pneumonia.

Clinical Findings

The clinical findings vary with the extent of atelectasis. Mild atelectasis is the most common cause of fever in the immediate postoperative period. As the patient begins ambulating and her secretions decrease, it usually resolves. On auscultation, the patient can have diminished breath sounds, particularly at the lung bases. They may also have areas of dullness to percussion, together with bronchial breathing and inspiratory rales. Chest radiograph findings include patchy opacities. Atelectasis and bronchopneumonia have a similar clinical picture, and may occur together.

Prevention

The prevention of postoperative atelectasis begins in the preoperative period. Patients should be

encouraged to stop smoking preoperatively. Patients with chronic lung disease should be given antibiotics and chest physical therapy if an acute or chronic infection is suspected. Bronchospasm should be treated with bronchodilators. Elective surgery should be postponed if upper respiratory infection is present.

Intraoperatively, the patient should be ventilated with adequate tidal volumes with the addition of positive end-expiratory pressure if signs of atelectasis such as decreasing oxygen saturation become apparent. Intraoperative atelectasis or small airway collapse is more commonly seen in patients with chronic lung disease or obesity and can be aggravated by the Trendelenburg position. Intraoperative humidification and suctioning of secretions are helpful.

Postoperatively, atelectasis is best avoided by minimizing pain, placing patients in the sitting position, and encouraging deep breathing and early ambulation. Incentive spirometry devices help patients to perform deep inspiration exercises. Patient-controlled analgesia or use of an epidural catheter for postoperative pain management can help by reducing respiratory depression.

Treatment

Treatment consists of intensive chest physical therapy and supplemental oxygen. Pain should be controlled because it is an obstacle to deep breathing. Patients should be monitored for pneumonia, for which they are at increased risk. In the rare instance of massive atelectasis, bronchoscopy can be used to manage mucous plugging. Very rarely, if there is inadequate tissue oxygenation, intubation and mechanical ventilation may be necessary.

Pneumonia

Postoperative pneumonia may follow atelectasis and is usually caused by aspiration of bacteria colonizing the oropharynx or upper gastrointestinal tract. Abundant tracheobronchial secretions from preexisting bronchitis also predispose to this complication. Other risk factors relevant to gynecologic surgery include obesity, age older than 70 years, chronic obstructive pulmonary disease, abdominal surgery, and smoking. Mortality rates as high as 10% have been suggested, particularly if sepsis ensues.

Fever in the first few postoperative days is usually from atelectasis. If it persists or is followed by higher temperatures, systemic toxicity, or respiratory difficulty, the patient may have pneumonia. Patients with pneumonia may have progressively worsening respiratory secretions and productive cough, although these symptoms can be masked if the patient's ability to cough is suppressed by medications or pain. Physical examination may reveal evidence of pulmonary consolidation, and numerous coarse rales are often present. Although the chest radiograph may show diffuse patchy infiltrates or lobar consolidation, this appearance may lag behind the clinical picture by as much as 24 hours.

The treatment of pneumonia includes deep breathing and coughing to mobilize secretions. The patient should be encouraged to change position frequently. Nasotracheal suction may be used to stimulate the cough reflex. Specific broad-spectrum antibiotic therapy should be instituted based on Gram stain and knowledge of pathogens specific to the institution, and revised as indicated by subsequent sputum culture and sensitivity tests. Induced sputum is more reliable as oral contamination of expectorated specimens occurs frequently. Positive-pressure ventilation may improve the depth of respiration and reduce the work of breathing in extremely ill patients.

A number of measures are supported by evidence and are suggested to decrease postoperative pneumonia, including the following:

Preoperative instruction, especially in patients with risk factors for postoperative pneumonia, in taking deep breaths and early ambulation.

Encouraging all postoperative patients to take deep breaths, move about the bed, and ambulate as soon

as medically safe.

Incentive spirometry for patients with risk factors for postoperative pneumonia.

Aspiration Pneumonitis

Aspiration pneumonitis is the acute lung injury that occurs after sterile gastric contents are inhaled into the lung. Essentially, gastric acid creates a chemical "burn" to the lung tissue. It occurs approximately once every 3000 surgeries where general anesthesia is used. It is responsible for 10–30% of anesthetic related deaths. It can also occur in patients whose gag reflex or ability to cough may be depressed, as in the immediate postoperative period. Risk factors include difficult intubations, passive regurgitation in the patient with an incompletely empty stomach, poor gastroesophageal sphincter tone in patients with hiatal hernia, inflation of the stomach with air, and pregnancy. Other risk factors include vomiting in patients with neurologic disease, sedation, and other causes of decreased gag reflex.

The chance of pulmonary aspiration at time of surgery can be minimized by:

1. Performing awake fiberoptic intubation on patients with predictably difficult airways.
2. Speeding the process of gastric emptying by intravenously administering metoclopramide 10 mg.
3. Increasing the pH of gastric contents by means of a nonparticulate antacid and use of H₂ blockers (this helps minimize pulmonary damage if aspiration does occur).
4. Using a rapid sequence induction with pentothal and cricoid pressure. Cricoid pressure closes off the esophagus to prevent passively regurgitated material from reaching the larynx. This pressure is maintained until the proper positioning of the tube in the trachea is verified.

Generally, a small amount of aspiration may be associated with mild atelectasis and cause temporary hypoxia. Some patients will have only arterial desaturation and radiologic findings without other symptoms. Other symptoms may include shortness of breath, wheezing, coughing, and pulmonary edema. More severe aspiration may lead to serious hypoxia requiring mechanical ventilation. Some patients will progress to ARDS (Chapter 60).

If known aspiration of gastric contents occurs during intubation, the upper airway should be suctioned. Prophylactic antibiotic use is not recommended, as gastric contents are usually sterile owing to the inhibition of bacterial growth by the elevated gastric pH. Broad-spectrum antibiotics should be considered in patients whose symptoms do not resolve after 48 hours. Routine corticosteroid administration is no longer recommended. Supportive measures, sometimes including mechanical ventilation, may be necessary.

Tension Pneumothorax

Tension pneumothorax is an uncommon complication and is most likely to occur during the first 24–48 hours after surgery. Pneumothorax can occur during positive-pressure ventilation and may not be apparent until the ventilation is stopped. Pneumothorax presents as acute respiratory distress with distant breath sounds on the affected side and frequently a marked mediastinal shift away from the affected side. The diagnosis is made by chest radiography. Immediate placement of a chest tube is essential; temporary improvement can be obtained by inserting one or more large-bore angiocatheters under local anesthesia through the intercostal space at approximately T6-T8 to allow escape of air until a chest tube can be inserted. Chest tube drainage is usually continued for several days, until the air leak has sealed.

Acute Respiratory Distress Syndrome

ARDS, a frequently catastrophic postoperative complication, is considered in Chapter 60.

GASTROINTESTINAL TRACT COMPLICATIONS

Gastrointestinal complications are most likely to occur after transabdominal operations, but they may also complicate vaginal procedures. Any serious illness or surgical procedure may cause malfunction of the gastrointestinal tract.

Ileus

Ileus is defined as transient impairment of bowel motility. Some degree of postoperative ileus occurs whenever the peritoneal cavity is entered. There does not appear to be any physiologic benefit to ileus as part of postoperative healing.

Clinical Findings

Ileus is characterized by decreased or absent bowel sounds, and can progress to include abdominal cramps and distention. Flatus and bowel movement are usually reassuring signs that ileus is resolving, but can occur with an ileus, reflecting incomplete return of bowel function. Some patients may have nausea and vomiting. On plain abdominal radiograph (kidneys, ureters, bladder), there is generalized dilatation and gaseous distention of both small and large bowels, although the small-bowel component may be more prominent.

Prevention

Holte and Kehlet present a number of strategies effective in decreasing postoperative ileus. In particular, opioid anesthetics clearly decrease bowel motility and may prolong an ileus. Strategies of minimizing opiates by using nonsteroidal anti-inflammatory drugs, or using postoperative epidural for pain relief have been shown effective in shortening the time to return of bowel function. Routine use of nasogastric intubation does not prevent ileus, and may lengthen hospitalization. Early ambulation is beneficial for many other reasons, but does not shorten the time to return of bowel function. They reviewed a number of studies on patients undergoing gynecologic surgery suggesting that rapid advancement of diet does not worsen ileus, and likely hastens return of bowel function. Early feeding may decrease ileus by stimulating overall gastrointestinal motility through initiation of propulsive reflexes and the secretion of intestinal hormones.

Treatment

If nausea, vomiting, or abdominal distention becomes severe, a nasogastric tube should be inserted into the stomach. Postoperative small bowel obstruction can present the same way, and should be ruled out by kidneys, ureters, bladderfilms. Electrolytes should be monitored and corrected in patients undergoing prolonged nasogastric suctioning. Enemas and suppositories are frequently used, but can obscure the diagnosis of a small-bowel obstruction by placing air and fluid in the rectum, and have not been proven effective. If the ileus is persistent, especially if accompanied by a febrile course, a retained foreign body should be considered, and can usually be ruled out by the same radiologic study. Urologic trauma with resultant extravasation of urine may be an unusual cause of persistent ileus, and can be diagnosed with an intravenous urogram.

Postoperative Intestinal Obstruction

Small-bowel obstruction may occur as a complication of any intraperitoneal operation. It most frequently occurs as a consequence of adhesion formation. Obstruction results when these adhesions trap or kink a segment of intestine. The resultant partial or complete bowel obstruction is usually noted between the fifth and sixth postoperative days; however, obstruction can occur sooner. Other causes include herniation through a laparoscopic trocar site, internal herniation, and inflammation, for instance from an intra-abdominal abscess. Most concerning is the risk that the involved bowel can strangulate. Delayed

small-bowel obstruction can also happen years after hysterectomy. Dense, fibrous adhesions develop after 8–12 weeks and can entrap bowel and cause delayed obstruction with a high incidence of bowel ischemia.

Clinical Findings

Obstruction is frequently characterized by abdominal pain, vomiting, distention, and obstipation. On examination, the bowel is distended. High-pitched bowel sounds heard on auscultation are noted to be synchronous with cramping pain. It is frequently difficult to differentiate from postoperative ileus. Obstruction should be suspected if the symptoms develop in a patient previously doing well, particularly if they were previously passing stool or flatus and are no longer doing so.

Diagnosis

Sajja and Schein review diagnostic modalities in their general review of early postoperative small-bowel obstruction. A plain abdominal radiograph usually reveals distention of a portion of the small bowel with air–fluid levels. In general, the colon is free of air. Upper gastrointestinal contrast studies can be used. If no contrast is visualized in the large bowel, obstruction is present. However, as contrast can pass through a partial obstruction, visualization of contrast in the large bowel does not eliminate the possibility. Gastrografin, a hyperosmolar agent, increases motility, and may help resolution of ileus or small-bowel obstruction. CT scan with oral contrast can differentiate ileus from small-bowel obstruction with a high degree of sensitivity and specificity, and can also detect other causes of obstruction including tumor, abscess, or hematoma.

Treatment

Small-bowel obstruction, with its risk of resultant bowel ischemia and infarction, is a serious complication requiring immediate intervention. It is frequently possible to treat postoperative bowel obstruction conservatively by bowel decompression with a nasogastric or long intestinal tube. Long intestinal tubes do not offer any advantage over nasogastric tubes unless they are properly placed, which generally requires fluoroscopic guidance. Tube decompression can result in realignment of the bowel and relief of the obstruction, or adhesions may relax or be released sufficiently to allow spontaneous decompression. If the obstruction does not respond to conservative management, or signs of bowel infarction occur, the patient will need to return to the operating room. Obstruction is associated with large fluid shifts into the bowel lumen, requiring vigorous hydration and careful electrolyte replacement. A special case is obstruction after laparoscopy. If herniation of bowel through a trocar site is suspected, early return to the operating room is warranted.

Constipation and Fecal Impaction

A reduction in the number of bowel movements is to be expected in the early postoperative period because of low food intake and ileus. In a postoperative patient with obstipation, where ileus and small-bowel obstruction are not suspected, a mild laxative (milk of magnesia, 30 mL orally) may be prescribed. A clear water enema or rectal bisacodyl suppository can also be used.

Fecal impaction can also cause diarrhea in the postoperative patient. If suspected, a digital rectal examination should be performed. If hard stool is encountered in the ampulla, the diagnosis of fecal impaction is verified. The condition is caused by limitation of oral fluids and is especially common in elderly patients and others confined to bed. It may be aggravated by previous gastrointestinal series or barium enema with accumulation of barium in the colon. The treatment of fecal impaction is digital disimpaction of the firm fecal masses after an oil-retention enema.

Diarrhea

Most postoperative diarrhea is likely related to antibiotic administration. Oral contrast agents can also cause diarrhea. Most antibiotic-related diarrhea is mild. Antibiotic administration alters the bacterial flora of the gastrointestinal tract. If overgrowth with *Clostridium difficile* occurs, a range of diseases may present, from asymptomatic colonization to mild diarrhea to pseudomembranous enterocolitis. This more significant complication may occur as a complication of any antibiotic administration, with penicillins and cephalosporins the most frequently implicated agents. This disease may be particularly devastating for the geriatric or debilitated patient.

Diagnosis

The diagnosis is made by detection of the *C. difficile* toxin in stool specimens. Enzyme immunoassays used in most labs are quite specific, but have false-negative rates of 10–20%. Pseudomembranous changes may be seen on colonoscopy.

Treatment

For any suspected antibiotic-related diarrhea, the patient should receive adequate rehydration with monitoring and repletion of electrolytes as necessary. When possible, the antibiotic should be discontinued, or changed to an antibiotic less likely to cause diarrhea. If *C. difficile* is detected or strongly suspected, oral metronidazole, 250 mg 4 times a day for 10 days, is the first-line therapy. Oral vancomycin, 125 mg every 6 hours for 10 days, is equally effective, but considerably more expensive. If the patient is unable to tolerate anything by mouth, only IV metronidazole is effective. Significant concentrations of vancomycin are not built up in the gastrointestinal tract if given intravenously. The infection is easily spread throughout hospitals, with up to 20% of hospitalized patients colonized after 1 week in the hospital. Once diagnosed, patients must be isolated and infection precautions initiated.

Fistulas

A full discussion of genital fistulas is beyond the scope of this chapter. Risk factors for fistulas after gynecologic surgery include malignancy, prior radiation therapy, intraoperative bowel, bladder, or ureteral injury, and obstetric trauma (eg, fourth-degree lacerations, breakdown of episiotomy repairs). Vesicovaginal, rectovaginal, and enterocutaneous fistulas are rare, but are the most commonly seen.

Vesicovaginal fistula should be suspected if the patient presents with a continuous watery discharge from the vagina. It can be diagnosed by direct observation or instillation of methylene blue into the bladder and placement of cotton balls or a tampon in the vagina. Discoloration of the cotton or tampon indicates a communication between bladder and vagina. Approximately 20% of fresh postoperative vesicovaginal fistulas will close spontaneously with prolonged catheter drainage. The remainder are usually repaired with a transvaginal surgical approach, which has a good success rate.

Rectovaginal fistulas occur after obstetric trauma or vaginal surgery. Primary transvaginal repair has an approximately 90% success of closure. Larger, recurrent, or irradiated defects may require diverting colostomy while the repair heals.

Enterocutaneous fistulas may present initially with wound erythema, followed by feculent drainage from the incision site. Treatment of enterocutaneous fistulas consists of keeping the patient from oral intake over a period of 2–4 weeks, supplementation with total parenteral nutrition, and nasogastric decompression. If spontaneous closure does not occur, surgical repair will be necessary.

URINARY TRACT COMPLICATIONS

Urinary Retention

Postoperative pain or surgery at the bladder neck can result in bladder dysfunction impairing bladder

emptying. Urinary retention should be considered if the patient is unable to void postoperatively or after urinary catheter removal. Most patients should be able to void by 4–6 hours after completion of minor surgery, or removal of the urinary catheter after a major case. The patient should be encouraged to get out of bed to void. If the normal capacity of the bladder is exceeded (500 mL) and the bladder overdistended, serious bladder dysfunction may result. Overdistention of the bladder can also occur in the patient with a kinked or clotted suprapubic tube or transurethral catheter.

Inability of the patient to void or difficulty in voiding often is a result of pain caused by using the voluntary muscles to start the urinary stream. With transvaginal procedures or bladder neck suspension procedures, sutures near the urethra or urethral edema may make voiding difficult or impossible. Occasionally retention after urinary incontinence procedures are caused by obstruction secondary to overcorrection of the bladder neck.

Treatment

The treatment for urinary retention is immediate bladder drainage with sterile catheterization. If more than 500 mL of urine is drained, the bladder muscle has likely lost tone, and 24–48 hours of continued drainage should be considered before another voiding trial. Decompression of the distended bladder can be complicated by hematuria, transient hypotension, and postobstructive diuresis. Patients with recurrent difficulties may have underlying urinary tract infections.

Prevention

After a major procedure in which postoperative bleeding or operative damage to the urinary tract is a possibility, bladder drainage by means of a urethral catheter or suprapubic cystostomy tube should be instituted despite the small risk of bladder infection. The catheter usually can be removed within 24–48 hours.

If prolonged drainage is required, intermittent self-catheterization or suprapubic drainage is preferable to transurethral catheter drainage because of increased patient comfort, ease of care, and a reduced incidence of infection. These modalities also may be useful in facilitating postoperative voiding trials after urogynecologic procedures. If a patient is facing a prolonged return to normal voiding function and has adequate visual acuity and manual dexterity, intermittent clean self-catheterization is the most attractive alternative.

Anxiety is thought to play a role in patients with difficulty voiding after surgery. Some providers believe benzodiazepines may be helpful in management due to both their anxiolytic and skeletal muscle-relaxant effects, although a recent randomized trial failed to show an effect.

Oliguria and Anuria

Oliguria is typically defined as urinary output of less than 30 mL/h. It usually results from intravascular volume depletion. Disturbances of electrolyte balance (eg, "water intoxication syndrome") or diminished renal blood flow (cardiac failure, shock) also can cause oliguria, as can volume overload causing congestive heart failure and pulmonary edema. After these possible causes of oliguria have been eliminated, an underlying serious disorder of the urinary tract should be considered.

Rarely, anuria may be caused by bilateral ureteral obstruction, a complication that must be considered when there is no urinary output on the operating table or during the immediate postoperative period. If an intravenous pyelogram (IVP) fails to reveal the cause of this serious postoperative complication, underlying kidney disease (eg, acute tubular necrosis) should be suspected.

Diagnosis

Patients with low or absent urine output should be evaluated immediately. Volume status since surgery

should be assessed by tallying and comparing fluids administered with total fluids lost (blood loss, urine output, and estimated insensible losses). Patients suspected of having fluid overload should be managed as in the pulmonary edema section above. Clinical signs suggestive of intravascular depletion can include tachycardia and hypotension, as well as dry mucous membranes and poor skin turgor. In patients who are suspected of being intravascularly depleted but whose calculated fluid intake and output appears balanced, there should be concern for continued blood loss. Patients can be diagnosed with an empiric trial of intravenous fluid challenge with 500–1000 mL of isotonic fluid. If there is concern regarding bleeding, hemoglobin and hematocrit should be checked immediately. They should also be checked if the patient fails to respond appropriately to the fluid challenge. Patients suspected of having bilateral ureteral injury should have an intravenous pyelogram.

Treatment

Major surgery predisposes to intravascular depletion, although most anesthesiologists will replace accordingly during the surgery. Prohibition of fluids before surgery, large insensible water losses during the operation, and inability to tolerate food or fluids postoperatively require major adjustments. Preoperative bowel preparations also cause large fluid losses.

In general, patients should initially have fluid administration that replaces their recognized and estimated insensible losses. This replacement must be individualized to the patient and her underlying medical issues. The healthy 28-year-old myomectomy patient will tolerate aggressive fluid replacement that could prove fatal to a frail 68-year-old patient with cardiopulmonary disease undergoing reconstructive vaginal surgery. Postoperative fluid replacement must be individualized, but in general, should maintain a urine output greater than 30 mL/h.

The composition of these fluids should address both electrolyte and glucose needs. Subsequent fluid requirements should be based on replacement of an average of 1000 mL of daily insensible water loss (higher in febrile patients) plus urinary output. A clinical estimate of the state of hydration can be made by noting the vital signs, urinary output, moistness of the mucous membranes, and skin turgor. If the patient is unable to take fluids orally in adequate amounts after 48 hours, potassium may need to be added to the intravenous fluids based on measurement of the serum electrolytes. If a complicated major procedure with substantial blood loss has been performed, blood product replacement will be necessary.

Patients who have abnormally low urine output despite being euvolemic may have underlying renal disease. In these patients, assessment of a urinalysis for casts to rule out acute tubular necrosis, as well as serial measurements of blood urea nitrogen (BUN) and creatinine are helpful. Consultation with a renal specialist can also be helpful.

Urinary Tract Infection

Urinary tract infection (UTI) may develop in the immediate postoperative period in any patient. Patients are at risk because of the urinary retention that follows surgery, anesthesia, or immobilization. The bladder usually is sterile before surgery and remains so unless bacteria are introduced by instrumentation or catheterization. Catheter-associated urinary tract infection is the most common nosocomial infection.

Although cystitis can cause frequency and dysuria, it should not cause fever. Pyelonephritis, however, can cause extremely high fever. UTI should be considered in the evaluation of any patient with postoperative fever. Clinical signs such as high fever and flank tenderness may be present. Patients with urosepsis may very rapidly become quite toxic. White blood cells and bacteria are seen on urinalysis. Postvoid residual urine, which is sometimes seen, tends to perpetuate the infection and predisposes to ascending infection and pyelonephritis.

Hydration should be increased and activity encouraged to facilitate complete emptying of the bladder. After urine specimens are obtained for culture, appropriate antibiotic therapy should be instituted. Antibiotic coverage may have to be adjusted based on culture and sensitivity results. Gram-negative organisms from the lower urogenital tract predominate. Reinstitution of catheter drainage may be necessary in patients with a postvoid residual urine of 100 mL or more, although, in general, discontinuing the catheter at the earliest possible time is useful for preventing and treating infection.

OTHER INFECTIOUS COMPLICATIONS

Hematoma and Pelvic Abscess

Small hematomas or seromas are frequent and usually resolve spontaneously, but some become infected. Insidious accumulations may occur either in the pelvis or under the fascia of the rectus abdominis muscles. They may first be suspected because of a falling hematocrit in association with a low-grade fever. Abscess should be considered in the postoperative patient with fever and no other source, particularly if they have not responded to initial antibiotic treatment for presumed cuff infection or endometritis. Hematoma may be suspected if there has been an unexpectedly large drop in hemoglobin levels postoperatively, or where there is significant unexplained postoperative pain.

Patients in whom hematoma or abscess is suspected should have an imaging procedure. Ultrasound is excellent for pelvic collections, but as patients can also have collections located in their abdomen, CT with contrast is usually the preferred method.

A collection under the rectus muscles, seen most frequently after a Pfannenstiel or Maylard incision or in conjunction with a retropubic urethropexy, may be difficult to outline clinically but can be clearly delineated by ultrasound.

Pelvic hematomas are not usually drained unless they fail to resolve on their own, or become infected. Some abscesses may respond to broad-spectrum antibiotic coverage, but many, especially large ones, will not resolve without drainage. If a posthysterectomy pelvic hematoma is easily accessible via the vaginal vault, it can often be managed by reopening the cuff. If an abscess is present this sometimes can be accomplished easily with finger or clamp, but may require a return to the operating room. Percutaneous drainage of intrapelvic and intra-abdominal collections are often possible via insertion of a large-caliber "pigtail" catheter under ultrasound or CT guidance. If percutaneous or transvaginal drainage is not possible and the abscess does not respond to antibiotics alone, the patient will usually need laparotomy with opening of the abscess, irrigation, and drain placement. In procedures at high risk for abscess or hematoma formation, many providers will place closed-suction drainage systems at the time of initial surgery.

Wound Infection

Risk factors for wound infection include the patient's age, health, nutritional status, and personal hygiene habits, as well as the presence of malignancy, history of smoking or diabetes, the use of corticosteroid medications, history of radiation therapy, and surgical technique. Active infection at the operative site (eg, pelvic abscess, ruptured appendix) or at a distant site will increase the risk of wound infection by direct contamination or hematogenous spread.

Appropriate preparation of the surgical site and prophylactic antibiotics are important preventative measures. Preoperative shaving of the operative site may cause microabscesses, resulting in increased risk of wound infection. Using clippers or omitting shaving entirely yields a lower wound infection rate. Extensive guidelines have been drafted by the CDC for prevention of surgical site infection. The use of antibiotic prophylaxis decreases infection risk with both abdominal and vaginal hysterectomy. Some

providers use subcutaneous drains to decrease postoperative wound disruption.

The diagnosis of wound infection is usually made during investigation of postoperative fever, often on about the fourth or fifth day. This diagnosis is based on the physical findings of redness, induration at the operative site, or purulent drainage. Facultative and anaerobic gram-negative rods, β -hemolytic streptococci, and staphylococci are the pathogens most commonly cultured from infected wounds. If an infected hematoma or seroma is present, the wound should be opened enough to allow easy packing. Antibiotics should be started if cellulitis is present. If the vaginal cuff has been opened or urogenital flora are suspected, then broad spectrum coverage is necessary. If cellulitis is not present, wound opening and local care are adequate therapy. Damp to dry dressings should be changed two to three times a day and the wound debrided daily until definite improvement is noted. Hydrogen peroxide, iodine compounds, antibiotics, or other chemicals in the wound-irrigating solution may be toxic or impede healing and should not be used. A drain or gauze packing may be required to keep the skin from prematurely sealing the wound. This should be continued until healing by secondary intention is complete. To decrease time to healing, secondary closure of wounds after all infection is resolved and healing has begun may be considered. Delayed primary closure can be considered for cases with obvious contamination or infection.

Wound Dehiscence and Evisceration

Rupture of transverse lower abdominal incision is quite rare, but can occur. Vertical incisions may carry a greater risk of breakdown. Risk factors for wound dehiscence and breakdown are similar to those for wound infections: age, nutritional status, diabetes, smoking, malignancy, steroid use, and presence of a prior scar at the incision site.

Evisceration is disruption of all layers of the abdominal wall with protrusion of the intestines through the incision; it is a life-threatening postoperative emergency. The hallmark of this complication is a profuse serosanguineous discharge exuding from the abdominal incision. Proper exploration and treatment of this problem should take place in the operating room and not on the ward or in the examining room. When the diagnosis of fascial dehiscence or evisceration is made, secondary closure must be performed immediately under general anesthesia. Interrupted nonabsorbable sutures through all layers of the abdominal wall are usually used. Broad-spectrum antibiotics should be initiated. When risk factors are present, consideration should be given to a mass closure technique at the time of initial surgery.

Necrotic Phenomena

Necrotizing fasciitis, a synergistic mixed facultative and anaerobic infection that involves the fascia and subcutaneous tissue, has been described in both abdominal and perineal sites and is extremely destructive and rapidly progressive. Despite early recognition, mortality is high. Group A streptococcus and anaerobes are important causes.

The skin near the incision site and surrounding area is usually cool, gray, and boggy. The patient usually appears floridly septic with fever and high white count. If necrotizing fasciitis is suspected, the patient should be brought to the operating room and fascial biopsy performed. If confirmed, radical debridement in the operating room is essential, followed by treatment with broad-spectrum antibiotics. Healing is usually by secondary intention with skin grafts often being necessary. This is a potentially lethal complication that requires timely intervention, and it should always be considered in the differential diagnosis when wound problems occur.

A second necrotic complication can result from a poorly planned incision. When a new incision is made near and parallel to an existing scar, sloughing of tissue secondary to ischemia can result. New incisions should either be made through the old incision, or at least several centimeters away to allow adequate blood supply for proper healing.

Current OB/GYN >Chapter 48. Therapeutic Gynecologic Procedures>

THERAPEUTIC GYNECOLOGIC PROCEDURES: INTRODUCTION

Four of the 10 most commonly performed operations in the United States are dilatation and curettage (D&C), tubal sterilization, abdominal hysterectomy, and vaginal hysterectomy. This chapter reviews these procedures, as well as other therapeutic operations. Indications, contraindications, technique, and complications are discussed for each procedure.

DILATATION AND CURETTAGE

Indications

The procedure of cervical dilatation and uterine curettage is usually performed for one of the following indications: diagnosis and treatment of abnormal uterine bleeding, management of abortion (incomplete, missed, or induced), tubal stenosis, or cancer of the uterus. The diagnosis of abnormal bleeding is discussed in Chapters 35 and 39; D&C a method of induced abortion is discussed in Chapter 36. This section discusses the remaining therapeutic uses of D&C.

Technique

CERVICAL DILATATION

Dilatation of the cervix may be conducted under paracervical, epidural, spinal, or general anesthesia, depending largely on the indication for the procedure. Cervical dilatation usually precedes uterine curettage but may be performed as a therapeutic maneuver for acquired or congenital cervical stenosis, dysmenorrhea, or insertion of an intrauterine contraceptive device (IUD) or radium device for treatment of cancer. Dilatation may also precede hystero-graphy or hysteroscopy.

The patient is placed in the dorsal lithotomy position, with the back and shoulders supported and the extremities padded. The inner thighs, perineum, and vagina are prepared as for any vaginal operation; the surgeon and assistant should adhere to surgical principles of asepsis. A thorough pelvic examination under anesthesia is mandatory prior to performing cervical dilatation, so as to determine the size and position of the cervix, uterus, adnexa and the presence of any abnormalities. The patient voids normally before the operation if possible; urinary catheterization is used only if significant residual urine is suspected.

A right-angle retractor is placed anteriorly to gently retract the bladder. A weighted speculum is placed posteriorly to reveal the cervix. Under direct vision, the anterior lip of the cervix is grasped with a tenaculum, avoiding the vascular supply at the 3 and 9 o'clock positions. The cervix is grasped firmly but with care taken not to compress or especially perforate the endocervical canal. With gentle traction, the cervix can be brought down toward the introitus. Before proceeding further, a complete visual examination should be made of the cervix and the four vaginal fornices, because the latter areas (especially posteriorly) are otherwise difficult to examine. Areas that appear abnormal (even benign inclusion cysts) should be noted and followed as appropriate. Areas that are clearly abnormal should be biopsied. After the cervix and vagina are evaluated, the uterine cavity is examined. A uterine sound is gently inserted into the endocervix and then advanced into the uterine cavity in the plane of least

resistance and most compatible with the position of the uterus as revealed by pelvic examination. The depth of the uterine cavity is recorded as well as any abnormalities such as leiomyomas or septa.

Perforation of the uterus during D&C is most likely to occur at the time of uterine sounding or cervical dilatation. According to two large classical studies, recognized uterine perforations during D&C occur at a rate of 0.63–1.0%. The majority of perforations are thought to be caused by misdirected or excessive force. Perforation is more likely to occur if the woman is postmenopausal (1 in 38), has cancer (1 in 48), or is postpregnancy (1 in 122). Other risk factors include having a retroverted or anteverted uterus or having cervical stenosis. Unless there is evidence of hemorrhage, injury to the bowel, or evulsion of the omentum, conservative treatment of uterine perforation is best. If severe cervical stenosis is suspected from the preoperative office examination, cervical softening agents such as misoprostol or *Laminaria* tents may be used. Both oral and vaginal misoprostol and laminaria tents have demonstrated a benefit over placebo in the ease of cervical dilatation in pregnant and premenopausal women. Preoperative vaginal and oral misoprostol do not reduce the need for cervical dilatation prior to diagnostic hysteroscopy or D&C in postmenopausal women. However, oral misoprostol does increase the ease of cervical dilatation prior to operative hysteroscopy in both postmenopausal women and in those who have been pretreated with gonadotropin-releasing hormone analogue. The most common dilators used are the Hegar, Pratt, and Hanks dilators. Hegar dilators are relatively blunt, gently curved, and numbered sequentially according to width (ie, a No. 9 dilator is 7 mm wide). For most purposes, particularly preceding curettage, dilatation to a No. 9 dilator suffices; if dilatation is being performed for dysmenorrhea, infertility, or stenosis, dilatation should proceed to a No. 11 dilator. Pratt and Hanks dilators differ from Hegar dilators in being more gradually tapered ("sharper"); they may have a solid core (Pratt) or a hollow center (Hanks), allowing egress of trapped blood and air. Pratt or Hanks dilators are measured in French sizes (a No. 20F Hanks dilator is approximately the same diameter as a No. 9 Hegar dilator). The choice of dilator is largely based on surgical training; many prefer not to use the more pointed Hanks dilator in a small postmenopausal uterus.

ENDOCERVICAL CURETTAGE

Fractional curettage should be used for abnormal uterine bleeding or if genital tract neoplasia is suspected. The cervical canal should be curetted prior to dilatation of the cervix and curettage of the endometrial cavity, so as to preserve the histologic characteristics of the endocervix and prevent contamination of the endometrial sample with endocervical cells. If cervical conization is planned for diagnosis or treatment of cervical intraepithelial neoplasia, uterine sounding precedes conization, but cervical dilatation and fractional curettage follow in order to minimize denuding of the endocervical epithelium. The Gusberg curet is a small, slightly curved instrument that is particularly well suited for endocervical curettage. The curet is placed in the endocervical canal to the level of the internal os; with a firm touch, each of the four walls is curetted with a single stroke, with the specimen delivered onto a coated cellulose sponge with a twirling motion of the curet. (The coated cellulose sponge is preferred over ordinary surgical sponges because tissue is less likely to adhere to it.) The cervix is then dilated as described earlier and curettage of the endometrium performed. The endocervical and endometrial specimens are immersed in fixative in separate containers and submitted to the pathologist.

Complications from endocervical curettage are rare in nongravid patients. Because of obvious risks to the fetus and membranes, endocervical curettage is contraindicated in pregnant women. Healing of the curetted endocervix may take 3 weeks or more; the cervical epithelium commonly takes 2 weeks to heal following a routine Papanicolaou smear. Tissue should be allowed to heal before follow-up Papanicolaou smears are taken, because regenerating cells are often mistaken for dysplastic cells.

ENDOMETRIAL POLYPECTOMY

The uterine cavity is explored with polyp forceps prior to diagnostic or therapeutic endometrial curettage. It is essential to remove polyps prior to curettage, preserving the histologic integrity necessary to differentiate benign uterine polyps from neoplasia. In a large series advocating routine exploration of the endometrial cavity preceding

curettage, 64% of 130 diagnosed endometrial polyps were removed by ureteral stone forceps. Twenty-five percent of the polyps were removed before curettage and 39% were removed after curettage, illustrating how difficult it is to remove polyps via curettage alone. Pedunculated or submucous leiomyomas, intrauterine and intracervical synechia, and uterine anomalies may be first suspected at passage of the polyp forceps.

The technique of polypectomy includes gentle insertion of the forceps in the plane most compatible with the position of the uterus (as for uterine sounding). The forceps are opened slightly, rotated 90 degrees, and removed. Many clinicians repeat this procedure through 360 degrees, completely exploring the uterine cavity.

Skillful use of hysteroscopy for diagnosis and treatment of synechia, septa, leiomyomas, and polyps is preferred blind polypectomy and curettage. With the new, narrow hysteroscope, the procedure is easily done as an office procedure similar to colposcopy for biopsy or laser conization.

ENDOMETRIAL CURETTAGE

Endometrial curettage is often both diagnostic and therapeutic. It is indicated for treatment of complications of pregnancy, including incomplete or missed abortion, postpartum retention of products of conception, and placental polyps. The procedure is also useful to stop the acute bleeding in women with menorrhagia who are hypovolemic. D&C should not be used to treat dysfunctional uterine bleeding in women without hypovolemia, because it has no effect on mean blood loss in subsequent periods (with the exception of the first period following the D&C) and is inferior to medical management. D&C is inferior to hysteroscopy in diagnosing and treating abnormal uterine bleeding caused by uterine fibroids or endometrial polyps. It is contraindicated in infection, such as acute endometritis, salpingitis, and pyometra. If infected placental tissue must be removed, the D&C should follow a period of parenteral antibiotics. The technique of endometrial curettage is tailored to the individual patient. In determining the hormone responsiveness of the endometrium, a small but representative sample may be obtained from the anterior and posterior walls. When curettage is being performed therapeutically, a systematic, thorough approach is indicated. The largest sharp curet that can comfortably fit through the dilated cervix is chosen. A serrated curet may cause injury to the underlying basalis layer of the endometrium and myometrium. The anterior, lateral, and posterior walls are scraped with firm pressure in a clockwise or counterclockwise fashion from the top of the uterine fundus down to the internal os. The top of the cavity is curetted with a side-to-side motion. The curettings are retrieved onto the waiting gauze and immersed in fixative as soon as possible. If endometrial curettage is being used for diagnosis of infection (eg, tuberculous endometritis), a portion of the curettings should be placed in containers appropriate for culture (without fixative).

A single curettage will not remove the entire endometrium. Thorough curettage by an experienced gynecologist often removes 50–60% of the endometrium, as determined by immediate postcurettage hysterectomy. If risk factors for endometrial cancer are present and clinical suspicion for neoplasia persists despite a histologic diagnosis of benign endometrium, further evaluation with hysteroscopically guided biopsy or hysterectomy is indicated.

Perforation of the uterus occurred in 0.63% of a large series of D&Cs. Perforation is suspected when the sound curet meets no resistance at the point expected by uterine size, consistency, and position determined by preoperative bimanual examination. Curettage may be continued if the area of suspected perforation is avoided. Should suction curettage be associated with perforation, laparoscopy must be used to continue the procedure to avoid aspiration of bowel into the uterine cavity. In the case of suspected perforation, the patient should be observed for at least 24 hours in the hospital for possible infection or hemorrhage. In a series of 70 uterine perforations, 55 were treated expectantly, and only 1 patient developed complications (pelvic abscess drained via colpotomy). In 7 patients, hysterectomy was elected but not indicated by operative findings. Today, laparoscopy is the method of choice for evaluating perforations in the hemodynamically stable patient.

ENDOMETRIAL BIOPSY

Outpatient curettage, or endometrial biopsy, should always be a diagnostic and not a therapeutic technique. The many techniques available, all compared to D&C under adequate anesthesia, are discussed in Chapter 33.

HYSTEROSCOPY

This section discusses the therapeutic uses of hysteroscopy.

Indications & Contraindications

See Table 48–1.

Table 48–1. Indications and Contraindications for Hysteroscopy.

Evaluation and treatment of abnormal uterine bleeding

Absolute contraindications

Premenopausal/postmenopausal bleeding with negative D&C.

Directed biopsy in patient with atypical adenomatous hyperplasia but at high risk for hysterectomy.

Evaluation of endocervix versus endometrium as origin of biopsy–proved adenocarcinoma.

Suspicion (on history or hystero-graphy) of uterine polyp or submucous leiomyoma amenable to hysteroscopic resection.

Evaluation and treatment of infertility

Habitual abortion.

Known uterine septum on previous hystero-graphy or curettage.

Suspected foreign body (eg, broken or imbedded IUD).

Suspected submucous leiomyoma on history, pelvic examination, or laparoscopy.

Suspected cornual occlusion on hystero-graphy.

Suspected intracervical, intrauterine, or intracornual adhesions.

Suspected congenital anomaly (eg, with known urologic anomaly).

Possible intrauterine infection (eg, tuberculosis).

Intrauterine insemination or embryo transfer in selected patients with known uterine fusion anomaly.

Suspected endometrial polyp.

Pelvic inflammatory disease, especially tubo–ovarian complex.

Uterine perforation.

Sensitivity to anesthetic or distention medium.

Lack of proper equipment, specifically, low–pressure insufflator for CO₂ distention.

Operator inexperience.

Relative contraindications

Heavy bleeding limiting visual field.

Known gynecologic cancer, especially endometrial, cervical, tubal, and ovarian, because of theoretic risk of flush cancer cells into the peritoneal cavity.

Indications	Contraindications
-------------	-------------------

Technique

The hysteroscope is a rigid endoscope similar in design to an operating laparoscope or a urologic resectoscope. Typically 6–10 mm in external diameter, the outer sleeve encloses a fiberoptic light source, a channel used to

introduce a medium to distend the uterus, and a channel through which probes, forceps, and electrocautery or laparoscopic instruments may be visually directed in the uterine cavity. Viewing angles vary from 10 to 45 degrees.

The uterine cavity, which is normally collapsed, must be distended by a medium: dextran-70, CO₂, sodium lactated Ringer's solution, glycine, mannitol, or sorbitol. Two disadvantages to the use of electrolyte solutions such as sodium chloride and lactated Ringer's solution are mixing of blood, which limits visualization, and the inability to use electrocautery because these solutions are electroconductors. Consequently, they should only be used for diagnostic, not operative, hysteroscopy. Pressure no greater than 100 mm Hg is required to achieve adequate uterine distention. Instillation of high-viscosity dextran can be done via a 50-mL syringe attached to the hysteroscope. The advantage of using dextran is that it is immiscible with blood, which allows for clear visualization in the presence of bleeding. However, dextran can cause rare but serious complications, including anaphylactic reactions, fluid overload, pulmonary edema, and coagulopathy. The manufacturer recommends that the patient be followed closely for pulmonary edema if the procedure lasts longer than 45 minutes, more than 250 mL of dextran 70 is absorbed, large areas of endometrium were resected, or intravenous fluids were administered at more than maintenance rate. If pulmonary edema develops, the patient may need plasmapheresis, because dextran-70 contains mainly high-molecular-weight molecules that are excreted slowly—or not at all—from the kidneys. CO₂ insufflation is favored by some gynecologic surgeons for both office and outpatient hysteroscopy. The addition of a cervical suction cup to prevent leakage has lost favor. The average flow rate needed to distend the uterus is 60 mL/min, and to avoid uterine injury or gas embolism, the maximum flow rate should not exceed 100 mL/min; therefore, laparoscopic insufflators must never be connected to a hysteroscope. The advantages of CO₂ gas over dextran are easier cleaning of instruments and improved comfort for the surgeon. A disadvantage is more difficult visualization because of mixing with blood or debris.

An increasing number of instruments are available for use in hysteroscopic procedures, including blunt probes, microscissors, alligator clamps with electrocautery attachment, rollerball electrode, and a wire loop for excision and electrocautery (resectoscope). The argon laser is useful for lysing septa, and the neodymium:YAG (yttrium, aluminum garnet) laser is available for polyp and myoma removal and endometrial ablation (Table 48–2).

Local or general anesthetics are chosen on the basis of expected hysteroscopic findings or procedures, concomitant operations planned, and the desires and cooperation of the patient. Most hysteroscopic examinations and virtually all therapeutic procedures are performed under general anesthesia. Following administration of anesthesia, the urinary bladder is drained, and the anterior lip of the cervix is grasped with a tenaculum. The cervix should then gradually dilated to the same diameter as the external sleeve of the hysteroscope so as to provide a snug fit. Concomitant laparoscopy is an option in any patient in whom a hysteroscopic therapeutic procedure is planned. Uterine perforation may be observed through the laparoscope, and excess distending media may be aspirated from the posterior cul-de-sac after a prolonged procedure.

An assistant must be constantly present during hysteroscopy to monitor uterine insufflation so that the pressure never exceeds 100 mm Hg, and the flow rate of the distending medium never exceeds 100 mL/min. The chance of fluid overload is markedly increased when the mean infusion pressure exceeds the mean arterial pressure. The lowest infusion pressure needed to obtain good visualization, should be used. The surgeon must be sitting comfortably, with all instruments available to perform the hysteroscopic procedure safely and expeditiously. Following the procedure, intrauterine instruments should be inspected for their integrity. The microscissors, in particular, are delicate and could break within the uterus. If dextran is used, it must be immediately flushed from the hysteroscope before it is allowed to dry.

Complications

Hysteroscopic surgery is generally safe in experienced hands. With laparoscopic observation, the serious complication of uterine perforation can almost always be prevented. If overt bleeding occurs during resection of septum, polyp, or leiomyoma, the laparoscopic probe can be held against the uterine vessels to slow the blood flow. A Foley catheter may be inserted into the uterine cavity and inflated to provide a tamponade for heavy endometrial bleeding. Infection is an unusual complication following hysteroscopy, and prophylactic antibiotics are not recommended. Complications of distending media include hyponatremia and pulmonary edema if an excessive amount results in vascular intravasation. The procedure should be expedited and electrolytes should be checked if the fluid deficit exceeds 1 L. When the fluid deficit reaches 1500 mL or the serum sodium is less than 125 mmol/L, the procedure must be terminated. These risks can be prevented with close monitoring of fluid use intraoperatively.

Prognosis

With proper selection of patients, hysteroscopic surgery has high success rates. Small pedunculated leiomyomas and polyps are usually retrieved by an experienced, patient surgeon. Submucous leiomyomas may be destroyed if they are not too vascular. In the treatment of intrauterine adhesions, the chance for success and restoration of a normal endometrial cavity depends on the density and extent of the adhesions and the area of normal endometrium remaining after dissection.

Following hysteroscopic surgery for infertility in which the endometrium is denuded, many physicians prescribe postoperative estrogen therapy to promote rapid endometrial growth.

LAPAROSCOPY

Laparoscopy is a transperitoneal endoscopic technique that provides excellent visualization of the pelvic structures and often permits the diagnosis and management of gynecologic disorders without laparotomy.

Most basic laparoscopes are 4–12 mm in diameter and have a 180-degree viewing angle. The instrument has an effective length of over 25 cm and can be utilized with a fiberoptic light box. In order to facilitate visualization, CO₂ must be instilled into the peritoneal cavity to distend the abdominal wall.

Use of a pneumatic insufflator permits continuous monitoring of the rate, pressure, and volume of the gas used in inflation. In addition to the equipment used for observation, a variety of other instruments for resection, biopsy, coagulation, aspiration, and manipulation can be passed through separate cannulas or inserted through the same cannula as the laparoscope. A laser (CO₂ or Nd:YAG) may be used with the laparoscope.

Although the laparoscope is an invaluable tool in both diagnostic and operative gynecologic procedures, its use requires considerable expertise, and it should always be used by a surgeon familiar with the management of complications. Laparoscopic procedures are *major* intra-abdominal operations performed through small incisions. This technique is rapidly performed and has a low morbidity rate and a short convalescence period. In many cases laparoscopy may replace conventional laparotomy for diagnosis and treatment of gynecologic problems. It is a cost-effective outpatient procedure.

Indications

The indications will increase with the clinician's experience and as technical innovations permit even more complicated procedures.

DIAGNOSIS

1. Differentiation between ovarian, tubal, and uterine masses, eg, ectopic pregnancy, ovarian cyst, salpingitis, myomas, endometriosis, and tuberculosis.
2. Pelvic pain, eg, possible adhesions, endometriosis, ectopic pregnancy, twisted or bleeding ovarian cyst, salpingitis, appendicitis, and nongynecologic pelvic pain.
3. Genital anomalies, eg, ovarian dysgenesis, uterine maldevelopment.
4. Ascites, eg, ovarian diseases versus cirrhosis.
5. Secondary amenorrhea of possible ovarian origin, eg, polycystic ovarian syndrome, arrhenoblastoma.
6. Pelvic injuries after penetrating or nonpenetrating abdominal trauma.
7. Staging of Hodgkin's disease and lymphomas.
8. Diagnosis of occult cancer.

EVALUATION

1. Infertility, eg, tubal patency, ovarian biopsy.
2. "Second look" after tubal surgery or treatment of endometriosis.
3. Assessment of pelvic and abdominal trauma.
4. Appraisal of bowel for viability after surgery, for mesenteric thrombosis.
5. Study of pelvic nodes after lymphography.
6. Peritoneal washings for cytology study.
7. Peritoneal culture.
8. Evaluation of uterine perforation.
9. Evaluation of pelvic viscera to determine the feasibility of vaginal hysterectomy.

THERAPY

1. Tubal sterilization:
 - a. Electrical: unipolar or bipolar technique.
 - b. Mechanical: Silastic bands, Silastic rings, or metal clips.

2. Lysis of adhesions, with or without laser.
3. Fulguration of endometriosis by laser or thermal cautery.
4. Aspiration of small unilocular ovarian cyst or of fluid for culture.
5. Removal of extruded intrauterine device.
6. Uterosacral ligament division (denervation).
7. Treatment of ectopic pregnancy.
8. Myomectomy.
9. Salpingostomy for phimotic fimbriae.
10. Removal of tuboplastic hoods or splints.
11. Ova collection for in vitro fertilization.
12. GIFT (gamete intrafallopian transfer for fertilization).
13. Mini-wedge resection of ovary.
14. Biopsy of tumor, liver, ovary, spleen, omentum, etc.
15. Placement of intraperitoneal clips as markers for radiotherapy.
16. Oophorectomy.
17. Ovarian cystectomy.
18. Laparoscopic-assisted vaginal hysterectomy, laparoscopic subtotal hysterectomy, and laparoscopic hysterectomy.
19. Reconstructive surgery for pelvic organ prolapse and urinary incontinence.

Contraindications

ABSOLUTE

Intestinal obstruction, generalized peritonitis, massive hemorrhage.

RELATIVE

Severe cardiac or pulmonary disease, previous periumbilical surgery, shock, cancer involving anterior abdominal wall.

Additional factors weighing against performing laparoscopic surgery include extremes of weight, intrauterine pregnancy after the first or early second trimester, presence of a large mass, inflammatory bowel disease, and known severe intraperitoneal adhesions.

Preparation for Laparoscopy

Careful explanation of the contemplated procedure must be given to each patient prior to surgery. Unless the individual is a poor operative risk, laparoscopy is usually an outpatient operation. Preparation includes no solid food for at least 8 hours prior to surgery, no liquids for more than 6 hours preoperatively, a history and physical examination, and routine blood studies. Abdominal or perineal shaving is usually unnecessary, but skin preparation with an antiseptic is routine.

Anesthesia

Local anesthesia, local anesthesia with systemic analgesia, spinal or epidural block techniques, or general anesthesia with or without endotracheal intubation may be used. Special hazards of anesthesia exist, eg, reduced diaphragmatic excursion because of the pneumoperitoneum and because the patient may be operated on in the Trendelenburg position. Because of these factors, most procedures in the United States are performed with the patient under general anesthesia with endotracheal intubation. With adequate understanding of the physiology involved, effective anesthesia and laparoscopy can be accomplished safely.

An alternative to general anesthesia is local anesthesia with intravenous sedation. The patient may experience transient discomfort during manipulation of the uterine tubes, but in selected patients this discomfort is easily tolerated.

Surgical Technique

The patient should be placed with her arms at her sides in the dorsal lithotomy position and draped after induction of anesthesia and preparation of the abdomen and pelvic area. The video monitor should be placed in a position that allows for easy viewing by the surgeon, usually at the patient's feet or side. The bladder must be emptied by catheterization to decrease the risk of injury during subsequent introduction and use of other instruments. After careful bimanual examination, a tenaculum is attached to the cervix, and a uterine manipulator (eg, olive-tipped Hasson, Harris-Kronner uterine manipulator-injector [HUMI], Hulka) is placed into the cervical canal to elevate the uterus, which places tissue on tension. A 1-cm incision is made within or immediately below the umbilicus. The peritoneal cavity can be entered blindly with a Veress needle or a trocar-cannula system, or under direct visualization via a mini-laparotomy called "open laparoscopy." Direct insertion of a cannula-trocar system can be accomplished safely if there have been no previous peritonitis or abdominopelvic surgeries. Open laparoscopy minimizes the risk of vascular injuries, but does not eliminate intestinal injuries. Carbon dioxide should then be introduced and monitored by the pneumatic insufflator. The amount of gas insufflated will vary with the patient's size, the laxity of the abdominal wall, and the planned procedure. In most patients, 2–3 L of gas will be needed to obtain adequate visualization. The maximum insufflation pressure should not exceed 15 mm Hg. If a Veress needle is used, it is withdrawn and the laparoscopic trocar and cannula inserted. After proper abdominal entry, the trocar may be withdrawn and replaced with the fiberoptic laparoscope. The examiner manipulates the intrauterine cannula so that the pelvic organs can be observed. To test for tubal patency, methylene blue or indigo carmine solution can be injected through the intrauterine cannula. Direct observation of dye leakage attests to tubal patency. A second trocar with a cannula may be inserted under direct laparoscopic vision through a 5-mm transverse midline incision at the pubic hairline. Additional punctures are used as necessary for the placement of other instruments. A num-

of instruments are available, including irrigators, the harmonic scalpel, forceps, scissors, and staple applicators. Surgical knots may be tied and sutures placed using specially made equipment.

The operation is terminated by evacuating the insufflated gas through the cannula, followed by removal of all instruments and closure of the incisions. The skin can be closed with 3-0 subcuticular suture, skin glue or Steri-Strips. Incisions greater than 10 mm require fascial closure to avoid incisional hernias. A small dressing is applied to the wound. In uncomplicated cases involving diagnosis only, operating time is about 10 minutes.

STERILIZATION

Electrical cautery, Silastic rings or bands, and metal spring clips achieve sterilization by occluding the uterine tube. The advantages or disadvantages of the different techniques are of less significance than the skill with which a physician can perform a particular technique; therefore, choice of method should depend on which technique is most comfortable for the physician. The failure rate of most sterilization methods is greater in women younger than 28 years old.

Cautery

Laparoscopic sterilization with electrical cautery is one of the most common laparoscopic sterilization methods. Although unipolar coagulation has a significantly lower pregnancy rate than bipolar coagulation (7.5 per 1000 vs 24.8 per 1000 over 10 years), bipolar coagulation is less likely to cause injury to adjacent structures (eg, bowel). Excessive tubal destruction is associated with an unacceptably high incidence of ectopic pregnancy, as it may create a tiny fistula from the uterus into the peritoneal cavity through which sperm may travel. Thus when using either form (unipolar or bipolar) of electrical coagulation, one should destroy only a short section of the midportion of the uterine tube, avoiding the uterine cornu if possible. Generally, the tube is burned at two to three different locations, and division of the tube by cutting is not necessary.

Silastic Bands

Tubal occlusion with Silastic bands or rings results in a slightly higher pregnancy rate (17.7 per 1000 over 10 years) but fewer ectopic pregnancies. Mechanical problems in placement of the bands and bleeding from the tubes during the procedure are more common.

Clips

Tubal occlusion with clips (Hulka or Filshie clips) have a wide range of failure. Failure rates are higher for the Hulka clip (36.5 per 1000 over 10 years) than for the Filshie clip (0–4 per 1000 over 6–10 years). The advantages of clips are that only a small portion of the tube is damaged (thus increasing the chance of successful sterilization reversal if the patient has regret) and that inadvertent burn injury to the bowel is avoided.

Interval Partial Salpingectomy

Compared to postpartum tubal ligation, interval partial salpingectomy has a higher failure rate of 20.1 per 1000 over 10 years.

INFERTILITY

In procedures of sterilization reversal, laparoscopic visualization may be needed prior to reanastomosis, particularly if the ligation procedure involved electrocautery. Peritubal adhesions may be lysed with electric scissors, and salpingostomy may be accomplished. The minimal trauma of these procedures using laparoscopy and the saving of a major operative procedure are obvious benefits. Laparoscopy should be considered for women with complaints of abnormal bleeding and unexplained pelvic pain. More liberal use of the laparoscope has led to the diagnosis of many unsuspected cases of endometriosis.

Electrical fulguration of areas of endometriosis or laser destruction of these diseased areas by laparoscopy is a safe, effective, and rapid treatment. The use of laser obviously allows implants on structures such as bowel, bladder, and the fallopian tubes to be treated with a fairly wide margin of safety. Relief may be immediate and striking, whether the woman has complained of dysmenorrhea, dyspareunia, or generalized pelvic pain. Among infertile patients v

lesser stages of endometriosis, pregnancy rates are similar to those in other published studies of treatment with danazol.

In infertility, the laparoscope has been important for ova collection for in vitro fertilization, GIFT, and other procedures. However, it is used less frequently now, as most egg retrievals for in vitro fertilization are performed under ultrasound guidance.

ECTOPI C PREGNANCY

In hemodynamically stable patients, laparoscopic linear salpingostomy is the preferred method for conservative management of tubal pregnancies. According to a recent Cochrane Database Systematic Review, the laparoscopic approach is less successful than the open approach in the elimination of tubal pregnancy as a cause of the high rate of persistent trophoblast tissue. However, it is feasible in virtually all patients, is safe, and is less costly compared to the open approach. Long-term follow-up shows a comparable intrauterine pregnancy rate and a low repeat ectopic pregnancy rate. Persistent trophoblast tissue after laparoscopic salpingostomy can be significantly reduced after a prophylactic single dose of systemic methotrexate. An alternative conservative approach for those who meet the criteria is methotrexate administration.

LAPAROSCOPIC HYSTERECTOMY

Laparoscopy can be used for total laparoscopic hysterectomy (LH), laparoscopic-assisted vaginal hysterectomy (LAVH), and laparoscopic subtotal hysterectomy (LSH; see section on Hysterectomy). Other procedures that can be done via the laparoscope include vault suspension and pelvic reconstruction such as retropubic Burch colposuspension and abdominal sacral colpopexy.

ABDOMINAL AND PELVIC PAIN

Laparoscopy has proved invaluable in differentiating various causes of acute and chronic pain. The technique may save the patient the necessity of a major exploratory operation. Fluid aspiration and tissue biopsy are possible through laparoscopy. Also, pelvic and intestinal disease can be differentiated. The appendix may be visualized and acute appendicitis may be diagnosed. Numerous cases of pain caused by intra-abdominal adhesions also have been diagnosed by laparoscopy, and relief has been obtained following laparoscopic adhesion resection.

TRAUMA

In cases of intra-abdominal trauma, laparoscopy can be used to exclude the need for a major abdominal operation.

MISCELLANEOUS

"Missing" IUDs have been removed from the intra-abdominal cavity. Mulligan plastic hoods from tuboplasty procedures, "lost" drains, and other foreign material have been removed from the abdomen by operative laparoscopy.

Postsurgical Care

Patients may be sent home following full recovery from anesthesia, usually in 1–2 hours. Recovery from more extensive procedures such as LH may require a longer hospital stay of 1–2 days. Postoperative pain is usually minimal, and patients are discharged with a prescription for a simple oral analgesic. The most common complaint is shoulder pain secondary to subdiaphragmatic accumulation of gas. Patients are encouraged to resume full activities except for sexual relations, the day following surgery. Sexual relations may be resumed several days postoperatively after a simple procedure, eg, tubal ligation. Following extensive operative laparoscopy or other gynecologic procedures, coitus should be delayed for an appropriate interval, ie, until it is unlikely to cause discomfort or damage to the operative site. Patients should routinely be seen in the office 1–2 weeks postoperatively.

Complications

A review of the world experience of laparoscopic gynecologic operations, including 1,549,360 patients, showed a

overall complication rate ranging from 0.2–10.3%. Higher complications rates were noted with prospective studies. The frequency of complications was less for nonoperative or minor procedures (0.06–7.0%) than for major operations (0.6–18%). Complications requiring conversion to laparotomy has been estimated to be 2.1% and is most commonly due to major vascular and intestinal injuries. The readmission rate to the hospital has been quoted to be 0.4–0.5%. The mortality rate for laparoscopy including 1,374,827 patients is 4.4 per 100,000 laparoscopies. The major causes of death are due to intestinal and vascular complications, and due to anesthesia.

VASCULAR INJURIES

Major vascular injuries are infrequent (0.04–0.1%), and are almost five times more frequent during blind entry during the laparoscopic operation itself. Catastrophic bleeding can occur if the aorta, the inferior vena cava, the common, internal and external iliac arteries and veins are injured. The mortality rate as a consequence of major vascular injuries is between 9% and 17%, and immediate conversion to laparotomy is almost always needed. Massive bleeding is often concealed in large retroperitoneal hematomas, and often only small amounts of intraperitoneal bleeding is seen. Open laparoscopic technique minimizes the risk of major vascular injury, but an injury has been reported in thin patients caused by the scalpel during the incision. The incidence of abdominal wall bleeding is 0.5%, and most injuries involve the inferior epigastric vessels (deep and superficial) and muscular vessels. Major bleeding requiring transfusion has been observed. The inferior epigastric vessels run in the lateral umbilical ligaments, and contrary to common belief, the inferior epigastric vessels cannot be seen via transillumination by the laparoscope. They are best avoided by placing the trocars lateral to the insertion of the round ligament into the anterior abdominal wall or 1–2 cm lateral to McBurney's point (one-third the way between the anterior superior iliac spine and the umbilicus).

INTESTINAL INJURY

Bowel injuries are uncommon (0.06–0.5%), but have a mortality rate of 2.5–5%. The colon and small bowel are injured at about the same rate, and they can be injured sharply or via thermal burns. About one third are related to entry and the rest are caused by operative procedures. Unfortunately, most bowel injuries are not recognized intraoperatively (mean 4.4 postoperative days), likely as a result of most patients with laparoscopic intestinal injury not presenting with the typical clinical signs of bowel perforation. Most patients present with low-grade fever, leukopenia, or normal leukocyte count. In a review of 266 cases of intestinal injury, pain at the trocar site near the injury, abdominal distention, and diarrhea with normal bowel sounds were commonly seen, but peritoneal signs, severe pain, nausea, vomiting and ileus were uncommon. Open laparoscopy has a similar rate of bowel injuries, they are recognized more commonly intraoperatively.

URINARY INJURIES

Urinary injuries during laparoscopy have a similar rate to open procedures (0.02–1.7%). Bladder injuries are more common than ureteral injuries and are recognized more frequently intraoperatively. About two-thirds of urinary injuries occur during laparoscopic-assisted vaginal hysterectomy.

HERNIA AT SITE OF ABDOMINAL WALL TROCHAR

Ventral hernia formation is about 10 times lower with laparoscopy than with laparotomy (0.06–1% vs 11–13%). Trocar wounds of 5 mm or less do not require closure, whereas larger trocar wounds do. Most surgeons close incisions greater than 10 mm because of the high rate of hernias. Richter's hernias, where only a portion of the intestinal wall is entrapped in a defect of the peritoneum or posterior fascia, can be difficult to diagnose, because an externally visible bulge is often absent. The condition needs a high index of suspicion and can be diagnosed with ultrasound or computed tomography scan.

SUBCUTANEOUS EMPHYSEMA AND GAS EMBOLISMS

Localized or generalized subcutaneous emphysema occurs in 0.3–2% of cases and generally has no clinical consequence. However, subcutaneous emphysema of the neck, face, and chest may be a manifestation of a pneumothorax or pneumomediastinum.

POSTOPERATIVE SHOULDER PAIN

Pain from diaphragmatic irritation can be referred to the shoulder causing discomfort. Irritation of the diaphragm, the formation of carbonic acid (because of use of CO₂), stretching of the phrenic nerve by pneumoperitoneum, and pressure from the abdominal organs during Trendelenburg position are possible etiologies. It can be treated with mild analgesics and reassurance.

OPERATIONS FOR STERILIZATION OF WOMEN & MEN: INTRODUCTION

Sterilization is a permanent method of contraception, and is the most commonly used contraceptive method used in the United States. Approximately 700,000 tubal sterilizations and 500,000 vasectomies are performed in the United States annually.

TUBAL STERILIZATION

Tubal sterilization was first performed in 1823 to prevent pregnancy in women who would need repeated cesarean sections. Since the first tubal sterilization was performed, more than 200 different techniques have been described. Table 48–3 lists the most common methods of tubal sterilization and their failure rates.

Table 48–3. Overall Failure Rates with Tubal Sterilization (over 10 Years Per 1000 Procedures).

Postpartum partial salpingectomy	7.5
Unipolar coagulation	7.5
Bipolar coagulation	24.8
Spring clip	36.5
Silicone rubber band	17.7
Interval partial salpingectomy	20.1
All methods	18.5

Reproduced with permission from Peterson HB et al: The risk of pregnancy after tubal sterilization: findings from U.S. Collaborative Review of Sterilization. *Am J Obstet Gynecol* 1996;174:1161.

Preoperative Counseling

Clear, comprehensive counseling is essential for women who are considering tubal sterilization. Possible medical and psychological complications must be carefully outlined (see Complications, later); women are more likely to regret having had the operation if they do not know what to expect.

The physician should be alert to signs that the patient is undecided about having the operation or is being pressured by her husband or others. Regret or dissatisfaction is more common if the procedure is done postpartum than at another time, and these women are more than twice as likely to feel that preoperative counseling was inadequate. Temporary stress associated with the pregnancy may have influenced a premature decision for sterilization in these women.

Patients should be told that tubal sterilization is usually irreversible. Some methods are sometimes reversible. Most studies estimate that approximately 1–2% of women who undergo tubal sterilization request reversal. The major risk factor for subsequent regret of sterilization is young maternal age (younger than age 30 years) at the time of

sterilization. Collaborative Review of Sterilization (CREST) study data showed that women who were younger than 30 years at the time of sterilization were twice as likely to seek information about reversal as women between the ages of 30 and 34 years. Another major risk factor for regret is marital disharmony at the time of sterilization. In addition, women who have postpartum sterilization are more prone to regret than are women who have interval sterilization. Parity has not been found to be a significant risk factor for regret when controlling for maternal age. Pregnancy rates after tubal ligation reversals range from 55–90% by laparotomy and 31–78% via laparoscopy. Success of tubal ligation reversal depends on the woman's age at the time of reversal (younger than 35 years old) and length of remaining fallopian tube segment (> 4 cm). Some studies have found improved pregnancy results when the initial sterilization procedure was performed using mechanical techniques rather than electrocautery.

Complications

Pain and menstrual disturbances (postbilateral tubal ligation syndrome) have been reported following tubal sterilization. The theory holds that destruction of the mesosalpinx might alter the blood supply and subsequent gonadotropin delivery to the ovary. Ovarian function and hormone production may then be altered. However, prospective controlled studies show that these problems are no more common than in women who have not undergone sterilization. Menstrual changes seem to be related to use of contraceptives—before sterilization. Oral contraceptives are associated with decreased menstrual flow and relief of dysmenorrhea; once they are discontinued, heavier flow and pain may recur. Complaints of menstrual changes are much less frequent in the second half of the first postoperative year. Patients should be told that pelvic pain or menstrual disturbances may develop after tubal sterilization but are no more common than in other women of similar age and parity.

Patients who have undergone tubal sterilization require hysterectomy more often than patients who have not undergone this procedure. This is probably because most women who have tubal sterilizations have had children and thus are more likely to have disorders typically treated with hysterectomy (eg, symptomatic pelvic relaxation, adenomyosis). Patients may have been sterilized secondary to medical reasons and gynecologic disorders that eventually require further surgery. Some studies suggest that women are more likely to accept a surgical treatment if they have been sterilized.

Failure of sterilization is most often secondary to poor technique such as improper application of a clip or ring. Fistula formation may occur. A complication of failure is ectopic pregnancy (7.3 per 1000).

Several studies show an association between decreased risk of ovarian cancer and tubal sterilization.

Technique

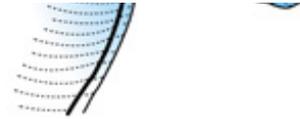

(See Figs 48-1, 48-2, 48-3, and 48-4.) Postpartum tubal ligation uses a small infraumbilical incision to access the tubes. Minilaparotomy involves a 2–3 cm incision made above the symphysis pubis. The incision is closed in two layers.

Figure 48–1.

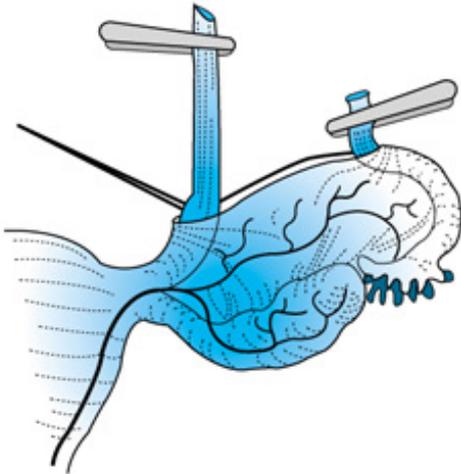

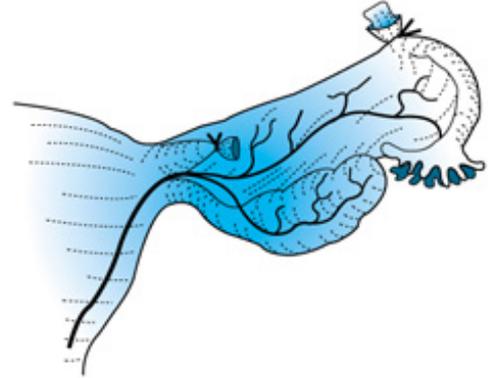

Saline with epinephrine injected below serosa, which becomes inflated locally. Muscular tube, and even blood vessels, can be separated from serosa, which is then cut open.

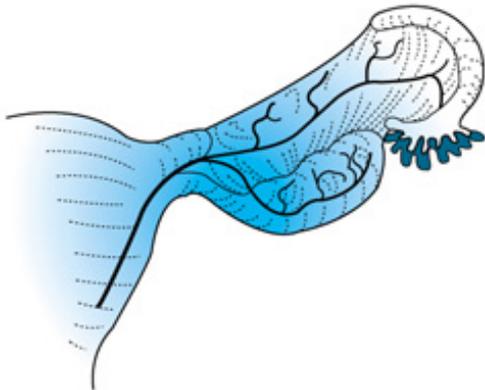

Muscular tube emerges through opening or is pulled to form a U shape.

Fimbriated end is untouched, while the end leading to the uterus is stripped of serosa. This can usually be done without damaging blood vessels.

About 5 cm of muscular tube is cut away; the end is buried automatically in serosa. Fimbriated end and serosa opening are closed and tied together.

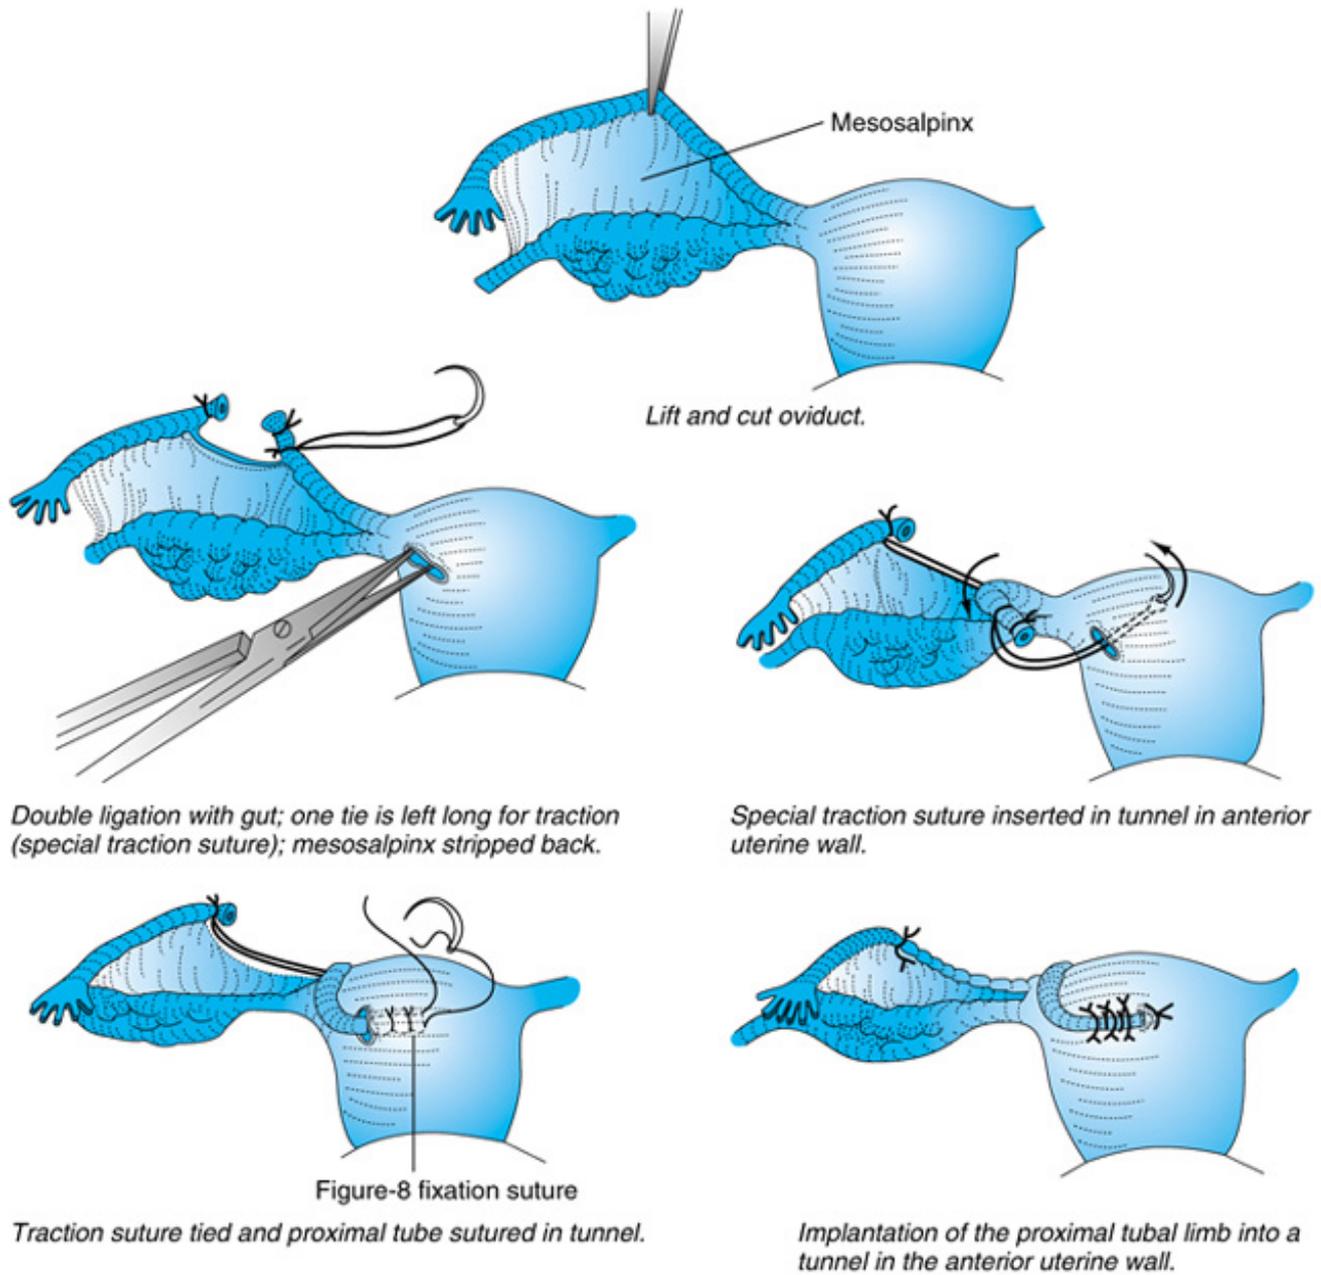

Blood supply continues normally between ovary and uterus. Hydrosalpinx or adhesion has not been noticed.

Sterilization by fimbriectomy.

OTHER METHODS OF FEMALE STERILIZATION

Because of relatively high morbidity and mortality rates in comparison with tubal occlusion procedures, hysterectomy is justified for sterilization only if there is another unequivocal indication for hysterectomy. Transvaginal tubal ligation via culdotomy or culdoscopy is technically more difficult than transabdominal sterilization and has a higher infection rate. However, there may be less discomfort postoperatively. A hysteroscopic tubal sterilization technique (Essure) was recently approved by the Food and Drug Administration (FDA) (Fig 48–5). It is an expanding spring device made of titanium, stainless steel, and nickel that contains Dacron fibers that induce an inflammatory response and final fibrosis of the intramural tubal lumen. It can be successfully placed in 95% of patients and its effectiveness at 1 year is 99.5%.

Figure 48–5.

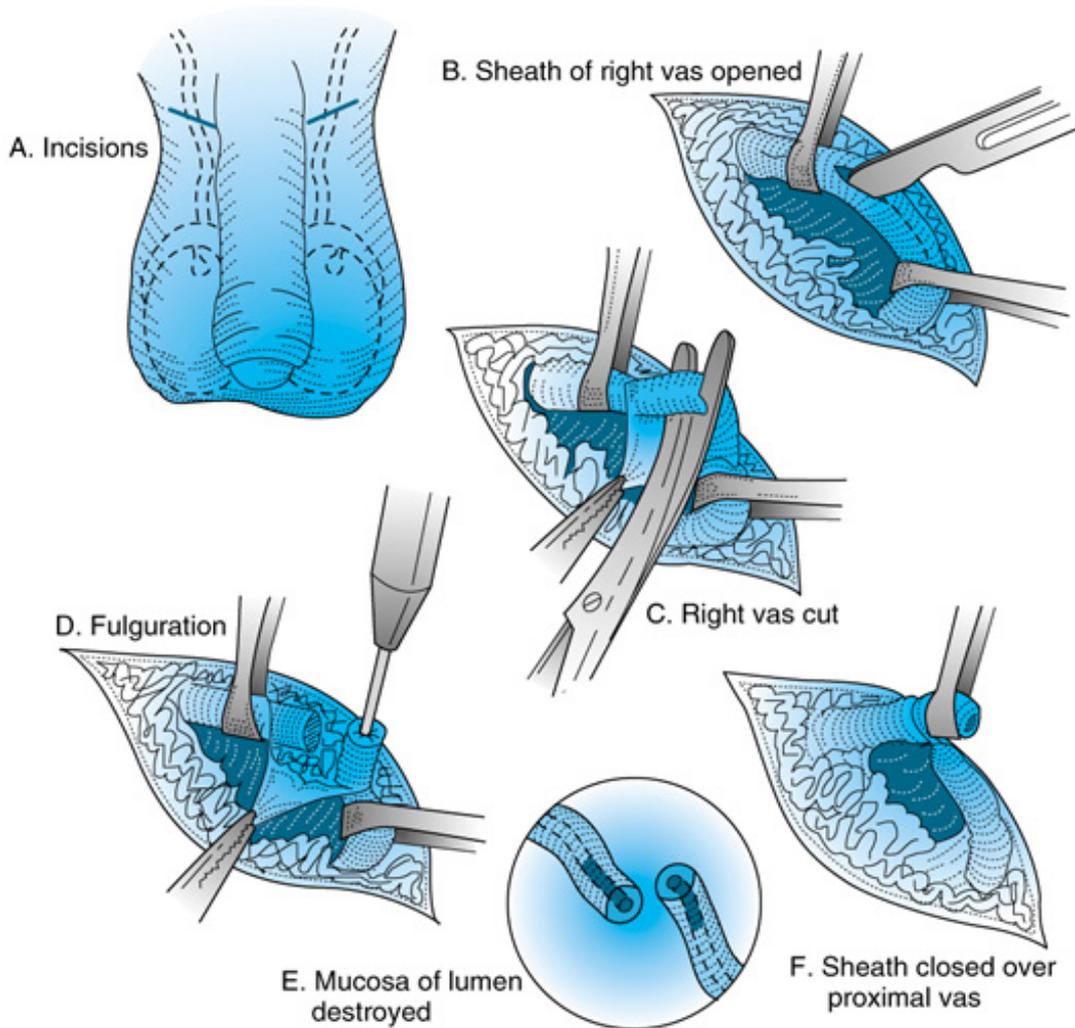

Hysteroscopic tubal sterilization technique.

VASECTOMY

Vasectomy, or vas occlusion, accounts for 8% of sterilizations worldwide. Partial vasectomy is usually done under local anesthesia via a small incision in the upper outer aspect of the scrotum (Fig 48–6). Sutures or clips are placed tightly around the vas, demarcating a 1–1.5-cm segment, which is then excised. The ligated and fulgurated ends are tucked back into the scrotal sac, and the incision is closed. The same procedure is performed on the opposite side. The no-scalpel technique requires no incision because a sharpened dissection forceps is used to pierce the skin and dissect the vas. Studies are being done on the efficacy of intravasal plugs to confer sterility. Microscopic examination confirms excision of vasal tissue.

Steps in vasectomy.

(Modified from a drawing by S. Taft. Reproduced with permission from Schmidt S: Vasectomy should not fail. *Contemp Surg* 1974; 4:13.)

The failure rate after vasectomy is 9.4 per 1000 at 1 year and 11.3 per 1000 at years 2, 3, and 5. Half of the vasectomy failures in the CREST study occurred within 3 months of the procedure. Thus, sterility is assumed only after ejaculates are completely free of sperm after 3 months and after periodic microscopic analysis.

Complications are infrequent, usually involving slight bleeding, hematoma formation, skin infection, and reactions to sutures or local anesthetics.

When vasal anastomosis is attempted (vasovasostomy), patency is achieved in 86–97% of patients, depending on the interval between vasectomy and vasovasostomy. Pregnancy rates are lower (18–60%). Skillful microsurgery performed by an experienced urologist optimizes the chances of pregnancy.

HYSTERECTOMY

Hysterectomy is complete removal of the uterus. With more than 598,929 procedures done each year, hysterectomy is the second most common major operation performed in the United States. With advancements in medical and conservative surgical therapy of gynecologic conditions, the need for hysterectomy has declined. More women n

wish to avoid major surgery if equally efficacious alternatives exist. Regulatory boards of gynecologists now support the use of hysterectomy as treatment for conditions refractory to more conservative management.

Indications

The indications for hysterectomy can be practically divided into those for the treatment of gynecologic cancer, benign gynecologic conditions, and obstetric complications. Hysterectomy for cancer of the uterus, ovary, and cervix is discussed in Chapters 53, 54A, and 54B. Hysterectomy for obstetric complications, including excessive bleeding and molar pregnancy, is becoming less common (see Chapter 31).

Table 48–4 lists the most common benign diseases and disorders that warrant hysterectomy.

Table 48–4. Benign Diseases and Disorders for Which Hysterectomy May Be Performed

Uterine leiomyomas

Symptomatic (abnormal bleeding or pelvic pressure)

Asymptomatic (presenting as a large uterus obscuring palpation of the adnexa and ultrasound unavailable)

Rapid growth of the uterus

Failed conservative management of bleeding (eg, cyclic progestin, D&C) or uterine pain (eg, nonsteroidal anti-inflammatory medications)

Symptomatic adenomyosis

Symptomatic endometriosis refractory to conservative surgical or medical therapy

Symptomatic pelvic relaxation syndromes

Chronic incapacitating central pelvic disorder refractory to conservative treatment (eg, hormonal suppression and nonsteroidal anti-inflammatory drugs) in a woman with a normal urologic and gastrointestinal evaluation

Definitive treatment of severe pelvic inflammatory disease or any pelvic abscess involving the genitalia if conservative therapy is not possible or desired by the patient

Preoperative Evaluation

DIAGNOSTIC TESTS TO DETECT OCCULT CANCER

All patients anticipating hysterectomy should have a baseline evaluation to detect occult cancer. A Papanicolaou smear should be performed within 3 months before the operation, and abnormalities should be followed with colposcopic examination and biopsy before surgery. Cervical conization is indicated prior to hysterectomy if (a) colposcopy fails to demonstrate the entire squamocolumnar junction, where cervical cancers typically arise; (b) colposcopically guided biopsies reveal dysplasia that differs by two or more grades than that shown on the Papanicolaou smear (eg, carcinoma in situ on smear but mild dysplasia on biopsy); (c) endocervical curettage demonstrates dysplastic endocervical cells; and (d) biopsy reveals microinvasive squamous cell carcinoma or

squamous adenocarcinoma in situ.

Cervical conization for the previous indications is performed to ensure that occult invasive cancer is not present within the endocervical canal. Frozen-section analysis of cervical conization tissue correlates well enough with "permanent" (hematoxylin and eosin) slide analysis so that if intraepithelial neoplasia with clear margins is found the surgeon may, with reasonable certainty, perform a hysterectomy that will totally include the tumor.

Biopsy for endometrial neoplasia must also be considered. Generally any woman older than age 35 years who presents with abnormal uterine bleeding should have endometrial evaluation (D&C, directed biopsies) before hysterectomy. However, certain clinical situations that produce an unopposed estrogen effect on the endometrium warrant preoperative endometrial evaluation at any age: chronic anovulation and secondary oligomenorrhea, unopposed estrogen therapy for menopause, and known ovarian disorders associated with endometrial neoplasia (eg, polycystic ovarian syndrome, granulosa cell tumors). Unfortunately, frozen-section analysis of endometrial curettings is neither practical nor accurate, so hysterectomy usually must wait for permanent section.

Occult cancer may also be present outside the genital tract. All patients should have their stool checked for occult blood preoperatively. In women 40 years of age or older, mammography is standard.

PREOPERATIVE EVALUATION OF THE PELVIS

In the woman with a small, mobile uterus with mobile adnexa, little diagnostic evaluation beyond bimanual examination is indicated. However, pelvic disease may have caused disturbance of normal tissue planes that endanger the urologic and gastrointestinal tracts. The following conditions may indicate the need for more extensive evaluation of the pelvis prior to hysterectomy: (a) pelvic inflammatory disease, especially if repeated, chronic, or associated with a tuboovarian complex; (b) endometriosis; (c) pelvic adhesions from other causes of pelvic inflammation (eg, appendicitis, cholecystitis, previous pelvic surgery); (d) chronic pelvic pain; (e) questionable origin of a palpable pelvic mass; and (f) clinical suspicion of cancer (eg, palpable adnexa in a postmenopausal woman).

The most commonly used preoperative adjunctive diagnostic evaluation is pelvic ultrasound, which has advantages over computed tomography (CT) scan. Ultrasound is helpful in detecting masses in the difficult-to-examine patient (eg, obese) and in confirming a pelvic mass detected on bimanual examination.

Intravenous pyelography (IVP) is helpful in delineating the course of the ureters through the pelvis. A preoperative intravenous pyelogram is especially useful for inflammatory conditions that could distort or obstruct the ureters. Also, patients with genital developmental anomalies should have a preoperative IVP to look for concomitant urologic anomalies.

Prehysterectomy evaluation of the colon (beyond screening for occult blood in the stool) is indicated in any patient with symptoms for rectal disease. In most cases, proctoscopy or flexible proctosigmoidoscopy is sufficient. In cases of severe pelvic inflammation, chronic pelvic pain, or suspected cancer, complete colonoscopy or barium enema is indicated. Preoperative diagnosis of bowel disease will aid in the selection of the incision. If necessary, a consult with a gastrointestinal surgeon can be present during the operation.

PREOPERATIVE BOWEL PREPARATION

See Chapter 46.

PROPHYLACTIC ANTIBIOTICS

The incidence of febrile morbidity occurs in approximately 18% of patients undergoing abdominal hysterectomy versus 8% with vaginal hysterectomy. Certain risk factors are associated with a higher likelihood of operative site infection. These factors include an abdominal surgical approach, blood loss greater than 750 mL, and no preoperative antibiotics. The American College of Obstetricians and Gynecologists (ACOG) also recommends giving additional doses of intraoperative antibiotics during lengthy operations, given at intervals of 1 or 2 half-lives of the

drug. A second dose of the prophylactic antibiotic may also be given in surgical cases with an increased blood loss: 1500 mL. Patients diagnosed with a vaginal infection during preoperative evaluation should be treated prior to surgery.

A broad-spectrum antibiotic should be chosen that will be effective against common (but not necessarily *all*) pathogens causing pelvic infection. The agent should have a low incidence of toxicity and side effects and should be easily administered and cost-effective. The proper dosage should be administered 30 minutes prior to surgery. Therapeutic levels must be achieved in tissue at the surgical site. It should *not* be an antibiotic reserved for serious infection. ACOG recommends intravenous cefazolin, cefoxitin, cefotetan, or metronidazole prior to vaginal or abdominal hysterectomy.

THROMBOEMBOLISM PROPHYLAXIS

The risk of calf vein thrombosis, proximal vein thrombosis, and pulmonary embolism can be minimized with the use of graduated compression stockings perioperatively and early ambulation postoperatively. Sequential compression devices will help prevent stasis as well. For patients at high risk for thromboembolic disease, a dose of 5000 U subcutaneous heparin is given preoperatively and then every 8–12 hours postoperatively. Risk factors include malignancy, obesity, previous radiation therapy, immobilization, estrogen use, prolonged anesthesia, radical surgery, history of thromboembolism, and personal or family history of hypercoagulability. Other less-often-used prophylactic modalities include low-dose diltiazem-heparin, dextran-70, and low-molecular-weight heparin.

BLOOD PRODUCTS

It may not be necessary to preoperatively cross-match all patients undergoing hysterectomy. Women who are at particular risk of needing a transfusion during hysterectomy should at least have blood typing and antibody screening prior to surgery. Patients undergoing peripartum hysterectomy or hysterectomy for gynecologic cancer are more likely to need blood transfusion. Patients undergoing elective hysterectomy are more likely to need a transfusion if the hematocrit is low (30%), if they have pelvic inflammatory disease or pelvic abscess or adhesions or if colporrhaphy is performed at the time of vaginal hysterectomy.

INFORMED CONSENT

Many women desire, and most insurance companies require, a second opinion prior to scheduling an elective hysterectomy. The patient must understand the diagnosis and be aware of alternative therapies and the risks and benefits of the operation. Common risks of surgery such as cuff cellulitis and blood loss are usually explained during preoperative counseling. The current medicolegal climate mandates the discussion of unusual complications, including the possibility of completing a vaginal operation via an abdominal route and the risks of viral illness following transfusion, severe postoperative infection (including adnexal abscess), ectopic pregnancy, and vaginal vault prolapse (see also Chapter 64).

TECHNIQUE

Vaginal versus Abdominal Hysterectomy

The route of hysterectomy is chosen according to the following guidelines.

PELVIC ANATOMY

The ideal candidate for vaginal hysterectomy has a gynecoid pelvis with a wide pubic arch, and a vaginal apex > 2 fingerbreadths at the apex. Some descent of the uterus is helpful but not mandatory; procidentia makes for a more complicated vaginal hysterectomy because of the greater vulnerability of the prolapsed ureters.

UTERINE SIZE

Most gynecologists will perform vaginal hysterectomy on a uterus equivalent in size to a uterus at 12 weeks' gestation or smaller, or a uterine weight of less than 280 g. More experienced surgeons have successfully removed uteri of up to 700 g vaginally using bivalve and morcellation techniques.

ADNEXA

In patients with symptoms or pelvic findings suggesting adnexal disease that may indicate adnexectomy, the abdominal route for hysterectomy is preferred. Such patients may be candidates for LAVH.

GASTROINTESTINAL TRACT

Especially in older patients or those with significant history of gastrointestinal complaints, the abdominal approach offers an opportunity for complete examination of the bowel.

UROLOGIC DISORDERS

If a retropubic urethropexy is planned, a laparoscopic or abdominal approach can be used. If anterior vaginal colporrhaphy only is planned, vaginal hysterectomy is preferred. Advanced degrees of cystocele, with marked prolapse of the urethrovesical angle, may be best treated with a combined vaginal and abdominal approach (see Chapters 44 and 45).

PELVIC RELAXATION

In the case of isolated rectocele, a vaginal approach is preferred. Culdoplasty for enterocele may be performed by either route.

PLASTIC PROCEDURES

As more women choose to undergo procedures such as abdominoplasty or suction-assisted lipectomy, an abdominal approach is indicated. Perineorrhaphy and vaginal repairs usually accompany vaginal hysterectomies but can also be done after abdominal hysterectomy.

MEDICAL DISORDERS

In patients with significant heart or lung disease, the vaginal approach is preferable when possible because of a lower incidence of postoperative pulmonary complications and earlier ambulation.

PREVIOUS SURGERY

Most surgeons are willing to perform a vaginal hysterectomy in patients with previous tubal ligation or cesarean section. The surgery would be more problematic in patients with a history of multiple cesarean births or complications (eg, postpartum endomyometritis) or with probable abdominal adhesions from previous laparotomy. LAVH may be used in these situations.

The preceding guidelines may certainly be adjusted to the individual patient based on the surgeon's experience and abilities. An examination performed under anesthesia when the physician first sees the patient may help to decide on the approach. Uterine size can be assessed with transvaginal ultrasound. Laparoscopic evaluation of the adnexa further aids in the decision-making process. All patients anticipating vaginal hysterectomy, LH, or LAVH should be told that the operation may have to be completed abdominally if difficulties arise.

Abdominal Hysterectomy

The technique of abdominal hysterectomy varies according to the indication for the operation, the size and placement of vital structures, including the ureters (which may be distorted), and the pelvic anatomy. A standard well-organized approach to abdominal hysterectomy is essential to avoid incidental injury. Modifications are made as necessary, always within an organized plan of operation.

The anesthetic of choice typically includes general endotracheal intubation, an inhalation agent, and an analgesic. Hysterectomies are of such duration and risk that using a mask alone is unwise. In patients with pulmonary compromise, spinal or epidural anesthesia may be used.

A sterile scrub of the abdomen and vagina is done, and a urinary catheter is placed so that the anesthesiologist can monitor urine output intraoperatively. The choice of incision is based on the suspected disease or disorder; most hysterectomies for benign disease can be accomplished through a transverse incision. However, a midline incision extending from 2 fingerbreadths above the pubic symphysis to the umbilicus offers the greatest exposure. Two modifications of the low transverse incision that improve exposure are the Maylard muscle-splitting procedure and the

the Cherney detachment of the rectus muscles from their insertion on the pubic symphysis.

The surgeon and assistants should rinse excessive talcum powder from their gloves before making the incision to prevent granulomatous tissue reaction in the wound. Once the incision is complete, peritoneal fluid may be aspirated if the possibility of gynecologic cancer exists. The pelvic organs are then inspected and the upper abdomen palpated in a systematic fashion: right gutter, right hemidiaphragm, liver, gallbladder, pancreas, stomach (assessing the position of the indwelling gastric decompression tube if present), and spleen and right hemidiaphragm (gently, because of the risk of trauma to the spleen), left gutter, paraaortic lymph nodes, and omentum. Excessive bowel manipulation should be avoided to decrease the severity of postoperative adynamic ileus; at the least, the appendix and cecum should be inspected, as well as the terminal ileum. Older patients and those with gastrointestinal complaints would benefit from careful palpation and inspection of the bowel from rectum to ligament of Treitz. If desired, the wound may be protected with moist towels, a self-retaining retractor placed, and the bowel packed into the upper abdomen.

The classic extrafascial hysterectomy performed by Richardson remains the mainstay of surgical technique in abdominal hysterectomy. Choice of suture and needle is made according to surgeon experience and preference; 0, 0, or 1 absorbable sutures on half-curved taper needles are standard choices. The uterus is grasped either by fundus with a Massachusetts double-toothed clamp or at the cornu with Ochsner or Kocher clamps. The round ligament is clamped proximal to the uterus; at its midportion, it is ligated by suture, and the suture is tagged with a small hemostat. The round ligament is divided about 0.5-cm proximal to the suture, thus opening the broad ligament at its apex. The anterior uterine peritoneum may be incised at the vesicouterine junction in preparation for advancement of the bladder. Only the peritoneum should be incised; the potentially vascular areolar tissue should be avoided. When this procedure is repeated on the contralateral side, the anterior leaves of the broad ligament are opened, the uterine vessels first become apparent, and attention is then directed to the posterior leaf of the broad ligament.

The posterior leaf of the broad ligament is incised beginning at the ligated round ligament. The extent of the incision is determined by the decision to preserve or remove the adnexa. If the adnexa are to be removed, the peritoneum is incised parallel to the infundibulopelvic ligament to the pelvic sidewall; the loose areolar tissue is dissected medial to the internal iliac (hypogastric) artery, which is typically 0.5-cm thick with a visually appreciable (and certainly palpable) pulse. The dissection will reveal a clear area of peritoneum under the infundibulopelvic ligament; below this area at a variable distance lies the ureter on this medial flap of peritoneum.

The intimate proximity of the ureters to the uterus makes ureteral dissection important. Whereas the ureter is usually 4–6 cm deep to the infundibulopelvic ligament at the lateral margin of the uterus, it is only 0.5–2 cm below this vascular bundle at the level of the pelvic brim. Observing the ureter through the peritoneum or palpating the characteristic "snap" of the ureter should serve only to guide dissection and should not be a substitute for identification of the entire ureter through its pelvic course. The ureter tolerates careful dissection well as long as blood-carrying adventitia is not stripped away. The ureter can always be found and dissection begun at the pelvic brim, where the ureter passes over the bifurcation of the iliac artery. The most serious ureteral injury is the unrecognized insult. The most common ureteral injuries during hysterectomy occur during ligation of the uterine artery, ligation of the infundibulopelvic ligament, and placement of the vaginal angle sutures.

Once the course of the ureters is well established, the adnexal component of the operation is completed. If the adnexa are to be removed, a ligating suture may be passed beneath the infundibulopelvic ligament and above the ureter; this step is repeated for a double ligature as a precaution. Traditionally, the infundibulopelvic ligament is clamped, divided, and ligated; the direct suture technique may avoid undue crushing of tissue. The ligament is ligated again adjacent to the uterus to avoid back bleeding; the infundibulopelvic ligament is divided and the peritoneum incised to the back of the uterine fundus, always cognizant of the proximity of the ureter. If the adnexa are to be preserved, a hole is made in the avascular portion of the posterior leaf of the broad ligament superior

the ureter. The uteroovarian ligament and fallopian tube are doubly clamped, divided, and ligated, with care taken to avoid incorporation of ovarian tissue into the ligature.

The final step is extending the peritoneal incision posteriorly around the uterus between the medial portions of the uterosacral ligaments. If the incision of the posterior leaf of the broad ligament is extended over the uterosacral ligaments, there is typically significant bleeding just lateral to the insertion of the ligament at the uterus. The advantages of making an incision between the uterosacrals include clear identification of the rectum and its separation from the uterus, ease of suturing the vaginal cuff, and improved mobility of the peritoneum to allow reperitonealization under less tension.

The bladder is advanced down off of the lower uterine segment prior to clamping the uterine vessels. Surgeons-in-training have more difficulty with advancement of the bladder than with other aspects of abdominal hysterectomy. The principal difficulty in mobilization of the bladder is failure to identify the proper cleavage plane between the bladder and the uterus. At the attachment of the bladder to the lower uterine segment, a median raphe is variably present; it is typically a 1-cm longitudinal band of thick connective tissue. The raphe is attenuated in pregnant or postmenopausal patients. The raphe is divided at midportion, and loose avascular fibroareolar tissue is seen immediately between the cervix and bladder. The uterus is retracted posteriorly and superiorly, roughly at an angle of 30 degrees to the long axis of the vagina. The midpoint of the peritoneal incision of the bladder flap is gently lifted with forceps; the avascular plane of the vesicovaginal and vesicocervical areolar spaces is continuous once the median raphe is divided. Metzenbaum scissors are pointed to the uterus, and sharp dissection reveals the shiny white pubocervical fascia overlying the cervix. Properly done, the dissection is bloodless, and the plane is recognized by the ease with which the bladder falls away from the cervix. The vesicouterine space is developed 2 cm beyond the anterior vaginal fornix. Care must be exercised in any dissection laterally, because the vesicouterine ligaments ("bladder pillars") may bleed because of the paracervical and paravaginal veins present laterally.

The uterine vessels may be skeletonized by separating the loose avascular areolar connective tissue from the vessels. The intraligamentous course of the ureter is again checked; it is typically 2–3 cm inferolateral to the insertion of the uterine vessels into the uterus. The uterine vessels are clamped with a curved crushing clamp (e.g., Heaney, Phaneuf, or curved Ballantine clamp). Double-clamping is used for larger vessels. It is not necessary to place another clamp on the uterine side of the pedicle to prevent back bleeding if the uterine arteries on both sides of the uterus are clamped before either pedicle is incised. The clamp is applied at the level of the internal os, with the tip of the clamp at a right angle to the long axis of the cervix; the temptation to clamp the entire cervix and "slide off" dragging paracervical tissue into the pedicle should be avoided in order to minimize the risk of the pedicle slipping out of the clamp. The uterine vessels are then ligated by suture at the tip of the clamp. Occasionally, a second application of the curved clamp is necessary to complete ligation of the uterine vessels.

Next, the cardinal ligament is assessed. Ordinarily, a single application of a straight clamp (Ochsner, Kocher, or Ballantine clamp) will include the cardinal ligament to the level of its attachment at the lateral edge of the cervix or upper vagina. A deep knife is often useful in dividing the cardinal ligament adjacent to the uterus, leaving a large pedicle, which is less likely to slip out of the suture than one remaining after cutting with scissors flush to the cervix. The suture ligation of the cardinal ligament is often tagged to aid in manipulation of the vaginal cuff.

The uterosacral ligaments are clamped at their insertion into the lower cervix, divided at their insertion, and ligated. Alternatively, they may be transected with large Mayo scissors while the vagina is entered posterolaterally. If division and suture ligation of either pedicle of the cardinal–uterosacral ligament complex fails to enter the vagina, the safest approach is to enter the vagina with the knife in the midline, either anteriorly or posteriorly, at the confluence of the vagina with the cervix. Once entered, the cervix is circumferentially incised, with long Ochsner clamps used to control point bleeders and elevate the vaginal cuff. The cervix is inspected to ensure complete excision.

Sutures are placed at each lateral vaginal angle to ligate small paravaginal vessels coursing upward through the

paravaginal tissues and to provide vaginal vault support. The suture is begun inside the vagina 1 cm from the upper border, incorporates the cardinal and uterosacral ligaments, and, finally, transverses the vagina again to end up within the vagina. This suture is tagged, and the procedure is repeated on the contralateral side.

Surgical management of the cuff is individualized. In the case of marked pelvic inflammation and persistent ooze the cuff may be left open to afford retroperitoneal drainage or allow egress of a closed drain system. In most cases closing the cuff may reduce granulation tissue and possibly minimize ascension of bacteria from the vagina. The cuff may be closed with either interrupted figure-of-eight sutures or a double running suture; the key points with either closure are inversion of the cut edges into the vagina and hemostasis.

The pelvis is irrigated and hemostasis checked in a systematic fashion from one lateral pedicle to the ipsilateral round ligament pedicle to the cuff and on to the other side. Small bleeding vessels must be ligated to minimize the risk of retroperitoneal hematoma formation, which may expand or become infected. For diffuse oozing, hemostatic agents such as thrombin powder or thrombostatic absorbable sponges may be useful. There is no advantage to closing the parietal peritoneum.

Retained ovaries may be suspended to minimize the risk of torsion and adherence to the vaginal cuff. The uteroovarian ligament can be conveniently attached to the round ligament stump to suspend the ovaries above the pelvis without placing the infundibulopelvic ligament under tension.

The abnormal appendix should be removed. In cases of hysterectomy for endometriosis, appendectomy will reveal microscopic endometriotic foci in some 3% of cases.

Supracervical Hysterectomy

Prior to the 1940s, 95% of hysterectomies were either supracervical/subtotal hysterectomy or removal of the uterine corpus without the cervix. Despite Papanicolaou's introduction of his cervical smear, concern over neoplastic changes occurring in the retained cervix made total abdominal hysterectomy (TAH) the leading approach to surgery from the 1950s and on. Debate has been renewed about which approach leads to decreased morbidity. Proponents of supracervical hysterectomy believe that there is less damage to sympathetic and parasympathetic innervation than might occur with paracervical dissection. Thus, bladder function and orgasm are less likely to be affected with supracervical hysterectomy. Also, by leaving the cervix, vault prolapse and vaginal shortening might be avoided. Those in favor of TAH suggest that it decreases the risk of cervical cancer, especially in women who might not follow up for routine Papanicolaou (Pap) smears. It also eliminates the small risk of cyclical bleeding (6.8%) that can occur after supracervical hysterectomy, if residual endometrium is left behind. A randomized, double-blind controlled trial showed no statistically significant difference in bladder, bowel, and sexual function between women who had undergone total versus supracervical hysterectomy. Current indications for supracervical hysterectomy include difficulty dissecting the cervix, distorted anatomy secondary to pelvic inflammatory disease or endometriosis, an compromised medical condition.

Following ligation of the uterine vessels, the uterine fundus may be amputated from the cervix; the level of amputation should be below the internal cervical os to avoid postoperative uterine bleeding from endometrial remnants. The cervical stump is closed with figure-of-eight sutures.

Vaginal Hysterectomy

Most vaginal hysterectomies are performed under general anesthesia. In the patient with medical complications, particularly pulmonary problems, spinal anesthesia may be elected. Following administration of the anesthetic, a bimanual examination is mandatory before beginning surgery. The perineum is shaved or trimmed as necessary and a sterile wash performed. The patient is placed in a modified dorsal lithotomy position and draped; the surgeon should participate in proper positioning of the patient, because excessive flexion of the hips can stretch the obturator and sciatic nerves and compress the femoral nerve; and excessive extension of the knee can jeopardize the peroneal nerves. All bony prominences and soft tissues in contact with the leg stirrups should be carefully

padded.

The urinary bladder may be drained by catheter, but this step is optional. The cervix is grasped with a tenaculum. Passage of a uterine sound will aid in determining the size and position of the uterus; some surgeons advocate performing a D&C at this point to rule out pyometra or endometrial neoplasia.

As the surgeon exerts gentle traction downward on the cervix, two assistants maintain exposure with lateral vaginal retractors and protect the bladder with an anterior Heaney retractor. If desired, the junction of the vagina and cervix can be injected with a 1% 1:1000 epinephrine solution to minimize blood loss during incision of the cervix. Beginning posteriorly to minimize obscuring the field with blood, the surgeon circumferentially incises the cervix down to the level of the pubovesicocervical fascia. Gentle traction with the bladder retractor and downward traction of the cervix will allow exposure of the fibers of fascia between bladder and cervix, which are incised. When the bladder has been advanced up off of the cervix, attention is given to the posterior attachment of the cervix. When the assistant pulls the uterus upward, the posterior vaginal mucosa is tented away from the cervix. With the patient in the Trendelenburg position to allow as much emptying of the posterior cul-de-sac as possible, the posterior cul-de-sac is incised with a single stroke of the scissors. A retractor is placed within the opening, exposing the uterosacral ligaments. The uterosacral ligaments are grasped with Heaney clamps, making certain that the peritoneum posterior to the ligament is within the clamp. The ligament is cut and ligated with 2-0 or 0 absorbable suture and tagged with a hemostat for later manipulation of the cuff.

The cardinal ligament may be clamped next if the bladder is safely advanced; likewise, the uterine vessels are included in the next application of the Heaney clamps. The anterior cul-de-sac is entered by blunt and sharp dissection to the anterior vesicouterine fold of peritoneum. The anterior retractor is placed within this opening as the bladder is gently lifted upward. The surgeon now clamps, incises, and ligates in pedicles the remaining portions of the broad ligaments bilaterally, incorporating the tissue between the anterior and posterior leaves of the broad ligament. The round ligament, uteroovarian ligament, and fallopian tube are excised from the uterus and incorporated into these pedicles, and the uterus is removed from the field. A larger uterus may require special manipulation for delivery through the vaginal introitus (eg, bivalving the uterus in the midline, morcellation of the uterus into multiple extractable segments, or myomectomy).

The final suture on the uteroovarian ligament is tagged to allow careful inspection of the tubes and ovaries. If ovarian disease is suspected or if prophylactic oophorectomy is planned, a clamp is placed above the ovary and uterine tube on the infundibulopelvic ligament for suture ligation, while traction is placed on the last stay suture. The entire ovary must be removed, because an ovarian remnant may become cystic and produce pain many years after the hysterectomy.

Once all pedicles are inspected and found to be hemostatic, some surgeons advocate closing the peritoneum with running 2-0 absorbable suture, incorporating the cardinal and uterosacral ligament pedicles for support of the vaginal vault. Lateral vaginal angle sutures are placed from the vaginal mucosa at the 2 o'clock position, inside the cuff and including the uterosacral pedicle, then out through the cuff to the 4 o'clock position. If anterior or posterior colporrhaphy is planned, that operation is completed prior to complete closure of the cuff. The cuff may be closed with an interrupted absorbable 0 suture, a running simple suture, or a running vertical mattress technique. The goals of closure are obliteration of the cuff's dead space back to the peritoneum and approximation of the cut edges of the vagina to afford healing and minimize postoperative granulation tissue. Modifications of the just-described technique are made by virtually every gynecologic surgeon based on operative findings and experience. Many surgeons will close the posterior cul-de-sac to prevent development of an enterocele or will shorten the uterosacral ligaments to suspend the vaginal vault. As in abdominal hysterectomy, the cuff can be left open to promote drainage with a running locked absorbable 0 suture. Another technique to drain the closure is insertion of a T-tube above the cuff, which is associated with a demonstrable reduction in postoperative febrile morbidity.

After the operation is completed, the vagina and perineum are gently cleansed. An indwelling bladder catheter is

inserted and a vaginal pack may be placed. The patient is returned slowly to the dorsal supine position.

Laparoscopic Hysterectomy

The laparoscope can be used to aid vaginal hysterectomy by freeing abdominal adhesions (LAVH) or to free the uterus in its entirety with removal via the vagina (total LH). Supracervical hysterectomy can also be done laparoscopically with morcellation and removal by culdotomy or through extended trocar sites. Advantages to LH include decreased length of hospital stay, decreased postoperative analgesia, and decreased convalescence period. There may be a lower complication rate compared to TAH but there is no difference versus vaginal hysterectomy. However, the laparoscopic approach requires significantly more operating time and a well-trained, experienced surgeon. Because of the costs for the endoscopic equipment, LH has been found to be more expensive despite the shorter hospital stay. Complications with LH include hemorrhage and bowel or urinary tract damage. Conversion to abdominal hysterectomy may occur, especially in cases with large leiomyomas obstructing access to upper pelvic

Postoperative Care of the Hysterectomy Patient

The details of postoperative care are dictated by the indications for surgery and the individual patient's overall medical condition. General guidelines include the following:

1. A Foley catheter is left indwelling for 24 hours.
2. Prophylactic antibiotics are given only within the first 24 hours postoperatively.
3. Hydration, 2–3 L/d of balanced electrolyte solution, is given intravenously, depending on blood loss and intraoperative replacement.
4. Sips of water may be given the first night, followed by clear liquids or regular diet on the next postoperative day depending on the patient's appetite. The diet is advanced based on return of bowel sounds and appetite, tolerance of the diet, and the passage of flatus.
5. Prophylactic heparin therapy, sequential compression device, or antiembolic stockings are used in patients according to risk for thromboembolic complications.
6. Ambulation is begun on the first postoperative day.
7. Adequate analgesia is given parenterally. Once the patient can tolerate a regular diet, she can be switched to oral analgesics.

Complications

Perioperative deaths may be a result of cardiac arrest, coronary occlusion, or respiratory paralysis. Postoperative deaths are usually the result of hemorrhage, infection, pulmonary embolus, or intercurrent disease. A recent study of factors contributing to the risk of death found that abdominal hysterectomies performed for complications of pregnancy or cancer (8% of all hysterectomies) account for 61% of deaths caused by hysterectomy. Overall mortality rates for abdominal or vaginal hysterectomy are 0.1–0.2%. Mortality rates increase with age and medical complications for both vaginal and abdominal hysterectomies.

The bladder may be injured in 1–2% of all hysterectomies. Consequences are slight if the injury is to the dome of the bladder—which is usually the case—away from the trigone. Ureteral injury occurs in 0.7–1.7% of abdominal hysterectomies and 0–0.1% of vaginal hysterectomies. The essential point is to recognize urologic injuries and correct them intraoperatively, avoiding the serious postoperative complications that occur from urinary extravasation.

Damage to the bowel is quite uncommon, particularly with vaginal hysterectomy. In preparation for abdominal hysterectomy for suspected extensive or inflammatory pathologic process (eg, ovarian cancer, endometriosis, pelvic inflammatory disease), preoperative bowel preparation will allow incidental colon surgery without the necessity of colostomy. Small-bowel injuries, assuming no obstruction, are closed in layers perpendicular to the long axis of the

bowel; a running layer of 3-0 sutures in the mucosa is supported by interrupted 2-0 silk sutures in the serosa. If transmural large-bowel injury occurs and no preoperative bowel preparation was given, a temporary diverting colostomy may be indicated to protect the suture line and lower the risk of peritonitis and sepsis.

The most serious postoperative complication is hemorrhage (0.2–2% of patients). Bleeding usually originates at lateral vaginal angles and is amenable to vaginal resuturing in most cases. Blood products are replaced as needed.

Infection remains the most common complication following hysterectomy. Even with immaculate technique and careful patient selection, the gynecologic surgeon can still expect a 10% rate of postoperative febrile morbidity. A postoperative temperature of 38 C (100.4 F) or higher on two consecutive determinations 6 hours apart must be investigated by (a) careful interview of the patient for localizing symptoms (eg, productive cough, intravenous line pain), (b) thorough physical examination (including pelvic examination for inspection and palpation of the cuff), (c) appropriate laboratory studies (eg, urinalysis, Gram-stained smear of sputum, or complete blood count).

Antibiotics are begun only if a focus of infection is identified or highly suspected. Broad-spectrum antibiotics covering anticipated pathogens are prescribed; single-agent semisynthetic penicillins (eg, piperacillin) and cephalosporins (eg, cefoxitin) offer sufficient coverage. In the presence of sepsis, multiagent comprehensive coverage (eg, a penicillin, an aminoglycoside, and an anaerobic agent such as clindamycin or metronidazole) must be prescribed.

Granulation of the vaginal vault is part of the normal healing process and is evident on speculum examination in over half of cases. The granulation is rarely troublesome; light cauterization with silver nitrate sticks or electrocautery eliminates the granulation tissue promptly in most cases. Many suggestions have been made on how to minimize granulation, including management of the cuff (open vs closed), choice of suture (plain gut vs chromic vs newer synthetics), and drainage techniques. The most important common denominator is close apposition of cut vaginal edges, which can be accomplished with any of the techniques.

Current OB/GYN > Chapter 49. Premalignant & Malignant Disorders of the Vulva & Vagina >

PREINVASIVE DISEASE OF THE VULVA

General Considerations

The vulvar skin is one component of the anogenital epithelium, extending from the distal vagina to the perineum and perianal skin. The lower genital tract epithelium is of common cloacogenic origin. Neoplasia of the vulvar skin is often associated with multiple foci of dysplasia in the lower genital tract. A strong association exists between sexually transmitted diseases and vulvar intraepithelial neoplasia (VIN), primarily human papillomavirus (HPV), but also gonorrhea, syphilis, *Gardnerella vaginalis*, trichomonas, and human immunodeficiency virus (HIV). Approximately 80% of VIN lesions are positive for high-risk HPV types, primarily HPV-16. Other risk factors include smoking and other genital precancers or cancers. VIN can also be classified into viral and nonviral etiologies. Younger women are more commonly affected by viral VIN than older women and are also more likely to exhibit multifocal disease. Although the incidence of VIN and HPV has increased over the past decade, the incidence of vulvar carcinoma has remained relatively constant. The long-term risk of malignant transformation of treated VIN III has been estimated at 3.4–7% and the risk for progression of untreated VIN is thought to be higher.

Premalignant lesions of the vulva occur in both premenopausal and postmenopausal women, with the median age being approximately 40 years. The average age is shifting toward younger women, with 75% of lesions occurring during the premenopausal period. There is no racial predisposition to VIN and the disease process is often asymptomatic. The most common presenting symptom is pruritus, which is seen in more than 60% of patients with VIN. The diagnosis is made by careful inspection of the vulvar area followed by biopsy of suspicious lesions.

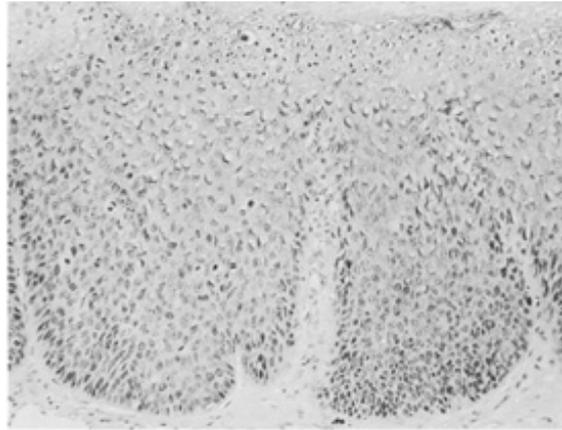

Pathology

In 1989, the International Congress of the International Society for the Study of Vulvar Disease (ISSVD) adopted a standard of reporting vulvar dysplastic lesions as VIN I, II, or III, depending on the degree of epithelial cellular maturation. The degree of loss of epithelial cellular maturation in a given lesion defines the grade of VIN. In VIN I, immature cells occur in the lower one-third of the epithelium. Complete loss of cellular maturation in the full thickness of epithelium is defined as VIN III, which is synonymous with carcinoma in situ of the vulva, or Bowen's disease. VIN II is intermediate between VIN I and VIN III.

In contrast to intraepithelial carcinoma of the cervix, which seems to arise from a single point of origin, dysplasia of the vulva is often multicentric. These lesions may be discrete or diffuse, single or multiple, flat or raised. They even form papules and vary in color from the white appearance of hyperkeratotic tumors to a velvety red or black.

The microscopic appearance of dysplastic vulvar lesions is characterized by cellular disorganization and loss of stratification that involves essentially the full thickness of the epithelium. Cellular density is increased, and individual cells vary greatly in size, with giant and multinucleated cells, numerous mitotic figures, and hyperchromatism (Fig 49–1). HPV cytopathic changes, such as perinuclear halos with displacement of nuclei, are also common.

Carcinoma in situ demonstrating hyperkeratosis, acanthosis, and parakeratosis. The rete ridges are elongated and thickened, and individual cells are atypical.

Diagnosis

Possibly 1–2% of young women with cervical dysplasia have multifocal disease that tends to involve the upper third of the vagina and the vulva, perineum, and perianal areas—these surfaces arising from a common cloacogenic origin. A spectrum of disease may be found ranging from mild dysplasia to carcinoma in situ. Involvement may not be appreciated without careful inspection with and without the green colposcopy filter. Clinically, the appearance of VIN can be quite variable. Lesions are typically white and hyperkeratotic, but may also appear gray, pink, or brown. Colposcopy and biopsy of any suspicious lesion should be performed and is considered the gold standard for diagnosis. In premenopausal women, lesions tend to be more multifocal, whereas in postmenopausal women, they are more often unifocal. An abnormal vascular pattern is most frequently associated with a severe degree of dysplasia, carcinoma in situ, or early invasive disease.

Treatment

Treatment options for VIN are individualized based on biopsy results and include wide local excision, laser ablation, topical application of 5-fluorouracil (5-FU) or imiquimod, or superficial vulvectomy with or without split-thickness skin grafting. Untreated VIN has the potential for progression to invasive carcinoma. This risk may be high for women older than age 40 years. In younger patients, spontaneous regression may occur.

Treatment modality depends on the extent of involvement of the vulva, perineum, and perianal skin, which is defined by colposcopy. Wide local excision of small foci of VIN is preferred. For unifocal lesions, a 1-cm margin of uninvolved skin is usually curative. Carbon dioxide laser may be used for multifocal disease. Disadvantages of the laser include painful recovery and lack of pathology specimens. The incidence of foci of microinvasion in VIN III has been reported to range from 10–22% in different series. Extensive disease may be best treated by superficial vulvectomy. The surgical goal is to preserve as much of the normal anatomy as possible. In the superficial "skinning" vulvectomy procedure, the excised vulvar skin can be closed with fine suture or may need to be replaced with a split-thickness skin graft (Figs 49–2 and 49–3) if the defect is too large.

Appearance after skinning vulvectomy and split-thickness skin grafting of the lesion shown in Figure 49–2.

Topical application of 5-FU, cryotherapy, and photodynamic therapy have each historically been proven useful in the treatment of some lesions, but surgery remains the hallmark treatment modality for VIN. Promising future directions for treatment of VIN involve the development of a vaccine for HPV, which is currently in the experimental phase, and use of immunomodulating agents, such as topical imiquimod.

Follow-Up

Intraepithelial carcinoma of the vulva is often one manifestation of multifocal disease. For this reason, affected patients must be examined periodically for a number of years. Recommended follow-up includes thorough pelvic examinations with colposcopy every 3–4 months until the patient is disease-free for 2 years. If the patient is disease-free for a 2-year period, examinations can be done every 6 months.

EXTRAMAMMARY PAGET'S DISEASE

General Considerations

Paget's disease of the skin is an intraepithelial neoplasia, or adenocarcinoma in situ, and accounts for less than 1% of all vulvar malignancies. Reports of long-term survivals suggest that the in situ stage of the disease persists for a long time or that invasive disease is a different clinicopathologic entity. It appears that there are two separate lesions: (a) intraepithelial extramammary Paget's disease and (b) pagetoid changes in the skin associated with an underlying adenocarcinoma. Experts believe that an adenocarcinoma associated with Paget's disease arises as a primary adenocarcinoma of an underlying apocrine gland, Bartholin's gland, or anorectum, and represents two separate disease entities, not a spectrum. Unlike mammary Paget's disease, less than 20% of vulvar Paget's disease is associated with an underlying adenocarcinoma. Paget's disease with an underlying adenocarcinoma metastasizes frequently to regional lymph nodes and distally. Paget's disease without an underlying adenocarcinoma behaves like an intraepithelial neoplasia and can be treated as such. However, patients with Paget's disease should be carefully examined for the presence of synchronous primaries elsewhere; 20–30% of these patients will be found to have carcinomas at other sites, including the breast, rectum, bladder,

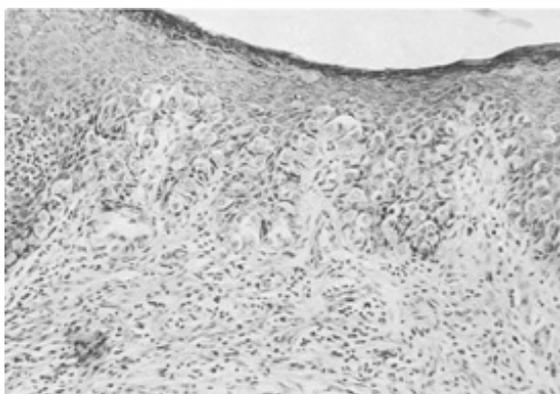

cervix, ovary, and urethra.

Pathology

The initial lesion may be confused with a number of benign forms of chronic vulvar pruritus. It is a pruritic, slowly spreading, velvety-red discoloration of the skin that eventually becomes eczematoid in appearance with secondary maceration and development of white plaques; it may spread to involve the skin of the perineum, the perianal area, and the adjacent skin of the thigh. Grossly, the lesion gives the impression of "cake icing." Because of the serpiginous growth pattern of Paget cells in the basal layer of the epidermis, the true extent of disease is difficult to assess.

Paget's disease of the vulvar skin is an intraepithelial disease. The typical Paget cell, pathognomonic of the disease process, apparently arises from abnormal differentiation of the cells of the basal layer of the epithelium (Fig 49–4). The appearance of malignant cells varies from that of the clear cell of the apocrine gland epithelium to a totally undifferentiated basal cell. It has been suggested that there may be both an intraepithelial and an invasive variety of the disease. The intraepithelial stage of the disease persists for years without evidence of an underlying adenocarcinoma.

Figure 49–4.

All rights reserved.

Paget's disease with typical cells in the basal layer of the epidermis.

Diagnosis

Paget's disease primarily affects postmenopausal white women in the seventh decade of life, but can be seen in younger patients. Pruritus and vulvar soreness are the most frequent symptoms. These symptoms may persist for years before the patient seeks medical attention. The lesion may be localized to one labium or involve the entire vulvar area. The lesion usually has an eczematoid appearance macroscopically and usually begins on the hair-bearing portions of the vulva. It is not unusual for the disease process to extend beyond the vulva to involve the perirectal area, buttocks, thighs, inguinal area, and mons. Intraepithelial extramammary Paget's disease presents as a lesion with hyperemic areas associated with a superficial white coating to give the impression of "cake icing." Although these lesions can be very extensive, most are confined to the epithelial layer. The diagnosis is made by vulvar biopsy. It is important to palpate the lesion in its entirety. A generous biopsy should be taken of any area that appears to be thickened to rule out an underlying adenocarcinoma.

Treatment

Because extramammary Paget's disease is an intraepithelial neoplasia it can be treated as such. Wide

local excision is the primary treatment modality for this disease process. The lesion needs to be excised in its entirety; however, wide margins need to be removed around the primary lesion as disease often extends beyond the clinically visible erythematous area. The underlying dermis should be removed for adequate histologic evaluation. Often such a resection involves a complete vulvectomy. Careful histologic examination of the entire operative specimen is necessary to delineate the true extent of disease, ensure free surgical margins, and detect the remote possibility of underlying adenocarcinoma. For this reason, laser therapy is unsatisfactory. Patients who have Paget's disease with underlying adenocarcinoma should be treated with radical local excision of the vulva and bilateral inguinal lymph node dissection as they would for any other invasive tumor involving the vulvar area.

Prognosis

Paget's disease of the vulva has a great propensity for local recurrence, which may represent persistence of the disease or development of new disease in the remaining vulvar skin. Extramammary Paget's disease characteristically requires repeated local excisions of recurrent disease after treatment of the primary disease by total vulvectomy. Invasive disease without evidence of lymph node metastases has a favorable prognosis; however, with nodal metastases, the disease is almost invariably fatal.

CANCER OF THE VULVA

Essentials of Diagnosis

- Typically occurs in postmenopausal women.
- Long history of vulvar irritation with pruritus, local discomfort, and bloody discharge.
- Appearance of early lesions like that of chronic vulvar dermatitis.
- Appearance of late lesions like that of a large cauliflower, or a hard ulcerated area in the vulva.
- Biopsy necessary for diagnosis.

General Considerations

Cancer of the vulva may arise from the skin, subcutaneous tissues, glandular elements of the vulva, or the epithelium of the lower third of the vagina. Approximately 90% of these tumors are squamous cell carcinomas. Less common tumors are extramammary Paget's disease with underlying adenocarcinoma, carcinoma of Bartholin's gland, basal cell carcinoma, melanoma, sarcoma, and metastatic cancers from other sites.

Cancer of the vulva is uncommon, accounting for approximately 5% of gynecologic cancers. Vulvar cancer is more common in the poor and elderly in most parts of the world, and no race or culture is spared. Vulvar cancer is primarily a disease of postmenopausal women, with a peak incidence in women ages 60–70 years. The average age at the time of diagnosis is 65 years, and 75% of patients are older than the age of 50 years. In general, the mean age of patients with carcinoma in situ is approximately 10 years less than that for patients with invasive cancer. Intraepithelial cancer of the vulva in women ages 20–40 years has increased remarkably in recent years, coincidentally with an increase in the incidence of diagnosis of dysplasia and carcinoma in situ of the cervix. HPV is strongly associated in younger women, though not in older women with vulvar cancer. Also, older women are more likely to have squamous hyperplasia in the tissue adjacent to the tumor.

Considering that cancer of the vulva is a disease of a body surface readily accessible to diagnostic procedures, early diagnosis should be the rule. This is not the case, however, and a 6- to 12-month delay in reporting symptoms of discovery of a tumor is common. Despite the advanced age of many of these patients and the frequent finding of a moderately large tumor, the disease is usually amenable to surgical

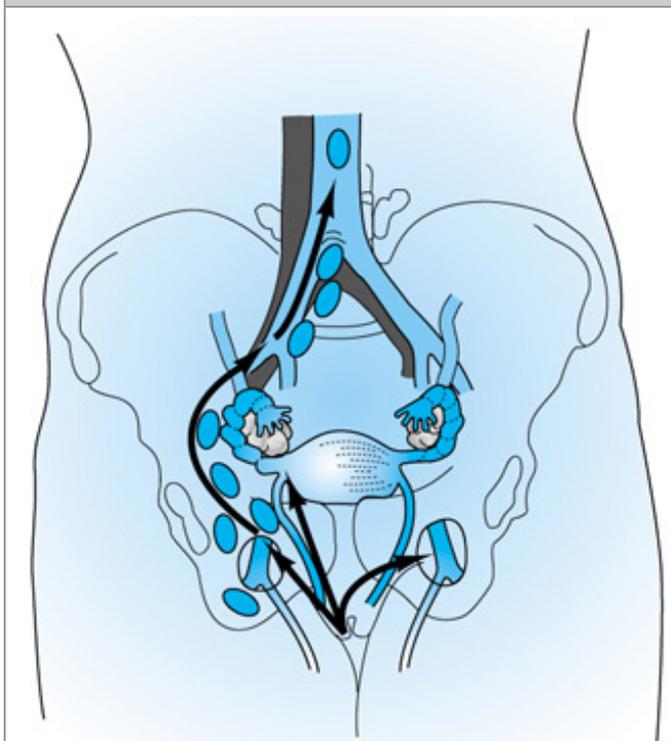

therapy. In stages I and II disease, the corrected 5-year survival rate is greater than 90%. A 75% corrected 5-year survival rate for all stages of vulvar cancer is reported by most institutions.

Associated disorders found most frequently with carcinoma of the vulva are obesity, hypertension, and chronic vulvar irritation secondary to diabetes mellitus, granulomatous venereal disease, or vulvar dystrophy.

Pathology

The gross appearance of vulvar cancer depends on the origin and histologic type. These tumors spread by local extension and, with few exceptions, by lymphatic embolization. The primary route of lymphatic spread is by way of the superficial inguinal, deep femoral, and external iliac lymph nodes (Fig 49–5). Contralateral spread may occur as a result of the rich intercommunicating lymphatic system of the vulvar skin. Direct extension to the deep pelvic lymph nodes, primarily the obturator nodes, occurs in approximately 3% of patients and seems to be related to midline involvement around the clitoris, urethra, or rectum, or to cancer of a vestibular (Bartholin's) gland. Extension of the tumor to the lower and middle thirds of the vagina may also allow access of tumor cells to lymph channels leading to the deep pelvic lymph nodes.

Figure 49–5.

Lymphatic spread of cancer of the vulva.

The following sections describe the gross and histologic appearance of the various types of vulvar cancers.

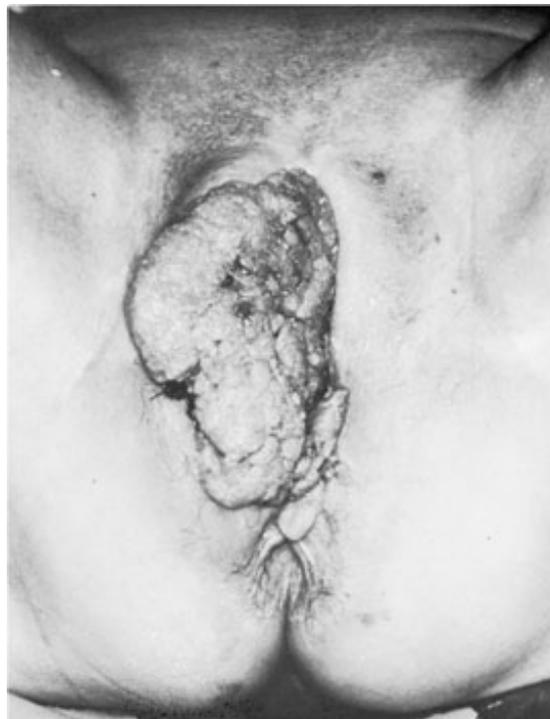

SQUAMOUS CELL CARCINOMA

Squamous cell carcinoma is by far the most common type of tumor and most frequently involves the

anterior half of the vulva. In approximately 65% of patients, the tumor arises in the labia majora and minora, and in 25% the clitoris or perineum is involved. More than one-third of tumors involve the vulva bilaterally or are midline tumors. These tumors are most frequently associated with nodal spread, particularly bilateral nodal metastases. Midline tumors that involve the perineum do not worsen the outlook unless they extend into the vagina or to the anus and rectum.

Squamous cell carcinoma of the vulva varies in appearance from a large, exophytic, cauliflowerlike lesion to a small ulcer crater superimposed on a dystrophic lesion of the vulvar skin (Figs 49–6 and 49–7). Ulcerative lesions may begin as a raised, flat, white area of hypertrophic skin that subsequently undergoes ulceration. Exophytic lesions may become extremely large, undergo necrosis, and become secondarily infected and malodorous. A third variety arises as a slightly elevated, red, velvety tumor that gradually spreads over the vulvar skin. There does not appear to be a positive correlation between the gross appearance of the tumor and either histologic grade or frequency of nodal metastases. The primary determinant of nodal metastases is tumor size.

Ulcerative squamous cell carcinoma of the vulva.

Squamous cell cancers may be graded histologically from I to III. Grade I tumors are well differentiated, often forming keratin pearls; grade II tumors are moderately well differentiated; grade III tumors are composed of poorly differentiated cells. The extent of underlying inflammatory cell infiltration into the stroma surrounding the invasive tumor is variable. The histologic grade of the tumor may be of some significance in tumors less than 2 cm in diameter. However, the lymph node status is the most significant prognostic factor.

A variant of squamous cell carcinoma, verrucous carcinoma, is a locally invasive tumor that seldom metastasizes to regional lymph nodes. Grossly, the tumor looks like a mature condylomatous growth. It is distinguished from squamous cell cancer by histopathology of the tumor base, which reveals papillary fronds without a central core. Local recurrence is common if a wide vulvectomy is not performed; lymphadenectomy is usually not recommended.

An attempt has been made to define a group of early vulvar cancers that might be described as microinvasive cancer and that exhibit little tendency for local recurrence or nodal metastases. Depth of stromal penetration has proved to be the key factor in determining invasive potential of the tumor. Early authors accepted 5 mm or less of dermal invasion as the definition of microinvasion, but this has not been universally accepted. A task force of the International Society for the Study of Vulvar Diseases suggested that the term "microinvasive cancer of the vulva" be discarded. The ISSVD defined stage IA carcinoma of the vulva as a single lesion measuring 2 cm or less in diameter and exhibiting one focus of invasion to a depth of 1 mm or less. The depth of invasion was measured from the epidermal–stromal

junction of the most superficial dermal papilla to the deepest point of tumor invasion.

CARCINOMA OF BARTHOLIN'S GLAND

Carcinoma of Bartholin's gland accounts for approximately 1% of vulvar cancers, and although rare, is the most common site for vulvar adenocarcinoma. Approximately 50% of Bartholin's gland tumors are squamous cell carcinomas. Other types of tumors arising in the Bartholin's glands are adenocarcinoma, adenoid cystic (an adenocarcinoma with specific histologic and clinical characteristics), adenosquamous, and transitional cell.

Because it may be difficult to differentiate by clinical examination a tumor of Bartholin's gland or duct from a benign Bartholin's cyst, any woman older than age 40 years should undergo biopsy to rule out cancer, as inflammatory disease is not common in this age group. Because of its location deep in the substance of the labium, a tumor may impinge on the rectum and directly spread into the ischioanal fossa. Consequently, these tumors have access to lymphatic channels draining directly to the deep pelvic lymph nodes as well as to the superficial channels draining to the inguinal lymph nodes.

BASAL CELL CARCINOMA

Basal cell carcinomas account for 1–2% of vulvar cancers. Most tumors are small elevated lesions with an ulcerated center and rolled edges. Some are described as pigmented tumors, moles, or simply pruritic maculopapular eruptions. These tumors arise almost exclusively in the skin of the labia majora, although occasionally a tumor can be found elsewhere in the vulva. The tumor is derived from primordial basal cells in the epidermis or hair follicles and is characterized by slow growth, local infiltration, and a tendency to recur if not totally excised. Most basal cell carcinomas of the vulva are of the primordial histologic type. Other histologic varieties that may be found are the pilar, morphealike, superficially spreading, adenoid, and pigmented cell tumors.

On microscopic examination the typical tumor consists of nodular masses and lobules of closely packed, uniform-appearing basaloid cells with scant cytoplasm and spherical or oval dark nuclei. Peripheral margination by columnar cells is usually prominent. In larger tumor nodules, there may be areas of central degeneration and necrosis.

If a sufficiently wide local excision is not performed, there is a tendency for local recurrence, estimated to be approximately 20%. If a basal-squamous cell-type tumor is diagnosed, appropriate therapy for invasive epidermoid cancer of the vulva should be undertaken.

MALIGNANT MELANOMA

Approximately 5% of vulvar cancers are malignant melanomas, the second most common vulvar cancer. Because only 0.1% of all nevi in women are on vulvar skin, the disproportionate frequency of occurrence of melanoma in this area may be a result of the fact that nearly all vulvar nevi are of the junctional variety. Malignant melanoma most commonly arises in the region of the labia minora and clitoris, and there is a tendency for superficial spread toward the urethra and vagina. A nonpigmented melanoma may closely resemble squamous cell carcinoma on clinical examination. A darkly pigmented, raised lesion at the mucocutaneous junction is a characteristic finding; however, the degree of melanin pigmentation is variable, and amelanotic lesions do occur. The lesion spreads primarily through lymphatic channels and tends to metastasize early in the course of the disease; local or remote cutaneous satellite lesions may be found. In contrast to squamous cell cancers, melanoma is staged according to depth of invasion. All small pigmented lesions of the vulva are suspect and should be removed by excision biopsy with a 0.5- to 1-cm margin of normal skin. In the case of large tumors, the diagnosis should be confirmed by a generous biopsy.

UNUSUAL VULVAR MALIGNANCIES

Sarcomas of the vulva constitute a variety of malignant neoplasms that account for 1–2% of vulvar cancers. The most common is leiomyosarcoma, followed in frequency of occurrence by the fibrous histiocytoma group and an array of other sarcomas. Clinically, sarcoma may present as a subcutaneous nodule or may be exophytic and fleshy. Prognosis is usually poor and depends on histologic type, extent of local invasion, and treatment. In general, radical vulvectomy and regional lymphadenectomy are indicated, with the exception of tumors such as dermatofibrosarcoma protuberans, which is a locally aggressive tumor that tends to recur locally but does not metastasize.

Adenocarcinoma of the vulva is exceptionally rare unless it arises from the Bartholin's gland or the urethra. Primary cancer of the breast from ectopic breast tissue has been reported. Rarely, a malignant tumor will arise from a vulvar sweat gland.

Metastatic cancers of the vulva constitute 8% of all vulvar tumors. They usually originate from a genital tract tumor, and 18% arise from the kidney or urethra. Advanced cervical cancer is the most common primary tumor. Other primary tumors have been reported, including malignant melanoma, choriocarcinoma, and adenocarcinoma of the rectum or breast. Cloacogenic carcinoma is primarily an anorectal neoplasm, occurring twice as often in women than in men; it may arise in anal ducts and present as a submucosal mass.

Metastatic epidermoid cancer tends to form nests of cells within the dermis. Adenocarcinoma, regardless of the primary site, invades the surface squamous epithelium. Because these tumors are a manifestation of advanced disease, the prognosis is uniformly grave.

Clinical Findings

The patient with vulvar cancer characteristically has had infrequent medical examinations. Approximately 10% are diabetic, and 30–50% are obese or hypertensive or demonstrate other evidence of cardiovascular disease. The incidence of complicating medical illness exceeds that expected in the age group under consideration.

Invasive squamous cell cancer is a disease mainly of the seventh and eighth decades of life, although approximately 15% of patients are age 40 years or younger. Approximately 20% of patients have a second primary cancer that was diagnosed prior to, at the time of, or subsequent to the diagnosis of vulvar cancer; 75% of these second primary cancers are in the cervix.

SYMPTOMS AND SIGNS

Pruritus vulvae or a vulvar mass is the presenting complaint in more than 50% of patients with vulvar cancer. Other patients complain of bleeding or vulvar pain, whereas approximately 20% of patients have no complaints, and the tumor is found incidentally during routine pelvic examination. A significant number of patients, approximately 25%, have seen a physician and received various medical treatments without benefit of a biopsy of the tumor or have undergone incomplete therapy consisting of a simple excision biopsy of an invasive tumor. The importance of performing a biopsy of any vulvar lesion cannot be overemphasized.

DIFFERENTIAL DIAGNOSIS

Differential diagnosis of vulvar disease and exclusion of cancer depend on an adequate biopsy. The tumor may be a diffuse white lesion, a discrete tumor, an ulcer, or diffuse papules, which may not be appreciated without thorough colposcopic examination of the skin of the vulva, perineum, and perianal area.

Benign ulcerative lesions may be the result of a sexually transmitted disease (syphilis, herpes, or granuloma inguinale), pyogenic infections, or a benign tumor, such as a granular cell myoblastoma.

Treatment

Staging and treatment for vulvar cancer is surgical (Table 49–1). The primary treatment for invasive vulvar cancer is complete surgical removal of all tumor whenever possible. The recent trend is toward a more conservative surgical approach, departing from traditional en bloc resections.

Table 49–1. International Federation of Gynecology and Obstetrics (FIGO) Staging of Vulvar Cancer.

Stage 0	
Cis	Carcinoma in situ, intraepithelial carcinoma
Stage I	
T1 N0 M0	Tumor confined to the vulva and/or perineum—2 cm or less in greatest dimension (no nodal metastasis)
Stage II	
T2 N0 M0	Tumor confined to the vulva and/or perineum—more than 2 cm in greatest dimension (no nodal metastasis)
Stage III	
T3 N0 M0	Tumor of any size with
T3 N1 M0	(1) Adjacent spread to the lower urethra and/or the vagina, or the anus, and/or
T1 N1 M0	(2) Unilateral regional lymph node metastasis
T2 N1 M0	
Stage IVA	
T2 N2 M0	Tumor invades any of the following: Upper urethra, bladder mucosa, rectal mucosa, pelvic bone, and/or bilateral regional node metastasis
T1 N2 M0	
T3 N2 M0	
T4 Any N M0	
Stage IVb	
Any T Any N M1	Any distant metastasis including pelvic lymph nodes

The number of preoperative studies ordered prior to surgery depends on the extent of disease and the general condition of the patient. A complete history and a thorough physical examination that includes cytologic study of the cervix and vulvoscopy should be performed. A large tumor may interfere with adequate pelvic examination. Bleeding may be caused by a lesion higher in the genital tract rather than the obvious vulvar tumor. In that case, the pelvic examination may be performed under anesthesia, and endometrial biopsy or dilatation and curettage (D&C) considered.

Chest radiography, complete blood count, and urinalysis are performed on all patients. Older patients require an electrocardiogram (ECG) and a biochemical profile. Other studies such as proctoscopy, pyelography, barium enema, and computed tomography (CT) scans are ordered on an individual basis. Enlarged lymph nodes do not require biopsy; they will be excised by lymphadenectomy or thoroughly sampled at the time of operation. Mechanical bowel cleansing is recommended for most patients, particularly if the perineal skin is involved. An antibiotic bowel preparation is prescribed if extensive

perianal dissection, skin grafting, or intestinal surgery (such as abdominoperineal resection) is anticipated. At least 2 units of packed red cells should be available for transfusion. Less than 50% of patients require a transfusion during or after the operation.

Historically, the basic operation was radical vulvectomy and regional lymphadenectomy. The trend, however, is shifting away from standard en bloc radical vulvectomy and bilateral lymph node dissection toward wide radical local excision of the primary tumor with inguinal lymph node dissection. For a unifocal stage I lesion with less than 1 mm stromal invasion, wide radical local excision with surgical margins of at least 1–2 cm should be performed. Patients with unilateral lesions with a depth of invasion greater than or equal to 1 mm should undergo ipsilateral groin dissection in addition to the above to determine nodal status. For patients with bilateral lesions or lesions impinging on or crossing the midline, bilateral inguinal femoral lymphadenectomy can be performed. When disease has spread to lymph nodes, adjuvant radiation therapy is generally recommended. The role of sentinel node mapping is also being evaluated for patients with squamous vulvar carcinoma and melanomas. In general, lymphatic spread occurs in a sequential manner from the superficial to the deep inguinal lymph nodes. Consequently, if the superficial nodes harbor no metastatic disease, there is reasonable assurance that the deeper nodes are not involved.

When the disease involves the anus, rectum, rectovaginal septum, proximal urethra, or bladder, an adequate surgical resection is only possible with pelvic exenteration combined with radical vulvectomy. Operative mortality is high for these procedures and the postoperative psychologic impact is significant. In addition, with advanced stage disease where ulcerated or fixed lymph nodes are palpated, attempts at lymphadenectomy have yielded very poor results. Based on data from the Gynecologic Oncology Group, this group of patients may benefit from preoperative chemoradiation resulting in higher rates of successful resection and reduced need for more radical surgery. Chemotherapeutic agents such as cisplatin and 5-FU have been combined with radiation therapy. These chemotherapeutic agents are used as radiation sensitizers in large necrotic tumor beds, enhancing the radiation effects.

There is controversy concerning the extent of surgery required for treatment of malignant melanoma of the vulva. For some years, standard treatment consisted of vulvectomy with superficial and deep inguinal and pelvic lymphadenectomy. It is also generally treated with a more conservative surgical approach. If depth of the vulvar lesion is less than 1 mm, vulvar melanoma may be adequately treated with local incision using a 1-cm margin. However, if the depth of invasion is between 1 and 4 mm, excision requires a 2-cm margin in addition to a bilateral groin node dissection. Advanced or recurrent melanoma may be best treated with chemotherapy, radiation, or immunotherapy.

Locally invasive but nonmetastasizing sarcomas such as dermatofibrosarcoma protuberans can be removed by wide local resection. Most other sarcomas are treated by radical vulvectomy and regional lymphadenectomy. The primary determinant of cure appears to be adequate wide removal of the primary lesion.

Operative Morbidity & Mortality

The most frequently encountered complication is wound breakdown, which occurs in well over 50% of patients undergoing radical vulvectomy and bilateral inguinal dissection. This complication is related to the amount of skin removed during the procedure, particularly at the groin areas. Separate groin incisions and careful handling of skin flaps have reduced the incidence of wound breakdown. Vigorous wound care with debridement almost always results in adequate healing.

Lymphedema occurs in approximately 65% of patients who have had radical vulvectomy. Hemorrhage, lymphocyst formation, thromboembolic disease, urinary tract infections, and sexual dysfunction are other

commonly associated morbidities.

Follow-Up

After the immediate postoperative period, patients should be examined every 3 months for 2 years and every 6 months thereafter to detect recurrent disease or a second primary cancer. Nearly 80% of recurrent vulvar cancer occurs in the first 2 years. Treatment modalities depend on the location of recurrence. Malignant melanomas and sarcomas may recur locally or metastasize to the liver or lungs.

Prognosis

The principal prognostic factors in cancer of the vulva are the presence or absence of regional lymph node metastases, size and location of the lesion, and the histologic type.

A 5-year survival rate of 75% and a 10-year survival rate of approximately 58% should be expected after complete surgical treatment of primary invasive squamous vulvar cancer. Lymph node status is the most important prognostic variable. Overall, the survival rate for patients with vulvar cancer and negative inguinal-femoral nodes is 90%, whereas rates drop to almost 40% with nodal metastasis. Several authors have reported no deaths from cancer among patients who were found to have negative lymph nodes. With tumors less than 2 cm in diameter, the incidence of nodal metastases is 10–15%. In general, approximately 30% of patients undergoing surgery will have positive lymph nodes. With nodal metastases, the approximate 5-year cure rates are as follows: 1 node, 94%; 2 nodes, 80%; and 3 nodes or more, less than 15%. Patients who have 3 or more positive lymph nodes in the groin usually demonstrate palpably suspicious nodes preoperatively. These patients have a high incidence of metastases to the pelvic lymph nodes; however, pelvic lymphadenectomy apparently does not improve survival rates. Involvement of contiguous organs such as the bladder or rectum increases the incidence of nodal metastases and worsens the prognosis accordingly.

The cure rate for adequately treated cancer of Bartholin's gland has not been established. There is a propensity for unresectable local recurrences under the pubic ramus despite a thorough primary operation.

Wide local excision of basal cell carcinoma should be curative. Some authors have reported an approximately 20% recurrence rate after local excision that may represent cases of incomplete excision.

Results of treatment of malignant melanoma are related to the level of penetration of the tumor into the dermis of the vulvar skin or the lamina propria of the vaginal mucosa and to the presence or absence of nodal metastases. The 5-year survival rate ranges from 14–50%, but patients who have metastases to groin lymph nodes have a survival rate below 14%. Amelanotic cutaneous melanomas are particularly virulent tumors. The survival rate for patients with superficial spreading melanomas is much better than for those with the nodular variety, which tend to have a smaller diameter and exhibit aggressive vertical invasion, increased incidence of nodal metastases, treatment failures, and distant recurrences. The most common site of recurrence is at the site of resection or the groin lymph nodes (if not previously resected).

Sarcomas of the vulva tend to recur locally, particularly if the initial resection is not extensive, and metastasize to the liver and lungs.

PREINVASIVE DISEASE OF THE VAGINA

General Considerations

Vaginal intraepithelial neoplasia (VAIN) can occur as an isolated lesion, but multifocal disease is more common. Although little is known regarding the natural history of VAIN, it is thought to be similar to that of cervical intraepithelial neoplasia (CIN). Many patients may have similar intraepithelial neoplastic

lesions involving the cervix or vulva. At least one-half to two-thirds of patients with VAIN have been treated for similar disease in either the cervix or the vulva. In addition, VAIN can reappear several years later, necessitating long-term follow-up in these patients. Several investigators have recognized a "field response" involving the squamous epithelium of the lower genital tract including the cervix, vagina, and vulva to be affected simultaneously by the same carcinogenic agent. The vagina lacks a transformation zone, whereas in the cervix immature epithelial cells are infected with HPV. Some theorize that the HPV entry mechanisms involve abrasions from coitus or tampon use. HPV may begin its growth in a healing abrasion in a similar fashion as in the transformation zone.

The upper third of the vagina is vulnerable to the development of dysplasia and carcinoma in situ whether or not hysterectomy has been performed previously for intraepithelial neoplasia. Each of these entities has a potential for progression to invasive cancer. For this reason, women who have had a hysterectomy with a history of HPV or intraepithelial neoplasia should continue to have periodic cytologic screening of the vaginal apex. A similar lesion may develop after prior irradiation for a pelvic malignancy; some authors report a 20% incidence of cervical or vaginal dysplasia. These tumors are usually asymptomatic and detected by routine vaginal cytologic studies. New invasive tumors in an irradiated field usually develop 15–30 years after therapeutic irradiation.

Condylomatous lesions of the lower genital tract often demonstrate associated dysplasias. For this reason a biopsy should be made of condylomatous growth of the vagina prior to treatment.

Pathology

As with other intraepithelial neoplasias occurring in the lower genital tract, VAIN is characterized by a loss of epithelial cell maturation. This is associated with nuclear hyperchromatosis and pleomorphism with cellular crowding. The thickness of the epithelial abnormality designates the various lesions as VAIN I, II, or III. VAIN III is synonymous with carcinoma in situ of the vagina.

Diagnosis

Almost all lesions of VAIN are asymptomatic. Lesions often accompany HPV infection, so patients may complain of vulvar warts. An abnormal Papanicolaou (Pap) smear is usually the first sign of disease. The diagnosis is made by colposcopic examination of the vagina with a directed biopsy. Colposcopic examination of the vagina can be difficult to perform, particularly if a hysterectomy has already been done. Techniques similar to those used for colposcopic examination of the cervix are used for examination of the vagina. After application of 3–5% acetic acid to the vagina, a lesion under the colposcope may appear as white epithelium, and may have mosaicism or punctation. Lugol's iodine may also help to identify the borders of a lesion. Lesions are often located along the vaginal ridges; they may appear to be raised or have spicules. Because the disease process tends to be multifocal, a thorough examination of the vagina from the introitus to the apex must be conducted.

Treatment

The primary treatment modality for VAIN is surgical excision or carbon dioxide laser ablation. VAIN I lesions usually do not require treatment, as lesions typically regress, are multifocal, and often recur. VAIN II and III can be treated by laser ablation or excision. VAIN III lesions are more often associated with an early invasive lesion; therefore, adequate sampling should be performed before any ablative procedure is employed. If the lesion is focal, it is best removed in its entirety with local excision. When carcinoma in situ of the cervix extends to the upper vagina, the upper third of the vagina can be removed at the time of hysterectomy. If multifocal disease is present, a total vaginectomy may be performed with a split-thickness skin graft vaginal reconstruction. Topical 5-FU may also be used in treating multifocal VAIN. Approximately 80% of patients can expect to have evidence of regression of

disease after one to two courses of treatment.

Follow-Up

Intraepithelial neoplasia of the vagina tends to be multifocal, with involvement of the cervix and vulva in many cases. These lesions can be difficult to eradicate with only one treatment modality or treatment session. This group of patients must be monitored closely every 3–4 months with colposcopic examinations of not only the vagina but also the entire lower genital tract.

CANCER OF THE VAGINA

Essentials of Diagnosis

- Asymptomatic: abnormal vaginal cytology.
- Early: painless bleeding from ulcerated tumor.
- Late: bleeding, pain, weight loss, swelling.

General Considerations

Primary cancers of the vagina are rare, representing approximately 3% of gynecologic cancers. Approximately 85% are squamous cell cancers, and the remainder, in decreasing order of frequency, are adenocarcinomas, sarcomas, and melanomas. A tumor should not be considered a primary vaginal cancer unless the cervix is uninvolved or only minimally involved by a tumor obviously arising in the vagina. By convention, any malignancy involving both cervix and vagina that is histologically compatible with an origin in either organ is classified as cervical cancer. Secondary carcinoma of the vagina is seen more frequently than primary vaginal cancers. Secondary, or metastatic, tumors may arise from cervical, endometrial, or ovarian cancer, breast cancer, gestational trophoblastic disease, colorectal cancer, or urogenital or vulvar cancer. Extension of cervical cancer to the vagina is probably the most common malignancy involving the vagina. HPV, early hysterectomy, and prior radiation are possible risk factors for vaginal cancer, but no specific etiologic agent has been identified.

Pathology

Squamous cell carcinoma may be ulcerative or exophytic. It usually involves the posterior wall of the upper third of the vagina, but may be multicentric. Direct invasion of the bladder or rectum may occur. The incidence of lymph node metastases is directly related to the size of the tumor. The route of nodal metastases depends on the location of the tumor in the vagina. Tumors in the lower third metastasize like cancer of the vulva, primarily to the inguinal lymph nodes (Fig 49–8). Cancers of the upper vagina, which is the most common site, metastasize in a manner similar to cancer of the cervix. The lymphatic drainage of the vagina consists of a fine capillary meshwork in the mucosa and submucosa with multiple anastomoses. As a consequence, lesions in the middle third of the vagina may metastasize to the inguinal lymph nodes or directly to the deep pelvic lymph nodes.

Figure 49–8.

An ulcerated epidermoid cancer of the lower third of the vagina.

Melanomas and sarcomas of the vagina metastasize like squamous cell cancer, although liver and pulmonary metastases are more common. Nevi rarely occur in the vagina; therefore, any pigmented lesion of the vagina should be excised or biopsied. The anterior surface and lower half of the vagina are the most common sites. Grossly, the tumors are usually exophytic and described as polypoid or pedunculated with secondary necrosis.

Sarcomas of the vagina occur in children younger than 5 years of age and in women in the fifth to sixth decades. Embryonal rhabdomyosarcomas or sarcoma botryoides, replace the vaginal mucosa of young girls and consist of polypoid, edematous, "grapelike" masses that may protrude from the vaginal introitus. Leiomyosarcomas, reticulum cell sarcomas, and unclassified sarcomas occur in older women. The upper anterior vaginal wall is the most common site of origin. The appearance of these tumors depends on the size and the extent of disease at the time of diagnosis.

Clear cell adenocarcinomas arise in conjunction with vaginal adenosis, which, in recent years, has been detected most frequently in young women with a history of exposure to diethylstilbestrol (DES) in utero (Fig 49–9). The Registry of Clear Cell Adenocarcinoma of the Genital Tract in Young Females was established in 1971 to study the clinicopathologic and epidemiologic aspects of these tumors in girls born in 1940 or later, the years during which DES was used during pregnancy. The risk of developing clear cell adenocarcinoma by age 24 years has been calculated to be 0.14–1.4 per 1000 exposed female fetuses.

Adenosis vaginae and adenocarcinoma do occur in sexually mature and postmenopausal women.

Figure 49–9.

Copyright ©2006 by The McGraw-Hill Companies, Inc.
All rights reserved.

A clear cell adenocarcinoma of the vagina in a 19-year-old patient. The lesion is on the posterior wall of the upper third of the vagina.

Metastatic adenocarcinoma to the vagina may arise from the urethra, Bartholin's gland, the rectum or bladder, the endometrial cavity, the endocervix, or an ovary, or it may be metastatic from a distant site. Hypernephroma of the kidney characteristically metastasizes to the anterior wall of the vagina in the lower third. These tumors are not primary vaginal cancers.

Clinical Findings

Vaginal cancer is often asymptomatic, discovered by routine vaginal cytologic examination, and confirmed by biopsy after delineation of the location and extent of the tumor by colposcopy.

Postmenopausal vaginal bleeding and/or bloody discharge are the most common presenting symptoms. Approximately 50% of patients with invasive vaginal cancer report for examination within 6 months after symptoms are noted. Less commonly, advanced tumors may impinge upon the rectum or bladder or extend to the pelvic wall, causing pain or leg edema.

A diagnosis of primary cancer of the vagina cannot be established unless metastasis from another source is eliminated. A complete history and physical examination should be performed, including a thorough pelvic examination, cervical cytologic examination, endometrial biopsy when indicated, complete inspection of the vagina, including colposcopy, and biopsy of the vaginal tumor. Careful bimanual examination with palpation of the entire length of the vagina can detect small submucosal nodules not visualized during the examination.

The staging system for cancer of the vagina is clinical and not surgical (Table 49–2).

Table 49–2. FIGO Staging of Carcinoma of the Vagina.

Preinvasive carcinoma	
Stage 0	Carcinoma in situ, intraepithelial carcinoma.
Invasive carcinoma	
Stage I	The carcinoma is limited to the vaginal mucosa.
Stage II	The carcinoma has involved the subvaginal tissue but has not extended to the pelvic wall.
Stage III	The carcinoma has extended to the pelvic wall.
Stage IV	The carcinoma has extended beyond the true pelvis or has involved the mucosa of the bladder or rectum. A bullous edema as such does not permit allotment of a case to stage IV.
Stage IVA	Spread of the growth to adjacent organs.
Stage IVB	Spread to distant organs.

FIGO, Federation of Gynecology and Obstetrics.

Differential Diagnosis

Benign tumors of the vagina are uncommon, are usually cystic, arise from the mesonephric (wolffian) or paramesonephric ducts, and are usually an incidental finding on examination of the anterolateral wall of the vagina (Gartner's duct cyst).

An ulcerative lesion may occur at the site of direct trauma, following an inflammatory reaction caused by prolonged retention of a pessary or other foreign body, or, occasionally, following a chemical burn. Granulomatous venereal diseases seldom affect the vagina but may be diagnosed with appropriate laboratory studies and a biopsy.

Endometriosis that penetrates the cul-de-sac of Douglas into the upper vagina cannot be differentiated from cancer except by biopsy.

Cancer of the urethra, bladder, rectum, or Bartholin's gland may penetrate or extend into the vagina. Cloacogenic carcinoma is a rare tumor of the anorectal region originating from a persistent remnant of the cloacal membrane of the embryo. The tumor accounts for 2–3% of anorectal carcinomas and occurs more than twice as often in women. Although these metastatic tumors often penetrate into the vagina as fungating or ulcerating lesions, they may present as a submucosal mass.

Biopsy should be performed to establish a histologic diagnosis.

Treatment

Following biopsy confirmation of disease, all patients should undergo a thorough physical examination and evaluation of the extent of local and metastatic disease. Pretreatment evaluation may include the following studies: chest radiography, intravenous pyelogram, cystoscopy, proctosigmoidoscopy, and CT scan of the abdomen and pelvis. The treatment of patients with invasive vaginal cancer primarily consists of combined external-beam and internal radiation therapy. In patients in whom coitus is an important factor, surgery should be considered. Also in patients with stages I and IIA lesions, radical hysterectomy with an upper vaginectomy may be performed. Therapy is complicated by the anatomic proximity of the

vagina to the rectum, bladder, and urethra. Most primary invasive epidermoid cancers of the vagina are treated by irradiation. Irradiation consists of whole-pelvis external therapy supplemented by internal radiation treatment. Interstitial therapy is commonly used unless there exists a small vault lesion, which may be adequately managed by a tandem and ovoid implant.

A select group of patients with stage III or IV disease may benefit from preoperative whole-pelvic radiation followed by radical surgery. However, most affected patients are treated by irradiation, which consists of whole-pelvis external irradiation followed by intracavitary or interstitial implants, or additional external therapy through a treatment field that has been reduced in size and localized to the affected parametrium. In some cases, carcinoma at the introitus may be treated like cancer of the vulva, using radical vulvectomy and bilateral superficial and deep inguinal lymphadenectomy. A very small and early lesion may be treated by total vaginectomy. However, the close proximity of the bladder and the rectum often precludes conservative surgery. Irradiation is essentially the same as that used for cancers of the upper vagina. When the lower third of the vagina is involved, the inguinal nodes must be treated with either irradiation or inguinal lymphadenectomy.

The principles of treatment of primary adenocarcinoma of the vagina are the same as those for squamous cell cancer. However, preferred therapy for clear cell carcinoma of the vagina and cervix in young women has not been established. Approximately 60% of tumors occur in the upper half of the vagina, and the remainder occur in the cervix. The incidence of nodal metastases is approximately 18% in stage I and 30% or more in stage II disease. If the disease is found sufficiently early and is confined to the upper vagina and cervix, radical abdominal hysterectomy, upper vaginectomy, and pelvic lymphadenectomy with ovarian preservation can be performed. More advanced lesions are treated with irradiation.

Sarcoma botryoides, a variety of rhabdomyosarcoma, is usually seen in patients who are younger than 5 years of age. Radiation therapy or local excision has yielded poor results; thus, historically, pelvic exenteration was the standard of therapy. Primary chemotherapy with vincristine, actinomycin D, and cyclophosphamide plus radiation leads to excellent results in treating patients with this disease. Melanoma of the vagina may be treated with radiation, conservative excision, and/or radical surgery.

Epidermoid cancers that recur after primary radiation therapy are usually treated by pelvic exenteration. Chemotherapy for recurrent disease has been relatively ineffective, but multidrug regimens incorporating cisplatin may prove to be more useful.

Prognosis

The size and stage of the disease at the time of diagnosis are the most important prognostic indicators in squamous cell cancers. The 5-year survival rate is approximately 77% in patients with stage I disease, 45% in patients with stage II disease, 31% in patients with stage III disease, and 18% in patients with stage IV disease.

Melanomas—even small ones—are very malignant, and few respond to therapy. The tumor recurs locally and metastasizes to the liver and lungs. Chemotherapy and immunotherapy have been used as adjunctive treatment.

Too few sarcomas of the vagina have been reported to generate survival data. These tumors have a propensity for local recurrence and distant metastases, and the prognosis is usually poor.

Current OB/GYN >Chapter 50. Premalignant & Malignant Disorders of the Uterine Cervix >

CERVICAL INTRAEPITHELIAL NEOPLASIA

Essentials of Diagnosis

- The cervix often appears grossly normal.
- Infection with the human papillomavirus is present.
- Dysplastic or carcinoma in situ cells are noted in a cytologic smear preparation (traditional Pap smear or liquid-based cytology).
- Colposcopic examination reveals an atypical transformation zone with thickened acetowhite epithelium and coarse punctate or mosaic patterns of surface capillaries.
- Iodine-nonstaining (Schiller-positive) area of squamous epithelium is typical.
- Biopsy diagnosis of cervical intraepithelial neoplasia (dysplasia or carcinoma in situ).

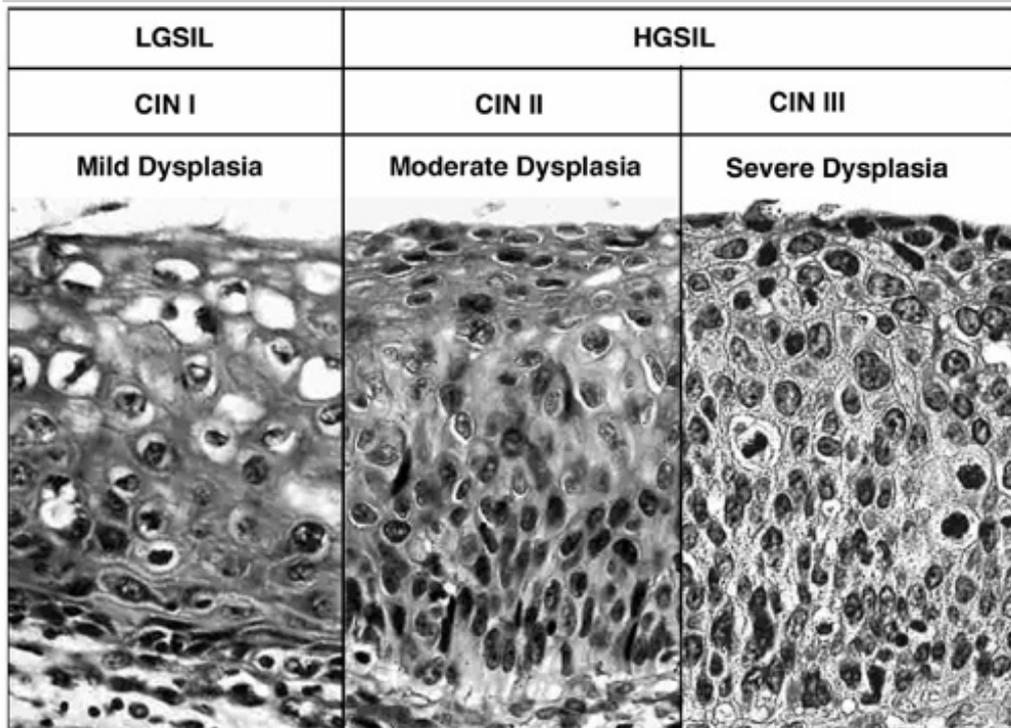

General Considerations

Lower genital tract squamous intraepithelial neoplasia is often multicentric (ie, affecting multiple anatomic sites which embryologically are derived from the same anogenital epithelium): cervical intraepithelial neoplasia (CIN), vaginal intraepithelial neoplasia (VAIN, see Chapter 49), vulvar intraepithelial neoplasia (VIN, see Chapter 49), and perianal intraepithelial neoplasia (PAIN). Approximately 10% of women with CIN have concomitant preinvasive neoplasia of the vulva, vagina, or anus. Conversely, 40–60% of patients with VIN or VAIN have synchronous or metachronous CIN.

Cervical intraepithelial neoplasia (CIN), formerly called dysplasia, means disordered growth and development of the epithelial lining of the cervix. There are various degrees of CIN. Mild dysplasia, or CIN I, is defined as disordered growth of the lower third of the epithelial lining. Abnormal maturation of the lower two-thirds of the lining is called moderate dysplasia, or CIN II. Severe dysplasia, CIN III, encompasses more than two-thirds of the epithelial thickness with carcinoma in situ (CIS) representing full-thickness dysmaturity (Fig 50–1). While histologically evaluated lesions are characterized using the CIN nomenclature, cytologic smears are classified according to the Bethesda system, which was most recently revised in 2001 (Table 50–1). Briefly, atypical squamous cells are divided into those of undetermined significance (ASC-US) and those in which a high grade lesion cannot be excluded (ASC-H). Low-grade squamous intraepithelial lesion (LSIL) encompasses cytologic changes consistent with koilocytic atypia or CIN I. High-grade squamous intraepithelial lesion (HSIL) denotes the cytologic findings corresponding to CIN II and CIN III. CIN may be suspected because of an abnormal cytologic smear, but the diagnosis is established by cervical biopsy. Spontaneous regression, especially of CIN I, occurs in a significant number of patients, allowing for expectant management with serial cytologic smears in the reliable patient. A certain percentage of all dysplasias, especially high-grade lesions, will progress to an invasive cancer if left untreated. Because it is not presently possible to predict which lesions will progress, it is recommended that patients with CIN II and CIN III be treated when diagnosed. The only exception to this recommendation concern

adolescents, in whom CIN II may be followed, as spontaneous regression is substantial and the risk of cancer almost nil.

Specimen Type

Indicate conventional smear (Pap smear) vs. liquid-based vs. other

Specimen Adequacy

Satisfactory for evaluation (*describe presence or absence of endocervical transformation zone component and a other quality indicators, eg, partially obscuring blood, inflammation, etc*)

Unsatisfactory for evaluation. . . (*specify reason*)

Specimen rejected/not processed (*specify reason*)

Specimen processed and examined, but unsatisfactory for evaluation of epithelial abnormality because of (*specify reason*)

General Categorization (optional)

Negative for intraepithelial lesion or malignancy

Epithelial cell abnormality: See Interpretation/Result (*specify squamous or glandular as appropriate*)

Other: See Interpretation/Result (*eg, endometrial cells in a woman \geq 40 years of age*)

Automated Review

If case examined by automated device, specify device and result

Ancillary Testing

Provide a brief description of the test methods and report the result so that it is easily understood by the clinician

Interpretation/Result

NEGATIVE FOR INTRAEPITHELIAL LESION OR MALIGNANCY (*when there is no cellular evidence of neoplasia state this in the General Categorization above and/or in the Interpretation/Result section of the report, whether or not there are organisms or other non-neoplastic findings*)

ORGANISMS:

Trichomonas vaginalis

Fungal organisms morphologically consistent with *Candida* spp.

Shift in flora suggestive of bacterial vaginosis

Bacteria morphologically consistent with *Actinomyces* spp.

Cellular changes consistent with herpes simplex virus

OTHER NON-NEOPLASTIC FINDINGS (*Optional to report; list not inclusive*):

Reactive cellular changes associated with inflammation (includes typical repair)

Radiation

Intrauterine contraceptive device (IUD)

Glandular cells status posthysterectomy

Atrophy

OTHER

Endometrial cells (in a woman \geq 40 years of age) (*Specify if negative for squamous intraepithelial lesion*)

EPITHELIAL CELL ABNORMALITIES

SQUAMOUS CELL

Atypical squamous cells of undetermined significance (ASC-US) cannot exclude HSIL (ASC-H)

Low-grade squamous intraepithelial lesion (LSIL) encompassing: HPV/mild dysplasia/CIN

High-grade squamous intraepithelial lesion (HSIL) encompassing: moderate and severe dysplasia, CIN 2 and CIN 3/CIS

Squamous cell carcinoma

GLANDULAR CELL

Atypical (AGC)

endocervical cells

endometrial cells

glandular cells not otherwise specified (NOS)

Atypical, favor neoplastic

endocervical cells

glandular cells NOS

Endocervical adenocarcinoma in situ (AIS)

Adenocarcinoma

endocervical

endometrial

extrauterine

not otherwise specified (NOS)

OTHER MALIGNANT NEOPLASMS: (*specify*)

Educational Notes and Suggestions (*optional*)

Suggestions should be concise and consistent with clinical follow-up guidelines published by professional organizations (references to relevant publications may be included)

Epidemiology & Etiology

Prevalence figures for CIN vary according to the socioeconomic characteristics and geographic area of the population studied, from as low as 1.05% in some family planning clinics to as high as 13.7% in women attending sexually transmitted disease (STD) clinics. CIN is most commonly detected in women in their 20s, the peak incidence of carcinoma in situ is in women ages 25–35 years, whereas the incidence of cervical cancer rises most significantly after the age of 40 years.

The epidemiologic risk factors for CIN are similar to those for cervical cancer and include multiple sexual partner early onset of sexual activity, a high-risk sexual partner (history of multiple sexual partners, human papillomavirus (HPV) infection, lower genital tract neoplasia, or prior sexual exposure to someone with cervical neoplasia), a history of STDs, as well as cigarette smoking, human immunodeficiency virus (HIV) infection, acquired immune deficiency syndrome (AIDS), other forms of immunosuppression, multiparity, and long-term oral contraceptive use.

HPVs are a prime etiologic factor in the development of CIN and cervical cancer. In fact, most of the above behavioral and sexual risk factors for cervical neoplasia become statistically insignificant as independent variable after adjusting for HPV infection. Analyses of cervical neoplasia lesions show the presence of HPV in more than 80% of all CIN lesions and in 99.7% of all invasive cervical cancers.

Infection with HPV is extremely common and varies with the patient's age. In the United States, the prevalence detectable HPV infection rises from 1% in newborns, to 20% in teenagers, to 40% in women 20–29 years of age with a slow decline thereafter to a plateau of 5% in women age 50 years and older. Condoms are not as protective against HPV as they are against other sexually transmitted diseases as transmission can occur from labial-scrotal contact.

More than 90% of immunocompetent women will have a spontaneous resolution of their HPV infection over a 2-year period and only approximately 5% will have cytologically detectable CIN. Women who have persistent HPV infections, especially with high viral loads, have a higher likelihood of developing CIN and cervical cancer.

The vast majority of women infected with HPV do not develop CIN or cervical cancer. This suggests that infection with HPV alone is insufficient for the development of CIN or cervical cancer and underscores the importance of other cofactors, such as cigarette smoking or immunosuppression.

There are more than 100 HPV types, half of which infect the anogenital epithelium. Based on their malignant potential, HPV subtypes are categorized into low-risk and high-risk types. Low-risk HPV types (eg, types 6, 11, 43, and 44) are associated with condylomata and low-grade lesions (CIN I), whereas high-risk HPV (such as types 16, 18, 31, 33, 35, 39, 45, 51, 52, 56, 58, 59, 68, 73, and 82) is, in addition to high-grade lesions (CIN II and III), found in invasive cancer.

Cigarette smoking and HPV infection have synergistic effects on the development of CIN, and cigarette smoking associated with a 2- to 4-fold increase in the relative risk for developing cervical cancer. Cigarette smoke carcinogens have been found to accumulate locally in the cervical mucus, and the cumulative exposure as measured by pack-years smoked is related to the risk of developing CIN or carcinoma in situ. However, the

mechanisms by which cigarette smoking contributes to cervical carcinogenesis are poorly understood.

The incidence of cervical neoplasia is increased in HIV-infected women, who, in some studies, have a 20–30% incidence of colposcopically confirmed CIN. With increasing immunosuppression there is an increased risk of de novo HPV infection, persistent HPV infection, and progressive cervical neoplasia. Since 1993, invasive cervical cancer has been included as an AIDS-defining illness.

Pathology

On cytologic examination, the dysplastic cell is characterized by anaplasia, an increased nuclear-to-cytoplasmic ratio (ie, the nucleus is larger), hyperchromatism with changes in the nuclear chromatin, multinucleation, and abnormalities in differentiation.

Histologically, involvement of varying degrees of thickness of the stratified squamous epithelium is typical of dysplasia. The cells are anaplastic and hyperchromatic, and show a loss of polarity in the deeper layers as well as abnormal mitotic figures in increased numbers. Benign epithelial alterations, particularly those of an inflammatory nature, the cytopathic effects of HPV, and technical artifacts may be mistaken for CIN I and CIN II.

The columnar epithelium of the mucus-secreting endocervical glands can also undergo neoplastic transformation. Adenocarcinoma in situ (ACIS) is defined as the presence of endocervical glands lined by atypical columnar epithelium that cytologically resembles the cells of endocervical adenocarcinoma, but that occur in the absence of stromal invasion. The diagnosis of ACIS can be made only by cone biopsy.

Clinical Findings

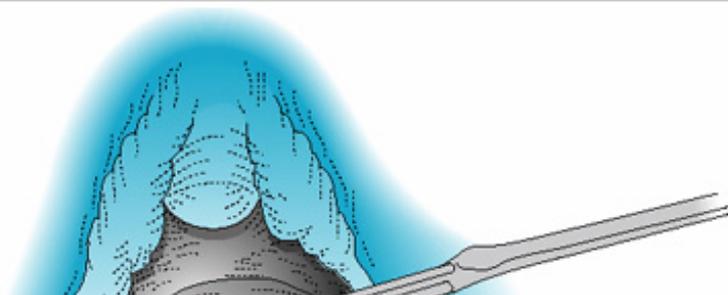

SYMPTOMS AND SIGNS

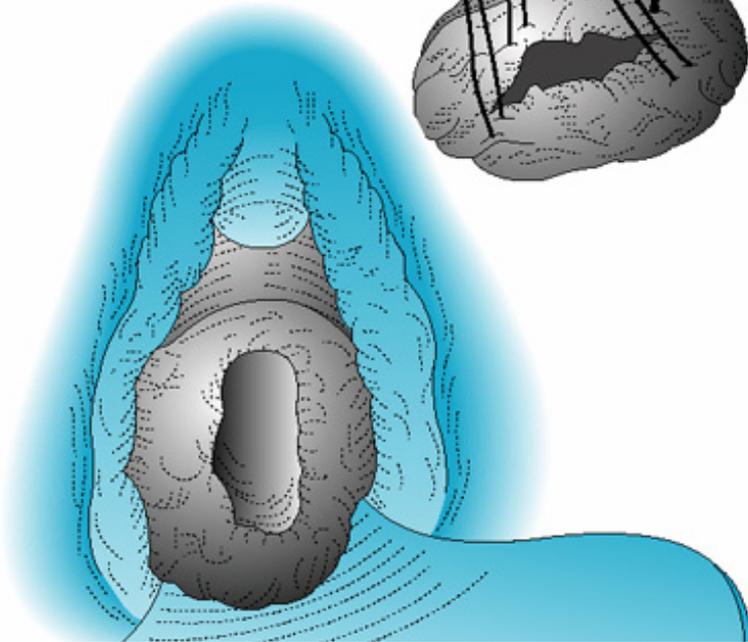

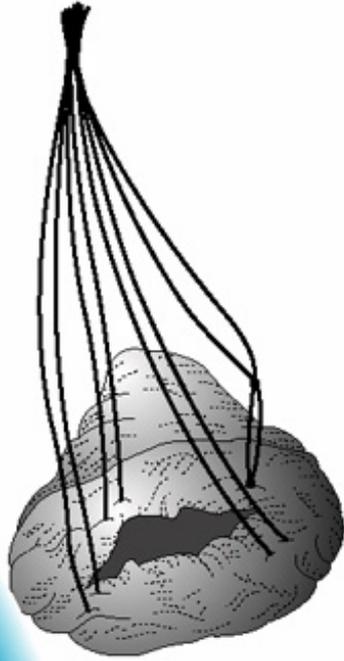

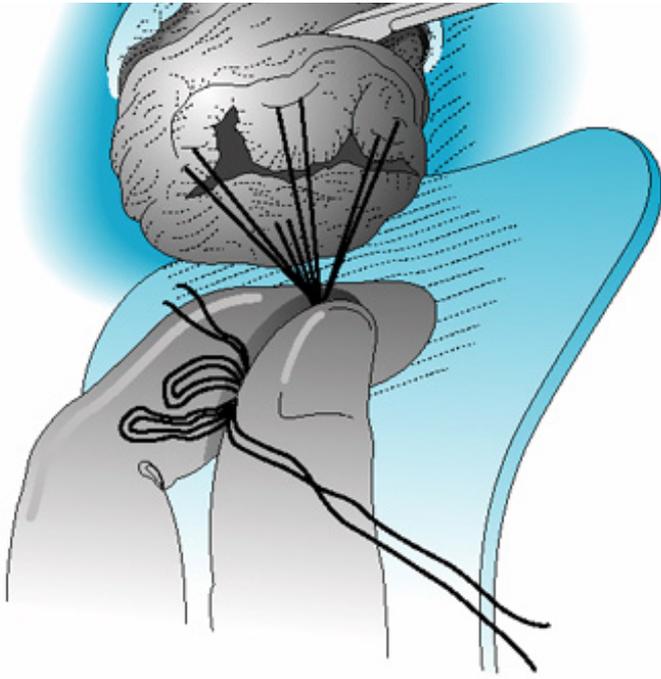

There are usually no symptoms or signs of CIN, and the diagnosis is most often based on biopsy findings following an abnormal routine cervical cytology smear. Because high-grade dysplasia probably is a transitional phase in the pathogenesis of many cervical cancers, early detection is extremely important. Based on the American Cancer Society guidelines, which were last revised in 2002, all women who have reached age 21 years, or who are 3 years past coitarche, should have a pelvic examination and collection of a cytologic smear. The cervical cytology smear should be performed annually in case of conventional Papanicolaou (Pap) smears, and biannually if using liquid-based cytology. Once a patient is age 30 years or older and has had 3 consecutive negative smears, the time interval between cervical cytology smears can be extended to every 3 years. Cervical cytology screening may be discontinued at age 70 years if the patient had 3 or more consecutive normal smears in the preceding 10 years. Screening cytology smears may also be discontinued if the patient has undergone a total hysterectomy, unless it was done for the treatment of cervical dysplasia or cancer.

SPECIAL EXAMINATIONS

All abnormal Pap smears require further evaluation, such as visual inspection of the cervix, repeat cytology, HPV testing, staining with Lugol's solution (Schiller test) or toluidine blue, colposcopy, directed biopsy, endocervical curettage, or diagnostic conization (see treatment section) (Fig 50–2). The objective is to exclude the presence of invasive carcinoma and to determine the degree and extent of any CIN.

Conization of the cervix.

Repeat Cervical Cytology

There are three acceptable initial evaluation steps for patients with minimally abnormal cervical cytology smears (eg, ASC-US): accelerated serial cytology smears, triage to colposcopy based on a positive HPV testing result, or immediate referral to colposcopy. All patients with ASC-H, LSILs, HSILs, atypical glandular cells (AGCs), or smears suspicious for cancer should be referred for immediate colposcopy.

Prior to performing a repeat smear for a patient with ASC-US, she should be evaluated and treated for potential underlying conditions that might contribute to an atypical smear, such as antimicrobials for infections or hormone therapy for atrophic vaginitis. The cervical cytology smear should be repeated every 6 months until there are two consecutive normal smears. The use of serial cytologic smears is important, as the false-negative rate of a single repeat smear following an ASC-US diagnosis is as high as 33% for biopsy-proven high-grade squamous intraepithelial lesions (CIN II/III). A second abnormal smear (atypical squamous cell [ASC] or worse) should be evaluated by colposcopy.

HPV Testing

Testing for low-risk HPV types has no role in cervical cancer prevention. Testing for high-risk HPV types has been investigated as an intermediary test for patients with minimally abnormal cervical cytology smears (ASC-US, LSIL). For patients with ASC-US, reflex HPV testing is the preferred approach, with triage of women who test positive for high-risk HPV to colposcopy. Reflex HPV testing refers to the concurrent collection of a specimen for cervical cytology and HPV testing, with the HPV testing being performed only in case of an abnormal cytologic screen. For ASC-US, this approach is the most cost-effective and has an equal or higher sensitivity for CIN II/III at the lower referral rate to colposcopy compared to the two alternate approaches (accelerated serial cytology or immediate colposcopy). Women with an ASC-US smear and a negative HPV test are followed with a cervical cytology smear every 1 year. The value of HPV testing for the triage of patients with LSIL is limited because nearly 85% of the lesions are HPV positive. HPV testing combined with a cervical cytology smear has been approved as a primary screening approach in the patient age 30 years and older, who still has her uterus and has no immunosuppression. If both results are negative, combined screening should not be repeated for 3 years. If cytology and HPV testing are positive, triaging to colposcopy is as outlined above. If cytology is normal, but HPV test is positive, repeat cytology and HPV test in 6–12 months is recommended, with colposcopy at that point if either test is abnormal.

Schiller Test

The Schiller test is based on the principle that normal mature squamous epithelium of the cervix contains glycogen which combines with iodine to produce a deep mahogany-brown color. Nonstaining, therefore, indicates abnormal squamous (or columnar) epithelium, scarring, cyst formation, or immature metaplastic epithelium, and constitutes a positive Schiller test. Lugol's solution is an aqueous iodine preparation and is commonly used for the Schiller test.

Colposcopic Examination

Colposcopy is the primary technique for the evaluation of an abnormal cervical cytology smear. The colposcope is an instrument that uses illuminated low-power magnification (5–15x) to inspect the cervix, vagina, vulva, or an

epithelium. Abnormalities in the appearance of the epithelium and its capillary blood supply often are invisible to the naked eye but can be identified by colposcopy, particularly after the application of 3–5% aqueous acetic acid solution. CIN produces recognizable abnormalities of the cervical epithelium in the majority of patients.

Indications for colposcopy are:

1. Abnormal cervical cytology smear or HPV testing;
2. Clinically abnormal or suspicious-looking cervix;
3. Unexplained intermenstrual or postcoital bleeding;
4. Vulvar or vaginal neoplasia; or
5. History of in utero diethylstilbestrol (DES) exposure.

Details of the colposcopy technique are described in Chapter 38.

Normal colposcopic findings are those of:

a) The original squamous epithelium, which extends from the mucocutaneous vulvovaginal junction to the original squamocolumnar junction.

b) The transformation zone, which is the metaplastic squamous epithelium between the original squamocolumnar junction and the active squamocolumnar junction. The original squamocolumnar junction is the junction between the stratified squamous epithelium of the vagina and ectocervix, and the columnar epithelium of the endocervical canal. In two-thirds of female infants, this original squamocolumnar junction is located on the ectocervix, in close to a third in the endocervical canal, and in a very small subset out in the vaginal fornices. During a woman's life cycle the squamocolumnar junction "migrates" as a consequence of various hormonal and environmental influences that alter the cervical volume and cause squamous metaplasia of everted endocervical columnar cells. Following menarche, the squamocolumnar junction is generally found on the ectocervix, with further eversion during pregnancy. In the postmenopausal patient, the squamocolumnar junction is frequently within the endocervical canal. This squamous metaplasia is a dynamic process and cervical neoplasia almost invariably originates within transformation zone. If the new squamocolumnar junction is visualized in its entirety, the colposcopic examination is called satisfactory; if it cannot be fully visualized, the examination is called unsatisfactory.

c) The columnar epithelium of the endocervical canal.

Abnormal findings indicative of dysplasia and carcinoma in situ (CIS) are those of:

1. Leukoplakia or hyperkeratosis, which is an area of white, thickened epithelium that is appreciated prior to the application of acetic acid and may indicate underlying neoplasia.
2. Acetowhite epithelium, which is epithelium that stains white after the application of acetic acid.
3. Mosaicism or punctation reflecting abnormal vascular patterns of the surface capillaries. As a general rule, capillary thickness and intercapillary distances correlate with the severity of the lesion and thus tend to be larger and coarser in higher-grade lesions.
4. Atypical vessels with bizarre capillaries with so-called corkscrew, comma-shaped, or spaghetti-like configurations suggest early stromal invasion (Figs 50-3, 50-4, and 50-5).

A colposcopically directed punch biopsy of the most severely abnormal areas should be done. The transformation zone extends into the endocervical canal beyond the field of vision in 12–15% of premenopausal women and in significantly higher percentage of postmenopausal women. Evaluation of the nonvisualized portion of the endocervical canal by endocervical curettage (ECC) should be performed using a brush or curette, at a minimum in every case in which colposcopy is unsatisfactory, where the lesion is extending into the endocervical canal, where the colposcopic impression does not explain the cervical cytology findings, or where ablative therapy is contemplated. ECC is not indicated in pregnancy. In up to 20% of patients with CIN, the endocervical curettage positive for dysplasia.

Diagnostic Conization

Following expert colposcopic evaluation, diagnostic conization of the cervix (Fig 50–2) is indicated if colposcopy is unsatisfactory, if the lesion extends into the cervical canal beyond the view afforded by the colposcope, if there is dysplasia on the endocervical curettage, if there is a significant discrepancy between the histologic diagnosis of a directed biopsy specimen and the cytologic examination, if adenocarcinoma in situ is suspected, or if microinvasive carcinoma is suspected.

Natural History

Understanding the natural history of the various degrees of CIN is central to the appropriate clinical management of these patients. In addition to the degree of dysplasia, it is likely that the course of a specific lesion is also influenced by a number of other factors, such as the patient's age, the inciting HPV type, the patient's immune competence, and smoking habits. As summarized in Table 50–2, the majority of CIN I lesions will spontaneously regress without treatment. However, 9–16% of patients with untreated CIN I are diagnosed with CIN II/III over 2-year follow-up. Spontaneous regression rates of CIN I overall are 60%; in young women, the rates are as high as 91%. Therefore, it is generally reasonable to expectantly follow the compliant patient with CIN I using surveillance with serial cervical cytology smears at 6-month intervals or an HPV test at 12 months. In the adolescent patient, observation is the preferred management approach. Because we currently lack the means to identify individuals at risk for progressive disease, immediate treatment might be appropriate for high-risk patients likely to be lost to follow-up, because up to 40% of these women may have persistent or progressive disease that will eventually require therapy. The majority of high-grade lesions will persist or progress (Table 50–2), so immediate treatment is generally warranted.

Treatment

Patient management is based on the correlation of the results of the cervical cytology smear, findings at colposcopy and biopsy, and ECC results, as well as individual patient characteristics, such as pregnancy, HIV infection, and the likelihood of compliance with management recommendations.

Treatment options fall into one of two main categories: procedures that ablate the abnormal tissue and do not produce a tissue specimen for additional histologic evaluation and procedures that excise the area of abnormality, allowing for further histologic study. Prior to any therapeutic intervention an assessment has to be made as to whether a patient qualifies for ablative therapy (eg, satisfactory diagnostic evaluation has excluded invasive disease) or if she requires an excisional procedure (conization) for further diagnostic work-up. In most cases, conization is also the appropriate therapeutic intervention. If the intraepithelial lesion is confined to the ectocervix, treatment with cryotherapy, laser ablation, or a superficial excision by the loop electrosurgical excision procedure (LEEP) is appropriate. If the lesion extends into the endocervical canal, the endocervical curettage contains dysplastic epithelium, or the colposcopic examination is otherwise unsatisfactory, the endocervical canal must be included in the treatment by a deeper LEEP or cone biopsy (Fig 50–6). A conization procedure is also indicated in cases of a significant discrepancy between cervical cytology and colposcopy/biopsy results, in cases of suspected microinvasive carcinoma or adenocarcinoma in situ.

Figure 50–6.

Copyright ©2006 by The McGraw-Hill Companies, Inc.
All rights reserved.

Plan for management of the abnormal cytologic smear with visible or no visible cervical lesion. SCCA = squamous cell carcinoma.

The five most common techniques for the treatment of CIN include two ablative techniques—cryotherapy and laser ablation—and three excisional procedures—cold knife conization, laser cone excision, and LEEP. Evidence from controlled trials show that these techniques are of equal efficacy, averaging 80–90% success rates in the treatment of CIN. Cure depends on the size of the lesion, endocervical gland involvement, margin status of any excisional specimen, and ECC results.

CRYOTHERAPY

In cryotherapy, an office procedure not requiring anesthesia, nitrous oxide or carbon dioxide is used as the refrigerant for a supercooled probe. The cryoprobe is positioned on the ectocervix where it must cover the entire lesion, which at times is not easily achieved. It is then activated until blanching of the cervix extends at least 7 mm beyond the probe in all directions in order to assure that freezing extends beyond the depth of the crypts of the glands into which the dysplasia might be extending. Introduction of a two-cycle freeze–thaw–freeze technique has improved efficacy. The advantages of cryotherapy include ease of use, low cost, widespread availability, and a low complication rate. Side effects include mild uterine cramping and a copious watery vaginal discharge for several weeks. Infection and cervical stenosis are rare. Follow-up colposcopic examinations can be unsatisfactory because of the inability to visualize the squamocolumnar junction.

CARBON DIOXIDE LASER

Carbon dioxide (CO₂) laser can be used either to ablate the transformation zone or as a tool for cone biopsies. The laser destroys tissue with a very narrow zone of injury around the treated tissue, and is therefore both precise and flexible. The tissue is vaporized to a depth of at least 7 mm to assure that the bases of the deepest glands are destroyed. Posttreatment vaginal discharge may last 1–2 weeks, and bleeding that requires reexamination can occur in a small percentage of patients. The technique is expensive and requires significant training and attention to safety, as well as local or general anesthesia.

LOOP ELECTROSURGICAL EXCISION PROCEDURE

LEEP is the procedure of choice for treating CIN II and CIN III because of its ease of use, low cost, and provision of tissue for histologic evaluation. LEEP uses a small, fine, wire loop attached to an electrosurgical generator to excise the tissue of interest. Various sizes of wire loop are available. Following LEEP excision of the transformation zone, frequently an additional narrow endocervical specimen is removed to allow for histologic evaluation while avoiding excessive damage to the cervical stroma. Fulguration with a roller ball electrode is then used to achieve complete hemostasis in the excision bed. LEEP can be performed as an office procedure under local anesthesia. An insulated speculum to prevent conduction of electricity, a grounding pad, and a vacuum to remove the smoke are necessary. Complications are less frequent than with cold knife conization and include bleeding, infection, and cervical stenosis.

COLD KNIFE CONIZATION

Cold knife conization of the cervix refers to the excision of a cone-shaped portion of the cervix using a scalpel. This technique can be individualized to accommodate the cervical anatomy and the size and shape of the lesion. For example, a wide, shallow cone specimen can be obtained from a young patient whose squamocolumnar junction is on the ectocervix. In an older patient, in whom the squamocolumnar junction tends to move more cephalad into the endocervical canal, a narrower, deeper cone is preferable. An endocervical curettage is performed after the conization to assess the remaining endocervical canal. Cervical cone biopsy is generally done in the operating room under local or general anesthesia. Complications include bleeding, infection, cervical stenosis, and cervical incompetence. The need to perform the procedure in the operating room and a higher complication rate are distinct disadvantages of cold knife conization. However, it results in a specimen devoid of any thermal artifact that may complicate the histologic diagnosis and margin assessment seen with LEEP and laser conization. This becomes particularly important with suspected microinvasive carcinoma and adenocarcinoma in situ.

Follow-Up

Most treatment failures are diagnosed within the first 1–2 years after therapy. Patients with positive margins or positive ECC after an excisional procedure are at higher risk for persistent/recurrent disease than are women with negative margins, necessitating close follow-up, including repeat endocervical sampling but not reexcision. Therefore, careful examination should be performed, with Pap smears every 6 months for 18 to 24 months and endocervical curettage if the endocervix was involved. Alternatively, HPV testing may be performed along with the first cytology smear 6 months after therapy. If both are negative, annual follow-up can be established.

Management of recurrent dysplasia follows the same guidelines outlined in Fig 50–6. If a woman has completed childbearing, recurrent dysplasia can be treated by a simple hysterectomy after invasion has been ruled out. Women with a history of cervical dysplasia have a higher incidence of vaginal dysplasia. These women continue need Pap smears after hysterectomy.

SPECIAL SITUATIONS

PREGNANCY

Pregnant women routinely undergo cervical cytology screening at their first prenatal visit. As a result, it is not uncommon that an abnormal cervical cytology smear is first discovered during pregnancy. Colposcopy is performed for the same indications as in the nonpregnant patient. However, biopsies are limited unless there are colposcopic signs suggestive of carcinoma in situ or invasive disease. Endocervical curettage is not performed in pregnancy because of the potential risk of abortion and infection. The physiologic changes of pregnancy render the transformation zone easily accessible for satisfactory colposcopy by 20 weeks' gestation in almost all women. Colposcopy during pregnancy can be challenging because pregnancy may produce changes in the cervical epithelium that mimic those of cervical dysplasia. Although the gravid cervix is more vascular, directed ectocervix biopsies can be performed safely with minimal increase in the risk of significant bleeding. After the diagnosis of dysplasia has been established, the patient can be carefully followed with colposcopic examinations and cervical cytology smears each trimester. Repeat biopsies are only performed for progressive lesions. Treatment is deferred into the postpartum period. Even high-grade lesions discovered during pregnancy have a high rate of regression in the postpartum period. Conization during pregnancy is indicated only if early invasive disease is suspected. Complications of a cone biopsy in pregnancy include abortion, hemorrhage, infection, and incompetent cervix.

ATYPICAL GLANDULAR CELLS ON CERVICAL CYTOLOGY SMEAR

Patients with atypical glandular cells on a cervical cytology smear have a up to 50% risk of having high-grade cervical neoplasia. The underlying lesion is most commonly CIN II or III, which is diagnosed in up to 34% of cases. Cervical adenocarcinoma in situ, invasive cervical adenocarcinoma, and endometrial disease, including hyperplasia and cancer, comprise the remaining 16%.

The 2001 Bethesda System divides glandular cell abnormalities into AGCs, AGC-favor neoplasia, endocervical adenocarcinoma in situ (AIS), and adenocarcinoma. Given the high risk for significant pathology, any patient with glandular cell abnormalities on a cervical cytology smear requires immediate evaluation, which includes, at a minimum, colposcopy with careful evaluation of the endocervical canal. Assessment of the endometrium is recommended in all patients older than age 35 years, in patients at any age with abnormal bleeding, in women with AGC (endometrial cells), and in women with AGC (nonspecified cell type) (see Table 50–1). Diagnostic conization is indicated in all cases of AGC-favor neoplasia, AIS, or suspected adenocarcinoma as well as persistent atypical glandular cell—not otherwise specified (AGC-NOS), unless a definitive diagnosis has been made on the colposcopy directed biopsy or endometrial sampling.

ADENOCARCINOMA IN SITU

The reported incidence of glandular neoplasia of the cervix is increasing, especially in young women, with up to 30% of cases occurring in women younger than 35 years of age. Adenocarcinoma of the cervix represents approximately 25% of all cervical cancers and there is convincing evidence that ACIS is a precursor lesion. Half of the women with ACIS have concomitant squamous CIN. Management is difficult. The lesion may be located high in the endocervical canal, involve the deeper portions of the endocervical clefts, or be multifocal with skip lesions. Conization is required to make the diagnosis. Follow-up surveillance after conization is difficult, as cervical cytology, endocervical curettage, or endocervical cytobrush sampling each have a sensitivity of only approximately 50%. This is of particular concern because the incidence of residual ACIS or invasive adenocarcinoma following conization for ACIS is as high as 58% with positive conization margins, and 19% with negative conization margins. Therefore, conservative management should be undertaken only in the young patient with a negative conization

margin who is fully counseled and desires to maintain her fertility. In all other patients, hysterectomy should be performed as a definitive therapeutic intervention because even with negative margins, as many as 8–16% may have invasive disease on the hysterectomy specimen. For the same reason, consideration should be given to the performance of a modified radical hysterectomy, especially if extensive disease and positive margins were found on the preceding conization specimen.

HIV INFECTION

Management of CIN in the HIV-infected patient presents a great challenge. Following treatment, the risk of recurrent CIN is high, especially in the immunocompromised patient with low CD4 counts and high viral loads. Recurrence rates may reach 80% within 3 years in markedly immunocompromised women. Use of highly active antiretroviral therapy (HAART) appears to reduce the risk of recurrent or progressive cervical neoplasia.

CANCER OF THE CERVIX

Essentials of Diagnosis

- Early disease is frequently asymptomatic, underscoring the importance of cervical cytology screening.
- Abnormal uterine bleeding and vaginal discharge are the most common symptoms.
- A cervical lesion may be visible on inspection as a tumor or ulceration; cancer within the cervical canal may be occult.
- Diagnosis must be confirmed by biopsy.

General Considerations

Cancer of the cervix is the sixth most common solid cancer in American women. In the United States, an estimated 10,370 new cases of invasive cervical cancer are diagnosed annually, and there are 3710 deaths from the disease. In contrast, with more than 370,000 new cases diagnosed annually and a 50% mortality rate, cervical cancer is the second most common cause of cancer-related morbidity and mortality among women in developing countries. This dichotomy is largely the result of a 75% decrease in the incidence of cervical cancer in developed countries following the implementation of population-based screening programs and treatment of preinvasive disease. The average age at diagnosis of patients with cervical cancer is 51 years. However, the disease can occur in the second decade of life and during pregnancy. More than 95% of patients with early cancer of the cervix can be cured.

Etiology & Epidemiology

The major epidemiologic risk factors for cervical cancer are the same as those for CIN and were discussed above. HPV is central to the development of cervical neoplasia. HPV DNA is found in 99.7% of all cervical carcinomas. HPV 16 is the most prevalent HPV type in squamous cell carcinoma, and HPV 18 the most prevalent in adenocarcinoma. Other associated risk factors are immunosuppression, infection with HIV or a history of other sexually transmitted diseases, tobacco use, high parity, and oral contraceptive use.

Pathogenesis & Natural History

HPV is epitheliotropic. Once the epithelium is acutely infected with HPV, one of three clinical scenarios ensues:

- a) Asymptomatic latent infection;
- b) Active infection in which HPV undergoes vegetative replication but not integration into the genome (eg, leading to condyloma or CIN I); or
- c) Neoplastic transformation following integration of oncogenic HPV DNA into the human genome.

Integration of HPV into the human genome is associated with cell immortalization allowing for malignant transformation. This involves an upregulation of the viral oncogenes E6 and E7. These oncoproteins interfere with

cell-cycle control in the human host cell. E6 and E7 have the ability to complex with the tumor suppressor genes p53 and Rb, respectively. The disabling of these two major tumor suppressor genes is thought to be central to cell immortalization and transformation induced by HPV.

Incipient cancer of the cervix is generally a slowly developing process. Most cervical cancers probably begin as a high-grade dysplastic change (see previous section) or carcinoma in situ with gradual progression over a period several years. At least 90% of squamous cell carcinomas of the cervix develop from the intraepithelial layers, almost always within 1 cm of the squamocolumnar junction of the cervix either on the portio vaginalis of the cervix or slightly higher in the endocervical canal.

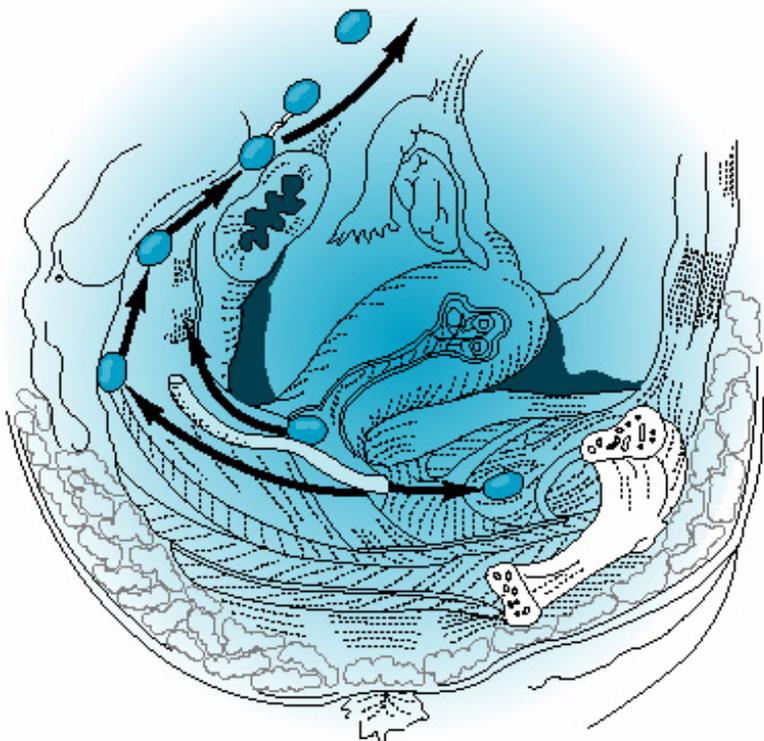

Early stromal invasion (stage IA1) up to a depth of 3 mm below the basement membrane is a localized process, provided there is no pathologic evidence of lymphovascular space involvement. Penetration of the stroma beyond this point carries an increased risk of lymphatic metastasis (Table 50–3). When the lymphatics are involved, tumor cells are carried to the regional pelvic lymph nodes (parametrial, hypogastric, obturator, external iliac, and sacral) (Fig 50–7). The more pleomorphic or extensive the local disease, the greater the likelihood of lymph node involvement. As the tumor grows, it also spreads by direct extension to the parametria.

Table 50–3. Risk of Any Lymph Node Metastasis for Patients with Microscopic Squamous Cell Carcinoma of the Cervix.

Lymphatic spread of carcinoma of the cervix.

Squamous cell carcinoma clinically confined to the cervix involves the regional pelvic lymph nodes in 15–20% of cases. When the cancer involves the parametrium (stage IIB), tumor cells can be found in the pelvic lymph nodes in 30–40% and in the paraaortic nodes in approximately 15–30% of cases. The more advanced the local disease the greater the likelihood of distant metastases. The paraaortic nodes are involved in approximately 45% of patients with stage IVA disease.

Ovarian involvement is rare, occurring in approximately 0.5% of squamous cell carcinomas and 1.7% of adenocarcinomas. The liver and lungs are the most common sites of blood-borne metastasis, but the tumor may involve the brain, bones, bowels, adrenal glands, spleen, or pancreas.

When cancer of the cervix is untreated or fails to respond to treatment, death occurs in 95% of patients within 2 years after the onset of symptoms. Death can occur from uremia, pulmonary embolism, or hemorrhage from direct extension of tumor into blood vessels. Life-threatening sepsis from complications of pyelonephritis or vesicovaginal and rectovaginal fistulas is possible. Large-bowel obstruction from direct extension of tumor into the rectosigmoid can be the terminal event. Pain from perineural extension is a significant management problem of advanced disease.

Pathology

Approximately 70–75% of cervical carcinomas are squamous cell; the remainder are composed of various types adenocarcinomas (20–25%), adenosquamous carcinomas (3–5%), and undifferentiated carcinomas.

SQUAMOUS CELL CARCINOMAS

Cervical squamous cell carcinomas have been classified according to the predominant cell type: large cell nonkeratinizing, large cell keratinizing, and small cell carcinomas. The large cell nonkeratinizing variety accounts for the majority of tumors.

VERRUCOUS CARCINOMA

Verrucous carcinoma, which has been associated with HPV 6, is a rare subtype of well-differentiated squamous carcinoma. It is a slow-growing, locally invasive neoplasm. Histologically, this tumor is composed of well-differentiated squamous cells with frondlike papillae and little apparent stromal invasion, but it is potentially lethal. Radical resection is the mainstay of therapy.

ADENOCARCINOMA

Adenocarcinoma of the cervix is derived from the glandular elements of the cervix. The incidence of adenocarcinomas, including the mucinous, endometrioid, clear cell, and serous types, has been rising over the last several decades, especially in women younger than 35 years of age. Part of this increase may be a result of an increasing prevalence of HPV infection and part may be a result of improvements in screening and prevention of squamous preinvasive disease, thus leading to a histologic shift toward adenocarcinoma. When the initial growth of adenocarcinoma of the cervix is within the endocervical canal and the ectocervix appears normal, this lesion might not be diagnosed until it is advanced and ulcerative. The so-called clear cell variety may be related to in utero exposure to DES. It has a prognosis comparable to that of other adenocarcinomas of the cervix. The villoglandular papillary variety of adenocarcinoma of the cervix tends to occur in younger women and have a more favorable prognosis.

ADENOMA MALIGNUM

Adenoma malignum or minimal deviation adenocarcinoma is an extremely well-differentiated adenocarcinoma that may be difficult to recognize as a malignant process. It represents approximately 1% of adenocarcinomas of the cervix and has been associated with Peutz-Jeghers syndrome. It occurs mainly in the fifth and sixth decades of life. Diagnosis is often delayed because of frequently normal cervical cytology smears. Punch biopsies are often nondiagnostic, requiring conization for further evaluation.

ADENOID CYSTIC CARCINOMA

Another uncommon variant of adenocarcinoma is adenoid cystic carcinoma. This lesion is considered more aggressive than most cervical adenocarcinomas and occurs more commonly in black women of high parity in the sixth and seventh decades of life. It should not be confused with adenoid basal carcinomas, which have an indolent growth pattern.

ADENOSQUAMOUS CARCINOMA

Adenosquamous carcinomas contain an admixture of malignant squamous and glandular cells. Glassy cell carcinoma is a poorly differentiated form of adenosquamous carcinoma and is considered to have an extremely aggressive course. It accounts for approximately 1–2% of cervical cancers. Synchronous adenocarcinomas and squamous cell carcinomas that invade each other are called collision tumors.

NEUROENDOCRINE CARCINOMAS

Approximately one-third of small cell carcinomas of the cervix stain positive for neuroendocrine markers. These tumors need to be distinguished from small cell type of squamous tumors. They have a high frequency of lymphovascular space invasion, lymph node metastases, recurrence, and poor survival. Carcinoid tumors, arising from the argyrophil cells of the endocervical epithelium, are malignant but have rarely been associated with the carcinoid syndrome. Because of their propensity for early systemic spread, systemic chemotherapy is an integral part of the treatment of neuroendocrine tumors of the cervix.

OTHER MALIGNANT TUMORS

Direct extension of metastatic tumors to the cervix include those originating from the endometrium, rectum, and bladder. Lymphatic or vascular metastases occur less often but are associated with endometrial, ovarian, gastric, breast, colon, kidney, and pancreas carcinomas. Sarcomas, lymphomas, choriocarcinomas, and melanomas are encountered rarely in the cervix.

Clinical Findings

SYMPTOMS AND SIGNS

Abnormal vaginal bleeding is the most common symptom of invasive cancer and may take the form of a blood-stained leukorrheal discharge, scant spotting, or frank bleeding. Leukorrhea, usually sanguineous or purulent, odorous, and nonpruritic, is frequently present. A history of postcoital bleeding may be elicited on specific questioning.

Pelvic pain, often unilateral and radiating to the hip or thigh, is a manifestation of advanced disease, as is the involuntary loss of urine or feces through the vagina, a sign of fistula formation. Weakness, weight loss, and anemia are characteristic of the late stages of the disease, although acute blood loss and anemia may occur in a ulcerating stage I lesion.

Physical examination findings include a grossly normal-appearing cervix with preclinical disease. As the local disease progresses, physical signs appear. Infiltrative cancer produces enlargement, irregularity, and a firm consistency of the cervix and eventually of the adjacent parametria. The growth pattern can be endophytic, lead to a barrel-shaped enlargement of the cervix, or exophytic, where the lesion generally appears as a friable, bleeding, cauliflowerlike lesion of the portio vaginalis. Ulceration may be the primary manifestation of invasive carcinoma; in the early stages the change often is superficial, so that it may resemble an ectropion or chronic cervicitis. With further progression of the disease, the ulcer becomes deeper and necrotic, with indurated edges and a friable, bleeding surface. The adjacent vaginal fornices may become involved next. Eventually, extensive parametrial involvement by the infiltrative process may produce a nodular thickening of the uterosacral and cardinal ligaments with resultant loss of mobility and fixation of the cervix.

BIOPSY

Because of the failure of malignant cells to desquamate and the obscuring effect of inflammatory cells, it is not uncommon for an invasive carcinoma of the cervix to exist despite a negative cytologic smear. Any suspicious lesion of the cervix should be sampled by adequate biopsy, regardless of cytologic examination result. Biopsy of any Schiller-positive areas or of any ulcerative, granular, nodular, or papillary lesion provides the diagnosis in many cases. Colposcopically directed biopsies with endocervical curettage or conization of the cervix may be required when reports of suspicious or probable exfoliated carcinoma cells are made by the pathologist and a visible or palpable lesion of the cervix is not evident. Colposcopic warning signs of early invasive cancer in a field of CIN include capillaries that are markedly irregular, appearing as commas, corkscrews, and spaghetti-shaped vessels with great variation in caliber and abrupt changes in direction, often causing acute angles. Ulcerations or a markedly irregular appearance of the cervix with a waxy, yellowish surface and numerous bizarre, atypical blood vessels are common. Bleeding may occur also after slight irritation.

CONIZATION

In the setting of a biopsy revealing carcinoma in situ, where invasion cannot be ruled out, or in the setting of a negative colposcopy in the face of a significantly abnormal cervical cytology smear, conization of the cervix should be performed to determine the presence or absence of invasion. If a cervical biopsy shows microinvasive cancer (3 mm of invasion), a cone biopsy is necessary to rule out deeper invasion. The conization specimen should be properly marked for the pathologist (eg, with a pin or small suture), so that the area of involvement can be specifically localized in relation to the circumference and margins of the cervix. Conization for a lesion grossly suggestive of invasive cancer is not indicated, as it only delays the initiation of appropriate therapy and predisposes the patient to serious pelvic infections and bleeding. The diagnosis of such a lesion can almost always be confirmed by simple cervical biopsy.

RADIOLOGIC FINDINGS

Chest radiographs are indicated in all patients with cervical cancer and an intravenous pyelogram (IVP) or computed tomography (CT) urogram should be performed to determine if there is any ureteral obstruction producing hydronephrosis. Magnetic resonance imaging (MRI), CT scan, lymphangiography, or

positron emission tomography (PET) scanning may demonstrate involvement of the pelvic or periaortic lymph nodes or other sites of metastases. The sensitivities of CT, MRI, and PET for lymph node metastases in cervical cancer are approximately 45%, 60%, and 80%, respectively. Although the latter imaging studies are not used to assign disease stage in the International Federation of Gynecology and Obstetrics (FIGO) classification, they may be of value for planning treatment, particularly the extent of the radiation therapy field or scope of surgery.

Clinical Staging

It is important to estimate the extent of the disease not only for prognostic purposes but also for treatment planning. Clinical staging also affords a means of comparing methods of therapy for various stages of the disease worldwide. The classification adopted by FIGO is the most widely used staging system (Table 50–4). Cervical cancer is staged by clinical examination, and evaluation of the bladder, ureters, and rectum. If the lesion is clearly confined to the cervix by office examination, only chest radiography and evaluation of the ureters by IVP or CT scan with intravenous contrast is necessary to assign the stage. If it is not possible to evaluate the extent of local disease in the office, examination under anesthesia with cystoscopy and proctoscopy may be necessary. Although CT scan, MRI, lymphangiography, and PET scan may offer information helpful for treatment planning, these findings do not change the FIGO stage of disease. The FIGO stage of disease is also not changed by surgicopathologic findings of metastatic disease at the time of radical hysterectomy or lymphadenectomy.

Table 50–4. FIGO Staging of Cervical Cancer (Adopted from FIGO Annual Report on the Results of Treatment in Gynecologic Cancer 1998).

Stage 0

Carcinoma in situ

Stage I

Cervical carcinoma confined to the cervix (extension to the corpus would be disregarded)

Stage IA¹

Invasive cervical cancer diagnosed by microscopy only

Stage IA1

Stromal invasion no deeper than 3 mm, no wider than 7 mm in horizontal spread

Stage IA2

Stromal invasion greater than 3, but less than 5 mm and no wider than 7 mm in horizontal spread

Stage IB

Clinically visible lesion confined to the cervix or microscopic disease greater than stage IA

Stage IB1

Lesion not greater than 4 cm

Stage IB2

Lesion greater than 4 cm

Stage II

Tumor extends beyond uterus but not to pelvic sidewall or lower third of vagina

Stage IIA

Vaginal involvement without parametrial involvement

Stage IIB

Parametrial involvement

Stage III

Tumor extends to pelvic sidewall and/or causes hydronephrosis and/or extends to lower third of vagina

Stage IIIA

Involvement of lower third of vagina with no extension to sidewall

Stage IIIB

Extension to pelvic sidewall and/or hydronephrosis

Stage IV

Extension beyond the true pelvis or into mucosa of rectum or bladder

Stage IVA²

Extension into adjacent organs

Stage IVB

Distant metastases

FIGO Stage	Definition

¹ The depth of invasion should be no more than 5 mm from the epithelial basement membrane of the adjacent most superficial epithelial papilla to the deepest point of invasion where the cancer originates. Vascular space invasion, venous or lymphatic, does not affect staging, but should be noted as it may affect future therapy. All macroscopically visible lesions (even with superficial invasion only) are allotted to stage IB.

² The presence of bullous edema is not sufficient to classify a tumor as stage IVA. The finding of malignant cells cytologic bladder washings requires further histologic confirmation in order to be considered stage IVA.

Differential Diagnosis

A variety of lesions of the cervix can be confused with cancer. Entities that must sometimes be ruled out include cervical ectropion, acute or chronic cervicitis, condyloma acuminata, cervical tuberculosis, ulceration secondary to sexually transmitted disease (syphilis, granuloma inguinale, lymphogranuloma venereum, chancroid), abortion or cervical pregnancy, metastatic choriocarcinoma or other cancers, and rare lesions such as those of actinomycosis or schistosomiasis. Histopathologic examination is usually definitive.

Complications

The complications of cervical cancer, for the most part, are those related to tumor size or invasion, necrosis of the tumor, infection, and metastatic disease. The natural history of the disease was outlined above. There are also problems pertaining to treatment of the disease (eg, radical surgery or radiation therapy; see Treatment, below).

Prevention

Until now, prevention of morbidity and death from cervical cancer largely involved recognition and treatment of preinvasive and early invasive disease. Currently, approximately 60% of women who develop cervical cancer in developed countries either never had been screened or had not been screened in the preceding 5 years. Risk factors must be recognized, and screening, treatment intervention, and patient education must be modified respectively.

Universal cytologic screening of all postpubertal women must be continued on a regular basis until better, more sensitive and specific means of screening are found, and outreach into underserved areas is improved. Women with preinvasive cervical neoplasia should be treated and followed up closely (Fig 50–6). It is important to remember that cervical cytology smears are of limited value in detecting frankly invasive disease, with some studies finding false-negative rates up to 50%. Sexual abstinence is an effective but impractical prophylactic measure. Education of young women and men about risk factors and the necessity for regular screening, as well as information about the association of HIV infection and smoking with the development of cervical cancers, is crucial.

Several HPV vaccines are currently in advanced stages of development. Gardasil a quadrivalent vaccine against HPV 16/18/6/11 received FDA approval in the United States in June 2006 for use in girls and women 9–26 years old. To date, large trials have demonstrated that the vaccines are generally safe, well tolerated and highly immunogenic with excellent efficacy in the prevention of persistent HPV infection and against the development of cytologic abnormalities.

Treatment

Invasive carcinoma of the cervix spreads primarily by direct extension and lymphatic dissemination. The therapy

patients with cervical cancer needs to address not only the primary tumor site, but also the adjacent tissues and lymph nodes. This is generally accomplished by either radical hysterectomy and pelvic lymphadenectomy, radiation with concomitant chemotherapy, or a combination thereof.

TREATMENT OF EARLY STAGE DISEASE (STAGE IA2 TO IIA)

Patients with early stage cervical cancer may be treated with either radical hysterectomy and pelvic lymphadenectomy or with primary radiation with concomitant chemotherapy. The overall 5-year cure rates for surgery and for radiation therapy in operable patients are approximately equal. The advantage of surgery is that the ovaries may be left intact and be transposed out of the radiation field if adjuvant postoperative therapy appears necessary, that the extent of disease can be determined surgicopathologically, and that grossly metastatic lymph nodes can be resected. Furthermore, surgery may be more appropriate in sexually active women with early stage disease as radiation causes vaginal stenosis and atrophy. Adjuvant radiation with concomitant chemotherapy is administered to selected patients at increased risk for recurrence following radical hysterectomy.

Radical Hysterectomy and Therapeutic Lymphadenectomy

Radical hysterectomy (techniques initially described by Wertheim, Meigs, and Okabayashi) with pelvic lymphadenectomy is the surgical procedure for invasive cancer limited to the cervix (stages I and II). The operation is technically difficult and should be performed only by those experienced in radical pelvic surgery. Surgery involves dissection of the ureters from the paracervical structures so that the ligaments supporting the uterus and upper vagina can be removed. When the operation is done vaginally, a deep Schuchardt (paravaginal) incision is required for exposure. Five different types of hysterectomy have been described based upon the extent of parametrial dissection and vaginal tissue removed (Table 50–5). Typically, a type I hysterectomy is indicated for patients with stage IA1 disease. An alternative treatment is cervical conization in the young patient wishing to preserve fertility. Stage IA2 to IIA are treated with a type II (modified radical) or type III (radical) hysterectomy. It is rarely necessary to remove as much vaginal tissue as was initially recommended. As long as complete tumor clearance can be provided, a modified radical hysterectomy appears to provide therapeutic outcomes comparable to a radical hysterectomy for stage IB and IIA disease, but with shorter operating time and lower urologic morbidity. Full pelvic lymphadenectomy is indicated at the time of radical hysterectomy, followed by paraaortic lymphadenectomy for tumors larger than 2 cm or those with suspicious pelvic lymph nodes. Resection of all grossly involved lymph nodes provides a distinct survival advantage. Microscopic evaluation of the lymph nodes allows for tailoring of the postoperative radiation field, if indicated.

Table 50–5. Types of Hysterectomy Based on Radicality.

Type I

Extrafascial hysterectomy with removal of all cervical tissue without dissecting into the cervix itself.

Type II

The uterine artery is ligated where it crosses over the ureter. The uterosacral and cardinal ligaments are divided midway towards their attachment to sacrum and pelvic sidewall. The upper third of the vagina is resected.

Type III

The uterine artery is ligated at its origin from the superior vesical or internal iliac artery. Uterosacral and cardinal ligaments are resected at their attachments to the sacrum and pelvic sidewall. The upper half of the vagina is resected.

Type IV

The ureter is completely dissected from the vesicouterine ligament, the superior vesical artery is sacrificed, and three fourths of the vagina is resected.

Type V

Involves the additional resection of a portion of the bladder or the distal ureter with ureteral reimplantation into bladder

Type of Hysterectomy	Principles of Procedure
----------------------	-------------------------

Adjuvant Postoperative Radiation

Postoperative adjuvant radiation therapy with concomitant chemotherapy is indicated in women with localized cervical cancer at high risk for recurrent disease, such as positive lymph nodes, positive or close resection margin or microscopic parametrial involvement. In this setting, adjuvant radiation with platinum-based chemotherapy is superior to adjuvant radiation alone, with an improvement in the 4-year progression-free interval from 63% to 80%. Women with intermediate-risk factors for recurrent disease, such as large tumor size, deep cervical stromal invasion, and lymphovascular space invasion, also benefit from postoperative adjuvant radiation. These patients have an improved 2-year recurrence-free survival of 88% with adjuvant radiation versus 79% without adjuvant therapy.

Primary Radiation with Concomitant Chemotherapy

For the treatment of early cervical cancer (stages IA to IIA), primary therapy with definitive radiation or radical surgery followed by tailored radiation if indicated by the surgical findings produce comparable outcomes. The choice of treatment depends on the tumor size, the general condition of the patient, and preferences of the oncologists at the treating institution. Surgery is often preferred for young patients in the hope of preserving ovarian function. If it is likely that the patient will need postoperative radiation therapy, transposition of the ovary to a location outside the radiation field can be performed. For primary radiation of cervical cancer, external beam radiation is used in combination with intracavitary irradiation (see Chapter 54). At least five controlled trials have demonstrated the superiority of radiation with concomitant platinum-based chemotherapy over radiation alone. This has led to the adoption of radiation plus concomitant chemotherapy as the standard of care whenever radiation therapy is given for the treatment of cervical cancer over a broad spectrum of disease stages.

Special Situations

STAGE IA1 DISEASE

The definitive diagnosis of microinvasive squamous cell carcinoma of the cervix can only be made by conization. These patients may be treated by simple abdominal or vaginal hysterectomy. For a young woman desiring to maintain fertility, only conization is an acceptable treatment modality for microinvasive squamous cell carcinoma with a depth of invasion of 3 mm or less, if the conization margins are negative, and if there is no evidence of lymphovascular space invasion. If margin and endocervical curettage are positive, the risk of residual disease is high as 33%. In this case, repeat conization should be performed if uterine preservation is the goal. FIGO staging is not influenced by the presence of lymphovascular space invasion, which occurs in close to 10% of patients with stage IA1 disease. These patients have a small but significant risk for lymph node metastases to parametrial and pelvic lymph nodes. This subgroup of patients should therefore be treated like patients with stage IA2 disease. There is considerable controversy regarding the existence of microinvasive adenocarcinoma and its pathologic diagnostic criteria, which is beyond the scope of this chapter.

RADICAL TRACHELECTOMY

During the last decade, radical trachelectomy has evolved as an alternative to radical hysterectomy in carefully selected young women with early stage (IA2 or small IB1) cervical cancer who wish to preserve fertility. A therapeutic lymphadenectomy is performed and following radical resection of the cervix a cerclage is placed. Experience with this technique is growing, and the oncologic outcome appears comparable to radical hysterectomy in carefully selected patients. A review of pregnancy outcomes in women who underwent radical trachelectomy revealed 16% first trimester miscarriages, 10% second trimester losses, 19% preterm deliveries, and a 49% term delivery rate.

BULKY CERVICAL CANCER

The management of patients with stage IB2 and bulky IIA disease is a matter of considerable debate. Proposed management strategies include the following.

Primary Radiation Therapy with Concomitant Chemotherapy and the Option of a Subsequent Adjuvant

Extrafascial Hysterectomy

Radiation therapy is usually recommended for patients with bulky cervical cancers, recently with the addition of concomitant chemotherapy. Many of these tumors, however, contain hypoxic central areas that do not respond well to radiation, as is reflected in a 15–35% pelvic failure rate. This provides the rationale for the performance of an adjuvant hysterectomy following radiation, which is associated with a significant reduction in pelvic recurrence to 2–5%. However, the impact of adjuvant hysterectomy on extrapelvic recurrences and survival is less-well established.

Primary Radical Hysterectomy and Therapeutic Lymphadenectomy, Followed by Tailored Radiation with Concomitant Chemotherapy When Indicated by Pathologic Findings

The potential benefits of this approach include the removal of the large primary tumor, complete surgical staging with the opportunity to resect any grossly involved lymph nodes, and the preservation of ovarian function as ovarian transposition can be performed if adjuvant radiation therapy is likely. If postoperative radiation becomes necessary, the radiation field can be tailored to the surgicopathologic findings. The resection of macroscopically involved lymph nodes has a therapeutic benefit because it improves survival to that of patients with microscopic lymph node metastases only. A primary surgical approach should be taken in patients with acute or chronic pelvic inflammatory disease, an undiagnosed coexistent adnexal mass, or anatomic alterations that make radiation therapy difficult.

Neoadjuvant Chemotherapy Followed by Radical Hysterectomy and Lymphadenectomy and Subsequent Chemoradiation When Indicated by Pathologic Findings

Neoadjuvant chemotherapy, frequently three cycles of platinum-based combination therapy followed by radical hysterectomy and lymphadenectomy, was recently proposed as a novel treatment strategy for these patients. Neoadjuvant chemotherapy is reported to improve the resectability of bulky lesions, pelvic disease control, and possibly long-term survival. Although this is a provocative treatment strategy, in most studies, patients ultimately received multimodality treatment with chemotherapy, radical surgery, and radiation. Further randomized studies are needed to determine the precise role of neoadjuvant chemotherapy in the treatment of these patients.

TREATMENT OF LOCALLY ADVANCED DISEASE (STAGE IIB TO IVA)

Patients with locally advanced cervical cancer are best treated with primary radiation (external beam plus brachytherapy; see Chapter 54A) with concomitant chemotherapy. Extended field radiation should be considered in the presence of paraaortic lymph node metastases documented at surgical staging or by imaging, especially when biopsy confirmed and in the absence of other systemic metastases. The benefit of cisplatin-based combined modality therapy over radiation alone for advanced disease has been demonstrated in at least three randomized controlled trials, which found a 30–50% reduction in the risk of death from cervical cancer for patients treated with chemoradiation compared to those treated with radiation alone. This difference is most significant for patients with stage II disease (and bulky IB disease) in whom, in one study, chemoradiation, compared to radiation alone, improved 5-year survival rates from 58% to 77%. For patients with more advanced disease, the benefits associated with chemoradiation versus radiation alone appear less pronounced, with the same study showing a small, statistically insignificant improvement in 5-year survival from 57% to 63%. The optimal drug regimen is not known, but combination therapy did not show superior results over weekly single-agent cisplatin, and the latter was associated with substantially less toxicity.

TREATMENT OF DISSEMINATED PRIMARY (STAGE IVB) AND PERSISTENT OR RECURRENT DISEASE

The use of chemotherapeutic agents in the treatment of cervical carcinoma has been discouraging. This is partly because most patients who may be candidates for this type of treatment either present with disseminated disease or have cancer that has already failed to respond to radical surgery or radiation therapy. Modest activity in recurrent or disseminated cervical cancer has been observed with single-agent cisplatin, ifosfamide, paclitaxel, and vinorelbine. There is a small therapeutic survival advantage to multiagent chemotherapy with cisplatin and topotecan. Combination therapy using paclitaxel and platinum offers very similar outcomes, with response rates

36% compared to 27% for cisplatin and topotecan, and a median survival of 9.7 months compared to 9.6 months with cisplatin and topotecan. Palliative pelvic radiation therapy may be indicated, especially for the control of hemorrhage. If a patient develops a palpable mass in the left supraclavicular region, it can be palliated with radiation therapy with concomitant chemotherapy, with or without resection.

TOTAL PELVIC EXENTERATION FOR ISOLATED CENTRAL PELVIC RECURRENCE OF DISEASE

Patients who develop a central recurrence of cervical cancer after primary therapy with radiation or after surgery followed by radiation may be candidates for this extensive, potentially curative surgical procedure if a complete evaluation fails to reveal evidence of metastatic disease. In a small proportion of patients with cancer of the cervix treated initially with radiation, a small recurrence of the cancer may be noted centrally within the cervix. A radical hysterectomy may be an alternative to total pelvic exenteration in this selected subgroup of patients. Surgery is the only potentially curative method of treating cancers that persist or recur centrally following adequate radiative therapy. In such instances, pelvic exenteration is often necessary to make certain that all of the cancer has been removed.

Pelvic exenteration is one of the most formidable of all gynecologic operations and requires removal of the bladder, rectum, and vagina, along with the uterus if hysterectomy has not yet been performed. This is followed by the reconstructive phase of the procedure. Urinary diversion needs to be provided, necessitating the creation of either a continent ileocolonic pouch or a noncontinent ileal conduit. In either case, a stoma is created in the anterior abdominal wall. If extensive rectal resection was required, a sigmoid colostomy serves for the passage of feces. If a low rectal anastomosis could be accomplished, a temporary diverting colostomy should be performed in all patients who had received prior radiation. The vagina can be reconstructed using various myocutaneous flaps, such as transverse rectus abdominis or gracilis myocutaneous flaps. Depending on the location of the lesion, an anterior (preservation of the rectosigmoid) or posterior (preservation of the bladder) exenteration is at times an alternative.

Because of the high surgical morbidity and mortality rates, stringent criteria are necessary to justify these procedures. Pelvic exenteration should be reserved primarily for problems that cannot be effectively managed in any other manner. In essence, this means (a) a biopsy-proven persistence or recurrence of cervical cancer following an adequate course of radiation therapy or radical surgery in which the recurrent or persistent tumor occupies the central portion of the pelvis (without metastases) and is completely removable; and (b) a patient who is able to cope with the urinary and fecal stomas in the abdomen created by the operation. Both psychological and physical preparation of the patient for this operation and its aftermath are of vital importance. Because of the extreme difficulties encountered in making an accurate assessment preoperatively, only about half of the patients explored for a total pelvic exenteration will intraoperatively be confirmed to have resectable, nonmetastatic disease. The 5-year survival rate following pelvic exenteration for recurrent cervical cancer averages 30–40%.

PALLIATIVE CARE

Comprehensive care of a patient with cancer involves in addition to antitumor therapy, good symptom relief, as well as personal and family support. The palliative care for patients with progressive cervical cancer poses many challenges. The emphasis should be to facilitate comfort, dignity, autonomy, and personal rehabilitation and development, especially in the face of an incurable disease.

Most patients with progressive cervical cancer eventually develop symptoms related principally to the site and extent of the malignant disease. Ulceration of the cervix and adjacent vagina produces a foul-smelling discharge. Tissue necrosis and slough may initiate life-threatening hemorrhage. If the bladder or rectum is involved in the tissue breakdown, fistulas result in incontinence of urine and feces. Pain caused by involvement of the lumbosacral plexus, soft tissues of the pelvis, or bone is frequently encountered in advanced disease. Ureteral compression leading to hydronephrosis and, if bilateral, to renal failure and uremia is a common terminal event. The comfort and well-being of the patient can be considerably enhanced even though cure cannot be effected. A foul, purulent discharge may be ameliorated by astringent douches and antimicrobial vaginal creams or suppositories.

Hemorrhage from the vagina often can be controlled by packing the area with gauze impregnated with a hemostatic agent; occasionally emergent radiation or hypogastric artery embolization is indicated.

Current management of severe pain combines the use of a long-acting narcotic such as morphine or a transdermal fentanyl patch with short-acting narcotics for breakthrough pain and nonsteroidal anti-inflammatory agents. Anxiolytics and antidepressants may be of considerable value. For patients with significant pain who are no longer responding to oral medications, a subcutaneous or intravenous morphine drip can be started. In patients with lower back or extremity pain, a peridural catheter can be placed and connected to a subcutaneous pump with a reservoir for continuous morphine instillation. This method gives pain relief without the sedating effects of oral parenteral narcotics.

Radiation therapy may be very helpful in the relief of pain caused by bony metastases and in the treatment of lesions that recur following primary surgical treatment of cervical cancer. In general, if initial therapy was accomplished by adequate radiation therapy, retreatment is contraindicated because it does little good and carries the potential of massive radiation necrosis.

Special Situations

CARCINOMA OF THE CERVIX DURING PREGNANCY

Invasive carcinoma of the cervix in pregnancy is found more frequently in areas where routine prenatal cytologic examination is done. Abnormal cervical cytology in pregnancy calls for immediate colposcopic evaluation and any other diagnostic modalities necessary to exclude invasive cancer (see section on preinvasive disease).

Invasive cervical cancer complicates approximately 0.05% of pregnancies. As is the case with nonpregnant patients, the principal symptom is bleeding, but the diagnosis is frequently missed because the bleeding is assumed to be related to the pregnancy rather than to cancer. The possibility of cancer must be kept in mind. The diagnosis and management of invasive cervical cancer during pregnancy presents the patient and the physician with many challenges. Pregnancy does not appear to affect the prognosis for women with cervical cancer and the fetus is not affected by the maternal disease, but may suffer morbidity from its treatment (eg, preterm delivery).

If the pregnancy is early and the disease is stage I to IIA, radical hysterectomy and therapeutic lymphadenectomy can be performed with the fetus left in situ, unless the patient is unwilling to terminate the pregnancy. Women at gestational age closer to fetal viability or who are unwilling to lose the baby may decide to continue the pregnancy after careful discussion regarding the maternal risks. Delivery in patients with cervical dysplasia and carcinoma in situ may be via the vaginal route. Patients with invasive cervical cancer should be delivered by cesarean section to avoid potential cervical hemorrhage and dissemination of tumor cells during vaginal delivery. A cesarean radical hysterectomy with therapeutic lymphadenectomy is the procedure of choice for patients with stages IA2–IIA disease as soon as adequate fetal maturity is established.

As in the nonpregnant patient, radiation with concomitant chemotherapy is used for the treatment of more advanced disease. In the first trimester, irradiation may be carried out with the expectation of spontaneous abortion. In the second trimester, interruption of the pregnancy by hysterotomy prior to radiation therapy is preferred, although some physicians advocate proceeding with immediate radiation treatment, again awaiting spontaneous evacuation of the uterus. In selected cases with locally advanced disease in which the patient declines pregnancy termination, consideration may be given to neoadjuvant chemotherapy in an effort to prevent disease progression during the time needed to achieve fetal maturity. Delivery should be by cesarean section. A lymphadenectomy can be performed at the same time. Postpartum the patient should receive chemoradiation following guidelines established for the nonpregnant patient.

CARCINOMA OF THE CERVICAL STUMP

Early stage cervical cancer noted on a cervical stump (left in situ following supracervical hysterectomy for an unrelated indication) should be treated with radical trachelectomy and therapeutic lymphadenectomy in the

medically fit patient. Surgery is preferred over chemoradiation in this setting as the delivery of an adequate radiation dose may be difficult in a patient with a short cervical stump. However, radiation with concomitant chemotherapy is the preferred treatment modality for patients with more advanced disease.

CERVICAL CANCER INCIDENTALLY DIAGNOSED AFTER SIMPLE HYSTERECTOMY

Women who are found to have microinvasive disease after a simple hysterectomy do not require any additional therapy. Patients with invasive disease who do not have gross parametrial disease are candidates for a radical parametrectomy, upper vaginectomy, and lymphadenectomy. This approach may be particularly desirable for young women in whom ovarian function can be preserved or for any surgically fit women with enlarged lymph nodes that should be resected prior to chemoradiation. Indications for chemoradiation follow the same guideline as outlined above.

Complications of Therapy

RADICAL SURGERY

The operative mortality rate in radical hysterectomy with lymphadenectomy has been reduced to less than 1%. The most common complication is prolonged bladder dysfunction. Approximately 75% of patients have adequate recovery of bladder function within 1–2 weeks after radical hysterectomy, and most patients will have satisfactory voiding function by 3 weeks. Serious complications include fistula formation; ureterovaginal fistula is the most common type (1–2%), followed by vesicovaginal and rectovaginal fistulas. Modified radical hysterectomy as compared to radical hysterectomy is associated with a shorter operating time, a more rapid return of bladder function, and fewer fistulas. Other complications are urinary tract infections, lymphocysts and lymphedema, wound sepsis, dehiscence, thromboembolic disease, ileus, postoperative hemorrhage, and intestinal obstruction.

The surgical mortality rate from pelvic exenteration has been reduced from approximately 25% to less than 5%, but as many as 50% of patients experience major morbidity. Complications include intraoperative and postoperative hemorrhage, infectious morbidity, urinary fistulas or obstruction, urinary pouch dysfunction, pyelonephritis, bowel obstruction or intestinal leaks and fistulas, stomal retraction, electrolyte disturbances, and other less common occurrences.

RADIATION THERAPY WITH CONCOMITANT CHEMOTHERAPY

See Chapters 54A and 54B.

Posttreatment Follow-Up

Approximately 35% of patients with invasive cervical cancer will have recurrent or persistent disease following therapy. Approximately 50% of deaths from cervical cancer occur in the first year after treatment, another 25% the second year, and 15% in the third year. This explains the generally accepted schedule of posttreatment surveillance in asymptomatic patients of every 3 months in the first year, every 4 months in the second year, and every 6 months in years 3–5. Symptomatic patients should be evaluated with appropriate examinations immediately when symptoms occur. The most common signs and symptoms of recurrent malignant disease are positive cytologic examination, palpable tumor in the pelvis or abdomen, ulceration of the cervix or vagina, pain in the pelvis, back, groin, and lower extremity, unilateral lower extremity edema, vaginal bleeding or discharge, supraclavicular lymphadenopathy, ascites, unexplained weight loss, progressive ureteral obstruction, and cough (especially with hemoptysis or chest pain).

Prognosis

The major prognostic factors affecting survival are stage, lymph node status, tumor volume, depth of cervical stromal invasion, lymphovascular space invasion and, to a lesser extent, histologic type and grade. After stage I disease, lymph node status is the most important prognostic factor. For example, following radical surgery, patients with stage IB or IIA disease have a 5-year survival of 88–96% with negative lymph nodes, compared to 64–73% in the presence of lymph node metastases.

Table 50–6 summarizes survival rates by stage of disease. These are based on the FIGO Annual Report on the Results of Treatment in Gynecological Cancer, in which results of treatment for each stage of cervical cancer are reported by more than 100 participating institutions worldwide. The results are equated in terms of 5-year cure rates, or those patients who are living and show no evidence of cervical cancer 5 years after beginning therapy.

Stage	Number of Patients (%)	Survival		
		1 year	2 years	5 years

Recurrences following radiation therapy are not often centrally located and thus amenable to exenteration procedures. Only approximately 25% of recurrences are localized to the central portion of the pelvis. The most common site of recurrence is the pelvic side wall.

ENDOMETRIAL HYPERPLASIA & CARCINOMA

Essentials of Diagnosis

- Abnormal uterine bleeding: menorrhagia, metrorrhagia, or postmenopausal bleeding.
- Risk factors: hyperestrogenism—long-term exposure to unopposed estrogens (polycystic ovarian syndrome, chronic anovulation, obesity, late menopause, and exogenous estrogens); metabolic syndrome including diabetes, hypertension; nulliparity; increasing age; history of breast cancer; genetic predisposition (hereditary nonpolyposis colon cancer syndrome).
- Diagnosis: endometrial sampling, ultrasonography.

General Considerations

In the United States, white women have a lifetime risk of endometrial carcinoma of 2.4% compared with 1.3% for black women. The peak incidence of onset is in the seventh decade, but 25% of cancers occur in premenopausal women and the disease has been reported in women ages 20–30 years. Endometrial carcinoma is the most common pelvic genital cancer in women. A doubling of the incidence of endometrial cancer in the 1970s correlated with unopposed estrogen use in hormone replacement and sequential oral contraceptives over the previous 10 years. The declining incidence in the 1980s paralleled progesterone use in hormone replacement regimens and low-dose estrogen combination birth control pills. The estimated incidence for the year 2005 is 40,300 new cases with 7000 deaths occurring from the disease. The onset of endometrial bleeding facilitates detection in the earlier stages of disease. Consequently, the overall prognosis is considerably better than for the other major gynecologic cancers.

Estrogens are implicated as a causative factor in endometrial carcinoma because there is a high incidence of this disease in patients with presumed alterations in estrogen metabolism and in those who take exogenous estrogens. Furthermore, patients with anovulatory cycles are at higher risk of developing endometrial cancer because of prolonged periods of estrogenic stimulation of the endometrium without the opposing effects of progesterone. Progesterone has an antiproliferative effect on the endometrium and can induce apoptosis of endometrial cells. Classically, endometrial carcinoma affects the obese, nulliparous, infertile, hypertensive, and diabetic white woman, but it can occur in the absence of all these factors. Unlike cervical cancer, it is not related to sexual history. The most common presenting symptom is abnormal vaginal bleeding, particularly postmenopausal bleeding. Less frequently, severe cramps from hematometra or pyometra caused by an obliterated endocervical canal in elderly patients may be the presenting symptom. In the asymptomatic patient, a diagnosis may be made incidentally from an abnormal Papanicolaou (Pap) smear, but cytologic discovery of endometrial cancer is not consistent and should not be relied on for early diagnosis. Screening for endometrial cancer in the general population is not recommended, but should be performed for patients with a hereditary nonpolyposis colon cancer (HNPCC) syndrome. The mainstay of treatment is surgery, including a total hysterectomy with bilateral salpingo-oophorectomy and staging with pelvic and periaortic lymphadenectomy. Further postoperative therapy depends on the particular histologic characteristics and the extent of the tumor.

Etiology

Most endometrial carcinomas arise on the background of endometrial hyperplasia and are well differentiated tumors. There are two major types of endometrial cancer. Type I is associated with either endogenous or exogenous unopposed estrogen exposure, and usually consists of a low-grade or well-differentiated tumor with a favorable prognosis. Type II tumors grow independent of estrogen and are associated with endometrial atrophy. The histology of this type is either poorly differentiated endometrioid or nonendometrioid and confers a high risk of relapse with poor prognosis.

Estrogens and progesterone are the two main hormones that influence the metabolic and proliferative state of the endometrium. In general, estrogens stimulate the endometrium, unlike progesterone, which has an antiproliferative effect. Long-term exposure to estrogens can lead to endometrial hyperplasia and, subsequently, to hormone-driven atypical endometrial hyperplasia and endometrial cancer. Clinical circumstances with chronically high levels of estrogenic stimulation include the metabolic syndrome, polycystic ovary syndrome, exogenous, unopposed estrogen replacement therapy, and chronic anovulation in the premenopausal women. Granulosa cell tumors of the ovary can produce high levels of estrogens but are a rare cause of hyperestrogenism. The antiestrogen tamoxifen has a weak estrogenic effect and increases the incidence of endometrial cancer by about 2- to 3-fold.

More than a dozen case-control studies indicate an association between estrogen administration and endometrial carcinoma. These studies report a 2- to 10-fold increase in the incidence of endometrial carcinoma in women receiving exogenous unopposed estrogens. The risk of cancer is related to both the dose and the duration of exposure and diminishes with cessation of estrogen use. The risk seems to be neutralized by the addition of cyclic progestin for 10 days at least every 1–3 months. In women without a hysterectomy, progestin should be added to the treatment to oppose the effect of estrogens on the endometrium. Endometrial biopsies to rule out endometrial hyperplasia or pelvic ultrasonography to evaluate the thickness of the endometrial stripe should be obtained if abnormal bleeding occurs.

Evidence is accumulating that there is a genetic factor in the development of endometrial cancer. Those women with a personal history of ovarian, colon, or breast cancer as well as those with a family history of endometrial cancer may be at higher risk. In HNPCC, there is an autosomal dominant pattern of inheritance for colon and endometrial cancers. Most cases of HNPCC are a result of alterations in mismatch repair genes MSH2 and MLH1. Certain oncogenes, such as Ha-, K-, and N-*ras*, *c-myc*, and Her-2/neu, have been found in endometrial cancers. Furthermore, alterations in the p53 and even more frequently in the PTEN tumor suppressor gene were recently identified. Certain vascular growth promoting factors like VEGF (vascular endothelial growth factor) have been found to be overexpressed in endometrial cancer.

Surgical Staging

(Table 51–1) In 1988, the Cancer Committee of FIGO (International Federation of Gynecology and Obstetrics) introduced a surgical staging system for endometrial carcinoma based on abdominal exploration, pelvic washings, total hysterectomy with salpingo-oophorectomy, and selective pelvic and paraaortic lymph node biopsies. Grade of the tumor is included in the staging description. The grade of the tumors refers to the architecture and nuclear atypia. The architecture of the tumor is judged by the percentage of differentiated (glandular) versus nondifferentiated (solid) elements within the tumor specimen. Grade 1 tumors consist of at least 95% glandular tissue and have less than 5% of a nonsquamous solid growth pattern. Areas of squamous differentiation are not considered to be solid tumor growth. Grade 2 tumors contain 6–50% of a nonsquamous solid growth pattern. Tumors with more than 50% of a solid pattern are classified as grade 3. The nuclear grade depends on the appearance of the nucleus, eg, size of nucleus, chromatin pattern, and is more subjective. An

architectural grade of 1 or 2 is raised by 1 point in the presence of significant nuclear atypia (nuclear grade 3).

Table 51–1. FIGO Surgical Staging of Carcinoma of the Corpus Uteri (1988).

Stage I
Stage Ia G123 Tumor limited to endometrium
Stage Ib G123 Invasion to less than one-half the myometrium
Stage Ic G123 Invasion to more than one-half the myometrium
Stage II
Stage IIa G123 Endocervical glandular involvement only
Stage IIb G123 Cervical stromal invasion
Stage III
Stage IIIa G123 Tumor invades serosa and/or adnexa, and/or positive peritoneal cytology
Stage IIIb G123 Vaginal metastases
Stage IIIc G123 Metastases to pelvic and/or paraaortic lymph nodes
Stage IV
Stage IVa G123 Tumor invades bladder and/or bowel mucosa
Stage IVb Distant metastases including intra-abdominal and/or inguinal lymph nodes

From International Federation of Gynecology and Obstetrics: Annual Report on the results of treatment in gynecologic cancer. *Int J Gynecol Obstet* 1991; 36(Suppl): 132.

Surgical stage I tumors account for 75% of all endometrial carcinomas, which explains the relatively good overall prognosis. Eleven percent of cancers are surgical stage II, and the remaining 11% and 3% are surgical stages III and IV, respectively.

Classification

ENDOMETRIAL HYPERPLASIA

The glandular hyperplasias of the endometrium are benign conditions that can be classified as simple or complex and either with or without atypia. Because of their association with hyperestrogenic states, the atypical hyperplasias are considered premalignant lesions. Because endometrial hyperplasia and endometrial carcinoma present clinically as abnormal bleeding, thorough endometrial sampling or fractional curettage is always necessary when hyperplasia is present to rule out coexisting carcinoma.

Hyperplasia Without Atypia

Microscopically, this type of hyperplasia shows crowding of glands in the stroma without nuclear atypia. This type of hyperplasia is frequently asymptomatic and found incidentally in hysterectomy specimens. When followed without treatment over a 15-year period, approximately 1% progressed to endometrial cancer whereas 80% spontaneously regressed.

Complex hyperplasia without atypia (previously designated "adenomatous hyperplasia") describes a complex, crowded appearance to the glands with very little intervening stroma. Complex hyperplasia regresses under progestin therapy in approximately 85% of cases, but progresses to cancer in 3–5% if untreated.

Hyperplasia with Atypia

The histology of hyperplasia with atypia is characterized by endometrial glands that are lined with enlarged cells. An increased nuclear-to-cytoplasmic ratio is a sign of increased nuclear activity, eg, transcription. The nuclei may be irregular with coarse chromatin clumping and prominent nucleoli. These hyperplasias are generally considered premalignant. Progression to carcinoma occurs in 10% of simple atypical and in 30–40% of complex atypical hyperplasias. The majority of lesions regress with progestin therapy but have a higher rate of relapse when therapy is stopped compared to lesions without atypia. In peri- and postmenopausal patients with atypical hyperplasias who relapse after progestin therapy, or who cannot tolerate the associated side effects, vaginal or abdominal hysterectomy is recommended.

A recent study demonstrated that in patients with untreated atypical endometrial hyperplasia on preoperative biopsy, 62.5% had a concurrent endometrial carcinoma at hysterectomy. Of women with endometrial hyperplasia without atypia who underwent hysterectomy, 5% had cancer. This new data will significantly alter how we counsel women with atypical endometrial hyperplasia.

The term *atypical endometrial hyperplasia* should be applied to endometrial neoplasia without invasion. Severe atypical endometrial hyperplasia or adenocarcinoma in situ describe preinvasive histologies that are frequently difficult to distinguish from early invasive endometrial cancer. It is still a matter of debate whether the term *adenocarcinoma in situ* should be used for endometrial pathology. In contrast, the precursor lesion for serous carcinomas in endometrial intraepithelial carcinoma shows pleiomorphic tumor cells in the epithelium of the endometrial surface and the underlying glands without stromal invasion.

ENDOMETRIAL CARCINOMA

Endometrial cancer is characterized by obvious hyperplasia and anaplasia of the glandular elements, with invasion of underlying stroma, myometrium, and vascular spaces. Although atypical complex hyperplasia is thought to be a precursor lesion, only approximately 25% of patients with endometrial carcinoma have a history of hyperplasia.

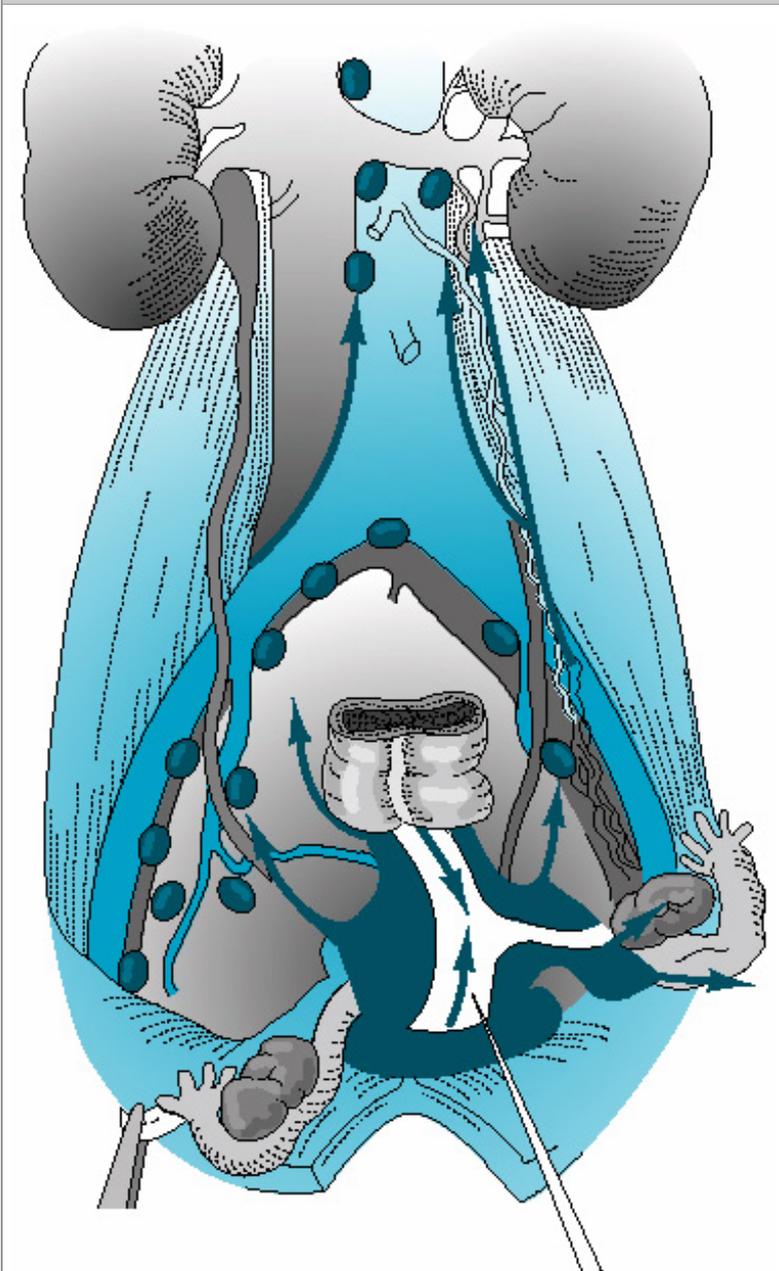

Important prognostic factors include stage, histologic grade and cell type, depth of myometrial invasion, presence of lymph vascular space involvement, lymph node status, involvement of the lower uterine segment, and size of tumor. Other prognosticators relate to tumor ploidy and the proportion of cells in S phase as determined by DNA flow cytometry.

Endometrial cancers of endometrioid histology of any grade are almost never associated with lymph node metastases if there has been no myometrial invasion. The depth of myometrial invasion and histologic grade are correlated with the incidence of pelvic and aortic lymph node metastases. Patients with poorly differentiated deeply invasive cancers have about a 35% incidence of involved pelvic nodes and a 10–20% incidence of aortic node metastases. Because patients with lymph node metastases are at very high risk for recurrence, these pathologic features have serious implications for treatment planning.

Endometrial cancer can spread by four possible routes: direct extension, lymphatic metastases, peritoneal implants after transtubal spread, and hematogenous spread. Undifferentiated lesions (grade 3) may spread to the pelvic and aortic nodes while still confined to the superficial myometrium. In serous and clear cell subtypes the spread pattern is similar to that of ovarian cancer, and upper abdominal metastasis are common. Hematogenous metastases to the lungs are uncommon with primary tumors

limited to the uterus but do occur with recurrent or disseminated disease. In contrast to the former belief that endometrial carcinoma spreads primarily to the aortic lymph nodes through infundibulopelvic and broad ligament lymphatics, recent studies indicate a dual pathway of spread to the pelvic and aortic lymph nodes (Fig 51-1). The aortic nodes are rarely involved when the pelvic nodes are free of metastases, but the pelvic nodes are sometimes involved when the aortic nodes are not. The lymph nodes most commonly involved in endometrial cancer are found in the obturator space.

Figure 51-1.

Dual lymphatic spread pattern of endometrial carcinoma.

Vaginal metastases occur by submucosal lymphatic or vascular metastases in approximately 3-8% of

patients with clinical stage I disease. The concept that these metastases occur by spillage of tumor through the cervix at the time of surgery lacks convincing support. However, vaginal metastases are more common with higher histologic grade and with lower uterine segment or cervical involvement.

Malignant cells identified in the peritoneal washings obtained at the time of hysterectomy are usually associated with the finding of other risk factors, such as deep myometrial invasion or lymph node metastases. Pathologists recognize various histologic types of endometrial carcinoma. Approximately 80% of all endometrial cancers are of the endometrioid type with several variants: villoglandular, secretory, with squamous differentiation, and with ciliated cells. These types have similar presenting symptoms and signs, patterns of spread, and general clinical behavior. For this reason, they can be considered collectively for purposes of clinical work-up, differential diagnosis, and treatment. Endometrial adenocarcinomas of the nonendometrioid phenotype show mucinous, serous, clear cell, squamous, small cell, mixed, or transitional cell differentiation.

Adenocarcinoma

The most common type of endometrial carcinoma is adenocarcinoma, composed of malignant glands that range from very-well-differentiated (grade 1), barely distinguishable from atypical complex hyperplasia to anaplastic carcinoma (grade 3). To determine stage and prognosis, the tumor is usually graded by the most undifferentiated area visible under the microscope (Fig 51–2). In the United States, adenocarcinoma comprises 80% of endometrial carcinomas.

Figure 51–2.

Adenocarcinoma of the endometrium. Note the sharp demarcation of the tumor at the isthmus.

Adenocarcinoma with Squamous Differentiation

Approximately 25% of endometrioid carcinomas contain focal to extensive squamous elements, ranging from bland squamous cells to foci that could be viewed as squamous carcinoma. The behavior of the tumors with squamous differentiation is dependent on the grade of the glandular component.

Serous Carcinoma

Histologically, this cancer is identical to the complex papillary architecture seen in serous carcinomas of the ovary. The frequency of this subtype varies from 1–10%. Women with serous carcinoma are more likely to be older and less likely to have hyperestrogenic states. These tumors account for 50% of all

relapses in stage I tumors. Serous tumors spread early and involve peritoneal surfaces of the pelvis and abdomen. The tumors also have a propensity for myometrial and lymphatic invasion. The prognosis is unfavorable, and patients with serous tumors should be treated in a manner similar to that of patients with ovarian tumors.

Clear Cell Carcinoma

This subtype is not associated with clear cell carcinomas of the cervix and vagina that are seen in young women with diethylstilbestrol exposure. Clear cell carcinomas encompass approximately 1% of all endometrial carcinomas. Its microscopic appearance is significant for clear cells or hobnail cells. Solid, papillary, tubular, and cystic patterns are possible. Clear cell carcinoma is commonly high grade and aggressive with deep invasion and is seen at an advanced stage. It occurs in older women (average age: 67 years), and like the serous subtype is not associated with a hyperestrogenic state.

Miscellaneous Subtypes

Mucinous carcinomas make up 9% of endometrial adenocarcinomas; they contain periodic acid-Schiff (PAS)-positive, diastase-resistant, intracytoplasmic mucin. Secretory carcinoma, present in 1–2% of cases, exhibits subnuclear or supranuclear vacuoles resembling early secretory endometrium. These rare cancers behave in a manner similar to that of typical endometrial carcinomas. Pure squamous cell carcinomas are extremely rare and are associated with cervical stenosis, pyometra, and chronic inflammation.

Clinical Findings

SYMPTOMS AND SIGNS

Abnormal bleeding occurs in approximately 80% of patients and is the most important and early symptom of endometrial carcinoma. An abnormal vaginal discharge, especially after menopause or intermittent spotting, is reported by some patients. During the premenopausal years, the bleeding is usually described as excessive flow at the time of menstruation. However, bleeding may occur as intermenstrual spotting or premenstrual and postmenstrual bleeding. Approximately 5–10% of patients with postmenopausal bleeding have underlying cancer, but the probability increases with age and depends on underlying risk factors. Approximately 10% of patients complain of lower abdominal cramps and pain secondary to uterine contractions caused by detritus and blood trapped behind a stenotic cervical os (hematometra). If the uterine contents become infected, an abscess develops and sepsis may supervene.

Physical examination is usually unremarkable but may reveal medical problems associated with advanced age. Speculum examination may confirm the presence of bleeding, but because it may be minimal and intermittent, blood might not be present. Atrophic vaginitis is frequently identified in these elderly women, but postmenopausal bleeding should never be ascribed to atrophy without a histologic sampling of the endometrium to rule out endometrial carcinoma. Bimanual and rectovaginal examination of the uterus in the early stages of the disease will be normal unless hematometra or pyometra is present. If the cancer is extensive at the time of presentation, the uterus may be enlarged, and may be misdiagnosed as a benign condition such as leiomyomata. In advanced cases, the uterus may be fixed and immobile from parametrial extension.

Vaginal, vulvar, or inguinal–femoral lymph node metastases are rarely identified in early disease, but are not uncommon in advanced cases or with recurrence following treatment. Ovarian metastases may cause marked enlargement of these organs.

LABORATORY FINDINGS

Routine laboratory findings are normal in most patients with endometrial carcinoma. If bleeding has been

prolonged or profuse, anemia may be present. Cytologic study of specimens taken from the endocervix and posterior vaginal fornix can reveal adenocarcinoma in symptomatic patients. More important, endometrial carcinoma will be missed in 40% of symptomatic patients by routine cytologic examination. Accuracy has been greatly increased by aspiration cytologic study or biopsy (discussed under Special Examinations). Nevertheless, the Pap smear is an integral part of the examination of all patients, because it identifies a small but definite percentage of patients with asymptomatic disease. Furthermore, the presence of benign endometrial cells in the cervical or vaginal smear of a menopausal or postmenopausal woman is associated with occult endometrial carcinoma in 2–6% of cases and in up to 25% with postmenopausal bleeding. Thus, any postmenopausal woman who shows endometrial cells on a routine cervical Pap smear requires evaluation for endometrial cancer, including endometrial sampling.

Routine blood counts, urinalysis, endocervical and vaginal pool cytology, chest radiography, stool guaiac, and sigmoidoscopy are useful ancillary diagnostic tests in patients with endometrial carcinoma. Liver function tests, blood urea nitrogen, serum creatinine, and a blood glucose test (because of the known relationship to diabetes) are considered routine. Serum CA-125 (cancer antigen-125), a well-established tumor marker for epithelial ovarian cancer, might be useful for endometrial cancer. Approximately 20% of patients with clinical stage I (preoperatively, the tumor appears to be confined to the uterus) have an elevated CA-125. In cases with extensive intraperitoneal spread or enlarged uterus, the tumor marker CA-125 may be markedly elevated. However, in contrast to patients with ovarian cancer, the value of CA-125 in the management of patients with endometrial cancer is limited.

IMAGING STUDIES

Chest radiography might reveal metastases in patients with advanced disease but is rarely positive in the early stages. Colonoscopy is usually unnecessary in a patient with a negative stool guaiac test and normal sigmoidoscopic examination, but should always be performed in the patient with gross or occult gastrointestinal bleeding or symptoms. In patients from families with HNPCC, a colonoscopy should be performed preoperatively, particularly if the patient screens positive for the HNPCC-associated DNA mismatch repair gene mutations.

Hysteroscopy can increase the diagnostic accuracy over office endometrial biopsy or dilatation and curettage. Hysteroscopy promotes the transtubal spread of tumor cells into the peritoneal cavity. However, the presence of a positive peritoneal cytology after hysteroscopy does not seem to alter the prognosis. Computer tomography is useful in assessing pelvic anatomy, visualizing enlarged lymph nodes in the pelvis and periaortic areas, and diagnosing distant metastasis in the liver and lungs. Magnetic resonance imaging (MRI) is particularly helpful in identifying myometrial invasion and lower uterine segment or cervical involvement.

SPECIAL EXAMINATIONS

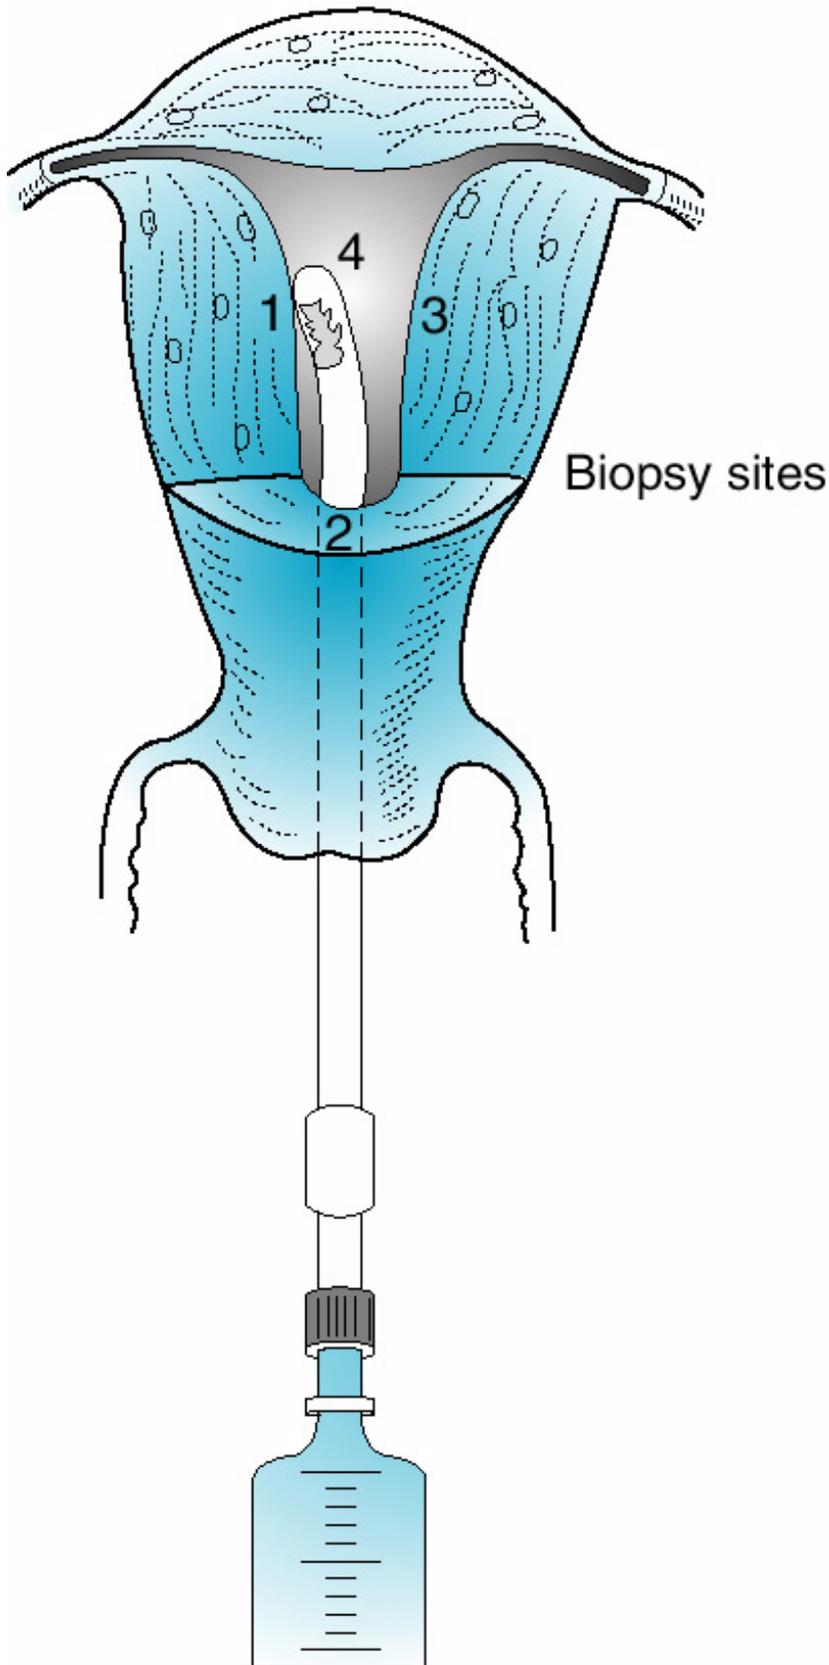

Fractional Curettage

Dilatation and fractional curettage (D&C) is the definitive procedure for diagnosis of endometrial carcinoma. It should be performed with the patient under anesthesia to provide an opportunity for a thorough and more accurate pelvic examination. It is carried out by careful and complete curettage of the endocervical canal followed by dilatation of the canal and circumferential curettage of the endometrial cavity. When obvious cancer is present with the first passes of the curette, the procedure should be terminated as long as sufficient tissue for analysis has been obtained from the endocervix and endometrium. Perforation of the uterus followed by intraperitoneal contamination with malignant cells, blood, and bacteria is a common complication in patients with endometrial carcinoma and can usually be avoided by gentle surgical technique and limitation of the procedure to the extent necessary for accurate diagnosis and staging. D&C is never considered curative in these circumstances and should not be performed with the same vigor as therapeutic curettage.

Endometrial Biopsy

This procedure is attractive because it can be performed in an outpatient setting, resulting in a substantial savings in cost. It can usually be done without anesthesia, although paracervical block is effective when necessary. There is a false-negative rate of approximately 10% and all symptomatic patients with a negative endometrial biopsy need to undergo a formal D&C. There are many types of office biopsy techniques including a Pipelle, Novak Curet (Fig 51–3), and Vabra aspirator (Fig 51–4). All types of endometrial biopsy are notoriously inaccurate for diagnosing polyps and will miss a significant number of cases of endometrial hyperplasia as well.

Pelvic Ultrasonography

Ultrasonography can be helpful in the surveillance of asymptomatic, high-risk patients, eg, breast cancer patients on tamoxifen and women with strong family histories of endometrial cancer. Pelvic and transvaginal ultrasonography yield information about the size and shape of the uterus, as well as the thickness and surface contour of the endometrium. In postmenopausal women, an endometrial thickness of more than 5 mm is considered to be suspicious for hyperplasia or malignancy and should be further evaluated with an endometrial biopsy. Transvaginal ultrasound, however, can yield a high false-positive rate in women who have been on tamoxifen for more than 2 years. The subendometrial edema that develops from tamoxifen use is indistinguishable from a thickened endometrial stripe. A sonohysterogram, which involves instilling sterile saline into the endometrial cavity prior to transvaginal ultrasound, can reduce false-positive results and better delineate the endometrial cavity.

Estrogen and Progesterone Receptor Assays

Estrogen and progesterone receptor assays should be obtained from the neoplastic tissue. This information helps in planning adjuvant or subsequent hormone therapy. Estrogen and progesterone receptor content are inversely proportional to histologic grade. In general, patients with tumors positive for one or two receptors have longer survival than patients with receptor-negative tumors. Furthermore, patients with receptor positive tumors might be candidates for hormone based therapy of recurrent tumor disease.

Differential Diagnosis

Clinically, the differential diagnosis of endometrial carcinoma includes all the various causes of abnormal uterine bleeding. In the premenopausal patient, complications of early pregnancy, such as threatened or incomplete abortion, must be considered initially. Other causes of bleeding in premenopausal patients are leiomyomata, endometrial hyperplasia and polyps, cervical polyps, an intrauterine device, and various genital or metastatic cancers. Cervical, endometrial, tubal, and ovarian neoplasms all can cause abnormal uterine bleeding. Although rare, metastatic cancers from the bowel, bladder, and breast have also been reported to cause abnormal uterine bleeding. After exclusion of anatomical causes for vaginal bleeding, a work-up for hemophilias should be performed. In the postmenopausal age group, the differential diagnosis includes atrophic vaginitis, exogenous estrogens, endometrial hyperplasia and polyps, and various genital neoplasms. The likelihood of cancer increases with age. In the patient with a normal pelvic examination and recurrent postmenopausal bleeding following a recent negative D&C, tubal and ovarian cancer must be strongly considered. Patients with recurrent unexplained episodes of

postmenopausal uterine bleeding should be considered for total hysterectomy and bilateral salpingo-oophorectomy.

Complications

Patients with advanced disease and deep myometrial invasion may present with severe anemia secondary to chronic blood loss or acute hemorrhage. If bleeding is significant and continuous, a short-term boost of radiation therapy is usually effective in slowing the hemorrhage.

The presence of a hematometra can be confirmed by sounding the uterus under anesthesia, followed by dilatation of the cervix to allow adequate drainage. When a pyometra is present, the patient may present with peritonitis or generalized sepsis, with all the consequent complications.

Perforation of the uterus at the time of dilatation and fractional curettage or endometrial biopsy is not an uncommon problem. If the perforating instrument is large, loops of small bowel may be inadvertently retrieved through the cervical canal. A large perforation warrants laparoscopy or laparotomy to evaluate and repair the damage. If significant contamination of the peritoneal cavity with blood or necrotic tumor has occurred, the patient should be treated with broad-spectrum antibiotics to prevent peritonitis. Perforation in the patient with endometrial cancer should be viewed as a serious complication, as spillage of tumor into the peritoneal cavity may alter her prognosis.

Prevention

Several modifiable risk factors for endometrial carcinoma have been described; in particular, obesity, diabetes, hypertension, and nulliparity. Prevention of endometrial cancer is primarily based on weight control, physical exercise, adequate control of diabetes and hypertension, and increased surveillance of women at high risk. In addition, a careful family history of each patient will help identify patients with a genetic predisposition for endometrial cancer, for example, as part of the HNPCC syndrome. If appropriate, these patients should undergo genetic counseling and genetic testing. A hysterectomy after the completion of childbearing is appropriate for patients with HNPCC syndrome given the lifetime risk for endometrial cancer of 60%. Hormone therapy in postmenopausal patients without hysterectomy should always include a progestational agent to oppose the action of estrogens on the endometrium. Estrogens should be administered either continuously or cyclically using the lowest dose that controls symptoms. Progesterone (10 mg of medroxyprogesterone acetate or 200 mg of micronized progesterone) should be added for the last 10–14 days of the cycle to neutralize the risk of endometrial carcinoma. Alternatively, if estrogen and progesterone are administered continuously, 2.5 mg of medroxyprogesterone acetate is given daily.

Treatment

The majority of endometrial cancer cases is diagnosed at an early stage and can be treated with high cure rates. The most important treatment modality is surgery with total simple or radical hysterectomy, bilateral salpingo-oophorectomy, and staging, including pelvic and periaortic lymphadenectomy. Primary radiation therapy is used only in patients with medical contraindications for surgery or advanced pelvic disease. It has been repeatedly demonstrated that radiation therapy can cure endometrial carcinoma in some patients. However, radiation therapy averages about a 20% lower cure rate compared to surgery in stage I disease. Primary chemotherapy is used infrequently and mostly in patients with metastatic disease.

Adjuvant treatment is dependent on the results of surgical staging and histology. For example, radiation therapy is frequently used in endometrioid type endometrial cancers to prevent pelvic recurrences. Advanced pelvic disease may be treated with radiation followed by chemotherapy. Serous cancers of the endometrium behave biologically similar to ovarian cancer and are treated with adjuvant platinum-based

chemotherapy possibly in conjunction with radiation.

Radiation therapy alone can cure endometrial carcinoma in some patients, and when used preoperatively it completely eradicates the primary tumor in more than 50% of stage I cases. Furthermore, adjuvant radiation therapy has reduced the incidence of vaginal vault recurrence following surgery for stage I patients from an average of 3–8% to 1–3%. Intracavitary vaginal irradiation can be performed by using a vaginal cylinder to deliver a surface dose of 5500–6000 cGy. Also, regional radiation therapy has eliminated microscopic nodal metastases in other tumor systems, and some patients with surgically proved nodal metastases from endometrial carcinoma are now alive more than 5 years following adjuvant radiation therapy to pelvic and aortic nodes. Accordingly, in the presence of extrauterine extension, lower uterine segment or cervical involvement, poor histologic differentiation, papillary serous or clear cell histology, or myometrial penetration greater than one-third of the full thickness, adjuvant radiation therapy is recommended. In the absence of these findings, it is difficult to justify the risk and morbidity of any additional treatment beyond simple total abdominal hysterectomy and bilateral salpingo-oophorectomy.

EMERGENCY MEASURES

Patients with endometrial adenocarcinoma may present with severe anemia after prolonged periods of vaginal bleeding. Acute and massive blood loss may lead to hypovolemic shock. The management of these patients includes stabilization of vital signs with volume substitution and blood transfusion. A tamponade of the uterus using vaginal packing might be useful, particularly in the presence of a bleeding cervical or vaginal tumor. Monsel's solution or silver nitrate can further aid in obtaining hemostasis. An emergency dilatation and fractional curettage might help to control the bleeding, but has to be performed with great caution to avoid perforation. If bleeding does not subside, a high-dosage radiation boost to the whole pelvis is usually the treatment of choice to acutely control uterine bleeding in this situation. Rarely, in the face of very advanced lesions, embolization of the hypogastric arteries via percutaneous selective angiography may be required to control hemorrhage before treatment can be initiated. Hysterectomy should always be considered if it can be accomplished safely without jeopardizing curative therapy.

Elderly patients may present with severe lower abdominal pain and cramping secondary to hematometra or pyometra; these complications result from endometrial carcinoma in more than 50% of cases. When adequate blood levels of broad-spectrum antibiotics are established, the cervix should be dilated and the endometrial cavity adequately drained. In this setting, vigorous D&C is contraindicated because of the high risk of uterine perforation. If the cervix is well dilated, an indwelling drain is usually unnecessary, but if sepsis is not controlled within 24–48 hours, the patient should be re-examined to ascertain cervical patency. Once the infection has completely subsided and the patient has been afebrile for 7–10 days, gentle fractional curettage should be performed if the diagnosis was not confirmed at the initial procedure.

RADIATION THERAPY

Radiation therapy is used as primary therapy in patients considered too medically unstable for laparotomy. Adjuvant preoperative radiation is no longer used unless the patient presents with gross cervical involvement. In this situation, after preoperative whole-pelvic radiation and an intracavitary implant, an extrafascial hysterectomy is performed. Relative contraindications to preoperative radiation therapy include the presence of a pelvic mass, a pelvic kidney, pyometra, history of a pelvic abscess, prior pelvic radiation, and previous multiple laparotomies (see Chapter 54A).

SURGICAL TREATMENT

Because bleeding is usually an early sign of endometrial carcinoma, most patients present with early disease and can be adequately and completely treated by simple hysterectomy. Staging includes a

bilateral salpingo-oophorectomy, peritoneal washings for cytology, and removal of pelvic and periaortic lymph nodes. Recently, laparoscopic-assisted vaginal hysterectomy with lymphadenectomy has been performed in patients with endometrial cancer. Initial studies show no difference in overall long-term survival when laparoscopy was compared to laparotomy. Patients undergoing laparoscopy tend to have a significantly shorter hospital stay and less blood loss.

Pelvic and paraaortic lymphadenectomy play an important role in the surgical staging of endometrial cancer. A gross pathologic assessment of the uterus should be performed during surgery to determine the need for surgical staging in patients with endometrioid adenocarcinomas grade 1 or 2. Patients who require surgical staging are patients with stage 1 disease with grade 3 lesions, tumors greater than 2 cm in maximum dimension, tumors with greater than 50% myometrial invasion, cervical extension, and evidence of extrauterine spread. Furthermore, staging should be performed in clear cell and papillary serous carcinomas in all cases because of a high incidence of lymphatic spread. However, the criteria for lymphadenectomy are not universally accepted and are under constant investigation. The therapeutic role of lymphadenectomy is still under investigation. Several studies have suggested that external-beam therapy may be omitted or the radiation field be reduced to the central pelvis if the lymph nodes are negative. Brachytherapy via a cylinder to the vaginal cuff is performed to prevent vaginal vault recurrence but has not been shown to alter long-term survival. Bulky, positive nodes, which are unlikely to respond to external-beam radiation, should be removed during surgery.

Radical hysterectomy for stage II tumors is an accepted procedure that has the potential to omit adjuvant radiation therapy. A radical hysterectomy can also be an effective treatment for patients with recurrence following treatment with radiation therapy alone or for those who have previously received therapeutic doses of pelvic radiation therapy for other pelvic cancers. The high risk of bowel or urinary tract injury in this setting must be understood and accepted by both patient and physician.

Patients who present with significant cervical involvement or vaginal and parametrial involvement should receive initial pelvic radiation. Exploratory laparotomy should then be considered in patients whose disease seems resectable. Hormonal therapy or chemotherapy is most appropriate for patients with clinical evidence of extrapelvic metastases. Palliative radiation to bone or brain metastases is beneficial for symptomatic relief. Pelvic radiation can be helpful for local tumor control and alleviation of bleeding.

HORMONE THERAPY

Progesterone has shown some efficacy in the treatment of recurrent endometrial carcinoma not amenable to irradiation or surgery. This type of therapy can be administered orally or parenterally. Oral megestrol, parenteral medroxyprogesterone acetate suspension, and parenteral hydroxyprogesterone caproate appear to have similar effectiveness. Overall, approximately 13% of patients with recurrent disease appear to achieve long-term remission with progesterone therapy. The average duration of response is 20 months and up to 30% of responders survive for 5 years. In general, the clinical response is better in patients with localized recurrence, well-differentiated tumors, and late recurrences. Because some patients do not achieve remission until after 10–12 weeks of therapy, the minimum duration of treatment should be longer than 3 months. Although progesterones have a somewhat encouraging record in the treatment of recurrent endometrial adenocarcinoma, they are disappointing as prophylactic agents. They have not improved survival or decreased recurrence when used following definitive treatment of early stage disease.

Tamoxifen either alone or in combination with progesterones has been used in advanced or recurrent endometrial cancer. Patients with well-differentiated, estrogen receptor-positive tumors and long disease-free intervals tend to have a better response to tamoxifen. Tamoxifen is administered orally at 10–20 mg twice daily. For single-agent tamoxifen, the overall response rate is approximately 15–20%.

Studies using combination tamoxifen-progestin therapy suggest a possibly better clinical response.

CHEMOTHERAPY

Doxorubicin and cisplatin are the two most active agents in the treatment of advanced or recurrent endometrial cancer. Doxorubicin used as a single agent has an overall response rate of 38%, with 26% of the patients achieving a complete response. The combination of cisplatin and doxorubicin shows slightly longer survival than either agent alone. The addition of Taxol to cisplatin and doxorubicin shows an overall response rate of 57% with improved long-term survival compared to the same regimen without Taxol. Other agents with antitumor activity against endometrial cancer include carboplatin, cyclophosphamide, hexamethylmelamine, and 5-fluorouracil.

Prognosis

The most important prognosticators for endometrial cancer are stage, histologic type, grade, myometrial invasion, and the presence of lymphovascular space invasion. Identification of these risk factors is crucial for treatment decisions, surveillance, and counseling of the patient. The prognosis is worse with increasing age, higher pathologic grade, advanced stage disease, increasing depth of myometrial invasion, and presence of lymphovascular space invasion. Because the prognosis for each patient is dependent on a variety of factors, overall 5-year survival stratified by stage is indicated as a range of percentages. The overall 5-year survival rates are 81–95% for surgical stage I, 67–77% for stage II, 31–60% for stage III, and 5–20% for stage IV.

These figures underline the increasing risk for treatment failure and recurrence with increasing bulk and extension of tumor. In the absence of risk factors, a simple total abdominal hysterectomy and bilateral salpingo-oophorectomy should result in survival greater than 95% at 5 years. However, in the presence of risk factors, a more aggressive surgical approach, and using adjuvant radiation and chemotherapy may be warranted.

SARCOMA OF THE UTERUS (LEIOMYOSARCOMA, ENDOMETRIAL SARCOMAS)

Essentials of Diagnosis

- Bleeding: metrorrhagia, menorrhagia, postmenopausal or preadolescent bleeding.
- Mass: rapid enlargement of the uterus or a leiomyoma.
- Pain: pelvic discomfort as a result of mass effect from the enlarged uterus.
- Malignant tissue: histology confirmed by dilatation and curettage or in hysterectomy specimen.

General Considerations

The uterine sarcomas are mesodermally derived highly malignant tumors and account for approximately 3–4% of all uterine malignancies. No common etiology has been identified in uterine sarcomas, but prior pelvic radiation therapy is associated with the mixed forms of uterine sarcoma.

Sarcomas can occur at any age but are most prevalent after age 40. They are well known as a source of hematogenous metastases, but with the exception of leiomyosarcomas, lymphatic permeation and contiguous spread are probably the most common methods of extension. Endometrial sarcomas can usually be diagnosed by endometrial biopsy or dilatation and fractional curettage, but the sarcomas derived from the myometrium (leiomyosarcoma) frequently require hysterectomy to obtain adequate tissue for analysis.

In general, uterine sarcomas follow a very aggressive growth pattern with early metastasis to the abdomen, liver and lung. There is no universal agreement on the histologic features that determine

outcome, but most authorities agree that the number of mitotic figures per high-power field, vascular and lymphatic invasion, serosal extension, and degree of anaplasia are all helpful. Surgery is the most common primary treatment approach, followed by radiation and chemotherapy. Chemotherapeutic agents reported to be active against sarcomas include doxorubicin, cisplatin, ifosfamide, gemcitabine, and the taxanes. Clinical response rates for combination chemotherapy in recurrent and advanced disease are reported to be as high as 54%. However, most responses are partial and only temporary.

Histogenesis, Classification, & Staging

Although several classification systems exist for uterine sarcomas, they can be separated into four major categories: leiomyosarcomas (LMSs), endometrial stromal sarcomas (ESSs), malignant mixed mesodermal tumors (MMMTs), and adenosarcomas. LMSs are thought to arise from the myometrial smooth muscle cell or a similar cell lining blood vessels within the myometrium. The ESS and MMMT arise from undifferentiated endometrial stromal cells, which retain the potential to differentiate into malignant cell lines that histologically appear native (homologous) or foreign (heterologous) to the human uterus. Because the undifferentiated stromal cells of the endometrium arise from specialized mesenchymal cells of the müllerian apparatus in the genital ridge, and ultimately from the mesoderm during embryogenesis, endometrial sarcomas have been variously termed "mesodermal," "müllerian," or "mesenchymal" sarcomas. The prognoses of patients with homologous and heterologous tumors is similar stage for stage, and this terminology has limited clinical usefulness. ESSs have been categorized in the older literature as "pure" and homologous endometrial sarcomas because they are composed of a single cell line. MMMTs, previously designated as "mixed" because of containing two or more cell lines, arise from an undifferentiated malignant stem cell. MMMTs contain both a carcinomatous or epithelium derived element and a sarcomatous or mesenchymal element and have also been called "carcinosarcomas." The carcinomatous element is usually an undifferentiated adenocarcinoma. The concept of this terminology is better understood by study of Fig 51–5, which graphically represents the histogenesis of uterine sarcomas. Table 51–2 combines the prevailing histogenetic terminology for endometrial sarcomas and depicts the various possibilities in each category.

Figure 51–5.

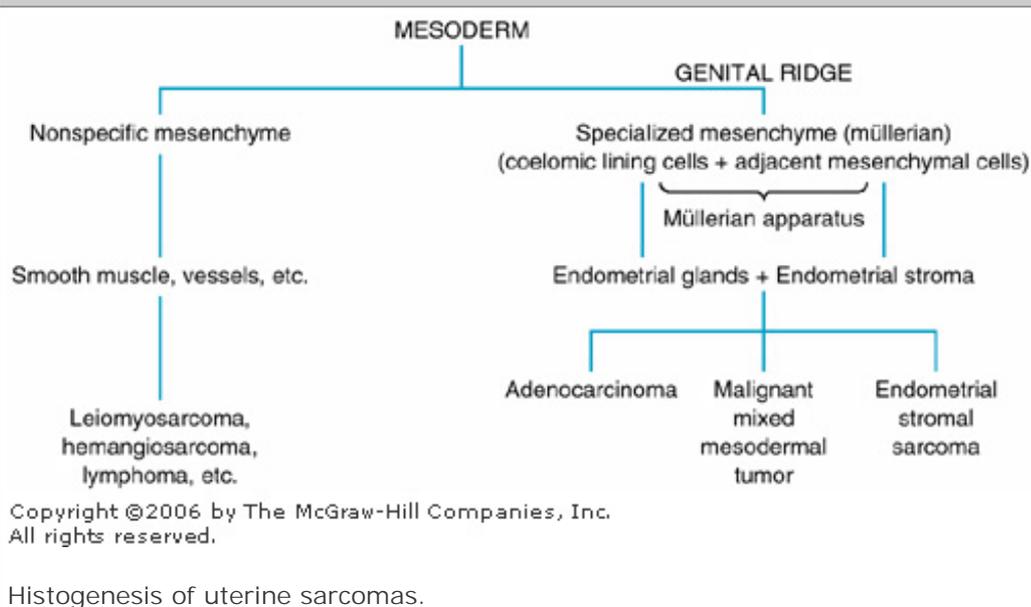

Table 51–2. Classification of Uterine Sarcomas.

Leiomyosarcoma (tumors of the uterine smooth muscle)
Endometrial stromal sarcoma (pure homologous endometrial sarcoma)
High grade
Low grade (endolymphatic stromal myosis)
Malignant mixed mesodermal tumor (mixed epithelial/stromal tumors)
Homologous carcinosarcoma
Heterologous carcinosarcoma
Adenosarcoma (mixed epithelial/stromal tumors)
Homologous
Heterologous

Pure heterologous sarcomas, such as rhabdomyosarcoma, chondrosarcoma, osteosarcoma, and liposarcoma, are extremely rare. Other uterine sarcomas, like hemangiosarcomas, fibrosarcomas, reticulum cell sarcomas, and lymphosarcomas, are indistinguishable from identical sarcomas elsewhere in the body and are therefore not considered specialized tumors of the uterus.

The commonly used staging system for uterine sarcomas follows the FIGO staging system for endometrial carcinoma (Table 51–1).

Major Types of Sarcomas of the Uterus

LEIOMYOSARCOMAS

LMSs make up 35–40% of all uterine sarcomas and 1–2% of all uterine cancers. LMS usually occurs between ages 25 and 75 years, with a mean incidence at about age 50 years. Younger patients with this disease seem to have a more favorable outcome than postmenopausal women. Like the benign leiomyomas, LMSs are 1.5 times more common in African American patients than in the white population. Leiomyomas are commonly identified in uteri containing leiomyosarcomas, but the incidence of malignant transformation of a leiomyoma is only 0.1–0.5%. Only approximately 5–10% of LMSs are reported to originate in a leiomyoma.

Abnormal uterine bleeding is the most common symptom of LMS, occurring in approximately 60% of patients; pelvic or abdominal pain and discomfort is reported by approximately 50% of all patients. Only approximately 10% of patients are aware of an abdominal mass. The diagnosis is by made by biopsy. Occasionally, a pedunculated tumor prolapses through the cervix and is easily accessible for biopsy. The deeply situated intramural position of most tumors impedes diagnosis by D&C, which is accurate in only 25% of cases. Abnormal cells might be identified on Pap smear. The diagnosis is more commonly made after pathologic analysis of a hysterectomy specimen.

LMSs spread by contiguous growth, invading the myometrium, cervix, and surrounding supporting tissues. Lymphatic dissemination is common in the late stages. Pelvic recurrence and peritoneal dissemination following resection are also common. In the more malignant types, hematogenous

metastasis to the lungs, liver, kidney, brain, and bones probably occurs early but is clinically evident only in the lungs until the advanced stages.

The clinical behavior of the tumor is generally aggressive with some correlation with the number of mitotic figures identified on microscopic examination. Low-grade LMSs are those with less than 5 mitoses per 10 high-power fields, with pushing rather than infiltrating margins. LMSs with 5–10 mitoses per 10 high-power fields are considered to be of intermediate grade, and tumors with mitotic counts greater than 10 per 10 high-power fields are highly malignant and usually lethal; less than 20% of these patients are alive at 5 years. The number of mitosis may be a useful prognostic indicator, but other factors have to be taken into account. An invasive pattern, particularly into the blood and lymphatic vessels and the surrounding smooth muscle, is important. By contrast, cellular characteristics, such as atypia, anaplasia, and giant cells, are not accurate prognosticators of aggressive behavior. Clinically, the most reliable prognostic feature of LMS is stage. The prognosis of patients with extrauterine disease is much worse compared to patients with disease confined to the uterus. Patients with LMS mostly present at stage I. A pelvic MRI can help delineate the extent of uterine involvement and can help in the preoperative determination of a benign versus a malignant smooth muscle tumor. Benign leiomyomata have sharp boundaries whereas sarcomas have infiltrating borders on MRI imaging.

Other unusual smooth muscle tumors of the uterus such as benign metastasizing leiomyoma and intravenous leiomyomatosis should be considered low-grade LMS. Although they are histologically benign, they are notorious for local recurrence and can cause death by compression of contiguous or distant vital structures. Intravenous leiomyomatosis has been known to grow up the vena cava into the right atrium, impeding venous return and precipitating congestive heart failure. Because of their slow growth, they can frequently be controlled by repeated local excision. The metastatic lung lesions of benign metastasizing leiomyoma have disappeared following resection of the primary lesion in some cases, perhaps indicating hormone dependency.

ENDOMETRIAL SARCOMAS

Endometrial Stromal Sarcomas

ESSs make up 8% of all sarcomas. They occur predominantly in postmenopausal women. Patients with these tumors most commonly present with bleeding or lower abdominal discomfort and pain. The diagnosis can be made accurately by D&C in approximately 75% of cases. Although no etiologic relationship to hormones has been established, a small number of metastatic lesions has responded to progesterone therapy.

ESSs can be divided into two distinct subtypes: low grade and high grade. The indolent low-grade ESSs—also called endolymphatic stromal myosis—have fewer than 10 mitoses per 10 high-power fields, with infiltrating margins and myometrial invasion. A benign form, the stromal nodule, contains pushing rather than infiltrating margins and fewer than 3 mitoses per 10 high-power fields, with no vascular or myometrial invasion.

The mean age at *onset* for endolymphatic stromal myosis is 5–10 years earlier than for high-grade sarcomas. This tumor infiltrates surrounding structures and is characterized by indolent growth and a propensity to vascular invasion. Patients frequently present with yellowish wormlike extensions into the periuterine vascular spaces. Under such circumstances, it may be confused grossly with intravenous leiomyomatosis, as previously described. It tends to recur late, sometimes after 5–10 years, and can often be controlled by repeated local excisions.

The high-grade ESSs display infiltrating margins and vascular and myometrial invasion and contain more than 10 mitoses per 10 high-power fields. These tumors are highly malignant and are associated with a poor prognosis, particularly when they extend beyond the uterus at the time of diagnosis. They spread

by contiguous growth via the serosal uterine surface and lymphatic metastasis. Distant hematogenous metastases to the lungs and liver are usually a late event.

Malignant Mixed Mesodermal Tumors

MMMTs account for 50% of all uterine sarcomas and 3–6% of all uterine tumors. They characteristically occur in postmenopausal women, with the exception of embryonal rhabdomyosarcoma of the cervix or vagina (sarcoma botryoides), which occurs also in infants and children. The incidence is about 3 times greater in black than in white women. Radiation therapy may be a predisposing cause, but the etiology of MMMTs is unknown. Many published series are available containing a significant number of patients with a history of pelvic radiation for benign or malignant conditions (Fig 51–6).

Figure 51–6.

Mixed sarcoma of the uterine fundus. Prior full-pelvic radiation therapy had little effect on the tumor.

As with the other types, the presenting symptom of MMMT is usually bleeding. Abdominal discomfort and pain or a neoplastic mass prolapsed into the vagina also occur. Because the tumors are endometrial in origin, approximately 75% can be diagnosed accurately by D&C. Histologically, MMMTs are usually highly anaplastic, with many bizarre nuclei and mitotic figures. They contain an epithelial and a sarcomatous component, hence the term malignant mixed mesodermal, or müllerian tumor, or carcinosarcoma. If the sarcomatous component is derived from the smooth muscle tissue of the uterus, they are called homologous MMMTs. If the sarcomatous component contains bone, striated muscle, cartilage, or fat, the term heterologous MMMT is applied. Clinically, this distinction does not influence treatment or prognosis. MMMTs spread by contiguous infiltration of the surrounding tissues and by early hematogenous and lymphatic dissemination. The metastatic deposits are usually composed of the epithelial malignant glands, but sarcomatous elements have been identified in some cases. The prognosis depends mainly on the extent of the tumor at the time of primary surgery; there are virtually no long-term survivors among those whose tumor has extended beyond the confines of the uterus at the time of diagnosis. Treatment includes total abdominal hysterectomy with bilateral salpingo-oophorectomy, lymphadenectomy, and tumor debulking if necessary and technically feasible. Active chemotherapeutic agents include cisplatin, ifosfamide, Adriamycin, epirubicin, carboplatin, Taxol, and gemcitabine.

ADENOSARCOMAS

Adenosarcoma is a distinctive mixed müllerian tumor that accounts for 1–2% of uterine sarcomas. It arises from the endometrium and is composed of a combination of benign-appearing glands and a

stromal sarcoma or fibrosarcoma. Adenosarcomas usually occur in the postmenopausal age group but have been reported in adolescents and women of reproductive age. Bleeding is the most common symptom. Recurrence occurs in 25% of patients and is usually late. The primary treatment is removal of uterus, tubes, and ovaries. Postoperative radiation therapy is recommended for those tumors with deep myometrial invasion.

OTHER UTERINE SARCOMAS

Embryonal rhabdomyosarcoma of the cervix (sarcoma botryoides), which occurs in infants and children, was previously lethal. However, combination therapy using surgery, radiation, and chemotherapy has considerably improved the outlook for these patients.

Fibrosarcoma, hemangiosarcoma, reticulum cell sarcoma, hemangiopericytoma, and other esoteric and bizarre uterine sarcomas are rare. In general, these sarcomas behave like the other intermediate-grade uterine sarcomas, but treatment must be individualized according to age, histologic type, and the patient's state of health.

Clinical Findings

SYMPTOMS AND SIGNS

Abnormal uterine bleeding is the most common manifestation of uterine sarcoma. Other recurring complaints include pelvic discomfort or pain, constipation, urinary frequency and urgency, and the presence of a mass low in the abdomen. Uterine sarcoma should be suspected in any nonpregnant woman with a rapidly enlarging uterus. Severe uterine cramps may exist if the tumor has prolapsed into the endometrial cavity or through the cervix. Pelvic examination may reveal the characteristic grapelike structures of sarcoma botryoides protruding from the cervix or the presence of velvety fronds of ESS in the cervical canal. A necrotic fungating mass at the vaginal apex should suggest an infarcted myoma, LMS, or MMT. The uterus is usually enlarged and often soft and globular. If the cancer has involved the cervix, cul-de-sac, or cardinal ligaments, fixation or asymmetry of the parametria may be found. In advanced cases, inguinal or supraclavicular node metastases may be evident. Patients with advanced uterine sarcomas may present with a large omental mass or ascites secondary to abdominal carcinomatosis.

LABORATORY FINDINGS

Standard laboratory evaluation of patients with uterine sarcoma should include a complete blood count and urinalysis, liver function studies (especially serum alkaline phosphatase, prothrombin time, and serum lactic dehydrogenase), blood urea nitrogen, and serum creatinine. CA-125 may be elevated. Estrogen and progesterone receptor analysis may indicate which patients are likely to respond to hormone therapy. Office endometrial biopsy or punch biopsy of a prolapsed vaginal mass is helpful only if positive.

RADIOGRAPH FINDINGS

The chest radiography may contain metastatic coin lesions characteristic of uterine sarcomas. Because uterine sarcomas commonly metastasize to the lung, a chest computed tomography (CT) scan should be considered when the routine films are negative, particularly before any radical extirpative surgery in the pelvis is performed. CT scan of the abdomen and pelvis is helpful in assessing the extent of abdominal disease, evaluating the kidneys for hydronephrosis, identifying enlarged retroperitoneal nodes, and identifying liver metastases. MRI scans are not routinely performed but may provide an accurate preoperative assessment of uterine size and degree of involvement.

SPECIAL EXAMINATIONS

Pelvic ultrasonography may confirm the presence of a pelvic mass or help to differentiate an adnexal from a uterine mass in the obese patient. Sigmoidoscopy should always be performed in older women,

and in young women if gastrointestinal bleeding or masses suspected of being malignant are present. Cystoscopy is indicated in locally advanced disease or in the presence of gross or microscopic hematuria.

Differential Diagnosis

The clinical diagnosis of uterine sarcoma is frequently overlooked. Diagnostic accuracy can be increased if the physician keeps these tumors in mind while investigating any pelvic mass. The tumor frequently does not present the classic picture of abnormal bleeding accompanied by a symmetrically enlarged soft globular uterus. It can masquerade as any condition causing uterine enlargement or a pelvic mass; of these, pregnancy, leiomyoma, adenomyosis, and adherent ovarian neoplasms or pelvic inflammatory disease are most likely to cause misinterpretation. When cytologic studies, endometrial biopsy, or dilatation and fractional curettage fail to provide the diagnosis—a situation not uncommon with LMS—laparotomy is necessary. At laparotomy, thorough evaluation is critical to the future management of the patient with uterine sarcoma and must include inspection (where possible) and palpation of all abdominal viscera, peritoneal and mesenteric surfaces, liver, both diaphragms, and retroperitoneal structures, especially the pelvic and aortic lymph nodes. Cytologic examination of peritoneal exudate is indispensable for treatment planning; if no free fluid is present, samples may be obtained by instilling 50–100 mL of normal saline into the abdominal cavity (pelvic washings). If a sarcoma is identified on frozen section of the hysterectomy specimen, suspicious lymph nodes should be removed. This information, gathered at the time of the initial exploration and carefully documented in the operative records, is critical for identification and staging of the neoplasm and for predicting outcome.

The pathologic diagnosis of uterine sarcoma is often extremely difficult and may require consultation with a gynecologic pathologist familiar with these tumors. As each cancer becomes more anaplastic, the parent cell or tissue becomes more difficult to identify histologically. Because proper treatment is predicated on accurate histologic diagnosis, every effort should be expended to identify the cell of origin.

Complications

Severe anemia from chronic blood loss or acute hemorrhage may be present. The severity and extent of other complications caused by uterine sarcomas are directly related to the size and virulence of the primary tumor. A pedunculated mass may protrude into the uterine cavity or prolapse through the cervix, causing bleeding or uterine cramps as the uterus attempts to expel the tumor. Infarction with subsequent infection and sepsis may ensue. Rupture of the uterus as a consequence of rapidly growing uterine sarcomas has been reported. Obstructed labor and postpartum uterine inversion secondary to endometrial sarcomas have also been noted. Extensive pulmonary metastases can produce hemoptysis and respiratory failure. Ascites is common in advanced disease with peritoneal metastases.

A wide variety of complications has been reported secondary to pressure or compression of a neighboring viscus or resulting from extension or metastases to other vital structures. Urethral elongation caused by stretching of the bladder over a rapidly growing mass can simultaneously produce obstruction and loss of sphincter control, with subsequent overflow incontinence. Colon compression may result in ribbon stools and, eventually, complete bowel obstruction. Ureteral obstruction is common, especially with recurrent pelvic sarcomas. Urinary diversion or colostomy may be required prior to treatment if life-threatening viscus obstruction is present in an untreated patient, but urinary diversion should not be performed unless there is some hope for cure or meaningful palliation, because it precludes a painless death from uremia.

Prevention

Indiscriminate use of radiation therapy for benign conditions in the pelvis should be avoided, as several clinical studies have suggested an etiologic role of pelvic radiation in the development of MMMT.

Treatment

EMERGENCY MEASURES

Hemorrhage from uterine sarcomas can be severe and requires prompt attention. In acute hemorrhage, blood volume should be replaced rapidly, using packed red blood cells, crystalloid solutions, volume expanders, and fresh-frozen plasma.

Emergency D&C should be used only to obtain tissue for analysis. Vigorous curettage is likely to aggravate or provoke bleeding. High-dose bolus radiation is a more reliable and safe method of controlling bleeding. A dose of 400–500 cGy administered daily to the whole pelvis over 2–3 days usually controls acute hemorrhage; this does not appreciably interfere with future management. If these measures are not successful, emergency embolization or ligation of the hypogastric arteries sometimes controls hemorrhage when hysterectomy is not indicated or technically feasible.

SURGICAL MEASURES

Extirpative surgery provides the best chance for long-term palliation or cure for patients with uterine sarcomas. Surgery is the cornerstone of the treatment plan and should be the central focus of attack against these cancers.

Because low-grade uterine sarcomas (some LMSs, endolymphatic stromal myosis, intravenous leiomyomatosis) have a propensity for isolated local spread and central pelvic recurrence, such patients should be considered for radical hysterectomy and bilateral salpingo-oophorectomy. The benefits of this type of therapy have not been conclusively shown, but, theoretically, the problem of local recurrence should be improved by more radical excision of the primary tumor. Lymph node metastases in these low-grade tumors are negligible; consequently, pelvic lymphadenectomy can be reserved for patients with enlarged or suspicious nodes. Pelvic recurrences of low-grade uterine sarcomas have been successfully treated by repeated excisions of all resectable tumor. Patients have been known to survive for many years following this type of conservative treatment. Partial or complete pelvic exenteration may occasionally be useful for recurrence of indolent tumors.

The high-grade uterine sarcomas (some LMSs, ESSs, all MMMTs) display early lymphatic, local, and hematogenous metastases, even when apparently confined to the uterus. For this reason, radical surgery has been abandoned in favor of simple total abdominal hysterectomy and bilateral salpingo-oophorectomy preceded or followed by adjunctive radiation therapy. At the time of surgical exploration, a thorough examination and evaluation of the abdominal contents must be performed and documented. Cytologic specimens and omental tissue should be obtained, and suspicious papillations, excrescences, and adhesions should be excised for pathologic analysis. A thorough staging procedure is important for prognosis and a postoperative treatment plan.

When uterine sarcomas recur in the lung and the metastatic survey is negative, unilateral isolated metastases can be excised after a chest CT scan has ruled out other lesions not apparent on the routine chest radiograph. Considering all sources, resection of isolated sarcoma metastases to the lung carries about a 25% 5-year cure rate.

CHEMOTHERAPY

Adjuvant doxorubicin reduces the distant recurrence rate for LMS. Although the data are not statistically significant, some authorities recommend the use of doxorubicin-based chemotherapy in high-grade LMS.

Because of the high hormone receptor content in ESS, adjuvant progestin or tamoxifen therapy is recommended. For receptor-negative tumors, doxorubicin-based chemotherapy is used.

Doxorubicin, cisplatin, carboplatin, paclitaxel, gemcitabine, and ifosfamide display significant activity against MMMTs. Cyclophosphamide and vincristine also show activity. Some data suggest that

combination chemotherapy is more effective than single-agent therapy. In advanced or metastatic disease, adjuvant combination chemotherapy is recommended. ET-743, a new agent, has been actively evaluated in sarcomas and appears to show some modest promise. Treatment with tyrosine kinase inhibitors like imatinib has been attempted.

RADIATION THERAPY

When used as the only modality of treatment for uterine sarcomas, radiation has produced dismal results—very few survivors are reported in the literature following treatment with radiation therapy alone for any of the uterine sarcomas. Radiation therapy does provide local tumor control and reduces local recurrences when used in combination with surgery for the treatment of some endometrial sarcomas. However, it is unclear whether a combined surgical and radiation approach changes overall survival. Collected data indicate that adjuvant radiation therapy improves the 2-year survival rate in patients with ESS by approximately 20% and may also improve survival for those with MMMTs, although less convincingly. Although an occasional 5-year survivor with LMS has been reported following radiation therapy alone, analysis of large numbers of patients from different institutions does not support its use for these tumors. Nevertheless, in advanced forms of LMS, radiation may prove useful for palliation and control of pelvic symptoms such as massive bleeding or pain.

Prognosis

In determining the prognosis for patients with uterine sarcomas, a constellation of factors must be examined simultaneously. Such considerations as the patient's age, state of health, and ability to withstand major surgery or radiation therapy (or both) must be evaluated. The most important clinical characteristic—and probably the overriding prognostic feature affecting the prognosis of these patients—is the stage of the disease at the time of diagnosis. In the high-grade sarcomas (LMS and mixed endometrial sarcoma), the presence of tumor outside the uterus at the time of diagnosis is a clear prognostic omen: fewer than 10% of patients survive 2 years. Even when the disease is apparently limited to the uterus, the prognosis is poor: 10–50% survive 5 years. In intermediate-grade LMS and high-grade ESS, the outcome is improved, with up to 80–90% of patients surviving 5 years if the disease is clinically limited to the uterus at the time of surgery. Low-grade ESS and low-grade LMS have a generally favorable outcome: 80–100% of patients survive 5 years following complete excision of the uterus. Low-grade stromal tumors have been known to recur locally after 10–20 years; this confuses the survival statistics. Undoubtedly, these patients must be followed closely for life.

Current OB/GYN > Chapter 52. Premalignant & Malignant Disorders of the Ovaries & Oviducts >

OVARIAN CANCER

Ovarian cancer accounts for 3–4% of cancer in women, and is the fourth most frequent cause of cancer-related death in females in the United States. In the year 2005, an estimated 22,220 new ovarian cancer cases were diagnosed in the United States and 16,210 patients succumbed to the disease. Ovarian cancer is the second most common gynecologic malignancy, endometrial cancer being the most common, but is the most common cause of death among women who develop a gynecologic malignancy. From 1985–2001, the incidence of ovarian cancer declined at a rate of 0.8% per year, the greatest decline seen among women age 65 years and older. In general, ovarian cancer is a disease of the postmenopausal woman, with the highest incidence among patients ages 65–74 years. The lifetime risk of developing ovarian cancer is approximately 1.4%, and the lifetime risk of dying from ovarian cancer is almost 1%.

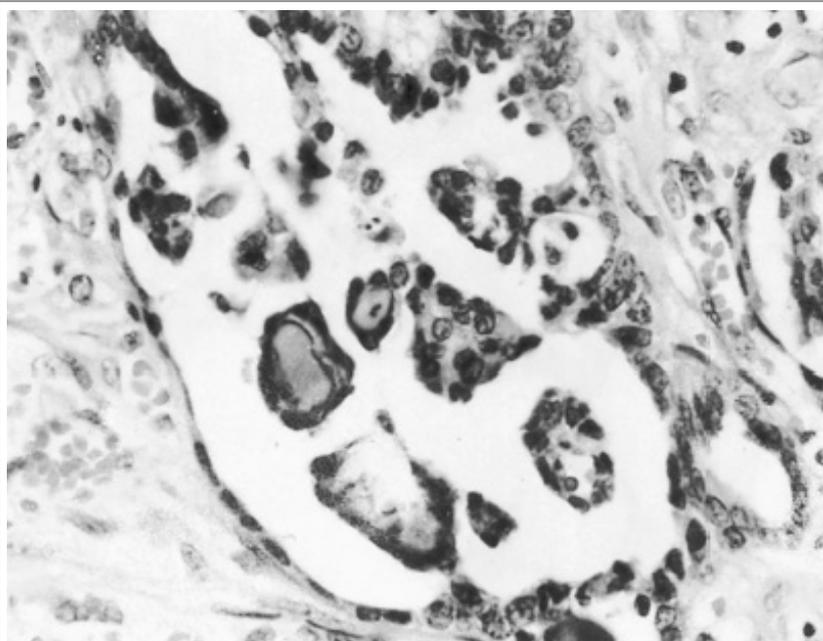

ETIOLOGY OF OVARIAN CANCER

Incessant ovulation is thought to play an important role in the underlying mechanism in the development of ovarian cancer. The repeated disruption and repair of the germinal epithelium may provide ample opportunity for somatic gene deletions and mutations to occur, which, in turn, can contribute to tumor initiation and progression. Supporting this theory are the observations that multiparity, use of oral contraceptive pills, and a history of breastfeeding are protective. Pregnancy is associated with a risk reduction of 13–19% per pregnancy, and in women who use oral contraceptives for 5 years or longer, the risk of epithelial ovarian cancer decreases by 50%. Considerable controversy surrounds the idea of whether infertility treatment is associated with an increased risk of ovarian cancer. A large pooled analysis of 5207 women with cancer and 7705 controls showed no associated increased risk with fertility drug exposure. Rather, infertility itself confers a higher risk of ovarian cancer as nulliparity compared to multiparity (> 4) and infertility for longer than 5 years (compared to < 1 year) carried relative risks of 2.42 and 2.7, respectively. Hormone replacement therapy was found to have a nonsignificant increase in risk for ovarian cancer.

A number of different studies suggest an association between dietary factors and ovarian cancer. Diets high in saturated animal fats seem to confer an increased risk by unknown mechanisms. Interestingly, Japanese women who move to the United States have an increased ovarian cancer risk. A recent Norwegian study of more than 1 million women showed a positive association between body mass index, height, and risk of ovarian cancer, particularly the endometrioid type in women younger than age 60 years. Other factors, like alcohol and milk product consumption, have been hypothesized as risk factors but never confirmed. Exposure to talc has also been proposed as a risk factor in women who place talcum powder on the external genitalia. The presence of talc granulomas in the ovaries of patients who have never been previously operated on is well documented and can be explained by the continuity of the introitus and peritoneal cavity via the endocervical canal, the endometrial cavity, and the fallopian tubes (Fig 52–1). The ability of foreign materials, including talc and asbestos, to act as carcinogenic substances is established in several models, but their role in ovarian carcinogenesis remains speculative.

Bilateral tubal ligation reduces the incidence of ovarian cancer, possibly by preventing carcinogenic substances from ascending into the müllerian ductal system.

Figure 52–1.

Papillary lesion with incorporated talc granules.

Approximately 90% of ovarian cancer develops sporadically. However, an estimated 10–12% of epithelial ovarian cancer patients have a genetic predisposition. Chromosomal abnormalities are commonly associated with ovarian malignancies. Patients with Turner's syndrome (45,XO) are at increased risk of dysgerminoma and gonadoblastoma. Hereditary ovarian cancer occurs in two forms, either as breast and ovarian cancer (BOC) syndrome, or the less common Lynch II syndrome, also known as hereditary nonpolyposis colorectal cancer (HNPCC) syndrome. BOC is most often associated with germ line mutations in the *BRCA1* gene located on chromosome 17 and less commonly with *BRCA2* mutations on chromosome 13. The overall frequency of *BRCA1* mutation carriers in the United States is approximately 1 in 800 women. Greater mutation frequencies have been found in Ashkenazi Jews and Icelandic women. Because these mutations are inherited in an autosomal dominant fashion, they require a careful pedigree analysis. Women with *BRCA1* mutations from high-risk families have a lifetime risk of ovarian cancer as high as 44%. The risk in women with *BRCA2* mutations have a lifetime risk of up to 27%.

The HNPCC syndrome involves a combination of familial colon cancer (Lynch I syndrome) and a high rate of ovarian, endometrial, gastrointestinal, and genitourinary malignancies. Genes involved in this syndrome include mainly DNA mismatch repair genes like *MLH1*, *MSH2*, *MSH3*, *MSH6*, *PMS1*, and *PMS2*. A woman who is a member of a family affected by this syndrome appear to have a lifetime risk for developing ovarian cancer of approximately 12%. Hereditary ovarian cancers generally occur in women about 10 years younger than those with nonhereditary tumors.

A number of molecular mechanisms related to ovarian cancer pathogenesis have been described. Allelic loss and mutations of the p53 tumor suppressor gene are found in approximately 55% of all ovarian cancers, with the highest frequency noted in serous and endometrioid ovarian cancers, particularly in

advanced stage disease. The *c-erb-B2* (HER2/*neu*) proto-oncogene is activated in a fraction of ovarian cancers, providing the potential for increased proliferation and metastasis. The anti-HER2/*neu* antibody therapy Herceptin, which is active against breast cancer, is currently being investigated as a therapeutic agent in ovarian cancer. Other molecular pathways include decreased expression of CDK (cyclin-dependent kinase) inhibitors, *k-ras* mutations, *p16* deletions, and activation of the *PI3kinase/Akt* pathway. These molecular pathways may provide targets for novel therapeutic approaches to ovarian cancer.

HISTOPATHOLOGY OF OVARIAN CANCER

Ovarian cancer can be divided into three major categories based on the cell type of origin (Table 52–1). The ovary may also be the site of metastatic disease by primary cancer from another organ site. Unlike carcinomas of the cervix and endometrium, precursor lesions of ovarian carcinoma have not been defined.

Table 52–1. Major Histopathologic Categories of Ovarian Cancer.

Epithelial

Serous, mucinous, endometrioid, clear cell, transitional cell (Brenner), undifferentiated

Germ Cell

Dysgerminoma, endodermal sinus tumor, teratoma (immature, mature, specialized), embryonal carcinoma, choriocarcinoma, gonadoblastoma, mixed germ cell, polyembryona

Sex Cord and Stromal

Granulosa cell tumor, fibroma, thecoma Sertoli-Leydig cell, gynandroblastoma

Neoplasms Metastatic to the Ovary

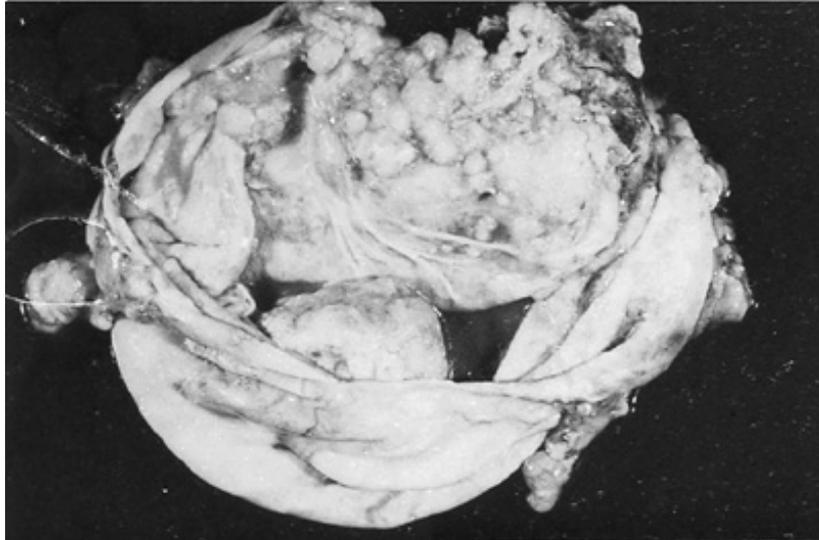

Breast, colon, stomach, endometrium, lymphoma

Epithelial Neoplasms

Epithelial neoplasms are derived from the ovarian surface mesothelial cells and include several cell types: serous, mucinous, endometrioid, clear cell, transitional cell, and undifferentiated. Epithelial tumors account for more than 60% of all ovarian neoplasms and for more than 90% of malignant ovarian tumors.

Ovarian serous cystadenocarcinoma is the most common malignant tumor of the ovary, accounting for 75–80% of all epithelial cancers. Grossly, these neoplasms are bilateral in 40–60% of cases, and 85% are associated with extraovarian spread at the time of diagnosis. More than 50% of serous tumors exceed 15 cm in diameter, and cut section reveals solid areas, areas of hemorrhage, necrosis, cyst wall invasion, and adhesions to adjacent structures. Unilocular or multilocular cysts often contain coarse papillae that project into the cystic lumen (Fig 52–2).

Figure 52–2.

Internal papillae characteristic of the papillary serous cystadenocarcinoma.

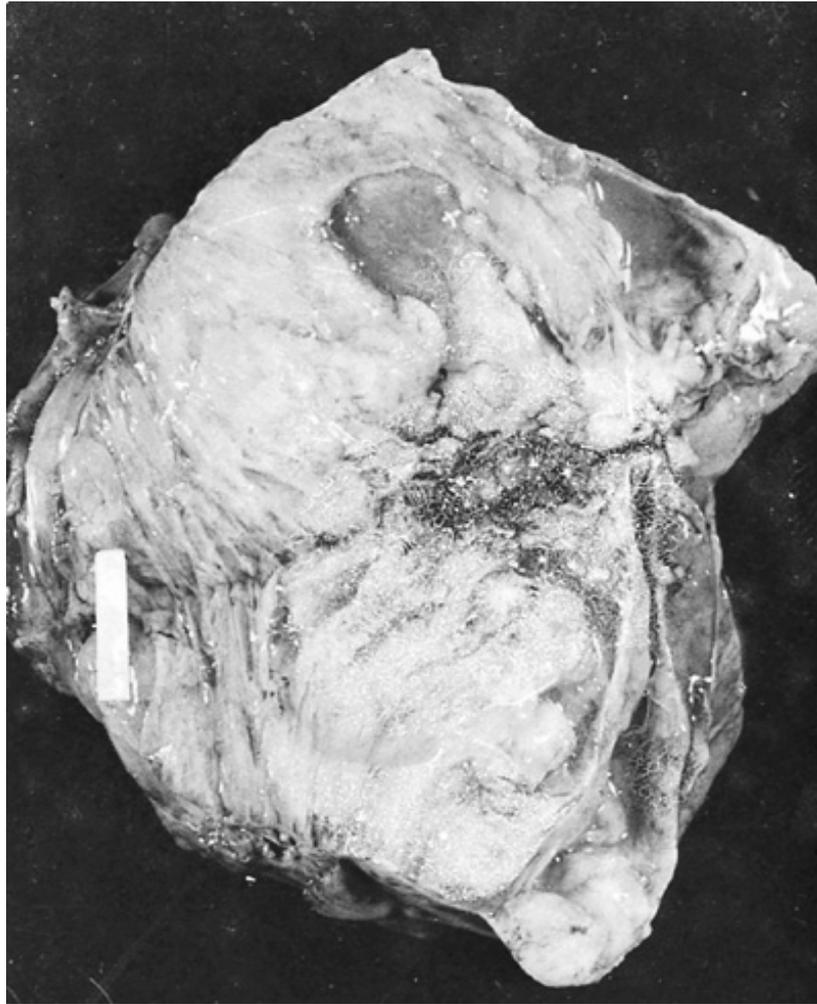

Histologically, serous carcinomas of the ovary resemble the endosalpinx and exhibit mild to moderate nuclear atypia and occasional mitotic figures of the stratified squamous epithelium, which often forms budding tufts. Psammoma bodies, irregular lamellar calcifications, are frequently found in serous tumors. The grade of differentiation of these neoplasms is based on the degree of preservation of the papillary architecture. Most serous carcinomas are poorly differentiated with trabecular and solid growth patterns.

Serous ovarian neoplasms of low malignancy potential exhibit histologic features suggestive of both carcinoma and benignity. Although marked cellular pleomorphism and mitotic figures are often present, there is no stromal invasion. Psammoma bodies are often present. These tumors may be associated with metastatic implants, invasive or noninvasive, although most remain confined to the ovary. Seen predominantly in premenopausal women, these tumors are associated with a good prognosis.

Mucinous neoplasms of the ovary account for 10% of all epithelial ovarian tumors. In contrast to serous tumors, mucinous tumors are bilateral in less than 10% of cases.

Mucinous tumors are notable for the large size that they may attain; neoplasms weighing more than 150 pounds have been reported. However, the median size of these lesions is 18–20 cm. Cut sections of these tumors typically reveal multilocular cysts filled with viscous mucin (Fig 52–3). The lining of these tumors is composed of atypical cells with numerous mitotic figures.

Figure 52–3.

Mucinous cystadenocarcinoma. Note the obvious mucinous component and the solid, more malignant areas.

Histologically, mucinous adenocarcinoma of the ovary resembles endocervical epithelium. The cells have large hyperchromatic nuclei and prominent nucleoli. Invasive mucinous ovarian carcinoma exhibits marked histologic variability from area to area within the tumor, and extensive sampling is required. It is recommended that at least one section per centimeter of tumor be examined to find the most malignant focus. The differentiation of mucinous cystadenocarcinoma is related to the preservation of glandlike architecture of the tumor. These tumors must be distinguished from metastatic mucinous tumors originating in the colon and rectum, appendix, endocervix, and pancreas because of similar cell architecture.

Both invasive carcinomas and tumors of low malignancy potential of the mucinous variety are recognized. Mucinous tumors of low malignancy potential are characterized histologically by several cell types, including endocervical-like columnar cells, intestinal-like columnar cells with eosinophilic cytoplasm, goblet cells, and basal endocrine cells. Although cellular atypia may be present with a moderate number of mitotic figures, cellular stratification does not exceed 2–3 layers and stromal

invasion is absent.

Pseudomyxoma peritonei is an unusual condition that may occur in association with mucinous neoplasms of the ovary resulting from the progressive accumulation of mucin in the abdominal cavity following its slow leakage from a neoplasm. It most commonly occurs in association with lesions of low malignancy potential; however, it is also reported to occur in association with cystadenocarcinoma of the ovary and appendix as well as mucocele of the appendix. Although rare and histologically benign in appearance, pseudomyxoma peritonei has a protracted and potentially morbid course frequently secondary to bowel obstruction, with a mortality rate that approaches 50%.

Endometrioid neoplasms of the ovary, accounting for 10% of epithelial tumors, exhibit an adenomatoid pattern that resembles endometrial adenocarcinoma (Fig 52–4). It is bilateral in 30–50% of cases. Rarely, this neoplasm arises in foci of endometriosis (less than 10% of cases). The degree of differentiation is based on the extent to which the glandular architecture is retained. As many as 30% of patients with endometrioid carcinoma of the ovary also have a synchronous endometrial carcinoma of the uterus that is a second primary rather than a metastatic focus of disease. A recent study showed that 25% of women 45 years or younger with type I endometrial cancer had coexisting ovarian malignancies. Of these tumors, 88% were classified as synchronous primaries and 92% showed endometrioid histology.

Figure 52–4.

Endometrioid carcinoma as seen with high-power field. Note the tall epithelium—not a tubal type or the mucoid variety.

Clear cell carcinoma of the ovary, also referred to as mesonephroid carcinoma of the ovary because their histologic features include "clear cells," as seen in renal cell carcinomas, accounts for less than 1% of epithelial ovarian cancers. These tumors rarely attain the size of serous and mucinous neoplasms of the ovary. Clear cell carcinomas of the ovary are biologically aggressive and can be associated with hypercalcemia and hyperpyrexia. On cut section, both cystic and solid areas are present. The external surface is smooth but has a bosselated contour. Histologically, two cell types may be present: the clear cell and the "hobnail cell" (Fig 52–5). Occasionally, clear cell carcinomas are difficult to differentiate from mucinous neoplasms. The periodic acid-Schiff reaction can be used to differentiate the two as it is only weakly positive in clear cell neoplasms but strikingly positive in mucinous tumors.

Figure 52–5.

All rights reserved.

Adenomatous pattern with papillary infolding and "hobnail epithelium." In many areas, clear cells can be seen with transitions to the hobnail type.

Transitional cell (Brenner) carcinoma of the ovary, accounting for < 1% of epithelial cancers, is composed of cells that resemble low-grade transitional cell carcinoma of the urinary bladder. Patients typically present with advanced stage disease and exhibit a poorer prognosis when compared with that of other histologic types of epithelial ovarian cancer.

Undifferentiated carcinoma of the ovary accounts for less than 10% of epithelial neoplasms. This neoplasm is characterized by the absence of any distinguishing microscopic features that permit its placement in one of the other histologic categories.

Germ Cell Neoplasms

Germ cell neoplasms arise from the germ cell elements of the ovary and include dysgerminoma, endodermal sinus tumor, embryonal cell carcinoma, choriocarcinoma, teratoma, polyembryoma, and mixed germ cell tumors. Unlike the epithelial neoplasms, which tend to occur during the sixth decade of life, this group of tumors tends to occur during the second and third decades and as a group is associated with a better prognosis. Many of these neoplasms produce biologic markers that can be monitored to assess response to therapy (Table 52–2).

Table 52–2. Tumor Markers That May Be Elevated in the Presence of Germ Cell Neoplasms.

Neoplasm	AFP	hCG
Dysgerminoma	*	+/-
Endodermal sinus tumor	+	-
Immature teratoma	+/-	-
Mixed germ cell tumor	+/-	+/-
Choriocarcinoma	-	+
Embryonal carcinoma	+/-	+

AFP, α -fetoprotein; hCG, human chorionic gonadotropin.

- = negative (not elevated);

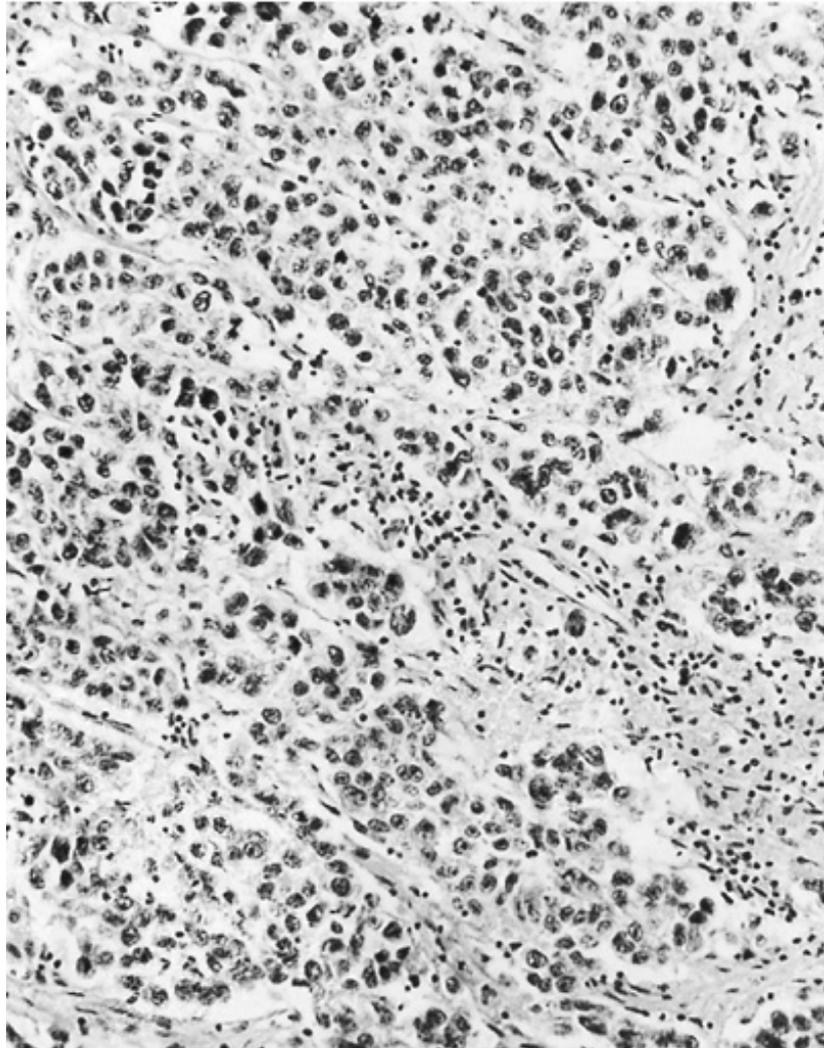

+ = positive (elevated above normal level);

* = borderline (<16 ng/mL) elevations in case reports.

Dysgerminoma of the ovary is the female counterpart of the seminoma in the male. It occurs primarily in young females and accounts for approximately 30–40% of germ cell tumors. Grossly, the tumor is rather rubbery in consistency, smooth, rounded, and thinly encapsulated, with a brown or grayish-brown color. This neoplasm is unilateral in 85–90% of cases. It is a solid neoplasm which may contain areas of softening as a result of degeneration.

Histologically, dysgerminoma mimics the pattern seen in the primitive gonad, with nests of germ cells that appear as large, rounded cells with central nuclei that contain one or two prominent nucleoli surrounded by undifferentiated stroma (Fig 52–6). Lymphocytes may invade the stroma and occasionally giant cells are identified. A lymphocytic infiltrate is considered a favorable prognostic indicator.

Figure 52–6.

Classic histologic picture of dysgerminoma. Note nests of germ cells of various sizes separated by fibrous trabeculae.

Endodermal sinus tumor of the ovary, previously called a yolk sac tumor, is the third most common germ cell neoplasm. It is bilateral in nearly 100% of cases. It holds the distinction of being the most rapidly growing neoplasm that occurs at any site. These lesions are friable, focally necrotic, and hemorrhagic. Patients commonly present with an acute abdomen.

Microscopically, endodermal sinus tumor is composed of primitive epithelial cells that form architectural patterns that recapitulate the primitive gut and the primitive liver. The pathognomonic finding is the Schiller-Duval body, which is a single papilla lined by tumor cells with a central blood vessel. This neoplasm commonly contains cells that produce α -fetoprotein (AFP), which as a serum marker is useful in following the response to therapy.

Immature teratomas of the ovary are the malignant counterpart of the mature cystic teratoma, or dermoid, and are the second most common germ cell malignancy. Malignant teratomas are found most commonly in patients younger than 20 years old. This malignancy is bilateral in less than 5% of cases, although the contralateral ovary commonly contains a dermoid cyst. The serum AFP is usually elevated in

patients with an immature teratoma.

Microscopic examination reveals a disordered collection of tissues derived from the three germ layers, with at least some of the components having an immature, embryonic appearance. The immature elements are commonly neuroectodermal and consist of small, round, malignant cells that may be associated with glia formation. Hyaline bodies stain positive for AFP. Immature teratomas can be graded from 1 to 3 based on the amount of immature neural tissue they contain. Tumor grade is correlated with prognosis and also guides recommendations regarding the need for chemotherapy. Metastatic implants may be composed entirely of mature neuroectodermal tissue. In this circumstance, the stage of the tumor is not increased and the prognosis is not diminished.

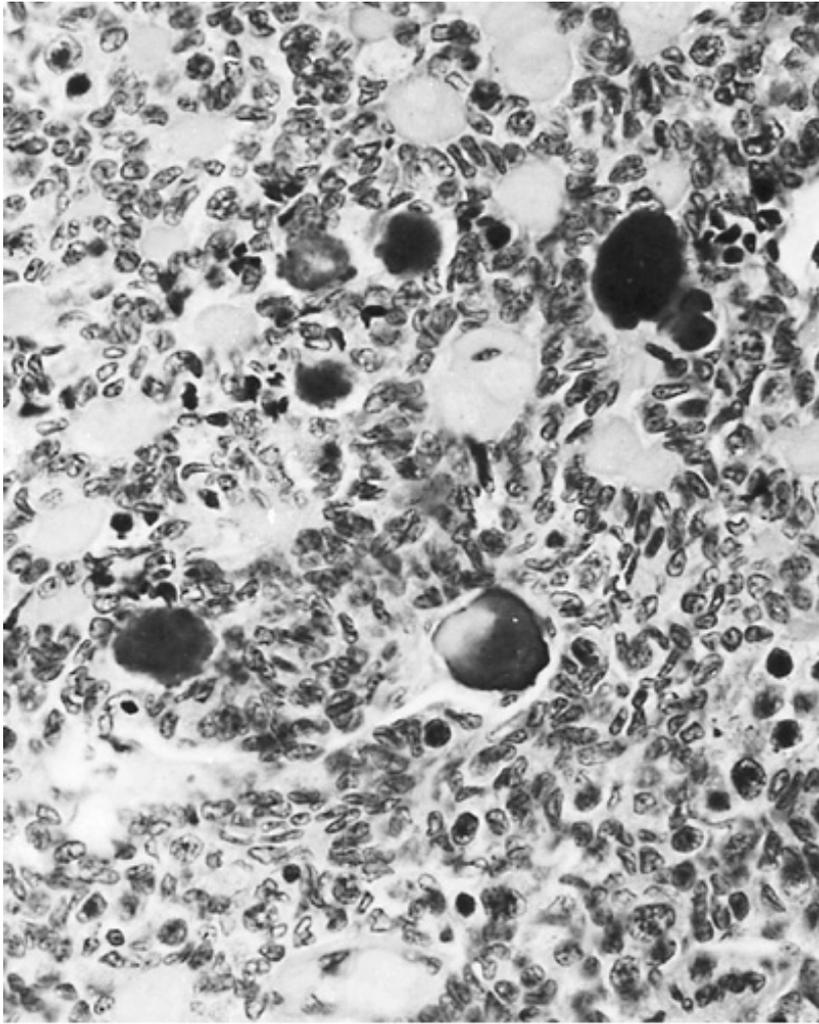

Mature teratomas or dermoids are common ovarian neoplasms, occurring primarily in women ages 20–30 years. They represent the most common neoplasm diagnosed during pregnancy. Less than 1% of all teratomas are malignant.

Embryonal carcinoma of the ovary is a very rare germ cell tumor with a mean age of diagnosis at 15 years. The neoplasm has a highly aggressive growth pattern with early extensive spread. Histologically, this neoplasm consists of solid sheets of large polygonal cells with pale, eosinophilic cytoplasm that appear to merge together as a syncytium because the cell membranes are poorly defined. Serum human chorionic gonadotropin (hCG) and serum AFP levels are usually elevated. In addition, estrogens can be produced by these tumors and may serve as a serum marker.

Choriocarcinoma of the ovary is another rare germ cell tumor that is unrelated to pregnancy. Unlike gestational choriocarcinoma, primary ovarian choriocarcinoma is associated with somewhat lower elevations of hCG. The endocrine activity of this neoplasm may cause precocious puberty, uterine bleeding, or amenorrhea. Microscopically, this neoplasm is composed of cytotrophoblasts, intermediate trophoblasts, and syncytiotrophoblasts.

Gonadoblastoma of the ovary is a rare neoplasm composed of nests of germ cells and sex cord derivatives that are surrounded by connective tissue stroma (Fig 52–7). These tumors are more common in the right ovary than in the left, and usually occur during the second decade of life. Gonadoblastomas are found in patients with abnormal gonadal development in the presence of a Y chromosome.

Figure 52–7.

All rights reserved.

Gonadoblastoma with folliculoid pattern, focal calcifications, and concretions.

Mixed germ cell tumors of the ovary account for approximately 10% of germ cell neoplasms. As implied by the name, these neoplasms contain two or more germ cell elements. A dysgerminoma and endodermal sinus tumor occur together most frequently. These neoplasms must be meticulously evaluated by the pathologist to identify all elements correctly, as different components may require treatment with different chemotherapeutic regimens.

Polyembryoma of the ovary is an extremely rare tumor most commonly seen in premenarchal girls with signs of pseudopuberty. The tumor secretes AFP and hCG, is composed of "embryoid bodies," and mimics the structures of the three somatic layers of early embryonic differentiation.

SEX CORD-STROMAL TUMORS OF THE OVARY

Sex cord-stromal tumors of the ovary account for 5–8% of all ovarian malignancies. Granulosa cell tumors are the most common malignant tumors of the sex cord-stromal tumor category, accounting for 70% of these tumors. They are associated with hyperestrogenism and may cause precocious puberty in young girls and adenomatous hyperplasia and vaginal bleeding in postmenopausal women.

Microscopically, the granulosa cells, which exhibit characteristic grooved or coffee bean nuclei, can exhibit microfollicular, macrofollicular, trabecular, insular, or solid growth patterns. Call-Exner bodies are

associated with the microfollicular growth pattern and represent multiple small cavities that contain eosinophilic fluid. Theca cells are present in varying amounts.

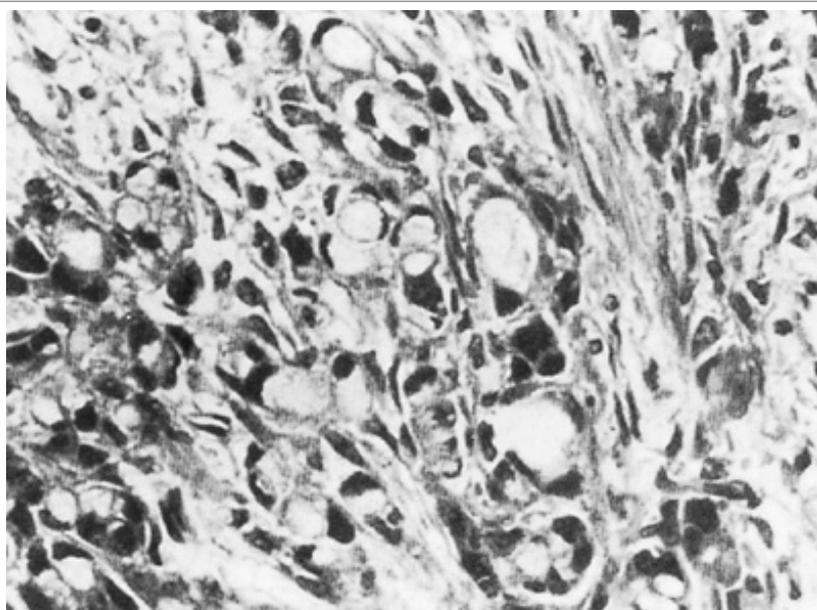

Like granulosa cell tumors, ovarian thecomas are associated with hyperestrogenism. This mostly benign ovarian tumor consists of lipid-laden stromal cells, which confer a yellow appearance on cut section. An ovarian fibroma is another benign tumor that is noteworthy because of its association with Meigs' syndrome. Meigs' syndrome refers to the occurrence of an ovarian fibroma, ascites, and pleural effusion, which collectively mimic the presentation of ovarian cancer.

Sertoli-stromal cell tumors are rare and consist of testicular structures at different stages of development. They are usually virilizing and occur most commonly during the third and fourth decades of life, with average age at diagnosis being 25 years. They are rarely bilateral. Microscopically, both Sertoli and Leydig cells are present. A variety of architectural patterns have been described.

NEOPLASMS METASTATIC TO THE OVARY

Cancer metastatic to the ovary accounts for 5–6% of all ovarian malignancies, most commonly from the female genital tract, the breast, or the gastrointestinal tract. Microscopically, the origin of an ovarian metastasis might be difficult to determine. In metastatic breast carcinoma, for example, the histologic appearance of the ovary may be different when compared to the primary breast tumor. Gastrointestinal carcinoma metastatic to the ovary often simulates a primary mucin-secreting adenocarcinoma of the ovary with the presence of characteristic signet ring cells (Fig 52–8). Large locules lined by tall columnar mucin-secreting epithelial cells are separated by fibrous trabeculae. The epithelium shows various degrees of differentiation.

Figure 52–8.

Copyright ©2006 by The McGraw-Hill Companies, Inc.
All rights reserved.

Metastatic ovarian cancer. Note the "signet cells," characteristic of the mucocellular nature of the tumor.

By definition, Krukenberg tumors represent carcinomas of the stomach metastatic to the ovary. However, the eponym is commonly used to denote any gastrointestinal carcinoma metastatic to the ovary.

Immunohistochemistry is commonly used to facilitate the characterization of ovarian tumors. The cytokeratin expression pattern can help to distinguish between a primary mucinous ovarian and a metastatic colon cancer. The ovarian tumor is expected to stain positive for cytokeratin 7 (CK7) and negative for CK20. In contrast, a metastatic lesion from a primary mucinous adenocarcinoma of the colon is likely to show the reverse pattern (CK7 negative, CK20 positive).

DIAGNOSIS OF OVARIAN CANCER

Ovarian cancer typically develops as an insidious disease, with few warning signs or symptoms. Most neoplastic ovarian tumors produce few symptoms until the disease is widely disseminated throughout the abdominal cavity. A history of nonspecific gastrointestinal complaints, including nausea, dyspepsia, and altered bowel habits, is particularly common. Early satiety and abdominal distention as a result of ascites are generally signs of advanced disease. A change in bowel habits, such as constipation and decreased stool caliber, is occasionally noted. Large tumors may cause a sensation of pelvic weight or pressure. Rarely, an ovarian tumor may become incarcerated in the cul-de-sac and cause severe pain, urinary retention, rectal discomfort, and bowel obstruction.

Menstrual abnormalities may be noted in as many as 15% of reproductive-age patients with an ovarian neoplasm. Abnormal vaginal bleeding may occur in patients with ovarian cancer in the presence of a synchronous endometrial carcinoma or as a consequence of metastatic disease to the lower genital tract. Rarely, excess androgens or estrogens are present in women with ovarian neoplasms, presumably because of stimulation of normal theca, granulosa, or hilar cells that surround the neoplasm. Ovarian stromal hyperplasia or hyperthecosis also may be associated with excess androgen production, which alters the normal menstrual cycle. Granulosa theca cell tumors are classically estrogen-producing tumors that present with abnormal vaginal bleeding.

The prognosis of ovarian cancer is significantly improved when the disease is detected while still confined to the ovary. However, despite the availability of various clinical tests as outlined below, general screening for the early detection of ovarian cancer so far is not an efficient strategy. Ultrasonographic evaluation can detect the majority of ovarian neoplasms but has poor specificity. The best-characterized tumor marker in epithelial ovarian cancer is cancer antigen-125 (CA-125). CA-125 is a secreted glycoprotein present in fetal amniotic and coelomic epithelium and its level can be detected in serum using immunoassay. The accepted upper limit of normal is 35 IU/mL, but this is a rather arbitrary cutoff. Routine screening using CA-125 of low-risk, asymptomatic women cannot be recommended at this time. However, CA-125 might play a role in screening of high-risk patients with genetic predisposition. Ovarian cancer screening to detect early stage disease will remain difficult until more specific and sensitive markers are defined. Unfortunately, routine pelvic examination is a notoriously poor screening method with limited sensitivity and specificity. Ten percent of masses less than 10 cm in size are missed on routine examination, and the size of a mass is correctly predicted within 2 cm in only 68% of patients. Current strategies for screening focus on the detection of tumor-associated antigens, such as CA-125, and ultrasound examinations of the adnexa. However, the limited prevalence of ovarian cancer and the lack of sensitivity and specificity of currently available tests have so far prevented the implementation of routine ovarian cancer screening in the general population.

EVALUATION OF THE PATIENT WITH A SUSPECTED OVARIAN NEOPLASM

A patient found to have a pelvic mass must be evaluated in a timely and cost-effective manner that is tailored to a realistic list of possible diagnoses. The differential diagnosis of a pelvic mass is influenced by the age of the patient, the characteristics of the mass on pelvic examination, and the radiographic appearance of the mass. In general, the prepubescent child and the postmenopausal woman are at

greatest risk for a malignant ovarian neoplasm. The reproductive age woman is more likely to have a functional ovarian cyst or endometrioma.

Physical Examination

Although the focus of the physical examination in a patient with a suspected adnexal neoplasm is the pelvis, it is important to perform a comprehensive examination. Particular attention should be paid to the lymph-node-bearing areas, particularly the supraclavicular and inguinal areas. Metastatic disease to the skin rarely occurs in the presence of ovarian cancer. Sister Mary Joseph's nodule refers to a metastatic implant in the umbilicus.

Examination of the abdomen often provides important information. Abdominal distention is one of the more common findings. The presence of flank fullness and shifting dullness implies the presence of ascites or a large pelvic-abdominal mass. Together with these signs, tympanitic percussion noted over the lateral abdomen is consistent with a large mass that displaces the bowel to the periphery. In contrast, a central tympanitic percussion note is suggestive of ascites. Recent eversion of the umbilicus in a patient with abdominal distention may result from an increase in intra-abdominal pressure secondary to ascites.

A careful and thorough pelvic examination provides many helpful clues regarding the etiology of a pelvic mass. Table 52–3 lists the characteristics of the mass that should be noted on pelvic examination.

Table 52–3. Characteristics of a Pelvic Mass That Should Be Noted on Physical Examination.

Benign	Malignant
Mobility	Fixed
Consistency	Solid or firm
Cul-de-sac	Bilateral
Mobile	Nodular
Cystic	
Smooth	
Unilateral	

Unilateral, cystic masses in reproductive-age women are benign in up to 95% of cases. These masses, particularly when less than 6–8 cm in size, are observed through a menstrual cycle as many represent functional cysts and spontaneously resolve. An enlarging mass or one that is associated with pain merits prompt intervention. A cystic, somewhat immobile adnexal mass may represent a hydrosalpinx or tuboovarian abscess. Fixed, bilateral masses and firm masses with nodularity are suggestive of, but not diagnostic of, an ovarian malignancy. Because no features seen on physical examination consistently distinguish malignant from benign neoplasms, further characterization must be accomplished with select radiographic examinations.

Radiographic Evaluation

Ultrasonography is the most common radiographic test to evaluate adnexal masses. Transabdominal examinations require a full bladder as an acoustic window for optimal visualization of the adnexa. In contradistinction, a transvaginal examination does not have this requirement but may not be as useful for the assessment of large adnexal masses. Table 52–4 provides examples of ultrasonographic

characteristics of benign compared to malignant ovarian masses. A number of different scoring systems are used, that include characteristics like ovarian volume, number and thickness of septations, presence of papillary projections, and solid components. Persistence of ultrasonic findings on a repeat scan after 4–6 weeks may help reduce the false-positive rate. However, there is no standardized system for evaluation of ovarian masses. The correlation between the ultrasonic appearance of an adnexal mass and the pathologic findings is imprecise. Color-flow Doppler studies that evaluate the vascular patterns of adnexal masses show promise as a means to improve the sensitivity and specificity of the radiographic diagnosis of benign and malignant lesions. Angiogenesis accompanying malignancy results in vascular abnormalities and increased blood flow compared with the vascular architecture and patterns of blood flow in nonmalignant lesions.

Table 52–4. Radiographic Characteristics That Help to Differentiate Benign and Malignant Adnexal Masses.

Benign	Malignant
Simple cyst, < 10 cm in size	Solid or cystic and solid
Septations < 3 mm in thickness	Multiple septations > 2–3 mm in size
Unilateral	Bilateral
Calcification, especially teeth	Ascites
Gravity-dependent layering of cyst contents	

Characterization of adnexal masses by computed tomography (CT) or magnetic resonance imaging (MRI) may provide clinically useful information in select instances. CT scanning provides information about the retroperitoneal structures in addition to the pelvic organs. MRI scans can add more information regarding the nature of the ovarian neoplasm. Because of the high cost and questionable benefit, this diagnostic procedure is infrequently used for ovarian tumors. However, it may be of particular benefit in the evaluation of pregnant patients because it avoids radiation exposure of the fetus.

A patient with suspected ovarian malignancy should undergo a radiograph of the chest to exclude metastatic parenchymal disease and to detect a pleural effusion.

If the patient notes a change in bowel habits or if guaiac-positive stools are detected, a barium enema should be obtained. Patients who appear to have advanced ovarian cancer, evidenced by a nodular pelvic mass with or without ascites may actually have colon cancer. Because of the genetic links among ovarian cancer, colon cancer, and breast cancer, a patient with a suspected ovarian malignancy should also undergo a screening mammogram study.

Laboratory Evaluation

If an ovarian malignancy is suspected, laboratory tests including complete blood count (CBC) and serum electrolyte test should be obtained in all patients. The serum hCG level should be measured in any female in whom pregnancy is a possibility. In addition, a serum AFP and lactate dehydrogenase (LDH) should be measured in young girls and adolescents who present with adnexal masses because of the greater likelihood of a malignant germ cell tumor. The serum CA-125 level should also be determined whenever an ovarian malignancy is included in the differential diagnosis. An elevated CA-125 in the postmenopausal patient is particularly suggestive of the presence of an ovarian malignancy, although it is not specific for the diagnosis. Cancers of the colon, breast, pancreas, stomach, uterus, and fallopian tube are also associated with an elevated CA-125 value. Benign conditions commonly diagnosed in younger

women, including pregnancy, endometriosis, leiomyomata, and adenomyosis, limit the usefulness of this test in premenopausal women. A normal CA-125 level does *not* exclude the diagnosis of cancer and does not represent a reason to delay surgery.

Paracentesis is not advocated as a routine procedure for the patient with ascites and a pelvic mass and in whom renal, cardiac, and hepatic failure has been excluded. False-negative results may occur in as many as 40% of patients with widespread intra-abdominal disease. In contrast to the role of paracentesis, diagnostic thoracentesis for cytology is recommended for staging purposes. In the presence of malignant pleural effusions, the patient has stage IV disease.

SURGICAL TREATMENT OF EPITHELIAL OVARIAN CANCER

Surgery is the cornerstone of therapy for ovarian cancer, regardless of cell type or stage of disease. Whenever ovarian cancer is considered a likely diagnosis, a gynecologic oncologist should be consulted and actively involved in the evaluation and subsequent management of the patient. A gynecologic oncologist is trained to address both the surgical and the medical needs of these patients.

Intraoperatively, several features have been described that assist in the differentiation of malignant from benign adnexal masses (Table 52–5). However, gross examination of a mass is never a substitute for histologic examination. Whenever the pathology of a pelvic or adnexal mass is in question, a frozen-section pathologic study should be requested. In the hands of experienced pathologists, false-positive and false-negative diagnoses occur in less than 5% of cases. Patients diagnosed with ovarian cancer have to undergo surgical staging to reduce the amount of disease and evaluate the extent of spread. Removal of the primary tumor, as well as the associated metastatic disease, is referred to as tumor debulking or cytoreductive surgery. In early stages and when fertility is desired, removal of the involved adnexa alone may be considered.

Table 52–5. Intraoperative Differentiation of Benign and Malignant Masses.

Benign	Malignant
Simple cyst	Adhesions
Unilateral	Rupture
No adhesions	Ascites
Smooth surfaces	Solid areas
Intact capsule	Areas of hemorrhage or necrosis
	Papillary excrescences
	Multiloculated mass
	Bilateral

The full extent of disease must be carefully documented. At the time of diagnosis, more than 70% of patients with epithelial ovarian cancer have metastases beyond the pelvis. The most common locations of metastases secondary to advanced stage ovarian cancer are the peritoneum (85%), omentum (70%), liver (35%), pleura (33%), lung (25%), and bone (15%). Lymphatic metastasis occurs frequently, with up to 80% involving pelvic lymph nodes and 67% involving paraaortic lymph nodes, depending on the stage of disease.

The information gained from accurate surgical staging guides discussion of prognosis and also influences treatment decisions. Surgical staging requires documentation of the primary neoplasm and determination

of the extent of disease by inspection, biopsy of peritoneal and intra-abdominal lesions, and biopsy of the retroperitoneal lymph nodes. Table 52–6 lists the procedures included in surgical staging of ovarian cancer. Any fluid in the peritoneal cavity should be aspirated. If no free fluid is present, "peritoneal washings" should be obtained by instilling 50–100 mL of saline into the right paracolic gutter, the left paracolic gutter, the pelvic cul-de-sac, and beneath each hemidiaphragm. The fluid is subsequently collected and submitted to the laboratory for cytologic examination. Complete surgical staging of ovarian cancer requires biopsy of pelvic and paraaortic lymph nodes. It is emphasized that palpation of the retroperitoneal node-bearing areas is inaccurate and is not a substitute for biopsy and histologic examination. Table 52–7 lists the current staging of ovarian cancer approved by the International Federation of Gynecology and Obstetrics (FIGO).

Table 52–6. Procedures in the Surgical Staging of Ovarian Cancer.

- Sample of ascites or peritoneal washings from the paracolic gutters and pelvic and subdiaphragmatic surface for cytology
- Complete abdominal exploration
- Intact removal of tumor
- Hysterectomy
- Infracolic omentectomy
- Biopsies of abdominal peritoneal implants; if none present, random biopsies from the paracolic gutter peritoneum, pelvic peritoneum, and right subdiaphragmatic peritoneal surface
- Pelvic and paraaortic lymph node biopsies
- Cytoreductive surgery to remove all visible disease

Table 52–7. International Federation of Gynecology and Obstetrics (FIGO) Staging of Ovarian Neoplasms.

Stage I. Growth limited to the ovaries

Ia—one ovary involved

Ib—both ovaries involved

Ic—Ia or Ib and ovarian surface tumor, ruptured capsule, malignant ascites, or peritoneal cytology positive for malignant cells

Stage II. Extension of the neoplasm from the ovary to the pelvis

IIa—extension to the uterus or fallopian tube

IIb—extension to other pelvic tissues

IIc—IIa or b and ovarian surface tumor, ruptured capsule, malignant ascites, or peritoneal cytology positive for malignant cells

Stage III. Disease extension to the abdominal cavity

IIIa—abdominal peritoneal surfaces with microscopic metastases

IIIb—tumor metastases < 2 cm in size

IIIc—tumor metastases > 2 cm in size or metastatic disease in the pelvic, paraaortic, or inguinal lymph nodes

Stage IV. Distant metastatic disease

Malignant pleural effusion

Pulmonary parenchymal metastases

Liver or splenic parenchymal metastases (not surface implants)

Metastases to the supraclavicular lymph nodes or skin

In general, the contralateral adnexa should be removed even when they are grossly normal. They are often the site of occult metastatic disease, and there is a significant risk of subsequent cancer. Exceptions to this generalization are made for young women with an apparent stage I epithelial ovarian neoplasm. If future fertility is desired and the patient is informed about a higher risk of recurrent disease, a more conservative surgical approach may be chosen. The histology and grade of the neoplasm, as well as the findings at the time of surgery, guide these decisions. Well-differentiated stage I lesions are associated with a much better 5-year survival rate than are moderately and poorly differentiated lesions. Mucinous and endometrioid neoplasms are associated with a better prognosis than serous and clear cell carcinomas of the ovary. If the frozen section during surgery does not reveal a reliable diagnosis of malignancy, the surgical procedure should be limited until the pathology results are finalized.

A hysterectomy is generally performed because the uterus is a common site for metastatic disease. There is also a risk of synchronous endometrial cancer in patients with endometrioid carcinoma of the ovary. In addition, removal of the uterus facilitates subsequent follow-up examinations and obviates potential problems secondary to uterine bleeding.

An infracolic omentectomy is recommended, even in the absence of gross tumor involvement, because it is a common site of microscopic metastatic disease. Removal of the omentum facilitates the distribution

of intraperitoneal agents, may decrease the rate of accumulation of ascites postoperatively, and provides palliation to those patients with omental metastases.

Cytoreductive surgery should always be attempted if possible. The rationale for aggressive reduction of tumor burden is based on three main considerations. First, the removal of tumor mass often relieves gastrointestinal symptoms and improves the overall nutritional status. Reduction of tumor cell mass also leads to a therapeutically favorable change in tumor cell kinetics because large bulky tumors are often poorly vascularized and oxygenated and thus are more resistant to chemo- and radiation therapy. Furthermore, large tumor masses consist of a higher proportion of cells in the resting phase of the cell cycle. Finally, a number of tumors including ovarian cancer are known to produce immunosuppressive factors that block antitumor immune responses by inhibiting the generation of cytotoxic T lymphocytes.

Peritoneal implants should always be sampled to confirm the clinical impression of metastatic disease. The differential diagnosis of peritoneal implants include endometriosis, tuberculous peritonitis, and talc or suture granulomas. Nodular, roughened, or otherwise suspicious areas should be biopsied.

After completion of initial therapy with surgery followed by chemotherapy, patients without clinical evidence of disease may undergo a second-look operation to determine the therapeutic response and assess the persistence of tumor disease. This is usually done in the setting of an investigational protocol. A laparotomy is performed to obtain multiple specimens from peritoneal surfaces and suspicious areas. Approximately 30% of patients without evidence of macroscopic disease are found to have microscopic metastasis. Patients with negative second-look laparotomy have significantly longer survival than those with residual disease. The likelihood of negative findings at second-look laparotomy is higher in patients that were initially diagnosed with early stage disease, low-grade tumors, residual tumor disease < 5 mm, and chemotherapy containing paclitaxel. However, even patients with negative biopsies have a recurrence rate of 30–50% after 5 years.

The indications for and realistic benefits of surgery in the patient with recurrent or persistent ovarian cancer require individualization and considerable surgical judgment. Removal of tumor disease after primary surgery is called secondary cytoreductive surgery. These procedures are performed in selected patients for whom resection may prolong life expectancy by reducing tumor burden to less than 5 mm, or for whom resection of tumor will relieve symptoms like gastrointestinal obstruction. Patients in whom complete resection of residual tumor burden is possible have a significantly longer survival compared to patients without complete resection.

SURGICAL TREATMENT OF GERM CELL NEOPLASMS

In contrast to epithelial ovarian neoplasms, most germ cell neoplasms are early stage at the time of diagnosis. This observation, in conjunction with the low incidence of bilaterality and the young age of most patients, for whom future fertility is desired, influences the surgical management of this group of neoplasms. For young women with a germ cell neoplasm of the ovary, removal of the involved adnexa with preservation of the normal-appearing contralateral adnexa and uterus is generally advocated. In view of the low incidence of bilaterality, biopsy or bivalving the contralateral ovary is not recommended because of the risk of peritubal and periovarian adhesions. Complete surgical staging of germ cell neoplasms is the same as for epithelial ovarian neoplasms and should be performed in all cases.

Certain characteristics unique to germ cell neoplasms make an impact on their surgical management. Dysgerminoma of the ovary has a propensity to metastasize to the pelvic and paraaortic lymph nodes in the absence of other evidence of metastatic disease. Biopsies of these structures is particularly important. Endodermal sinus tumor of the ovary is the most rapidly growing neoplasm known to occur at any site. This diagnosis must be considered in a young woman with a rapidly enlarging pelvic or

abdominal mass. Immature teratoma of the ovary may present with numerous peritoneal implants consistent with metastatic disease. It is important to adequately sample these lesions to determine whether or not they contain malignant elements.

CHEMOTHERAPY OF EPITHELIAL OVARIAN CANCER

In patients with stage Ia disease and grade 1 tumors, chemotherapy following initial surgical treatment has no influence on survival. Therefore, this group of patients, if selected carefully, does not require chemotherapeutic treatment. However, all other patients should undergo systemic chemotherapy. Agents shown to be active against epithelial ovarian cancer include cisplatin, carboplatin, cyclophosphamide, and paclitaxel. Combination therapies have been demonstrated to be superior to single-agent treatment.

Currently the most effective regimen uses a combination of paclitaxel and carboplatin. This combination has replaced the former treatment with cyclophosphamide and cisplatin because it was shown to be more efficacious in a number of clinical trials. A typical regimen includes systemic administration of carboplatin and paclitaxel for 6 cycles at 3-week intervals. Potential toxicities of this treatment include nausea, vomiting, diarrhea, alopecia, nephrotoxicity, and myelosuppression.

Carboplatin is a second-generation platinum analogue that shows clinical efficacies and survival rates similar to cisplatin when used in combination with paclitaxel. However, the frequency of gastrointestinal side effects and neurotoxicity associated with carboplatin were found to be lower compared to cisplatin.

Assessment of response to combination chemotherapy is based on physical examination, changes in size of palpable or radiographically measurable lesions, and changes in the CA-125 level. Although the preoperative CA-125 level does not correlate with tumor burden, changes in response to chemotherapy appear to be of some prognostic benefit. An elevated CA-125 (> 35 IU/mL) predicts persistent disease at second look in more than 97% of patients. However, a normal CA-125 level does not completely exclude the possibility of residual, subclinical disease.

Most patients develop resistance to platin-based regimens during the course of treatment. Salvage therapy for ovarian cancer is rarely curative, although significant prolongation of survival may be achieved in some instances. The response to re-treatment with platinum-based chemotherapy is influenced by the time interval between completion of the initial regimen and subsequent disease recurrence: the greater the interval, the greater the likelihood of a beneficial response.

Patients with platinum- or paclitaxel-sensitive tumors as evidenced by the clinical response to initial chemotherapy will likely benefit from re-treatment with a platinum- or paclitaxel-based regimen.

Chemotherapy of Germ Cell Neoplasms

Significant advances have been made in the treatment of germ cell neoplasms of the ovary. Once associated with 5-year survival rates of less than 20–30%, these neoplasms are now considered curable in a majority of cases following the introduction and refinement of combination chemotherapy.

Dysgerminoma is the most radiation-sensitive neoplasm identified. Historically, it has been treated with whole abdominal radiation therapy with excellent results. More recently, chemotherapy with cisplatin-containing regimens has been administered with excellent results. A significant advantage of chemotherapy is the potential to preserve future reproductive potential compared with radiation therapy.

The other germ cell neoplasms are rare, and the optimal chemotherapy and duration of therapy have not been established. Regimens including vinblastine-bleomycin-cisplatin, vincristine-actinomycin D-cyclophosphamide, and bleomycin-etoposide-cisplatin have been used with encouraging results. Response to chemotherapy is based on physical examination and the decrease in serum tumor markers, if initially elevated.

Complications of Chemotherapy

Combination chemotherapy invariably makes an impact on the patient's day-to-day activities and can be associated with a variety of potentially life-threatening side effects. Table 52–8 lists the most common toxicities of some of the more commonly used drugs in the treatment of ovarian cancer.

Table 52–8. Chemotherapy-Associated Toxicities.

Agent	Toxicity
Cisplatin	Nephrotoxicity, neurotoxicity, ototoxicity
Carboplatin	Thrombocytopenia, neutropenia
Cyclophosphamide	Hemorrhagic cystitis, pulmonary fibrosis
Paclitaxel	Myelosuppression
Altretamine	Peripheral neuropathy
Etoposide	Myelosuppression
Bleomycin	Pulmonary fibrosis
Doxorubicin	Cardiac toxicity
Vincristine	Neuropathy
Ifosfamide	Hemorrhagic cystitis, central neurotoxicity

Nausea, vomiting, and alopecia are side effects anticipated and feared by many patients. The development of new, more effective antiemetics permits improved control of nausea and a reduction in the number of emesis episodes. Unfortunately, suggested strategies to prevent alopecia, such as scalp tourniquets and local hypothermia, are generally ineffective. Patients should be counseled that all chemotherapy regimens do not invariably result in hair loss.

Myelosuppression is another common side effect of chemotherapy. Complete blood counts with differential and platelet counts are typically monitored between cycles of therapy. Most regimens cause granulocytopenia and thrombocytopenia between days 10 and 18. Synthetic erythropoietin and colony-stimulating factor can be administered to lessen the severity and duration of anemia and granulocytopenia.

RADIATION THERAPY

Currently, radiation therapy plays a limited role in the treatment of patients with epithelial ovarian cancer mainly because of radiation damage to the small bowel, liver, and kidneys. Radioisotopes such as intraperitoneal ^{32}P may be of benefit in patients with stage Ic disease and those with microscopically positive second-look operations.

With respect to germ cell neoplasms, radiation therapy has been used successfully in the treatment of patients with dysgerminoma.

ALTERNATIVE THERAPIES

A number of alternative therapies have been applied for the treatment of epithelial ovarian cancer. Cytokines like interleukin-2 and interferon- γ either alone or in combination with chemotherapy have shown some promising effects. Monoclonal antibodies directed against ovarian cancer-associated antigens, including CA-125, HMFG (human milk-fat globulin), and HER-2/*neu* have been used with variable clinical responses. Recently, antibodies against vascular epithelial growth factor (VEGF) have

shown efficacy in patients with ovarian cancer. Anti-VEGF antibodies are currently being tested in combination with carboplatin and paclitaxel in first-line chemotherapy for ovarian cancer patients. Gene therapy trials have used different antitumor approaches, including the delivery of tumor suppressor gene p53 via recombinant adenovirus into the peritoneal cavities. The early trials have not shown significant clinical response, mainly as a result of the inefficiency of intraperitoneal and intratumoral gene transfer.

PROGNOSIS

The prognosis for patients with ovarian cancer is primarily related to the stage of disease. The 5-year survival rate for patients with stage I epithelial ovarian cancer is, depending on tumor grade, between 76% and 93%. The 5-year survival rate for those with stage II disease is 60–74%. Stage III ovarian cancer is associated with a 5-year survival rate of approximately 23–41%. The survival rate for a patient with stage IV disease is approximately 5–11%. Within each stage of disease, other factors are related to response to chemotherapy, disease-free survival, and overall survival. In general, patients with well-differentiated, diploid neoplasms with an S-phase fraction of less than 8–10% do better than patients who have poorly differentiated, aneuploid, rapidly proliferating (eg, high S-phase fraction) neoplasms.

In general, germ cell tumors are associated with better 5-year survival rates than epithelial ovarian neoplasms. Patients with dysgerminoma have a 5-year survival rate of 95%. Immature teratomas are associated with 5-year survival rates of 70–80%. An endodermal sinus tumor is associated with a 5-year survival rate of 60–70%. Embryonal carcinoma, choriocarcinoma, and polyembryoma are very rare lesions, and it is difficult to assess 5-year survival estimates. Epithelial ovarian neoplasms of low malignancy potential are characterized by 5-year survival rates of 95%, reflecting their protracted and indolent biologic behavior.

DIAGNOSIS AND MANAGEMENT OF CANCER METASTATIC TO THE OVARY

Typically, patients with cancer metastatic to the ovary present as if they have primary ovarian cancer. Several clinical scenarios may be encountered. Primary colon cancer or gastric carcinoma may present as a pelvic mass, ascites, and a change in bowel habits or early satiety. Recurrent metastatic breast cancer may present as an asymptomatic pelvic mass.

The role of surgery in patients with cancer metastatic to the ovary must be individualized. When the diagnosis is unclear, exploratory laparotomy to establish the diagnosis is appropriate in most cases. However, the role of tumor-reductive surgery in patients with known metastatic disease is less clear. No long-term survivors of gastric cancer metastatic to the ovary are known, regardless of treatment. Survival following surgery and combination chemotherapy for breast and colon cancer metastatic to the ovary is poor, ranging from 4–12 months.

MALIGNANT NEOPLASMS OF THE FALLOPIAN TUBE

Etiology

Primary carcinoma of the fallopian tube is the least-common cancer arising in the female genital tract, accounting for approximately 0.3% of all such cancers. Fallopian tube cancers are similar to epithelial ovarian cancer in regards clinical presentation and biologic behavior.

Clinical Presentation

The patient with carcinoma of the fallopian tube is usually in the fifth or sixth decade of life. The signs and symptoms are often similar to those noted in patients with ovarian cancer. In fact, it is difficult to differentiate tubal from ovarian carcinomas preoperatively.

Fewer than 15% of patients are noted to have the classic triad of symptoms and signs associated with fallopian tube cancer including hydrops tubae profluens (a watery vaginal discharge), pelvic pain, and a palpable adnexal mass.

Positive vaginal cytology in the absence of endometrial or cervical neoplasia suggests the possibility of a tubal cancer, but this is rarely diagnostic.

Histopathology

At least 95% of all primary carcinomas of the fallopian tube are papillary carcinomas. Bilaterality is found in 40–50% of cases, and this is believed to represent synchronous neoplasms rather than metastatic disease from one tube to the other. Grossly, the affected tube is fusiform or sausage-shaped. On initial inspection, these neoplasms resemble pyosalpinx or tuboovarian inflammatory disease. However, there is usually little associated serosal reaction with adhesion formation, as is noted with an inflammatory process.

Classically, the neoplastic fallopian tube contains solid or necrotic cancer tissue and a dark-brown or serosanguineous fluid. The fimbriated end of the fallopian tube is patent in as many as 50% of cases, and often tumor extrudes from the ostium to adhere to adjacent structures. Histologically, papillary carcinomas may exhibit papillary, papillary–alveolar, and alveolar growth patterns. There is no prognostic significance attached to these differences. Of note, women with *BRCA1* and *BRCA2* mutations are at substantially higher risk of fallopian tube cancer; consequently, women who have prophylactic oophorectomies should also have complete resection of the oviducts.

Treatment

The surgical therapy of fallopian tube carcinoma is the same as that recommended for epithelial ovarian cancer. In addition, the same type of surgical staging should be performed if for no other reason than it is often not clear at the time of surgery whether the primary cancer is of ovarian or fallopian tube origin. The staging system for ovarian cancer is often applied to neoplasms of the fallopian tube, although this is by custom rather than FIGO recommendations.

Chemotherapy for fallopian tube cancer has evolved along the same lines as that for epithelial ovarian cancer. The currently used chemotherapeutic regimen is similar to that of epithelial ovarian cancer and includes platinum combination chemotherapy. Radiation may also be used in select cases with no residual disease after surgery. Because there is little data on well-staged tubal lesions, it is unclear if patients with early stage disease benefit from adjuvant therapy.

Prognosis

The prognosis for patients with fallopian tube carcinoma is based on the stage of disease. The overall 5-year survival rate is approximately 56%. The prognosis for early stage disease is much better than for advanced disease, as 5-year survival with stage I disease is 84%, with stage II, 52%, and with stage III, 36%.

Current OB/GYN > Chapter 53. Gestational Trophoblastic Diseases >

Essentials of Diagnosis

- Uterine bleeding in first trimester.
- Absence of fetal heart tones and fetal structures.
- Rapid enlargement of the uterus or uterine size greater than anticipated by dates.
- β -human chorionic gonadotropin (β -hCG) titers greater than expected for gestational age.
- Vaginal expulsion of vesicles.
- Hyperemesis gravidarum.
- Theca lutein cysts.
- Onset of preeclampsia in the first trimester.

General Considerations

Gestational trophoblastic neoplasms include the tumor spectrum of hydatidiform mole (complete and partial), invasive mole (chorioadenoma destruens), choriocarcinoma, and placental-site trophoblastic tumor (PSTT). These tumors are unique in that they develop from an aberrant fertilization event and hence arise from fetal tissue within the maternal host. They are composed of both syncytiotrophoblastic and cytotrophoblastic cells, with the exception of PSTT, which is derived from intermediate trophoblastic cells. In addition to being the first and only disseminated solid tumors that have proved to be highly curable by chemotherapy, they elaborate a unique and characteristic tumor marker, human chorionic gonadotropin (hCG).

Hydatidiform mole is the most common form of gestational trophoblastic disease and is benign in nature. Its incidence varies worldwide from 1 in 125 deliveries in Mexico and Taiwan to 1 in 1500 deliveries in the United States. The incidence is higher in women younger than 20 and older than 40 years of age, in nulliparous women, in patients of low economic status, and in women whose diets are deficient in protein, folic acid, and carotene. The most remarkable findings are that blood group A women impregnated by group O men have an almost 10-fold greater risk of developing choriocarcinoma than group A women impregnated by group A partners. Furthermore, women with blood group AB tend to have a relatively worse prognosis.

Hydatidiform mole should be suspected in any woman with bleeding in the first half of pregnancy, passage of vesicles, hyperemesis gravidarum, or onset of preeclampsia prior to 24 weeks. Absent fetal heart tones and a uterus too large for the estimated gestational age on physical examination further support the diagnosis. Ultrasonography and serial β -hCG determinations are necessary to establish a firm diagnosis of hydatidiform mole.

Invasive mole is reported in 10–15% of patients who have had primary molar pregnancy. Although considered a benign neoplasm, invasive mole is locally invasive and may produce distant metastases.

Choriocarcinoma and PSTT comprise the spectrum of gestational trophoblastic neoplasia.

Choriocarcinoma is rare, being reported in 2–5% of all cases of gestational trophoblastic neoplasia. The incidence in the United States is 1 in 40,000 pregnancies, but it is higher in Asia. In about half of all cases of choriocarcinoma, the antecedent gestational event is hydatidiform mole. One-fourth of cases follow a term pregnancy, and the remaining one-fourth follow an abortion.

PSTT is a rare variant of gestational trophoblastic tumor. It may arise either from a hydatidiform mole or, less commonly, from a normal-term pregnancy. The tumor is generally confined to the uterus and metastasizes late in its course. Syncytiotrophoblastic cells are generally absent from this tumor, resulting in minimal secretion of β -hCG in relation to tumor burden. However, human placental lactogen (hPL) is secreted and its levels can be monitored to follow response.

A generalization worth repeating is that any woman with a recent history of molar pregnancy, abortion, or normal pregnancy who presents with vaginal bleeding or a tumor in any organ should have at least one β -hCG assay to ensure that metastatic gestational trophoblastic neoplasia is not the cause. This is important given that the cure rate of properly treated metastatic gestational trophoblastic neoplasia approaches 90%.

Etiology & Pathogenesis

Gestational trophoblastic tumors arise in fetal rather than maternal tissue. Cytogenetic studies demonstrate that complete moles are usually (perhaps always) euploid, paternal in origin, and sex chromatin-positive—46 XX or 46 XY. A complete mole arises when an empty ovum (with an absent or inactivated nucleus) is fertilized by a haploid sperm that duplicates its chromosomes or by two haploid sperm. A partial mole, on the other hand, is triploid—69 XXY (70%), 69 XXX (27%), or 69 XYY (3%). It arises when an ovum with an active nucleus is fertilized by a duplicated sperm or two haploid sperm. This cytogenetic information provides important insight into the pathogenesis of gestational trophoblastic neoplasms, because this process results in a homozygous conceptus with a propensity for altered growth.

Hydatidiform mole is thought to arise from extraembryonic trophoblasts. Histologic similarities between molar vesicles and chorionic villi support the view that one is derived from the other. However, a detailed morphologic study of a hysterectomy specimen containing an intact molar pregnancy presents a new concept regarding the genesis of hydatidiform mole as a transformation of the embryonic inner cell mass at a stage just prior to the laying down of endoderm. At this stage in embryogenesis, the inner cell mass has the potential to develop into trophoblasts, ectoderm, or endoderm. If normal development is interrupted, such that the inner cell mass loses its capacity to differentiate into embryonic ectoderm and endoderm, a divergent development pathway is created. This pathway may then result in formation of trophoblasts (from the inner cell mass) that develop into cytotrophoblasts and syncytiotrophoblasts. Sufficient differentiation can lead to the production of extraembryonic mesoderm and molar vesicles with loose primitive mesoderm in their villous core.

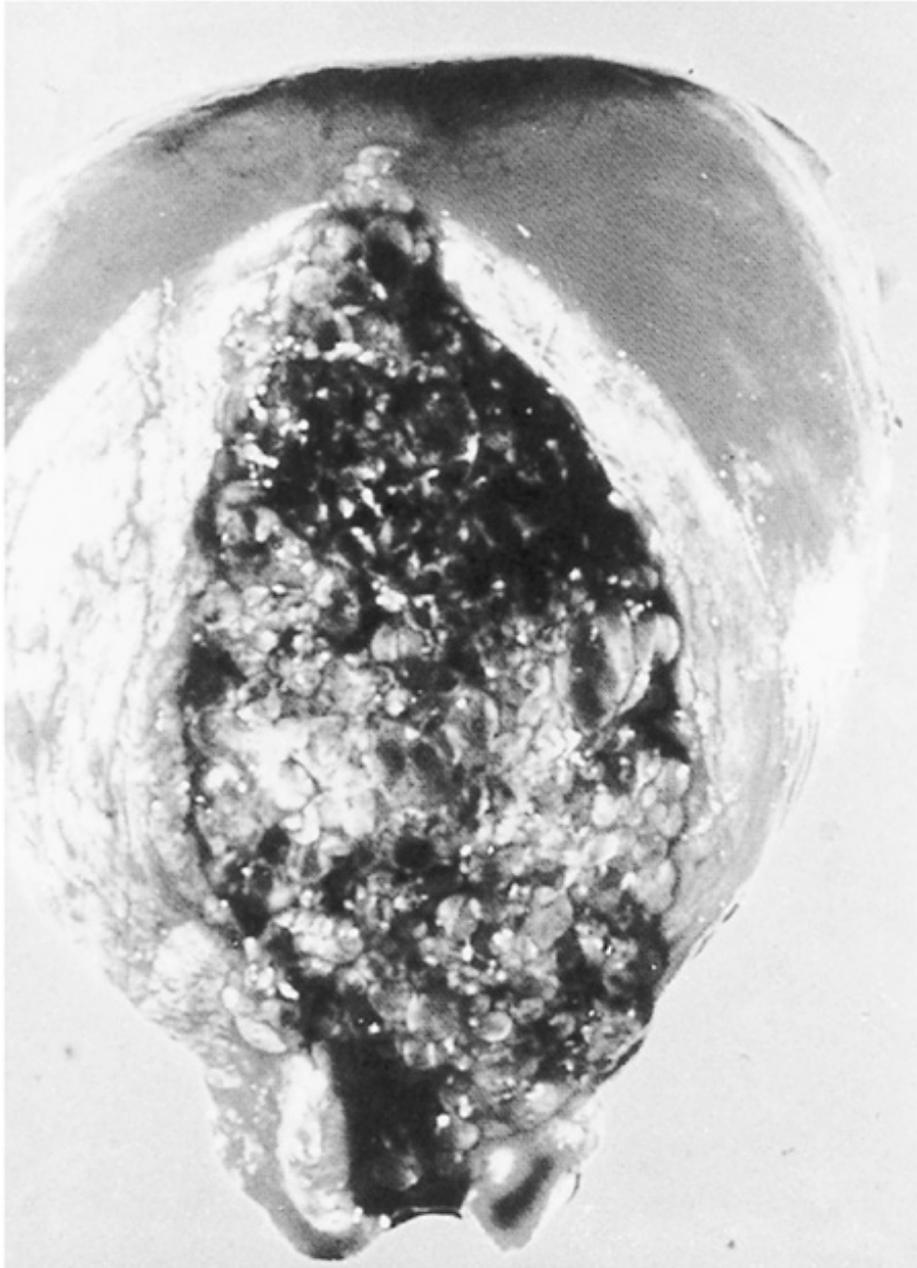

Pathology

As stated earlier, four distinct forms of gestational trophoblastic neoplasia are recognized: hydatidiform mole, invasive mole (chorioadenoma destruens), choriocarcinoma, and PSTT.

HYDATIDIFORM MOLE

Hydatidiform mole is an abnormal pregnancy characterized grossly by multiple grapelike vesicles filling and distending the uterus, usually in the absence of an intact fetus (Fig 53–1). Most hydatidiform moles are recognizable on gross examination, but some are small and may seem to be ordinary abortuses.

Figure 53–1.

Hysterectomy specimen with anterior wall incised, displaying typical miliary, clear, "grapelike" vesicles filling the uterine cavity. Hysterectomy was performed for primary treatment for molar gestation.

Microscopically, moles may be identified by three classic findings: edema of the villous stroma, avascular villi, and nests of proliferating syncytiotrophoblastic or cytotrophoblastic elements surrounding villi (Fig 53–2). Today with earlier clinical diagnosis, the classic pathologic presentation of molar pregnancies is less common. Therefore, it can be more difficult to differentiate histologically between a molar pregnancy and a nonmolar hydropic abortion. The likelihood of malignant sequelae is higher in patients whose trophoblastic cells show increased proliferation and anaplasia. Although histologic study of the

trophoblast provides some basis for predicting a benign or malignant course for the mole, the correlation is not absolute, and it is essential to obtain accurate, sensitive gonadotropin assays in all patients who have had hydatidiform moles.

Figure 53–2.

Photomicrograph of hydatidiform mole characterized by well-developed but avascular villi with stromal edema and minimal trophoblastic proliferation.

Two forms of hydatidiform moles exist: complete (true) and partial moles. Table 53–1 outlines the clinical, pathologic, and genetic characteristics of both.

Table 53–1. Comparison of Complete and Partial Hydatidiform Moles.

	Complete	Partial
Karyotype	Diploid (46,XX or 46,XY)	Triploid (69,XXX or 69,XXY)
Embryo	Absent	Present
Villi	Hydropic	Few hydropic
Trophoblasts	Diffuse hyperplasia	Mild focal hyperplasia
Implantation-site trophoblast	Diffuse atypia	Focal atypia
Fetal RBCs	Absent	Present
β-hCG	High (> 50,000)	Slight elevation (< 50,000)
Frequency of classic clinical symptoms ¹	Common	Rare
Risk for persistent GTT	20–30%	< 5%

¹Hyperemesis, hyperthyroidism, excessive uterine enlargement, anemia, and preeclampsia. The frequency of these symptoms has decreased as a consequence of earlier diagnosis of molar pregnancies through evaluating β-hCG levels and ultrasonography.

GTT = gestational trophoblastic tumor.

INVASIVE MOLE (CHORIOADENOMA DESTRUENS)

An invasive mole occurs in 20% of patients who have undergone evacuation of a molar pregnancy. It is essentially a hydatidiform mole that invades the myometrium or adjacent structures. It has the potential to completely penetrate the myometrium and cause subsequent uterine rupture and hemoperitoneum (Fig 53–3). However, it also has the ability to spontaneously regress. The microscopic findings are similar to that of a hydatidiform mole (Fig 53–4). Because adequate myometrium is rarely obtained at curettage and fewer hysterectomies are being performed in patients with trophoblastic disease, the diagnosis is less often made by histologic analysis.

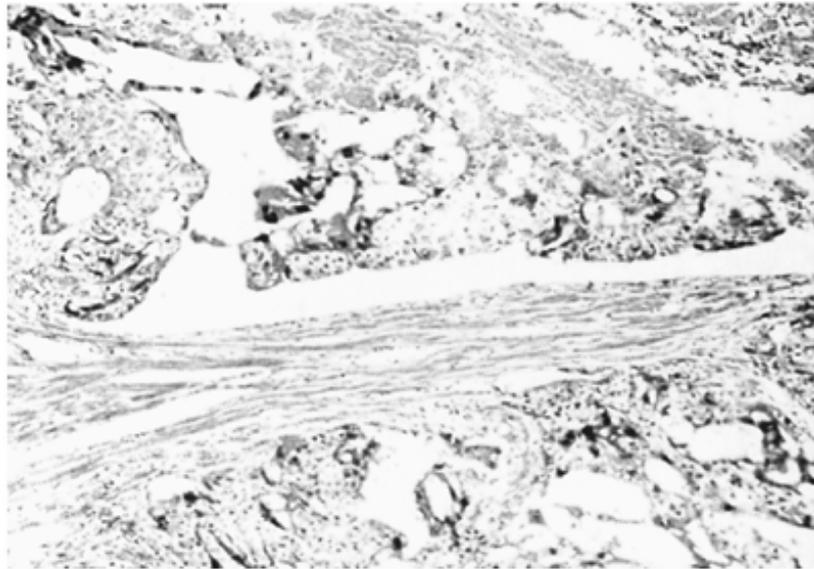

Figure 53–3.

Photomicrograph of invasive mole. The pattern of hydatidiform mole is maintained with avascular villi and stromal edema, but they are deep within the uterine wall, interspersed among smooth-muscle bundles.

CHORIOCARCINOMA

Choriocarcinoma is a pure epithelial tumor composed of syncytiotrophoblastic and cytotrophoblastic cells. It may accompany or follow any type of pregnancy. It usually presents as late vaginal bleeding in the postpartum period. An enlarged uterus, enlarged ovaries, and vaginal lesions may be noted during the physical exam. Histologic examination of the tumor discloses sheets or foci of trophoblasts on a background of hemorrhage and necrosis but no villi.

Assessment of trophoblastic tissue following or accompanying pregnancy may prove difficult because of the histologic similarities of the trophoblastic patterns in very early pregnancy and choriocarcinoma. Consequently, the curettage specimen must be processed in its entirety as the specimens may contain only small, isolated areas of choriocarcinoma.

A histopathologic diagnosis of choriocarcinoma in any site is an indication for prompt treatment after confirmation by gonadotropin excretion measurements. In perplexing situations, β -hCG testing may clarify the diagnosis as well as the need for therapy.

PLACENTAL-SITE TROPHOBLASTIC TUMOR

PSTT is derived from the intermediate trophoblasts of the placental bed, with minimal or absent syncytiotrophoblastic tissue. Histologically, local invasion occurs into the myometrium and lymphatics and less commonly into the vasculature. PSTT may occur with any type of pregnancy or present months to years thereafter.

Clinical Findings

SYMPTOMS AND SIGNS

Abnormal uterine bleeding, usually during the first trimester, is the most common presenting symptom, occurring in more than 90% of patients with molar pregnancies. Three-fourths of these patients present

prior to the end of the first trimester.

Nausea and vomiting have been reported in 14–32% of patients with hydatidiform mole and may be confused with nausea and vomiting of pregnancy. Ten percent of these patients may have nausea and vomiting severe enough to require hospitalization.

About half of patients will have a uterine size that is greater than that appropriate for their gestational age. However, in one-third of patients, the uterus may be smaller than expected.

Multiple theca lutein cysts causing enlargement of one or both ovaries are seen in 15–30% of women with molar pregnancies. In about half these cases, both ovaries are enlarged and may be a source of pain. Involution of the cysts proceeds over several weeks and usually parallels the decline of β -hCG values. Surgical treatment of these cysts is indicated only if rupture, torsion, or hemorrhage occur, or if the enlarged ovaries become infected. In studies, patients with theca lutein cysts appear to have a greater likelihood of developing malignant sequelae of gestational trophoblastic neoplasia.

Preeclampsia in the first trimester or early second trimester—an unusual finding in normal pregnancy—has been said to be pathognomonic for a hydatidiform mole. It is seen in 10–12% of patients.

Hyperthyroidism from stimulation of thyrotropin receptors by hCG occurs in up to 10% of patients with hydatidiform mole. The disease is usually subclinical and most patients remain asymptomatic. Treatment involves evacuation of the mole. An occasional patient may require brief antithyroid therapy.

Because of the earlier diagnosis of molar pregnancies, the classic presenting symptoms and signs of gestational trophoblastic disease are now less prevalent. For instance, at the New England Trophoblastic Disease Center, the incidence of excessive uterine enlargement, hyperemesis, and preeclampsia was 28%, 8%, and 1%, respectively. The incidence of hyperthyroidism and respiratory insufficiency was negligible. Although the number of cases presenting with these classic signs and symptoms has decreased, the incidence of persistent postmolar gestational trophoblastic disease has remained static. This highlights the importance of vigilant postmolar β -hCG surveillance.

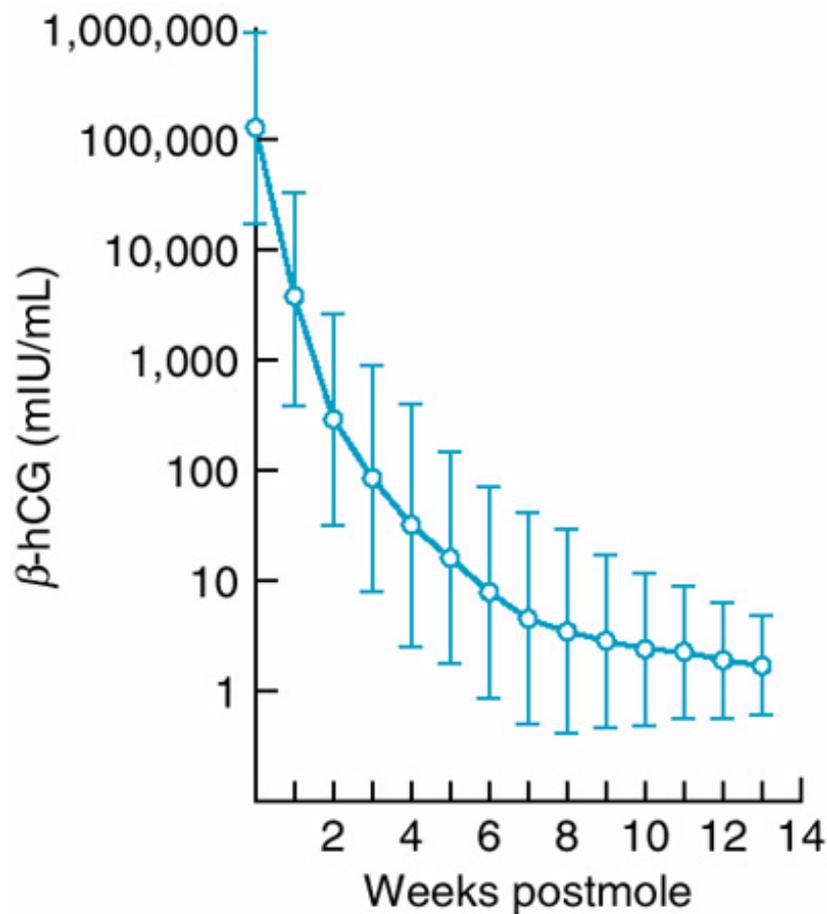

LABORATORY FINDINGS

The principal characteristic of gestational trophoblastic neoplasms is their capacity to produce β -hCG. This hormone may be detected in the serum or urine of virtually all patients with hydatidiform mole or malignant trophoblastic disease and its levels correlate closely with the number of viable tumor cells present. Consequently, monitoring of β -hCG levels is a necessary tool for the diagnosis, treatment, and follow-up of the disease process.

The usefulness of a serum gonadotropin assay depends on the level of the patient's β -hCG titer and the sensitivity of the test. Today, sensitive and specific immunoassays are available to differentiate β -hCG from luteinizing hormone (LH) by measuring the beta chain of hCG. Serial β -hCG levels are best monitored in the same laboratory using the same immunoassay technique.

The rate of the decline in β -hCG titers is also important. Using the serum β -hCG radioimmunoassay, a normal postmolar pregnancy hCG regression curve highlighting the weekly hCG levels in patients undergoing spontaneous remission has been constructed (Fig 53–5). This provides a reference for the comparison of random or serial values. In most instances, the β -hCG values exhibit a progressive decline to nondetectable levels within 14 weeks following evacuation of a molar pregnancy. If the hCG titer rises or plateaus, it must be concluded that viable tumor continues to persist. If the levels of hCG are very low and not responsive to treatment, a false-positive hCG result caused by cross-reaction of heterophilic antibodies with the hCG test should be considered.

Figure 53–5.

ULTRASONOGRAPH FINDINGS

The simplicity, safety, and reliability of ultrasonography define it as the diagnostic method of choice for patients with suspected molar pregnancy. In a complete molar pregnancy, the characteristic ultrasound pattern consists of multiple hypoechoic areas corresponding to hydropic villi, at times described as a "snowstorm" pattern. A normal gestational sac or fetus is not present. Theca lutein cysts may also be seen. In a partial mole, focal areas of trophoblastic changes and fetal tissue may be noted. An ultrasonogram of a choriocarcinoma reveals an enlarged uterus with a necrotic and hemorrhagic pattern, whereas that of PSTT can show an intrauterine mass.

An ultrasonograph should be obtained in any patient who presents with bleeding in the first half of pregnancy and has a uterus greater than 12 weeks gestational size. Even when the uterus is appropriate for gestational age, ultrasonography can be key in differentiating between a normal pregnancy and a hydatidiform mole.

Differential Diagnosis

Gestational trophoblastic disease must be distinguished from a normal or ectopic pregnancy. Ultrasonography is useful, and quantitative β -hCG levels improve the accuracy of the diagnosis.

Analysis of tissue obtained from a dilatation and curettage for histology and DNA content will prove invaluable.

Treatment

HYDATIDIFORM MOLE

Evacuation

When the diagnosis has been confirmed and a complete blood count, liver and renal function tests, and preevacuation chest radiograph have been obtained, the molar pregnancy should be terminated. Suction curettage is the method of choice. It is safe, rapid, and effective in nearly all cases. Intravenous oxytocin should be started after a moderate amount of tissue has been removed and may be continued for 24 hours postevacuation if necessary. Suction curettage with the largest curette possible should be followed by gentle sharp curettage, and tissue from the decidua basalis should be submitted separately for pathologic study. Suction curettage can be safely accomplished even when the uterus is the size of a 28-week gestation. Blood loss usually is moderate, but precautions should be taken for the possibility of a transfusion. When a large hydatidiform mole (> 12 weeks in size) is evacuated by suction curettage, a laparotomy setup should be readily available, as hysterotomy, hysterectomy, or bilateral hypogastric artery ligation may be necessary if perforation or hemorrhage occurs.

Before the use of suction curettage, hysterectomy was frequently used for patients with uteri beyond 12–14 weeks in size. Hysterectomy remains an option for good surgical candidates not desirous of future pregnancy and for older women (who are more likely to develop malignant sequelae). If theca lutein cysts are encountered at hysterectomy, the ovaries should remain intact, because regression to normal size will occur as the hCG titer diminishes. Hysterectomy does not eliminate the need for careful follow-up with β -hCG testing, although the likelihood of metastatic disease following hysterectomy for gestational trophoblastic disease decreases from 20% to 3.5%.

Hysterotomy is no longer a method of choice in typical cases. Current recommendations restrict hysterotomy to cases complicated by hemorrhage.

Medical induction of labor with prostaglandin, oxytocin, intra-amniotic instillation of prostaglandin or hypertonic solutions (eg, saline, glucose, urea) are no longer acceptable methods for evacuation of a molar pregnancy.

After the completion of the evacuation, all Rh-negative patients should receive Anti-D immune globulin.

Complications

The maternal–fetal barrier contains leaks large enough to permit passage of cellular and tissue elements. As a result, deportations of trophoblastic tissue to the lungs are frequent. Spontaneous regression of these ectopic trophoblastic tissues will occur. However, less commonly, a syndrome of acute pulmonary insufficiency may result. A patient can present with dyspnea and cyanosis within 4–6 hours after evacuation of the molar pregnancy as a result of massive deportation of trophoblasts to the pulmonary vasculature and subsequent formation of pulmonary emboli. Pulmonary edema leading to high-output congestive heart failure can also result from excessive fluid administration, preeclampsia, anemia or hyperthyroidism.

Prophylactic Chemotherapy

It is controversial whether prophylactic chemotherapy (with methotrexate or dactinomycin) following a

complete hydatidiform molar pregnancy should be offered to patients considered at high risk for persistent gestational trophoblastic disease (age > 35 years, history of prior molar pregnancy, trophoblastic hyperplasia) or in whom poor follow-up is anticipated. Several studies indicate that the incidence of postmolar gestational trophoblastic disease may be decreased with prophylactic chemotherapy. However, further studies are required to determine if the potential side effects warrant such treatment.

Surveillance Following Molar Pregnancy

Regardless of the method of termination, close monitoring with serial β -hCG titers is essential for every patient because of the 20–30% incidence of malignant disease. Following evacuation of a hydatidiform mole, the patient should have serial β -hCG determinations, beginning within 48 hours after evacuation and then at weekly intervals until serum β -hCG declines to nondetectable levels on three successive assays. If titer remission occurs spontaneously within 14 weeks and without a titer plateau, the β -hCG titer should then be repeated monthly for at least 1 year before the patient is released from close medical supervision (in cases of partial moles, β -hCG may be followed for 6–12 months). Thereafter, the patient may enter into a regular gynecologic care program.

Despite earlier diagnosis of molar pregnancies, the incidence of persistent gestational trophoblastic disease has not decreased. Three-fourths of patients with malignant nonmetastatic trophoblastic disease and half of patients with malignant metastatic disease develop these tumors as sequelae to a hydatidiform mole. In the remainder, disease arises following term pregnancy, abortion, or ectopic pregnancy.

Several clinical features of hydatidiform mole are recognized as having a high association with malignant trophoblastic neoplasia. In general, at diagnosis, the larger the uterus and the higher the β -hCG titer, the greater the risk for malignant gestational trophoblastic disease. The combination of theca lutein cysts and uterine size excessive for gestational age is associated with an extremely high risk (57%) of malignant sequelae. Pathologic specimens with marked nuclear atypia, presence of necrosis or hemorrhage, and trophoblastic proliferation may also increase the risk of persistent disease.

Effective contraceptive measures should be implemented and maintained throughout the period of surveillance in these patients. Oral contraceptives are the most widely used method.

A gynecologic examination should be done 1 week after evacuation, at which time blood may be taken for the β -hCG titer. Estimates of uterine size and presence of adnexal masses (theca lutein cysts) and a careful search of the vulva, vagina, urethra, and cervix should be made for evidence of genital tract metastases. Unless symptoms develop, the examination should be repeated at 4-week intervals throughout the observation period.

If preevacuation chest radiography reveals pulmonary metastases, chest radiographs should be repeated at 4-week intervals until spontaneous remission is confirmed, then at 3-month intervals during the remainder of the surveillance period.

A patient who has entered into spontaneous remission with negative titers, examinations, and chest radiographs for 1 year and who is desirous of becoming pregnant may terminate contraceptive practices. Successful pregnancy is usual, and complications are similar to those of the general population.

Therapy for progressive gestational trophoblastic neoplasia after evacuation of a hydatidiform mole is usually instituted because of an abnormal β -hCG regression curve. The most critical period of observation is the first 4–6 weeks postevacuation. Although the β -hCG titer usually returns to normal by 1–2 weeks after evacuation of a hydatidiform mole, it should normalize by the 8th week. Approximately 70% of patients achieve a normal β -hCG level within 8 weeks postevacuation. Few patients whose β -hCG titers

are normal during this interval will require treatment.

In the past, therapy was recommended if the β -hCG titer remained elevated at or beyond 8 weeks after termination of the molar pregnancy. However, current data suggest that an additional 15% of patients demonstrate a continuous decline in titers and ultimately achieve normal titers without treatment. Approximately 15% of patients who have elevated titers at 8 weeks postevacuation demonstrate a rising or plateauing titer. Nearly half of these patients will have histologic evidence of an invasive mole, and the other half will have choriocarcinoma.

Delayed postevacuation bleeding is uncommon after molar pregnancy and signifies the presence of an invasive mole or choriocarcinoma. It is invariably attended by an enlarging uterus and abnormal β -hCG regression pattern. On pelvic examination, the enlarged uterus may have the characteristics of an intrauterine pregnancy. Curettage is effective in stopping the bleeding, although little intracavitary tissue will be present in most of these cases.

The indications for initiating chemotherapy during the postmolar surveillance period are (a) β -hCG levels rising for 2 successive weeks or constant for 3 successive weeks; (b) β -hCG levels elevated at 15 weeks postevacuation; (c) rising β -hCG titer after reaching normal levels; and (d) postevacuation hemorrhage. Treatment should also be instituted whenever there is a tissue diagnosis of choriocarcinoma. However, histologic confirmation is unnecessary, because the development of metastases is a sufficient justification for chemotherapy.

MALIGNANT GESTATIONAL TROPHOBLASTIC NEOPLASIA

Malignant gestational trophoblastic neoplasia may be diagnosed in the setting of invasive mole, choriocarcinomas, placental-site trophoblastic tumors, and plateauing or rising postmolar β -hCG values (a plateau of 4 values \pm 10% over a period of 3 weeks, a rise in β -hCG of $>$ 10% of 3 values over a period of 2 weeks, or persistence of detectable β -hCG $>$ 6 months after evacuation).

Once the diagnosis of malignant trophoblastic disease is established, an accurate history and physical examination are crucial. Most patients will have an enlarged uterus as well as ovarian enlargement caused by theca lutein cysts. Sites of metastasis must be sought, especially in the lower genital tract. A chest radiograph can diagnose lung metastases, whereas liver metastases may be diagnosed with ultrasonography or computerized tomography (CT) scan. Brain metastases are best evaluated with a CT scan or magnetic resonance imaging (MRI). The ratio of serum β -hCG values to the concentration of β -hCG in cerebrospinal fluid (normal $>$ 60:1) may prove helpful. Baseline hematologic counts, coagulation studies, and hepatic and renal function tests are critical in assessing the risk for drug toxicity.

After all sites of metastases have been identified and the patient's desires for preservation of reproductive function are determined, specific therapy should be initiated.

Nonmetastatic Gestational Trophoblastic Disease

Trophoblastic disease confined to the uterus is the most common malignant lesion seen in gestational trophoblastic neoplasia. The diagnosis is usually made during the follow-up period after evacuation of a molar pregnancy. Therapy for patients with nonmetastatic malignant trophoblastic disease includes (a) single-agent chemotherapy and (b) combined chemotherapy and hysterectomy, with surgery done on the third day of drug therapy if the patient does not wish to preserve reproductive function and her disease is known to be confined to the uterus.

Table 53–2 summarizes the recommended chemotherapy regimens available for nonmetastatic gestational trophoblastic disease (and low-risk gestational trophoblastic disease). Single-agent chemotherapy using methotrexate or dactinomycin has demonstrated clear-cut superiority over other protocols. The therapeutic efficacy of the two drugs is apparently equivalent; however, no randomized

controlled studies have compared the response rate and side-effect profiles of single-agent chemotherapy with methotrexate to that of dactinomycin. Thus the regimen of choice has not been established. However, weekly intramuscular methotrexate injections provide a convenient and cost-effective alternative to the more intense 5-day regimens with methotrexate or dactinomycin, and with minimal side effects. Treatment failure (indicated by rising β -hCG or presence of new metastases) or intolerable side effects should result in administration of the alternative agent. Overall, the complete response rate ranges from 60–98% with salvage rates approaching 100%. Methotrexate is contraindicated in the presence of hepatocellular disease or when renal function is impaired. Each treatment cycle should be repeated as soon as normal tissues (bone marrow and gastrointestinal mucosa) have recovered, with a minimum 7-day window between the last day of one course and the first day of the next course.

Table 53–2. Chemotherapy Regimens for Nonmetastatic or Low-Risk Gestational Trophoblastic Disease.

Drug/dosage:

Methotrexate 30–60 mg/m² IM once a week.¹

Methotrexate 0.4 mg/kg/d IV or IM for 5 days, repeat every 14 days

Methotrexate 1 mg/kg IM on days 1, 3, 5, and 7 and folinic acid 0.1 mg/kg IM on days 2, 4, 6, and 8, repeat every 15–18 days

Dactinomycin 1.25 mg/m² IV every 14 days

Dactinomycin 10–12 μ g/kg/d IV for 5 days, repeat every 14 days

Follow-up:

Follow β -hCG titer weekly. Switch to alternative drug if β -hCG titer rises 10-fold or more, titer plateaus at an elevated level, or new metastasis appears.

Obtain labs daily during treatment cycle or weekly as indicated. Hold chemotherapy for WBC count < 3000 (absolute neutrophil count < 1500); platelets < 100,000; significantly elevated BUN, Cr, AST, ALT, or bilirubin; or for significant side effects (severe stomatitis, gastrointestinal ulceration, or febrile course).

Oral contraceptive agents or other form of birth control should be taken concurrently, and continued for at least 1 year following remission.

Chemotherapy continued for one course after negative β -hCG titer.

Follow-up program: β -hCG titer weekly until 3 consecutive normal titers; monthly β -hCG titer for 12 months thereafter; β -hCG titer every 2 months for 1 additional year or every titer for 6 months indefinitely.

Physical examination including pelvic examination and chest radiography monthly until remission is induced; at 3-month intervals for 1 year thereafter; then at 6-month intervals indefinitely.

¹For nonmetastatic disease only.

During treatment, weekly quantitative β -hCG titers and complete blood counts should be obtained.

Before each course of therapy, liver and renal function assessments should be done. At least one additional course of drug therapy should be given after the first normal β -hCG value is obtained. The number of treatment cycles necessary to induce remission is proportionate to the magnitude of the β -hCG concentration at the start of therapy. An average of 3 or 4 courses of single-agent therapy is required. After remission has been induced and treatment is completed, β -hCG assays should be obtained monthly for 1 year.

Metastatic Gestational Trophoblastic Disease

Treatment in metastatic disease uses either single-agent chemotherapy (Table 53–2) or multiple-agent chemotherapy. Multiple-agent chemotherapy is used in cases where resistance to a single agent is anticipated. Several systems have been developed to help determine which patients will, at onset, require more aggressive therapy.

Clinical Classification of Malignant Gestational Trophoblastic Disease

NATIONAL CANCER INSTITUTE

This system is used in the United States to determine if the patient will have a good or poor prognosis in response to single-agent chemotherapy (Table 53–3).

Table 53–3. Categorization of Gestational Trophoblastic Neoplasia.

A. Nonmetastatic disease: No evidence of disease outside uterus.

B. Metastatic disease: Any disease outside uterus.

1. Good-prognosis metastatic disease—

- a. Short duration (< 4 months).
- b. Serum β -hCG < 40,000 mIU/mL.
- c. No metastasis to brain or liver.
- d. No significant prior chemotherapy.

2. Poor-prognosis metastatic disease

- a. Long duration (> 4 months).
- b. Serum β -hCG > 40,000 mIU/mL.
- c. Metastasis to brain or liver.
- d. Unsuccessful prior chemotherapy.
- e. Gestational trophoblastic neoplasia following term pregnancy.

WORLD HEALTH ORGANIZATION (WHO)

This scoring system is based on an individual's risk factors, including age, type of antecedent pregnancy, interval from antecedent pregnancy to initiation of chemotherapy, pretreatment β -hCG level, size of largest tumor, site of metastases, number of metastases, and prior chemotherapy. Patients are categorized into low- or high-risk categories based on their total score. A total score of 0–6 is considered low-risk and a total score ≥ 7 is categorized as high-risk (Table 53–4).

Table 53–4. Modified WHO Prognostic Scoring System as Adapted by FIGO.

Scores	0	1	2	4
Age	< 40	≥ 40	—	—
Antecedent pregnancy	Mole	Abortion	Term	—
Interval months from index pregnancy	< 4	4–< 7	7–< 13	≥ 13
Pretreatment serum hCG (IU/mL)	< 10 ³	10 ³ –< 10 ⁴	10 ⁴ –< 10 ⁵	≥ 10 ⁵
Largest tumor size (including uterus)	—	3–< 5 cm	≥ 5 cm	—
Site of metastases	Lung	Spleen, kidney	Gastrointestinal	Liver, brain
Number of metastases	—	1–4	5–8	>8
Previous failed chemotherapy	—	—	Single drug	2 or more drugs

Reproduced with permission from FIGO Committee Report: FIGO staging for gestational trophoblastic neoplasia 2000. *Int J Gynecol Obstet* 2002;77:286.

REVISED FIGO (INTERNATIONAL FEDERATION ON GYNECOLOGY AND OBSTETRICS)

The revised 2000 FIGO staging system combines the use of both anatomic and nonanatomic factors. A patient is assigned a stage based on the anatomic location of disease and given a risk factor score based on the WHO prognostic scoring system. The goal of the revised FIGO staging is to improve the assessment and clinical management of patients. It also aims to unify staging to allow for comparisons in treatment success internationally (Table 53–5).

Table 53–5. FIGO Anatomic Staging.

Stage I	Disease confined to the uterus
Stage II	GTN extends outside of the uterus, but is limited to the genital structures (adnexa, vagina, broad ligament)
Stage III	GTN extends to the lungs, with or without known genital tract involvement
Stage IV	All other metastatic sites

Reproduced with permission from FIGO Committee Report: FIGO staging for gestational trophoblastic neoplasia 2000. *Int J Gynecol Obstet* 2002;77:286.

GOOD-PROGNOSIS PATIENTS

Based on the clinical classification of malignant disease, patients can be expected to respond satisfactorily to single-agent chemotherapy if (a) metastases are confined to the lungs or pelvis, (b) serum β-hCG levels are below 40,000 mIU/mL at the onset of treatment, and (c) therapy is started within 4 months of apparent onset of disease.

The most common site of metastases is the lung. When a patient develops pulmonary metastases and elevation of the β-hCG titer, choriocarcinoma is a more likely cause than metastatic mole. Invasive mole may also metastasize to the lungs, and hydatidiform mole has occasionally been reported to metastasize to the chest. Probably any form of metastases (even benign deportation) should suggest metastatic trophoblastic disease.

In these patients, single-agent chemotherapy (Table 53–2) is generally successful. Methotrexate is considered the drug of choice. Ideally, the 5-day treatment cycle is given every other week, because tumor regrowth becomes significant after treatment gaps of 2 weeks or longer. Once negative titers have been achieved, an additional course is administered. If resistance to methotrexate occurs, manifested either by rising or plateauing titers or by the development of new metastases, or if negative titers are not achieved by the fifth course of methotrexate, the patient should be given dactinomycin. Dactinomycin also should be initiated for patients who experience severe side effects with methotrexate.

The advantage of single-agent chemotherapy is that it is less toxic and its toxicity is less apt to be irreversible than is the case with multiple-agent chemotherapy.

There is a tendency not to be aggressive in treating these patients, probably because of the "good-prognosis" (low-risk) designation. But failure of drug therapy does occur in approximately 10% of cases, and meticulous care by physicians familiar with these problems is necessary for good results.

POOR-PROGNOSIS PATIENTS

Poor-prognosis patients, based on the Clinical Classification of Malignant Disease, are those with any of the following risk factors: (a) serum β -hCG titers greater than 40,000 mIU/mL at the onset of treatment; (b) diagnosis of disease more than 4 months after molar pregnancy; (c) brain or liver metastases; (d) prior unsuccessful chemotherapy; or (e) onset following term gestation. These patients respond poorly (< 40% response rate) to single-agent therapy. A poor response is also seen in patients with advanced revised FIGO stages and WHO scores \geq 7. These patients present a serious challenge. Many have been previously treated with chemotherapy and have developed resistance to that treatment while accumulating considerable toxicity and depleting bone marrow reserves. Prior unsuccessful chemotherapy is one of the worst prognostic factors.

Generally, these patients require prolonged hospitalization and multiple courses of chemotherapy. They often need specialized care and other life-support measures, including hyperalimentation, antibiotics, and transfusions, to correct the effects of marrow depression.

Central nervous system involvement, particularly brain metastases with focal neurologic signs suggestive of intracranial hemorrhage, is common in choriocarcinoma. Because patients with brain or liver metastases are at great risk of sudden death from hemorrhage from these lesions, it is standard practice when treating them to include immediate institution of whole-brain or whole-liver irradiation concomitantly with combination chemotherapy. It is uncertain whether radiation therapy exerts its beneficial effect by destroying tumor in combination with drug therapy or by preventing fatal hemorrhage and thus keeping the patient alive until remission with chemotherapy can be achieved. For acute bleeding episodes, surgical intervention or angiographic embolization can be considered.

Cerebral metastases should be treated over a 2-week period with radiation given in a dosage of 3 Gy daily, 5 days a week, to a total organ dose of 30 Gy. Whole-liver irradiation is usually accomplished over 10 days to attain a 20-Gy whole-organ dose given at a rate of 2 Gy daily, 5 days a week. Other treatment options include selective hepatic artery chemotherapy infusion.

Prior treatments for poor prognosis/high-risk gestational trophoblastic disease have included MAC (methotrexate, dactinomycin, and chlorambucil or cyclophosphamide) and the modified Bagshawe protocol (CHAMOCA: cyclophosphamide, hydroxyurea, methotrexate, vincristine, cyclophosphamide, and dactinomycin). Currently, EMACO (etoposide, methotrexate, actinomycin D, cyclophosphamide, and vincristine) chemotherapy (Table 53–6) provides the best response rate (approximately 80%) with the lowest side-effect profile. The cycle is repeated every 2 weeks. The same tests must be employed to detect toxicity as are used when single-agent chemotherapy is given, but monitoring must be even more

vigilant because of the possibility of combined toxicity.

Table 53–6. Current Treatment Regimens for High-Risk Gestational Trophoblastic Disease.

EMA/CO ¹		
Day		
1	Etoposide	100 mg/m ² IV (infused over 30 min)
	Actinomycin D	0.5 mg IV bolus
	Methotrexate ²	100 mg/m ² IV bolus
		200 mg/m ² IV (infused over 12 h)
2	Etoposide	100 mg/m ² IV (infused over 30 min)
	Actinomycin D	0.5 mg IV bolus
	Folinic acid	15 mg IM infusion or orally every 12 hours for 4 doses beginning 24 hours after start of methotrexate
8	Cyclophosphamide	600 mg/m ² IV infusion
	Vincristine	1 mg/m ² IV bolus
Other options:		
Salvage therapy: Substituting etoposide (100 mg/m ² IV) and cisplatin (80 mg/m ² IV) (EMA-EP) for cyclophosphamide and vincristine. Adjuvant surgery (hysterectomy and thoracotomy) for chemotherapy-resistant disease.		
With failure of EMA-EP, treatment with: BEP (cisplatin 20 mg/m ² IV, etoposide 100 mg/m ² IV on days 1–4 every 21 days, with bleomycin 30 units IV on day 1 then every week), G-CSF (granulocyte colony-stimulating factor) 300 µg SC on days 6–14.		
VIP (etoposide 75 mg/m ² IV, ifosfamide 1.2 g/m ² IV, cisplatin 20 mg/m ² IV each day for 4 days every 21 days). Mesna 120 mg/m ² IV bolus prior to first ifosfamide dose, followed by 1.2 mg/m ² 12-hour IV infusion daily after each ifosfamide dose, G-CSF 300 µg SC on days 6–14.		
High-dose chemotherapy with autologous bone marrow transplantation.		
Taxanes (paclitaxel and docetaxel) and camptothecins (topotecan and irinotecan).		

¹Mild toxicity with 5-year survival 80%. Repeat cycles on days 15, 16, and 22 (every 2 weeks).

²Increase to 1 g/m² as 24-h infusion with CNS metastases, with folinic acid increased to 15 mg every 8 h for nine doses beginning 12 h following completion of methotrexate infusion. Also may receive methotrexate 12.5 mg by intrathecal injection on day 8. Another option is whole-brain irradiation 3000 cGY in 200-cGY fractions given over 10–14 days during chemotherapy.

Chemotherapy should be continued for at least 3 cycles after negative β -hCG.

As with nonmetastatic and low-risk disease, oral contraceptive pills or other form of birth control should be utilized if not contraindicated.

Treatment of malignant trophoblastic disease must be continued with repeated courses of combination chemotherapy until β -hCG titers return to nondetectable levels. Complete remission is documented only after three consecutive weekly normal β -hCG titers have been achieved. It is recommended that all high-risk patients receive at least three courses of triple-agent chemotherapy after β -hCG titers have returned to normal. After remission is achieved, follow-up is the same as for hydatidiform mole and nonmetastatic or good-prognosis disease.

Salvage therapy for disease not responsive to EMACO substitutes cisplatin and etoposide (EP-EMA) for cyclophosphamide and vincristine (CO) (Table 53–6). Close monitoring of renal function is required because of nephrotoxicity secondary to cisplatin and as methotrexate is renally excreted. Other treatment options include such agents as paclitaxel, topotecan, and high-dose chemotherapy with autologous bone marrow transplantation.

In resistant cases, adjunctive measures along with chemotherapy may include hysterectomy, resection of metastatic tumors, or irradiation of unresectable lesions.

Placental-Site Trophoblastic Tumor

Because treatment of PSTT generally is resistant to chemotherapy, hysterectomy is the recommended route of treatment. Partial uterine resection involving the tumor is possible if the patient desires to retain fertility. Chemotherapy is indicated in cases of metastatic disease. EP-EMA is the preferred regimen over EMACO, with paclitaxel and topotecan used when resistance develops. The greatest adverse outcomes are associated with an interval > 2 years from antecedent pregnancy to diagnosis.

Prognosis

The prognosis for hydatidiform mole following evacuation is uniformly excellent, although surveillance is needed as outlined in the text. The prognosis for malignant nonmetastatic disease with appropriate therapy is also quite good, as almost all patients are cured. More than 90% of patients can preserve reproductive function, but first-line therapy fails in 6.5% of patients with nonmetastatic disease. In one large reported series, no death from toxicity occurred, and only one patient died of the disease.

In poor-prognosis metastatic disease, the best results are with EMACO chemotherapy and concurrent radiation as indicated. Seventy-five percent to 85% of patients achieve remission with a 69% salvage rate. This is a similar response to agents used previously (MAC) but with fewer side effects. Brain and liver metastases have the worst prognosis with reports of survival ranging from 0–60% for hepatic involvement and 50–80% for central nervous system (CNS) involvement at diagnosis. Survival decreases to < 20% when prior chemotherapy agents have been used or if CNS metastases develop while undergoing treatment. Deaths from toxicity have decreased considerably. Recurrence, when it happens, is usually in the first several months after termination of therapy but may be as late as 3 years.

Secondary Tumors

Multiple-agent chemotherapy (specifically using etoposide) but not single-agent chemotherapy is associated with a 50% increased risk for secondary tumors. One retrospective study found that the relative risk for developing myeloid leukemia and colon cancer was 16.6 and 4.6, respectively. When survival exceeded 25 years, the relative risk for developing breast cancer was 5.8.

Subsequent Pregnancy Outcome

Subsequent pregnancies are not at increased risk for complications such as preterm labor, anomalies, or stillbirth. These pregnancies should, however, be monitored early with ultrasonography and β -hCG levels because there is a 1–2% risk of recurrent gestational trophoblastic disease following one molar pregnancy and a 25% risk of recurrence following two molar pregnancies. Following delivery, the placenta should be sent to pathology and a β -hCG level should be checked at the 6-week postpartum visit.

In cases where pregnancy occurs prior to the completion of standard postmolar surveillance (<1 year), the pregnancy may be continued with close observation, and the risks discussed with the patient. Most pregnancies end with a good outcome, but there is a small risk for delayed diagnosis of recurrence.

Current OB/GYN > Chapter 54A. Radiation Therapy for Gynecologic Cancers >

RADIATION THERAPY FOR GYNECOLOGIC CANCERS: INTRODUCTION

Two European discoveries in the late 1800s led to future radiation treatment of human malignancies. While studying the penetrating power of cathode ray emission in Germany, Wilhelm Roentgen discovered x-rays on November 8, 1895. In France, the Curies isolated radium from uranium ore in 1898. Soon thereafter, Robert Abbe of New York City introduced radium for medical therapy, and Howard Kelly of Baltimore pioneered radium treatment of cervical cancer. Since then radiation therapy has evolved to become a major modality in the treatment of many cancers, particularly those of the female reproductive tract.

Types of Radiation

Radiation oncology may be defined as the therapeutic manipulation of radiation delivered to a target for cure or for palliation. Such radiation may be electromagnetic or particulate, both of which transfer energy to the electrons or nuclei of the target atoms.

Electromagnetic radiation is energy that is transmitted at the speed of light through oscillating electric and magnetic fields. The energy contained in these fields can be described as discrete units known as photons. The energy of each photon is proportional to the frequency of the wave associated with that photon. Because radiation with a shorter wavelength has greater frequency, it carries greater energy per photon, allowing deeper tissue penetration. The most clinically relevant forms of electromagnetic radiation are x-rays and gamma rays. For therapeutic applications, x-rays are mechanically produced by linear accelerators that accelerate electrons to very high energies. These electrons then strike a target within the accelerator, usually tungsten, to produce a beam of x-rays which is targeted at the patient. Gamma rays are produced by the decay of radioactive substances. Currently, the most commonly used radioisotopes for gynecologic cancer treatments are cesium-137 and iridium-192.

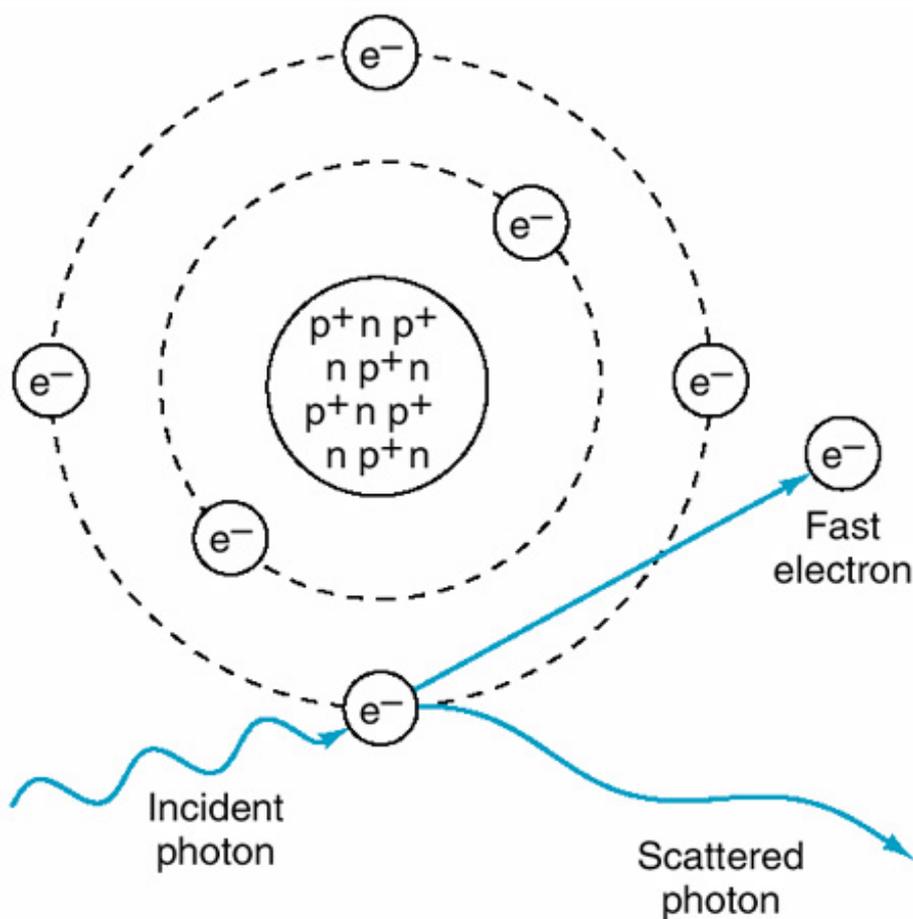

Particulate radiation uses subatomic particles (electrons, neutrons, protons), instead of photons, to deliver the dose of radiation. Compared with electromagnetic radiation, particle-beam therapy enables more precise dose localization and better depth dose distribution.

Interaction of Photons with Matter

The first step in the absorption of an incident photon with matter is the conversion of the energy of that photon into the kinetic energy of an electron, or electron–positron pair. Depending on the energy of the photon, this conversion takes place either through the photoelectric effect, the Compton effect, or pair production. In the photoelectric effect, an incident photon interacts with a tightly bound inner shell electron of the target tissue. The energy of the photon is completely absorbed and the electron is ejected from the atomic orbit with kinetic energy equal to the photon energy. With the photoelectric effect, absorption is influenced by atomic number; the tissues bearing elements of higher atomic number (eg, calcium in bone) absorb proportionately greater and possibly detrimental levels of radiation. In the Compton effect, an incident photon transfers energy to an outer-shell electron in the target tissue, causing ejection of this electron. The photon is incompletely absorbed; instead, it is scattered at an angle

to its original path. This secondary photon interacts with tissue multiple times in the same manner, ionizing with each interaction (Fig 54A–1). The atomic number of the tissue elements does not determine the amount of absorbed radiation. The Compton effect accounts for the biologic effects on tissues seen in radiation therapy. Pair production refers to the complex interaction of an incident photon with the nucleus of a target atom, resulting in an electron–positron pair. Because the pair production interaction typically predominates at energy levels above the range that is usually used in therapy, it plays a small role in most clinical settings.

Figure 54A–1.

Absorption of an x-ray photon by the Compton process. The photon interacts with a loosely bound planetary electron of an atom of the absorbing material. Part of the photon energy is given to the electron as kinetic energy. The photon, deflected from its original direction, proceeds with reduced energy. e⁻ = electron; p⁺ = proton; n = neutron.

(Reproduced with permission from Hall EJ: *Radiobiology for the Radiologist*, 4th ed. JB Lippincott, 1994, p. 7.)

In the lower range of energy transfer, the photoelectric effect predominates, while in the transfer of higher levels of energy, the Compton effect and pair production are more prevalent.

Interaction of Photons with Tissue

As a radiation beam travels through a patient, it deposits energy in the tissue through interactions such

as the Compton effect. These interactions set secondary electrons in motion which result in further ionizations. These ionizations lead to the breakage of chemical bonds and subsequent damage to molecules and structures within the cell. The most significant result of cell damage is cell death.

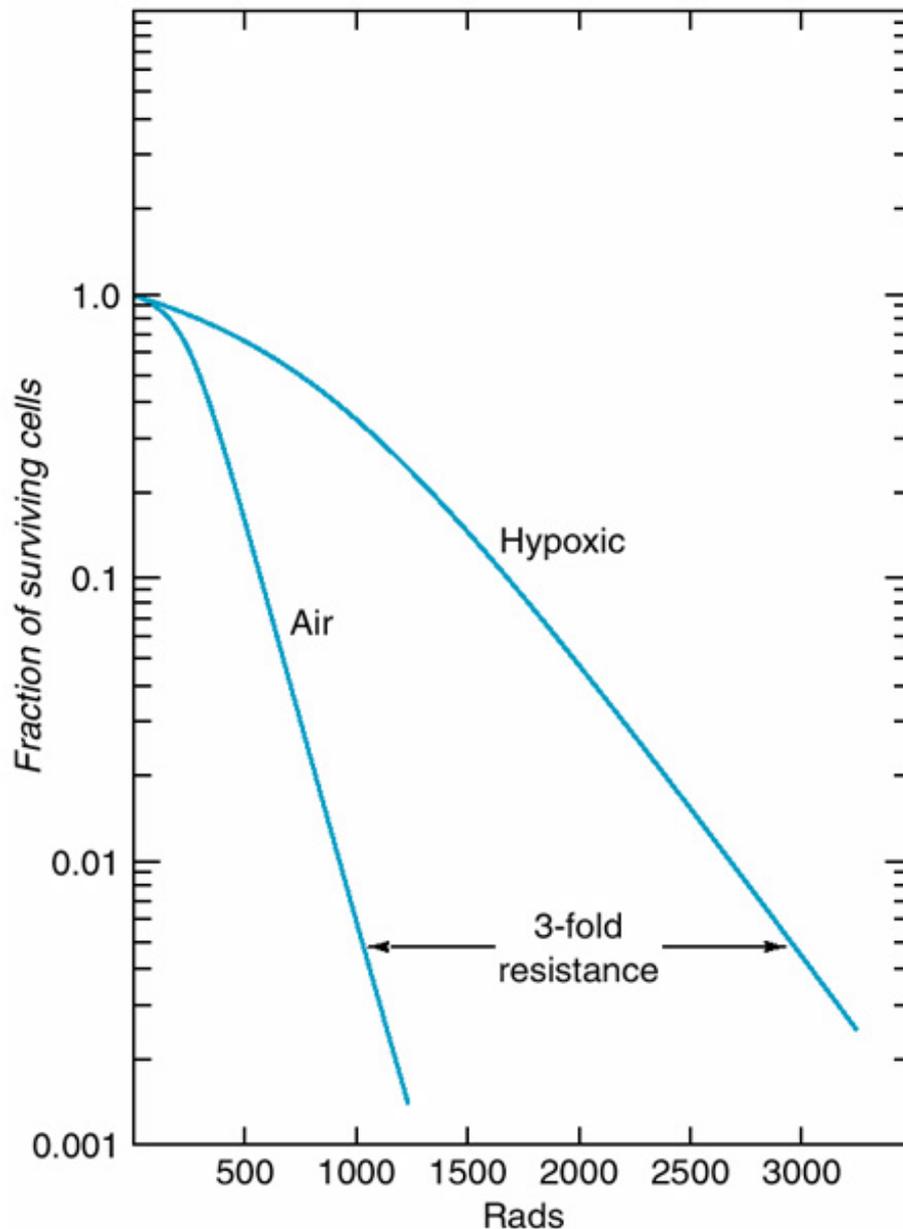

The most critical target for damage within the cell is DNA. Direct damage occurs when a photon becomes absorbed by the an atom in the DNA and the DNA becomes ionized and damaged. More commonly, however, DNA damage is indirect. The water surrounding the DNA is ionized by the radiation, creating oxygen radicals, hydroxyl radicals, peroxide, and hydrated electrons. These highly reactive species then interact with the DNA to cause damage.

Dosage Theory

Normal tissue as well as malignant cells are susceptible to toxicity induced by radiation therapy, the extent of which depends on total dose, fractionization, and tumor volume.

After exposure to radiation, tissue survival follows a predictable curve that essentially constitutes the number of viable clone cells (Fig 54A–2). The shoulder represents the cell's enzymatic ability to reverse radiation-induced damage. As radiation increases, cells become incapable of self-repair and a logarithmic pattern of cell destruction occurs. Importantly, for every increase in dosage that occurs beyond the shoulder, a constant fraction of cells is eliminated (log-kill hypothesis).

Figure 54A–2.

Typical radiation survival curve for mammalian cells. These cells have been irradiated and then plated out in culture, and the number of survivors has been determined by measuring the colonies (clones) of cells that survive. The curve is characterized by an initial shoulder followed by a log-linear region. Cells irradiated in air are considerably more sensitive than those irradiated in nitrogen (hypoxic), and the difference between the levels of killing is frequently about 3-fold. It is believed that most clinically demonstrable tumors have areas of hypoxia that lead to radioresistance.

(Reproduced with permission from Morrow CP, Curtin JP, Townsend DE [editors]: *Synopsis of Gynecologic Oncology*, 4th ed. Churchill Livingstone, 1993, p. 449.)

The implications of these observations provide some of the rationale for dividing (fractionating) the total dose of radiation therapy administered in the clinical setting. It is helpful to consider the so-called 4 Rs of radiobiology to understand the effects of fractionated doses at the cellular level.

REPAIR OF SUBLETHAL INJURY

When a specified radiation dose is divided into two doses given at separate times, the number of cells surviving is higher than that seen when the same total dose is given at one time. Fractionation allows the administration of amounts of radiation that would not be tolerated if the specified dose were given in only one treatment.

REPOPULATION

The reactivation of stem cells that occurs when radiation is stopped is necessary for further tissue growth; thus those tissues with increased numbers of progenitor cells have a greater ability to regenerate.

REOXYGENATION (OXYGEN EFFECT)

Hypoxic cells are known to be relatively resistant to radiation. Experimental and clinical evidence has confirmed that molecular oxygen must be present before radiation damage can occur. Cells located farther than 100 mm from capillary flow are at risk for hypoxia and may not be killed by radiation therapy. If these hypoxic cells are malignant, they may not be killed by radiation therapy. For this reason, it is important to correct anemia in patients undergoing radiation treatment so that tissue oxygen perfusion will be enhanced and tissues will become more radiosensitive. As tumor regresses with radiation treatment, previously anoxic areas may be brought into contact with capillary flow and increased oxygenation.

RADIATION-INDUCED SYNCHRONY

Malignant cells are most sensitive to radiation while in the mitotic phase of the cell cycle. If a segment of the malignant cell population can be destroyed in this phase of the cell cycle, the remaining malignant cells may be synchronized for selective destruction at a later time.

Clinical experience shows that prolonged interruption of radiation therapy has a deleterious effect on cure, as malignant cells have a greater chance to regenerate.

Dosimetry

Dosimetry is the measurement of the amount of radiation absorbed by target tissue. The unit of absorbed dose is the Gray (Gy), which is defined as the joules of energy absorbed in a kilogram of tissue (J/kg). One Gy is equal to 100 rads. External pelvic irradiation is expressed in those terms, whereas internal irradiation is also described in milligram hours. This latter unit is obtained by multiplying the number of milligrams of radioactive substance used in the internal applicators by the number of hours the applicators have been in place.

The exact conversion factor between milligram hours and Gray is difficult to determine, but computer-directed dosimetry permits the calculation of isodose curves, points of equal dose surrounding a radioactive source, that permit critical considerations in avoiding overdose to the bladder and rectum. Unfortunately, the radiation tolerance of the bladder and rectum is close to the dosage levels required for curative radiation therapy of common pelvic cancers.

In the United States, radiation doses are usually administered in 1.8–2.0 Gy per day.

TREATMENT METHODS

For gynecologic cancers, therapeutic radiation is delivered as external radiation (teletherapy), internal radiation (brachytherapy), or a combination of both.

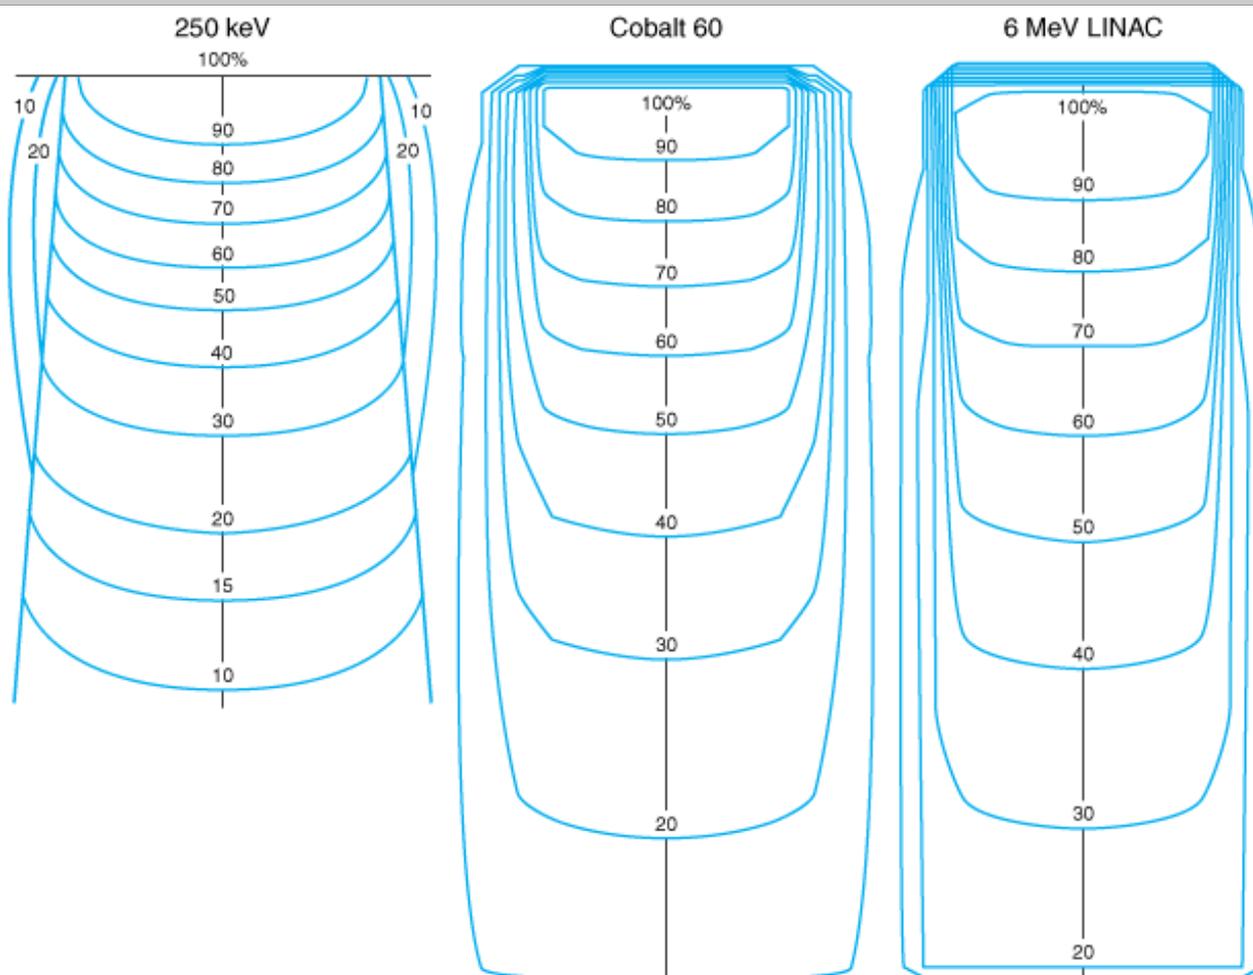

External Irradiation (Teletherapy)

Early radiation therapists used electric x-ray sources that were basically modifications of Roentgen's experimental apparatus. Electrons were accelerated across a vacuum tube to strike a tungsten target with the subsequent liberation of photons. These orthovoltage (140–400 keV) units were limited in their

power to penetrate tissue effectively because of their relatively low energy output. Consequently, pronounced fibrotic skin changes and high absorbed bone radiation levels limited their usefulness in some patients.

As units generating higher levels of energy were developed, the penetrating power of the x-rays produced was enhanced, and less scattering of radiation was seen at the margins of the treatment area. The surface skin dose was also diminished, of particular importance in the treatment of obese patients, and less-toxic bone radiation was achieved (Fig 54A–3).

Figure 54A–3.

Typical isodose curves for orthovoltage (250 keV), cobalt 60, and a 6-MeV linear accelerator (LINAC). The most important difference between the megavoltage (cobalt 60 and LINAC) beams in comparison with the 250-keV beam is the movement of the 100% isodose line several millimeters beneath the surface. This results in elimination of the severe skin reactions characteristic of earlier radiation sources. In addition, the higher energy leads to deeper penetration as the energy of the beam increases.

The goal of external radiation treatment is to ensure that radiation is delivered to the target tissue without affecting uninvolved tissues and that the amount of radiation received is as uniform as possible. Traditionally, the planning of radiation treatment has been done in two dimensions (height and width).

Today, this is achieved by optimized three-dimensional conformal planning to more precisely target a tumor with radiation beams (height, width, and depth). Patients undergo computed tomography (CT) scanning in the treatment position and the volume of abnormal tissue, that is, the gross tumor volume (GTV), is delineated. Given the possibility of microscopic extension along tissue planes, a margin of tissue is added to the GTV. This larger volume, the clinical tumor volume (CTV), is the volume of tissue to be irradiated. Using information from these images, special computer programs design radiation beams that "conform" to the shape of the tumor.

Internal Irradiation (Brachytherapy)

Brachytherapy is radiation therapy in which the source of therapeutic ionizing radiation is placed close to the treatment area.

The chief advantage of local irradiation is that a relatively high dose of radiation can be applied to a limited anatomic region. The inverse square law has critical implications in clinical applications. The principle of the inverse square law states that the intensity of radiation is inversely proportional to the square of the distance from the source. An important implication is that the rapid falloff of radiant energy supplied by a central source precludes the achievement of cancerocidal doses at the margins of the pelvis. Consequently, external therapy must be used to provide adequate radiation to eliminate tumor at the periphery of large lesions and at the pelvic side walls, where metastatic disease may be present.

Brachytherapy can be delivered using an intracavitary approach with a variety of applicators, or via an interstitial approach using needles or catheters. Most applicators for intracavitary brachytherapy consist of an intrauterine tandem and paired colpostats or ovoids which are placed in the lateral vaginal fornices. Interstitial applicators consist of multiple needles that are inserted into the tissue at or near the target site. Radioactive isotopes are then loaded into the applicators at the beginning of the treatment.

Several isotopes are available for brachytherapy. The most commonly used in the United States is a low-dose rate (LDR) approach employing cesium-137. However, acceptance of a high-dose rate (HDR) therapy, usually with iridium-192, is quickly gaining acceptance. HDR brachytherapy offers some significant advantages over LDR as it can be employed on an outpatient basis, eliminates radiation exposure to medical personnel, and has shorter treatment times.

TREATMENT OF GYNECOLOGIC CANCER

Cervical Cancer

Treatment of cervical cancer is considered a prime example of the successful application of radiation therapy. The relative accessibility of the central lesion, a metastatic pattern of cervical squamous cell carcinoma that can be predicted with reasonable accuracy, and the radiation tolerance of the cervix and surrounding tissues often permit curative radiation therapy.

Radiation therapy with curative intent uses both external-beam and intracavitary radiation. Palliative radiation for advanced cervical cancer may use either modality for control of bleeding, management of disease in the pelvis, and relief of pain.

The goal of external irradiation in cervical cancer is to sterilize metastatic disease to pelvic lymph nodes and the parametria and/or to decrease the size of the cervix to allow optimal placement of intracavitary radioactive sources.

The size of the radiation field used to treat a patient with carcinoma of the cervix must be carefully designed to encompass those structures at risk for regional spread of the cancer.

Definitive radiation therapy is an acceptable alternative to radical surgery for women with early stage

disease (stages IA, IB1, and nonbulky IIA). However, concurrent cisplatin-based chemotherapy should be employed whenever radiation therapy is administered for the treatment of cervical cancer. Numerous studies show that concomitant radiation therapy and chemotherapy (chemoradiation) improves overall and progression-free survival in patients with cervical cancer. Advantages of combined treatment theoretically include no delay time in starting definitive irradiation; decreased treatment time overall; and possible interaction of chemotherapy with radiotherapy by mechanisms such as repair of sublethal and lethal damage, cell phase distribution changes, effect on vascularity of tumor, effects on repopulation, effects on hypoxic cells, alteration of cell survival curve, and modification of apoptosis.

The treatment volume for women undergoing adjuvant external radiation therapy usually involves the whole pelvis, with larger fields for patients with higher stage disease.

Patients with known or suspected metastatic disease to periaortic lymph nodes may be considered for extended field irradiation.

Endometrial Cancer

The decision to use radiation treatment for endometrial cancer is often made after adequate surgical staging has been performed and is dependent on the estimated risk of recurrent disease.

Patients who have adnexal or pelvic metastases, involvement of lymphovascular space, grade 2 disease with invasion > 50% into the myometrium, or grade 3 disease with any amount of myometrial invasion, are deemed to be at high risk of recurrence. These patients may benefit from adjuvant radiation therapy. For high-risk disease confined to the uterus, whole-pelvic therapy or vaginal brachytherapy may be used. For high-risk disease outside of the uterus but confined to the pelvis, whole-pelvis radiation with or without vaginal brachytherapy should be employed. Women with more extensive disease undergo extended-field radiation or whole-abdomen radiation.

Women who have a grade 1 or 2 tumor at either stage IC or stage II, no lymphovascular involvement, and no evidence of metastases are at intermediate risk of recurrence. The use of adjuvant radiation therapy is very controversial in this group. Studies show that use of adjuvant radiation therapy may improve local control, but overall survival is not significantly improved. Adjuvant therapy is not routinely used for women at low risk of recurrence.

Primary radiation therapy may be employed in women who are considered to be at high surgical risk, such as the elderly and those with significant comorbidities. Patients with well-differentiated adenocarcinoma may be managed with tandem and ovoids or intrauterine Simon capsules. Patients with moderately or poorly differentiated cancers or those with involvement of the cervix are at risk for parametrial and pelvic lymph node spread and should receive whole-pelvic irradiation prior to brachytherapy.

Ovarian Cancer

Since the introduction of combination chemotherapy, the role of radiation therapy in the management of ovarian cancer has become controversial. There are no well-structured trials that demonstrate the benefit of external radiation in the treatment of ovarian cancer.

Several studies have compared the use of intraperitoneal chromic phosphate (^{32}P) with platinum-based chemotherapy in early stage ovarian cancer. None of these trials showed a difference in 5-year survival rates, but they did show late bowel complications in the ^{32}P group.

Vaginal Cancer

Radiotherapy remains the primary treatment for vaginal cancer, which is one of the rarest human

malignancies, and historically one of the gravest. A 1954 review of a published series of 992 patients reported an overall 5-year survival rate of 18%. More recent studies, however, have show overall 5-year cure rates of 40–50%. Such improvement in survival rates is attributed to megavoltage external therapy along with physical and technical advances in local irradiation. Despite radiation therapy being the primary treatment modality for vaginal cancers, there are no standardized treatment protocols. With squamous cell carcinoma comprising the most common form of vaginal cancer, most of these patients undergo whole-pelvic radiation therapy followed by intracavitary or interstitial brachytherapy. Patients with lesions involving the lower third of the vagina should have the inguinal and femoral lymph nodes included in the external-beam treatment field. Extended field radiation to include periaortic lymph nodes may be needed if imaging studies reveal bulky pelvic or periaortic disease.

Vulvar Cancer

Slightly more common than vaginal cancer (5% vs 2% of female malignancies), vulvar cancer also is usually squamous cell in origin. However, the mainstay of treatment of stages I and II vulvar cancer is surgical, often consisting of radical vulvectomy plus inguinal and pelvic lymphadenectomy. Adjuvant radiation therapy benefits patients with close or positive surgical margins, as well as patients with positive inguinal lymph nodes.

In patients with more advanced vulvar squamous cancer (stage III or IV) chemoradiation may reduce the need for more radical surgery, including primary pelvic exenteration.

Complications of Radiation Therapy

Radiation therapy regimens are formulated to maximize the chances for cure while incurring the smallest amount of damage to normal tissues. The effects of radiation on normal tissue is what limits the doses of therapeutic radiation that can be administered. In gynecologic cancers, the most serious complications are those involving the gastrointestinal or genitourinary systems.

Complications of radiation therapy are classified as early or delayed. Acute effects result from direct damage of parenchymal cells in organs that are sensitive to radiation. These include enteritis, proctosigmoiditis, cystitis, vulvitis, and, occasionally, depression of bone marrow elements. Bowel side effects usually comprise cramping and diarrhea that require dietary adjustments and the judicious use of antidiarrheal agents. Such problems usually respond to appropriate medication, but occasionally radiation therapy must be interrupted or curtailed because of fulminant acute reactions.

Late radiation effects are believed to be caused by slow vascular damage along with direct damage of parenchymal cells. Such injury may be manifested by chronic proctosigmoiditis, hemorrhagic cystitis, small- and large-bowel strictures, and the formation of rectovaginal and vesicovaginal fistulas. Pelvic fibrosis and loss of ovarian function may affect sexual activity in younger patients.

New Directions in Radiation Therapy

In addition to radiation sensitizers, neutron beam therapy and altered fractionation schemes are being evaluated for effectiveness against the tumor-protective effects of hypoxia, which is a common problem with gynecologic cancers. Intensity-modulated radiotherapy has emerged as a new teletherapy technique that can use radiation beams of varying intensities to deliver different doses of radiation to small areas of tissue at the same time. This allows for the delivery of higher doses of radiation within a tumor while sparing adjacent normal tissue. As newer computer technologies are wedded to imaging techniques, further advances in anatomic contouring for planning and treatment are expected to translate into better local control rates, as well as improved survival with a wider margin of safety.

Current OB/GYN >Chapter 54B. Chemotherapy for Gynecologic Cancers>

CHEMOTHERAPY FOR GYNECOLOGIC CANCERS: INTRODUCTION

Effective chemotherapy for gynecologic cancers exploits characteristic differences between tumor cells and normal cells to selectively kill malignant cells without producing serious, irreversible harm to vital organs and tissues. Knowledge of the scientific basis of cancer chemotherapy is derived from research in molecular biology and cell kinetics and is indispensable to the development of better drugs, establishment of a more rational basis for the design of protocols, and the optimal use of presently available antineoplastic drugs.

Long-lasting remissions and occasional cures for several types of cancer have been achieved with antitumor drugs. For example, up to 90% of patients with metastatic choriocarcinoma achieve a normal life expectancy, and almost 100% of patients without metastases are cured now that the effect of drugs can be monitored by the level of β -hCG (β -human chorionic gonadotropin), which provides a reliable index of tumor growth. For most tumors, however, no such specific and sensitive assay or tumor marker exists. Now that multiple-drug regimens are being used for primary chemotherapy of carcinoma of the ovary, objective response rates of 60–80% are achieved. The objective response rate of 20–40% achieved by chemotherapy in patients with primary carcinoma of the breast and endometrium warrants the use of chemotherapy as an integral part of an initial treatment program.

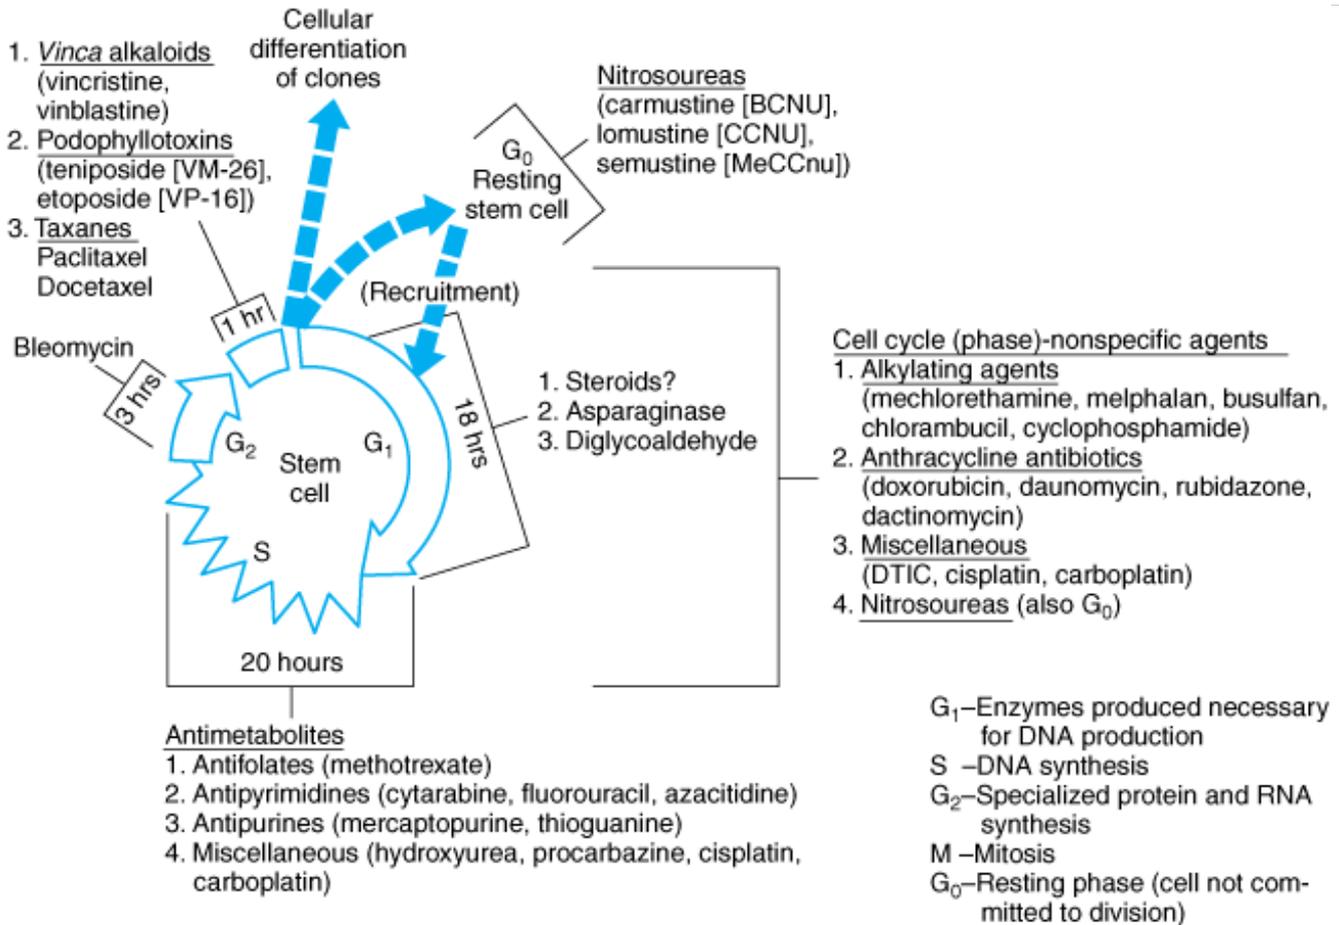

In spite of extensive experience, the use of cytotoxic agents for carcinomas of the vagina and vulva is still on a clinical trial basis, as these tumors usually grow more slowly, and cytotoxic drug treatment has been palliative but not curative; these types of cancer are better controlled by surgery and radiation therapy, and chemotherapy should be considered only when these standard methods have proved ineffective.

Among the uncommon gynecologic cancers that may require chemotherapy are germ cell tumors of the ovary and primary ovarian, uterine, vaginal, or vulvar sarcomas. Because these tumors are rare, little is known about their sensitivity to antitumor drugs.

The Normal Cell Cycle

Figure 54B–1 represents the cell cycle in a clockwise progression. The phases and their durations are depicted, and the phases during which some specific chemotherapeutic agents exert their effects are included for reference.

Figure 54B–1.

Model of the cell cycle with progression proceeding clockwise. Phases and their durations are depicted, along with points in the cell cycle at which some chemotherapeutic agents exert their effects.

Cell Kinetics

Knowledge of tumor cells has been derived from clinical and laboratory methods of tumor growth measurement, including direct measurement of cell-cycle parameters, clinical measurement of doubling times, and use of biologic markers, such as hormone production or polyamines and other abnormal proteins. A knowledge of the terminology of cell kinetics is helpful in understanding the dynamics of tumor cells, in which some cells divide more slowly than others, some cells enter or leave a nondividing state, and some are lost from the tumor population entirely.

The mitotic index (MI) is the fraction of cells in mitosis in a steady-state condition. The MI may be calculated by giving a drug such as a *Vinca* alkaloid that halts further cellular progression through mitosis and then counting the number of cells in mitosis. Another method uses tritiated thymidine, which is incorporated only into the DNA of cells in the S phase; the tritiated thymidine emits rays that can then expose the silver in a photographic emulsion during cell mitosis to produce percent-labeled mitosis (PLM) curves. Radioactive tagging of DNA during synthesis provides the labeling index (LI), which is the percentage of cells in the S phase at a particular time.

Growth fraction (GF) is the overall proportion of proliferating tumor cells in a given tumor. The growth fraction is important because most antitumor drugs inhibit only proliferating cells. Thus a major difference between tumor and normal cell populations may be the relative percentage of each in the growth fraction. The

selective effect of antitumor drugs on tumor cells may be explained by the characteristic higher growth fraction of tumor cells. Toxicity results from the effects of antitumor drugs on normal cells in the mitotic cycle or growth fraction; consequently, the toxicity of most antitumor drugs occurs in those normal cell populations with rapid turnover, eg, the hematopoietic and gastrointestinal systems. Consequently, alopecia, bone marrow suppression and diarrhea are common side effects.

Cell-cycle time denotes the amount of time needed by a proliferating cell to progress through the cell cycle and produce a new daughter cell. Cell cycle times vary widely according to histologic type (18–217 hours in solid tumors), but are relatively constant for a specific tumor type.

Doubling time is the time required for the tumor cell population to double. Human tumors often have doubling times greater than those of comparable normal tissues and, in advanced stages of disease, may exhibit a range of doubling times, but 30–60 days is typical. In the model ascites system, cell doubling time remains constant at near 100% throughout almost the entire life cycle of the tumor, whereas in solid tumor systems, a gradual slowing of the tumor doubling time and reduction of the proliferation rate of cells occur with tumor enlargement as a result of decreased accessibility to nutrients.

Cell loss may be a major determinant of the tumor growth rate. Cells are lost from a tumor mass in various ways, including death, migration, and metastases. Cell loss is frequently high in advanced tumors.

Stem Cell Theory

The stem cell theory states that only certain relatively undifferentiated cells, or stem cells, of a particular tissue type are able to divide and reproduce the entire tissue. Examples include rapidly proliferating tissues such as bone marrow, the lining of the gastrointestinal tract, and the basal cell layer of the skin. In other words, most cells making up a particular tissue have matured or have become highly differentiated after clonal division from the reproducing cell or a specific stem cell.

Not all cells of a particular stem cell population are committed to division at a given time. A significant proportion of stem cells are in the G_0 , or resting phase, as is the case in normal bone marrow, in which at any one time from 15–50% of stem cells are in G_0 . Numerous stimuli may recruit this reserve (resting) population of stem cells into the cell cycle. The equilibrium between the number of cells in division and those at rest, and the requirement for controls on such growth, are important. Some of the controls are understood, whereas others are unknown.

The stem cell theory also describes neoplastic growth. The clonality of many tumors such as epithelial ovarian cancer suggests that tumors originate from single stem cells. Therefore, tumors may consist of a small percentage of stem cells that, as a result of failed growth control mechanisms, continuously provide malignant cells. Based on this assumption, any therapeutic intervention should target this stem cell population to avoid recurrences.

Cell-Kill Hypothesis

The fundamental kinetic consideration in cancer chemotherapy is the cell-kill hypothesis, which states that the effects of cancer chemotherapy on tumor cell populations demonstrate first-order kinetics; ie, the proportion of tumor cells killed is a constant percentage of the total number of cells present. In other words, chemotherapy kills a constant proportion of cells, not a constant number of cells. The number of cells killed by a particular agent or combination of drugs is proportional to one variable: the dose used. The relative sensitivity of cells is not considered, and the growth rate is assumed to be constant.

Because chemotherapy follows an exponential (log-kill) model, treatment may be said to have a specific exponential, or log-kill, potential. For example, a log kill of 2 reduces a theoretical human tumor burden of 10^9 cells to 10^7 cells. Although this represents a reduction of 99%, at least 10 million (10^7) viable cells remain. A

log kill of 3 achieves a reduction of 99.9%, but 1 million (10^6) cells remain. Theoretically, therefore, such fractional reductions by antineoplastic agents can never reduce a tumor cell population to zero. This traditional cell-kill model is based mainly on exponentially growing tumors in laboratory models, eg, L-1210 murine leukemia.

Although the cell-kill hypothesis probably explains some aspects of drug selectivity, other mechanisms are involved. The more responsive tumors are those with large growth fractions. Normal tissue can withstand greater cell loss caused by chemotherapy than can tumors, although the proportion killed in both systems may be identical.

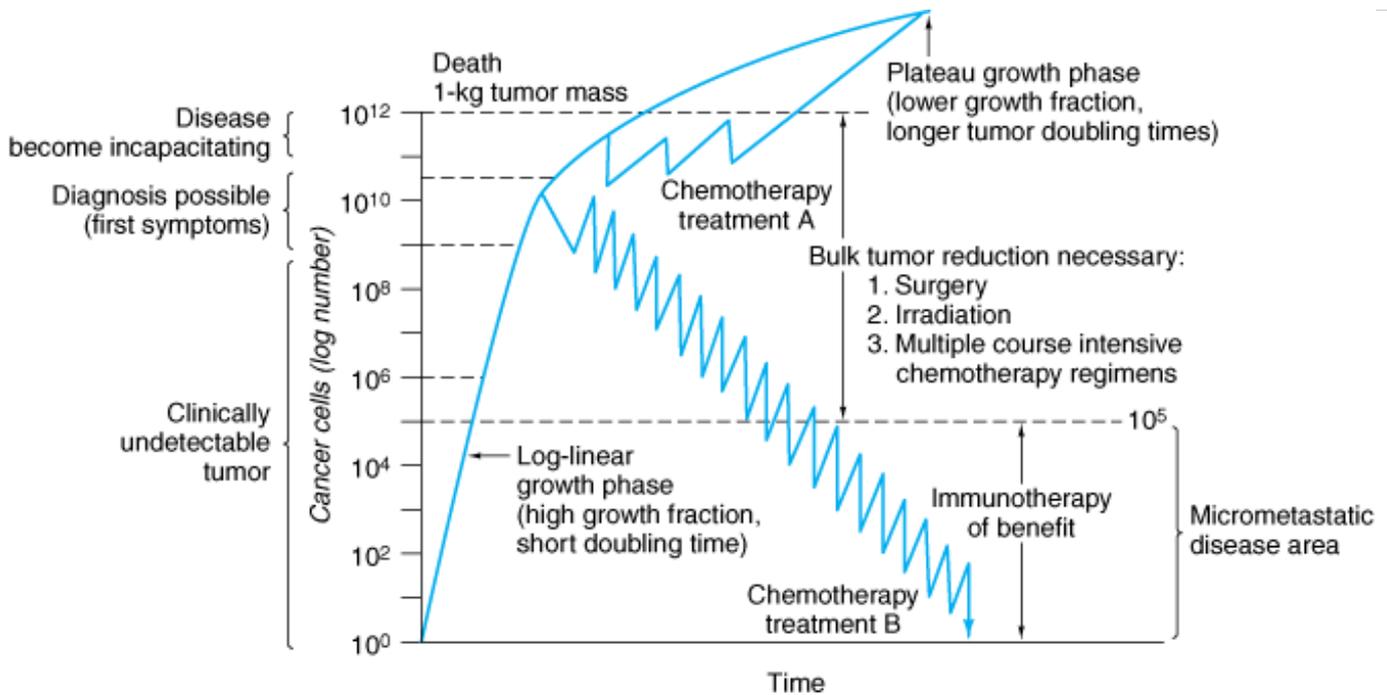

Another theory states that clinical tumor regression as a result of chemotherapy is best explained by the relative growth fraction in the tumor at the time of treatment. Thus very small and very large tumors are less responsive than those of intermediate size, which have the biggest growth fraction. Consequently, log kills occur only at times of maximal tumor growth fraction. Although this hypothesis has not been directly confirmed clinically, it explains some clinical observations of responses to chemotherapy in large and small human tumors.

Gompertzian Model of Tumor Growth

Gompertz, a German insurance actuary, depicted the relationship of an individual's age to the expected time of death by means of an asymmetric sigmoid curve. This mathematical model approximates tumor proliferation in experimental systems wherein tumors initially grow rapidly. As the tumor increases in size, a plateau effect develops, and the apparent doubling time is much longer than at the beginning.

Figure 54B–2 demonstrates several current chemotherapeutic principles plotted against a gompertzian tumor growth curve and the large tumor cell burden required to produce clinical expression of symptoms. The minimum palpable subcutaneous lesion is about 60 mg and contains 6×10^7 cells. In superficial tumors, 1 cm³ or 1 g of tumor is not an uncommon size at the time of diagnosis and contains about 10^9 cells, whereas most patients with visceral tumors of 10–100 g are estimated to have 10^{10} – 10^{11} tumor cells at the time of diagnosis. Because death occurs with a tumor burden of 10^{12} cells, which is only 1–2 orders of magnitude less than the total number of cells in the human adult, a significant proportion of the life cycle of a clinically recognizable tumor has already transpired when it is finally detected. The importance of early diagnosis of malignant disease is, therefore, even more essential.

Gompertzian tumor growth curve. The model depicts the relationship between tumor growth and diagnosis, appearance of symptoms, and various treatment regimens.

Figure 54B–2 illustrates the outcome of the two chemotherapeutic treatment regimens, A and B, the influence of the fractional kill achieved by drug therapy, and the effect of volume of tumor at the onset of therapy. Chemotherapy treatment A in a patient with a visceral solid tumor composed of 10^{11} cells achieves a good response when the tumor cell population is reduced by the characteristic percentage of first-order kill, regardless of the actual number of tumor cells present. Thus, an agent with a 1-log cell kill reduces the cell concentration by 90% from a palpable 10-g mass to a nonpalpable 1-g mass and induces an apparently tumor-free state, yet a residual tumor burden remains that may contain more than 1 billion cells. After a brief delay, the remaining 10% of tumor cells resume their former rate of proliferation. After tumor cell repopulation has occurred, treatment again results in reduction of tumor volume, but resistance develops that results in death of the host at a predictable time.

Although normal tissues do not develop resistance to antitumor drugs, the larger the initial tumor volume and the smaller the fractional kill, the more likely is the development of resistance in tumor cells. The effect of successive drug doses in sensitive tumors depends on the number of existing cells when treatment is begun, the fractional kill, the number of cells surviving the preceding treatment, and the tumor cell production between treatment cycles. Obviously, cell destruction must exceed cell production for chemotherapy to be successful.

Nonlethal damage to cells can occur as a consequence of chemotherapy and is well known after radiation therapy. Consequently, a key principle of theory is to schedule chemotherapy, radiation therapy, or both at appropriate intervals to allow normal cells to recover from nonlethal damage but to preclude the recovery of tumor cells, which is slower. It is important that the interval between treatments be reduced to the bare minimum required for restoration and recovery of normal tissues.

In chemotherapy treatment B, repeated doses of a chemotherapeutic agent are used to destroy a large tumor cell population. Such consecutive log-kill reductions cannot be consistently achieved because the cell-kill potential of a drug is limited in comparison with the size of the tumor cell population in most clinical situations;

however, in Fig 54B–2, a reduction of a 10^{10} (10 billion)-cell population by 90% as a result of a single course of drug therapy produces complete clinical remission. Repeated treatment at shorter intervals may result in enhanced destruction of tumor cells as long as toxic effects remain tolerable and resistant cell lines are not selected out by the drug. A drug becomes curative once the tumor cell kill exceeds the order of magnitude of repopulation and (statistically) less than one tumor cell remains. Additional courses of drug therapy are required to eradicate the last surviving cell of the so-called exponential iceberg if each course kills the same fraction of cells and not the same number.

On the other hand, fewer cycles of chemotherapy may produce a tumor-free host if subclinical tumor containing only 10^4 cells is present at diagnosis. Unfortunately, the usual inability to detect tumors so early in clinical situations makes this model less realistic.

Alternatively, the tumor population may be reduced by surgery or radiation so that subsequent adjuvant chemotherapy has a rational basis. Initial therapy for many solid tumors involves surgery or irradiation to reduce tumor bulk. Adjuvant chemotherapy, immunotherapy, or both are added as appropriate to eradicate micrometastatic or subclinical tumor masses. The same general principle guides therapy of hematologic cancer, in which intensive induction chemotherapy is used to achieve reduction of tumor bulk and induce remission; less-intensive consolidation and remission maintenance doses of chemotherapy are then used to control subclinical tumor burdens.

Effects of Chemotherapy on the Cell Cycle

Knowledge of the site of action of antitumor drugs within the mitotic cell cycle may help to explain the mechanism of their effectiveness and may suggest ways to enhance their carcinostatic properties.

Chemotherapy and radiation therapy are thought to alter the proliferation kinetics of both tumor and normal cells. Initially, individual sensitive cells are killed or incapacitated, thereby leaving a more resistant residual population. This large reduction in tumor cell mass stimulates recruitment of quiescent cells from G_0 into G_1 . This shift favors an increased growth fraction in the tumor, so that the LI and the MI are increased and tumor doubling times are decreased (ie, the tumor mass doubles in less time than before). The effect is a shift to the left along the gompertzian curve.

Some drugs may not kill cells but can halt or slow the progression of a cell through a particular phase of the cell cycle. Because cells accumulate in a particular phase, this process has been termed cell-cycle synchronization. Generally, these effects occur at lower doses than those necessary for cell killing. Blockage may be either temporary or permanent and does not occur predictably in all cell populations treated.

The effects of various classes of anticancer agents on tumors depend on the basic events occurring in the four main phases of the cell cycle and the pharmacologic mechanisms of drug action, and these cytotoxic effects influence the design of rational drug regimens. Two basic classes of antineoplastic drugs are recognized: cell cycle (phase)-specific agents and cell cycle (phase)-nonspecific agents.

CELL CYCLE (PHASE)-SPECIFIC DRUGS

Cell cycle (phase)-specific drugs are much more effective in tumors in which a large proportion of cells are actively dividing, as occurs when the cell mass is low. The major cytotoxic activities of anticancer drugs in this class are manifested during a particular phase of the cell cycle, and these drugs are technically phase-specific rather than cycle-specific agents. These drugs have been termed schedule-dependent agents because they produce a greater cell kill if the drug is given in multiple, repeated fractions rather than as a large single dose.

In pharmacologic terms, these cell cycle (phase)-specific agents are most often described as antimetabolites, because each drug causes some type of unique biochemical blockade of a particular reaction that occurs in a single phase of the cell cycle.

Most cell cycle (phase)-specific agents, such as methotrexate and fluorouracil, exert their most significant effects in the S phase. Corticosteroids and asparaginase appear to be most active in G_1 , bleomycin appears to be most active in G_2 , and the *Vinca* and podophyllin alkaloids have marked activity in the M and G_2 phases.

CELL CYCLE (PHASE)-NONSPECIFIC AGENTS

In contrast, the cell cycle (phase)-nonspecific agents are effective in large tumors in which the growth fraction, LI, and MI are low. Drugs in this group are dose-dependent, as a single bolus injection generally kills the same number of cells as do repeated doses totaling the same amount; ie, the degree of cell kill is directly proportionate to the absolute dose given. In pharmacologic terms, the alkylating agents are the prototypes of this class, which also includes the nitrosoureas, the anthracyclines, and others.

The cell cycle (phase)-nonspecific drugs do not require a large growth fraction to exert maximal effects. The effectiveness of their cytotoxic activities generally depends on cellular attempts either to divide or to repair drug-induced damage. The attempt to perform these activities triggers expression of the damage already sustained, and the cell dies. This mechanism of cell death is important, because cancer cells in G_0 (resting phase) are not generally susceptible to cytotoxic agents, with the possible exception of the cell cycle (phase)-nonspecific mustard-type alkylators and the nitrosoureas.

Selectivity of Anticancer Drugs

There is a common belief that cancer chemotherapy is generally nonselective and kills both normal and cancerous tissues. However, most anticancer drugs are more active against tumor than normal tissues. The cell-kill hypothesis probably explains some drug selectivity, but other mechanisms also are involved. The selectivity of cytotoxic agents appears to correlate inversely with cell-cycle specificity, as cell cycle (phase)-nonspecific agents, such as the nitrosoureas and mechlorethamine (an alkylator), tend to be more toxic in normal bone marrow than in tumor cells. The selectivity of most antitumor drugs must still be based largely on differences in the cell kinetics of normal and neoplastic cell lines. Normal systems can withstand greater cellular losses caused by chemotherapy than can tumors, even though the proportion of cells killed in both might be identical. Recovery from damage produced by a tumor-inhibiting drug may be more protracted in tumor cells than in normal host cells. Increased antitumor selectivity can be provided by the judicious use of a second dose of drug following return of normal tissue function but before recovery of tumor cell function. This approach to selective recovery from chemotherapeutic damage may provide enormous benefit by enhancing the antitumor activity of presently available drugs.

Most agents are equally effective at key enzymatic sites in either normal or neoplastic cells, but some anticancer drugs kill cancer cells by taking advantage of unique biochemical differences in the cancer cells; eg, the enzyme asparaginase takes advantage of a relative deficiency of aspartic acid synthetase in some leukemic cells to cause cell death. Cancer cells demonstrate a selective uptake of high concentrations of methotrexate, and this selectivity can be experimentally enhanced by vincristine or asparaginase and inhibited by aminoglycosides and cephalosporins.

Sensitivity to drugs based on the type of tissue is recognized in some anticancer agents; eg, the antimetabolite fluorouracil is more active in neoplasms arising from endodermal tissues such as the gastrointestinal tract and the breast. Dacarbazine has some selective action for melanoma cells, and bleomycin is active against epithelial tumors such as squamous cell cancers of the lung and cervix. When a tumor is derived from an organ characterized by a distinct biochemical feature (eg, the thyroid gland's ability to accumulate iodine, the sensitivity of the adrenal cortex to mitotane, or the selective destruction of the pancreatic islet cells by streptozocin), chemotherapy can be devised that attacks that tumor preferentially.

Although individual differences between the cells of a particular tumor and normal cells have been discovered, no single biochemical feature has been detected that pertains exclusively to one or the other. Studies suggest

numerous possibilities for exploiting small quantitative differences between tumor and normal tissue. These include selective uptake of drugs into tumors, enhanced anabolism in tumors of "prodrugs" requiring activation, diminished catabolism of drugs by tumors, diminished repair of tumor cell damage, and reduced availability of a protecting metabolite in tumor tissue.

Chemotherapy Resistance of Cancer Cells

A major problem in the treatment of cancers with chemotherapeutic agents is the development of drug resistance. According to the Goldie-Coldman hypothesis, most mammalian cells start with intrinsic sensitivity to antineoplastic agents but subsequently develop resistance at variable rates. This model has important clinical implications; tumors are only curable if no resistant cell lines are present or develop during the course of chemotherapy. To minimize the development of drug resistance, multiple-drug regimens are preferred to single-drug therapies.

Development of resistance is mainly based on the occurrence of spontaneous mutations, which occur at a frequency of 1 in 10,000 to 1 in 1,000,000 cells. Mechanisms of drug resistance involve decreased cellular uptake or increased efflux of the chemotherapeutic agents via cellular pumps, decrease in drug activation, increase in drug degradation, inactivation of active metabolites by binding to sulfhydryl compounds, increase in DNA repair mechanisms, or increase in level of target enzyme (dihydrofolate reductase). Several genes have been implicated in drug resistance, eg, the multiple-drug resistance (MDR) gene. Gene therapy approaches are currently being studied to reverse drug resistance in tumor cells. Alternatively, the transfer of drug resistance genes into normal cells like bone marrow cells might confer increased protection to chemotherapeutic agents and possibly allow a dose increase.

Poor Host Defenses

The normal individual's immunologic defenses against an invading tumor cell population are unreliable and still poorly understood. They operate only if the tumor mass is relatively small, and they become less effective as the person ages. As tumor growth progresses, the body's diminishing immunocompetence compounds the difficulties of therapy. A complicating factor is the immunosuppressant properties of most antitumor drugs. Treatment schedules to minimize immunosuppression while permitting adequate therapeutic effectiveness should be more intensive but actually must be practiced sparingly because of the lack of antitumor selectivity.

Protected Tumor Sanctuaries

Antitumor drugs frequently fail to reach all sites of tumor cells, and so-called sanctuaries may exist that permit the establishment and unimpeded proliferation of a tumor once it has been successfully eradicated from the remainder of the body. Sanctuaries may develop because of the metastatic spread of tumors to distant sites, and the problem may be accentuated by a lack of knowledge regarding the mechanism of drug access to such secondary neoplasms and their susceptibility to various drugs.

The central nervous system is impermeable to many drugs and often represents such a protected site. Attempts to reach sequestered cells have included intrathecal administration of drugs or use of more highly lipid-soluble drugs capable of rapidly penetrating the blood-brain barrier. The success of peripheral chemotherapy in the leukemias is partly a result of the ease with which high levels of drug can be achieved in tumor cells; on the other hand, leukemic cells that have penetrated the central nervous system are no longer affected by most drugs and the disease progresses.

A more common problem, however, is the diminished blood supply in many solid tumors that blocks delivery of antitumor drugs to the tumor core, which, although necrotic, may still contain active cells sensitive to antitumor drugs. It should be remembered that high doses of radiation (as used in the primary treatment of many gynecologic cancers) produce vascular damage leading to the formation of ischemic sanctuaries for cells that might otherwise be sensitive to drug treatment.

Secondary Malignancies

Antineoplastic agents have the potential to induce secondary malignancies. The alkylating agent melphalan is associated with a cumulative 7-year risk of acute nonlymphocytic leukemia in 9.6% of patients treated for more than 1 year. The development of acute leukemia is also associated with combined chemotherapy and radiation. Secondary malignancies usually occur between 4 and 7 years after successful therapy.

Route of Administration

Chemotherapeutic drugs can be administered orally, intravenously, intramuscularly, intraperitoneally, or intra-arterially. Pleural and intraperitoneal clearance of the agent is usually slower than plasma clearance, leading to prolonged and increased concentrations of the drug. Clinical trials in ovarian cancer have used intraperitoneal cisplatin and paclitaxel with significantly improved survival compared to systemic chemotherapy. The treatment is usually well tolerated. Frequent local side effects include peritoneal irritation with abdominal discomfort and complications related to the intraperitoneal administration, such as infection at the catheter site. Systemic side effects were unexpectedly reported to be worse with intraperitoneal treatment.

Principles of Clinical Chemotherapy

The chief aim of therapy is to achieve maximum cell kill with minimum toxicity. To this end, the dose and schedule of drugs critically influence the therapeutic index. The steep dose–response curve for most drugs indicates that the highest tolerable dose producing an acceptable degree of reversible toxicity should be used in the treatment of sensitive tumors, in which a 2-fold increase in dose may produce a 10-fold increase in the fractional kill.

Therapy must also take into account the length of time a therapeutic concentration of drug is maintained. The maximal effectiveness of some oncolytic drugs depends mainly on peak tissue concentration, whereas that of others depends on the duration of exposure.

In principle, a therapeutic concentration of the cell cycle (phase)-specific drugs is best maintained by 5-day courses of treatment (about 2 average cell-generation times). Such prolonged exposure permits a higher fraction of proliferating cells to pass through vulnerable phases of the cell cycle, as proliferating cells do not progress through the cell cycle in a synchronized fashion. In contrast, the cell cycle (phase)-nonspecific drugs are best administered as an intravenous bolus of the highest tolerable dose, and the dose repeated when normal target tissues have recovered.

High-dose, intermittent therapy has been the most successful schedule against tumors with a large growth fraction. Slow-growing tumors have a large component of permanently nondividing cells and a small growth fraction. Theoretically, drugs active against cells in G_0 and given on a continuous basis should produce the best results in these tumors.

Chronic therapy is feasible only if toxicity is negligible. Some myelosuppression is acceptable, as recovery occurs between treatment cycles. Immunosuppression is a side effect of most cytotoxic drugs and is more pronounced when drugs are given continuously.

Antitumor drugs have been combined concurrently or sequentially in an effort to increase their effectiveness. It is logical to assume that drugs with different dose-limiting toxicities and different modes of action may increase the fractional cell kill without a parallel rise in damage to normal tissues and immunocompetent cells. Because tumors are composed of numerous cell clones that vary in their sensitivity to drugs, the use of multiple agents should lessen the chance of development of resistance and repopulation of the tumor by a resistant cell clone. Sequential, concomitant, or complementary blockade of metabolic pathways should avoid the problem of drug resistance secondary either to the use of alternative pathways or the emergence of a protective random mutation.

As a rule, drugs selected for multidrug therapy must be effective as single agents if improved results are to be expected. Unfortunately, the toxicities of most antitumor drugs are similar, and selecting drugs that have no overlapping side effects is usually not possible. Nevertheless, combination chemotherapy has proved superior to single-agent therapy in leukemia, lymphoma, and some rapidly proliferating solid tumors, including ovarian cancer.

In summary, successful drug therapy requires the administration of an effective agent using the best possible dose and schedule. The tumor must have a high growth fraction and must be accessible to drugs so that they can exert their antitumor effects (ie, cells must not be in tumor sanctuaries). The tumor volume must be small or the fractional cell kill large to avoid the emergence of a resistant cell clone or the development of tolerance in previously sensitive cell clones. Normal tissue must recover from drug injury faster than tumor can regenerate to pretreatment levels.

CANCER CHEMOTHERAPEUTIC AGENTS

Cancer chemotherapeutic agents are commonly classified into six general categories on the basis of their mechanism of action: alkylating agents, antimetabolites, plant alkaloids, miscellaneous agents, hormonal agents, and immunotherapeutic agents. This section presents a broad overview of the mechanism of action and general toxicities of the four major groups of cytotoxic cancer chemotherapy drugs.

Alkylating Agents

CLASSIC ALKYLATING AGENTS

The alkylating agents evolved from products developed for chemical warfare. The parent chemical, dichlorethyl sulfide (sulfur mustard), was first synthesized during the mid-19th century and used during World War I because of its blistering properties on skin and mucous membranes. These agents also produced atrophy of lymphoid and myeloid tissues, a finding that led workers to explore their use in treating lymphomas and leukemias.

The 3 chemical subgroups of classic alkylating agents in use today are (a) the bis(chloroethyl)amines, which include chlorambucil, cyclophosphamide, ifosfamide, mechlorethamine, melphalan, and uracil mustard; (b) the ethyleneimines, which include triethylenethiophosphoramide (thiotepa); and (c) the alkylsulfonates, which include busulfan and improsulfan hydrochloride.

Alkylating agents induce cytotoxic effects on cells by binding to DNA, particularly at the N-7 position of guanine. This binding interferes with correct base pairing and produces single- and double-stranded DNA breaks. Consequently, DNA replication in S phase is inhibited. In addition to these cytotoxic and mutagenic effects, alkylating agents also inhibit cellular glycolysis, respiration, and synthesis of various enzymes, protein, and nucleic acids.

Most alkylating agents are cell cycle (phase)-nonspecific drugs that are active against both resting and dividing cells; thus they are effective in tumors with a small growth fraction. Cyclophosphamide is unique in that it appears to inhibit DNA synthesis in certain tumors and may therefore have some cell cycle (phase) specificity in the S phase not possessed by the other alkylating agents.

The major toxicities associated with the classic alkylating agents are related to their cytotoxic effects, although each drug has its own unique side effects. Normal tissues most affected are those with a rapid growth rate, eg, the hematopoietic system, the gastrointestinal tract, and gonadal tissue. Nausea and vomiting occur with use of most of these agents, particularly with the intravenous route, and may result from a direct effect on the chemoreceptor trigger zone in the medulla. If extravasation of mechlorethamine occurs during administration or if skin or mucous membranes are exposed to this agent, tissue necrosis develops, and sloughing will occur later, producing a slow-healing ulcer. The myelosuppression associated with classic alkylating agents is mainly a leukopenia, with the lowest cell counts occurring in 10–14 days and recovery occurring in 21–28 days.

Busulfan and chlorambucil have slightly more prolonged myelosuppressive effects. Bone marrow depression causes the most serious complications of therapy associated with the alkylating agents; patients are at increased risk for bleeding episodes caused by thrombocytopenia and infection caused by leukopenia. Anemia from depressed levels of erythrocyte production occurs less frequently.

NITROSOUREAS

The nitrosoureas include carmustine (BCNU), lomustine (CCNU), semustine (methyl CCNU), estramustine, streptozocin, and chlorozotocin. Although nitrosoureas probably act mainly as alkylating agents, they may also cause the inhibition of several key enzymatic steps necessary for the formation of DNA. The cytotoxic activity of these drugs is thought to be mediated through the action of metabolites that can alkylate DNA. Like other alkylating agents, the nitrosoureas are cell cycle (phase)-nonspecific. The nitrosoureas are lipid-soluble and cross the blood–brain barrier. These agents may undergo some enterohepatic circulation, but they are rapidly metabolized. The largest fraction of these drugs is excreted in the urine as metabolites, with only a small fraction excreted in the active form. Streptozocin is a naturally occurring nitrosourea that is particularly useful in the treatment of insulinomas because of its marked specificity for pancreatic β and exocrine cells.

The major adverse reaction associated with the nitrosoureas is a notable delayed and dose-dependent depression of the hematopoietic system occurring with commonly used dosage levels. In contrast to the classic alkylating agents, maximal depression of the white cell count occurs in 3–5 weeks with use of the nitrosoureas; it may persist for several weeks or longer. Severe nausea and vomiting may limit the dosage that can be given. Pain at the injection site is associated with the use of carmustine.

ANTI-TUMOR ANTIBIOTICS

The antitumor antibiotics are products of microbial fermentation and include the anthracyclines and the chromomycins. Although most antitumor antibiotics exert some antimicrobial properties, the cytotoxic effects of these agents generally preclude their use as such.

Anthracyclines

The anthracyclines include daunorubicin, doxorubicin, and rubidazole. These drugs effectively interfere with nucleic acid synthesis and block DNA-directed RNA and DNA transcription. The anthracyclines are probably effective in all phases of the cell cycle and are therefore cell cycle (phase)-nonspecific.

Disposition kinetics of the anthracyclines are complex. Their half-life is relatively long, ranging from 15 hours to several days for doxorubicin. These drugs are extensively metabolized in the liver, and some of the metabolites retain antitumor activity. Biliary excretion appears to be the major means of elimination, but a small portion of drug is excreted in the urine.

Many of the adverse effects of the anthracyclines are similar to those of the alkylating agents. Acute toxicity is manifested as bone marrow depression that may be severe enough to require limiting of dosage; the nadir usually occurs in 10–14 days, with recovery by 21 days in most patients. The anthracyclines also produce tissue necrosis and sloughing if extravasation occurs during intravenous injection. A unique cardiomyopathy has been observed when high cumulative doses of the anthracyclines have been administered.

Chromomycins

Another group of antitumor antibiotics is the chromomycins, which include chromomycin A₃, mithramycin (plicamycin), and dactinomycin. All act similarly to block DNA-directed RNA synthesis by intercalating and anchoring in DNA, as do the anthracyclines. Bone marrow depression because of use of chromomycins is a significant, but usually not dose-limiting, toxicity characterized by thrombocytopenia with some leukopenia.

Chromomycin A₃ (totomycin) is rapidly cleared from plasma, is excreted via the urinary and biliary tracts, and causes nausea and vomiting, renal toxicity, and severe local reactions at the injection site.

Mithramycin crosses the blood–brain barrier and is well distributed in the cerebrospinal fluid. It is excreted mainly in the urine. Gastrointestinal effects include nausea and vomiting, anorexia, and diarrhea. Liver and kidney toxicity is common. A toxicity unique to this agent is a hemorrhagic syndrome heralded by facial flushing. Mithramycin has been used to lower serum calcium levels in patients with hypercalcemia.

Dactinomycin is rapidly cleared from serum and is excreted mainly in the bile with minimal biotransformation. Gastrointestinal effects include mucositis characterized by oral ulceration. Nausea and vomiting may be severe enough to limit the dosage. Other toxicities include bone marrow depression and alopecia.

Other Antitumor Antibiotics

Other antitumor antibiotics include mitomycin, piperazinedione, and bleomycin. Mitomycin probably functions as an alkylating agent by causing cross-linking of DNA. Mitomycin is rapidly cleared from the vascular compartment and is found in most body tissues except the brain; it is excreted via the kidneys and in bile. Delayed bone marrow depression may occur, with the nadir occurring 3–5 weeks after administration. Myelosuppression may be more severe with repeated doses and is the major dose-limiting toxicity. Renal toxicity may be observed, whereas gastrointestinal effects and alopecia occur less frequently.

Piperazinedione appears to function as an alkylating agent by inhibiting the incorporation of several DNA nucleotides into DNA synthesis. Although cell progression through G₂ is delayed, piperazinedione is probably not cell cycle (phase)-specific. Myelosuppression is the major dose-limiting toxic effect and is manifested as granulocytopenia followed by thrombocytopenia, with the nadir and recovery from myelosuppression varying by patient. The level of activity against neoplasms resistant to alternative alkylating agents and antimetabolites has not been high enough to warrant expanded clinical trials.

Bleomycins are antineoplastic antibiotics produced by fermentation of *Streptomyces verticillus*. More than a dozen fractions have been isolated, but the major constituent of commercially available preparations is bleomycin A₂. Inasmuch as the exact composition of the drug may vary, the drug is rated in units of activity. Bleomycin contains DNA- and ion-binding moieties. The mechanism of action most likely involves the production of single- and double-stranded breaks leading to inhibition of DNA synthesis, and to a lesser extent, inhibition of RNA and protein synthesis. Bleomycin is cell cycle (phase)-specific for mitosis and G₂. This cycle specificity has been useful experimentally to achieve cell-cycle synchronization in combination chemotherapy. Bleomycin appears to exert much less myelosuppressive activity than most other antineoplastic drugs and is therefore useful in patients who already have depressed bone marrow counts. Cutaneous reactions are dose-related and include hyperpigmentation, edema, erythema, and thickening of the nail beds. They are the most common side effects because the drug is concentrated in the skin. The most serious toxicity is pneumonitis related to the total dose received; the disease is characterized by dyspnea, rales, and infiltrates that progress to fibrosis. A high incidence of hypersensitivity reactions ranging from fever and chills to anaphylaxis is also associated with bleomycin.

Antimetabolites

The antimetabolites exert their major activity during the S phase and therefore are most effective against tumors that have a high growth fraction. The antimetabolites are structural analogues of naturally occurring metabolites and interfere with normal synthesis of nucleic acids by substituting different compounds for the normal purines or pyrimidines in metabolic pathways. The antimetabolites are subdivided into the folate antagonists, the purine antagonists, and the pyrimidine antagonists.

FOLATE ANTAGONISTS

Methotrexate is a 4-amino-4-deoxy-*N*-methyl analogue of folic acid and is the classic antimetabolite prototype. Methotrexate is a cell cycle (phase)-specific agent that exerts its cytotoxic effect in the S phase by binding to dihydrofolate reductase, thereby blocking the reduction of folic acid. Thymidine and purine synthesis are halted,

thus arresting DNA, RNA, and protein synthesis. For maximal effect, intracellular levels of methotrexate must be sufficiently high to bind almost all of the dihydrofolate reductase, of which only small quantities are required to maintain adequate levels of the reduced folate pool. Resistance is thought to develop as a consequence either of increased levels of dihydrofolate reductase or of decreased cell uptake.

Methotrexate enters the cell through an active carrier-mediated cell membrane transport system that it shares with leucovorin calcium (folinic acid, citrovorum factor) and its metabolite, 5-methyltetrahydrofolate. When this transport system is functional in tumor cells, adequate intracellular levels of methotrexate are easily achieved. Because some tumors lack or have reduced transport capabilities, high levels of methotrexate are required to facilitate transport by a passive method instead. To limit toxicity, treatment requiring high doses of methotrexate is followed by "rescue" of normal cells with leucovorin calcium.

Another antifolate is ethane sulfonic acid compound, or Baker's antifol (triazinate). It is actively transported into the cell by a different transport carrier than is methotrexate, but the target enzyme is the same. Thus, these two antifolates may have different tumor specificity, even though their general mechanism of action is the same.

Both compounds produce bone marrow depression, with the lowest cell counts occurring in 7–14 days. Stomatitis and gastrointestinal distress are frequent. Skin rashes are common side effects of ethane sulfonic acid compound, but occur in fewer patients treated with methotrexate. Central nervous system abnormalities may also occur with either agent.

PURINE ANTAGONISTS

Mercaptopurine and thioguanine are analogues of the natural purines hypoxanthine and guanine. The purine antagonists have specific antitumor effects on the S phase.

Mercaptopurine acts as a false metabolite because of its close chemical similarity to hypoxanthine. It competes for the enzymes responsible for the conversion of inosinic acid to adenine and xanthine ribotides, and thus interferes with normal DNA and RNA synthesis. Simultaneous administration of allopurinol may block the metabolism of mercaptopurine and azathioprine by xanthine oxidase and require reduction of the dose to one-fourth or one-third the normal amount. This drug interaction does not occur with thioguanine, because its detoxification occurs by methylation.

Thioguanine also acts as a false metabolite; its substitution for the corresponding guanine nucleotide blocks purine synthesis.

The indications for use and efficacy of thioguanine and mercaptopurine are the same. Their toxicities are identical, and the two drugs are mutually cross-resistant.

Azathioprine is an imidazolyl derivative. It is used as an immunosuppressant but has cytotoxic properties similar to those of mercaptopurine and thioguanine because it is extensively metabolized to mercaptopurine.

The major dose-limiting toxicity of the purine antagonists is myelosuppression consisting mainly of leukopenia, with lesser effects on platelets and red blood cells. Gastrointestinal distress is common, and hepatotoxicity may occur with use of any of the purine antagonists.

PYRIMIDINE ANTAGONISTS

Fluorouracil (5-fluorouracil, 5-FU) is the classic antimetabolite. It is cell cycle (phase)-specific and inhibits the enzyme thymidylate synthetase to block DNA synthesis. It is catabolized in the liver by dihydrouracil dehydrogenase.

Ftorafur is hydrolyzed to 5-FU in the liver and stomach and therefore may act as a depot form of 5-FU.

Fluorouracil and ftorafur cause myelosuppression that reaches a nadir in 1–14 days, but ftorafur appears to

cause less myelosuppression, which may be a result of its slower release of 5-FU. Both agents commonly produce gastrointestinal toxicities, including occasional glossitis and stomatitis. Neurotoxicities may also occur because these drugs cross the blood–brain barrier.

The cytidine and deoxycytidine analogues include gemcitabine, cytarabine, cycloctidine (ancitabine), and azacitidine. The active form of these nucleoside analogues stops DNA synthesis by competitively inhibiting DNA polymerase and production of deoxycytidine. Cytarabine is metabolized by cytidine deaminase in the liver, granulocytes, and gastrointestinal tract. Small amounts of cytarabine cross the blood–brain barrier. Because cycloctidine is not inactivated by cytidine deaminase, it slowly releases the more active cytarabine, which prolongs plasma levels; cycloctidine can therefore be regarded as a depot form of cytarabine that has a biphasic half-life occurring at 3–15 minutes and at 2 hours.

Cytarabine and cycloctidine are active only in the S phase. Although azacitidine is most active during the S phase, it appears to exert activity in all phases of the cell cycle by inhibiting DNA, RNA, and protein synthesis. Although it has some cross-resistance with the other cytidine analogues, this is not complete. These facts suggest that azacitidine has an additional mechanism of action not found in cytarabine and cycloctidine.

The toxicities of gemcitabine, cytarabine, cycloctidine, and azacitidine are similar to those of other pyrimidine antagonists and include myelosuppression and gastrointestinal abnormalities, which may be severe. Cytarabine produces a flulike syndrome, and cycloctidine commonly produces unusual jaw pain and hypotension.

Plant Alkaloids

VINCA ALKALOIDS

Although the periwinkle plant has a long history in folklore medicine, clinical research to evaluate its possible therapeutic effects was not begun until 1945; by 1958, several active alkaloids had been isolated, but to date, only vinblastine and vincristine have had extensive clinical use. Although they are quite similar chemically and structurally, vincristine and vinblastine have markedly different clinical activities and toxicities. The precise mechanism of action of these compounds is not clearly understood, but they appear to cause arrest of metaphase by crystallization of the microtubular spindle proteins. *Vinca* alkaloids may also inhibit nucleic acid and protein synthesis, but these effects become apparent only after high concentrations are reached. There appears to be no cross-resistance between the *Vinca* alkaloids and radiation therapy, alkylating agents, or each other. The differences in their therapeutic spectrum, toxicity, and potency may be related to each drug's ability to enter different types of cells.

The dose-limiting toxicity of vinblastine and vindesine is bone marrow depression, manifested chiefly by leukopenia 4–10 days after administration, with recovery occurring within 10–21 days. Vincristine does not usually cause leukopenia and can be given with relative safety to leukopenic patients.

Neurotoxicity is a major dose-limiting effect of vincristine and vindesine, but occurs infrequently with vinblastine. Vincristine neurotoxicity consists of peripheral neuropathy with loss of deep tendon reflexes, numbness, and, eventually, severe weakness. Cranial nerve palsies, vocal cord paralysis, and autonomic nervous system dysfunction, manifested as urinary retention, tachycardia, or gastrointestinal symptoms of constipation or paralytic ileus may occur. All of the *Vinca* alkaloids cause severe local necrosis if extravasation occurs, and vindesine may produce pain and phlebitis even without evidence of infiltration.

PODOPHYLLOTOXINS

The two podophyllotoxins presently used are semisynthetic compounds derived from the root of the mayapple plant. The mechanism of action of etoposide (VP-16) and teniposide (VM-26) is similar to that of *Vinca* alkaloids in that they cause a mitotic spindle toxicity resulting in arrest of metaphase. Podophyllotoxins prevent cells from entering mitosis, thereby causing an increase in the MI; at high concentrations, the drugs cause lysis of cells entering mitosis. They also suppress DNA synthesis and, to a lesser degree, RNA and protein synthesis.

Thus both the *Vinca* alkaloids and podophyllotoxins are cell cycle (phase)-specific and exert their major activity in the M phase; they also demonstrate some activity in the G₂ and S phases.

Etoposide and teniposide are extensively protein-bound and are mainly eliminated by biliary excretion, with some enterohepatic recirculation. Both drugs may cause severe hypotension if infused too rapidly. Other adverse effects include nausea and vomiting, diarrhea, alopecia, and phlebitis at the injection site. The podophyllotoxins produce mild bone marrow depression and leukopenia, with the nadir occurring from 3–14 days following therapy.

TAXANES

The taxanes, paclitaxel and docetaxel, are relatively novel antimetabolic agents. Taxanes arrest cells at the G₂ /M phase of the cell cycle by preventing depolymerization of the microtubuli structure. The cells therefore are unable to divide and will eventually undergo apoptosis. Both taxanes have demonstrated significant activity against many solid tumors as single agents and in combination with other chemotherapeutic agents. In addition, taxanes have been used in combination with chemotherapy in a variety of cancers including non-small cell lung cancer (NSCLC), cancers of the head and neck, and cancers of the gastrointestinal tract.

Paclitaxel has been used extensively in patients with gynecologic malignancies, particularly ovarian and endometrial cancer. Major side effects include bone marrow toxicity, hypersensitivity reactions, arthralgias, peripheral neuropathy, and alopecia.

Miscellaneous Agents

Cisplatin was the first inorganic compound to be used to treat human cancers. Crosslinking of DNA may be somewhat different from that of other alkylators, in that the interatomic distance is much smaller than with the traditional alkylating agents; this characteristic may account for some of the toxicity associated with cisplatin. Cisplatin is cell cycle (phase)-nonspecific and is excreted mainly unchanged in the urine. Adverse reactions include anaphylaxis, nausea and vomiting, nephrotoxicity, ototoxicity, and myelosuppression that is usually mild.

Carboplatin is a derivative of cisplatin with equal clinical efficacy. Compared to cisplatin, it causes more hematopoietic toxicity but less ototoxicity, neuropathy, and nephrotoxicity.

Dacarbazine was originally thought to be an antimetabolite but is now recognized as an alkylating agent that is activated in the liver and excreted in the urine. It has somewhat less bone marrow toxicity than standard alkylating agents but typically causes severe nausea and vomiting similar to that caused by cisplatin.

Hexamethylmelamine does not act as an alkylating agent in vitro, even though it is structurally similar to triethylenemelamine, which is an alkylator. Although the precise mechanism is unknown, it is possible that hexamethylmelamine is activated to an alkylating agent in vivo. Hexamethylmelamine is rapidly metabolized in the liver and excreted in the urine. Gastrointestinal, neurologic, and hematologic toxicities occur.

Hydroxyurea is cell cycle (phase)-specific for the S phase. In addition to holding cells in G₁, the drug exerts a lethal effect on cells in the S phase by inhibiting ribonucleotide reductase and DNA synthesis without interfering with RNA or protein synthesis. Hydroxyurea may also act as an antimetabolite in that incorporation of thymidine into DNA appears to be inhibited. The major adverse reactions are bone marrow depression, gastrointestinal disturbances, and rarely, dermatologic reactions and renal impairment.

Procarbazine appears to be cell cycle (phase)-specific for the S phase; it apparently interferes with DNA synthesis, but its exact mechanism of action is unclear. Oxidative breakdown products, hydrogen peroxide, formaldehyde, azoprocarbazine, and free hydroxyl radicals may be responsible for the characteristic chromosomal breakage observed after use of procarbazine. Procarbazine may demonstrate dangerous interactions with a number of other drugs. Adverse reactions include myelosuppression, a flulike syndrome, and

dermatologic and various central nervous system reactions.

Topotecan is a semisynthetic inhibitor of topoisomerase I. It is cycle (phase)-specific for the S phase and is excreted in urine. Myelosuppression is a dose-limiting reaction. Nausea and vomiting are common, but mild.

Most normal cells possess the ability to synthesize the amino acid asparagine. Some tumor cells, such as those in acute lymphoblastic leukemia, do not possess this ability and require exogenous asparagine. Asparaginase converts asparagine to nonfunctional aspartic acid, thereby depriving the tumor cell of this crucial amino acid to block protein synthesis. Side effects include protein depletion and pancreatic and hepatic damage. Allergic reactions are frequent, as asparaginase is a biologic product obtained from bacteria.

Chemotherapy in Gynecologic Cancers

OVARIAN CANCER

Chemotherapy is standard in most ovarian cancers after initial surgery. Of all gynecologic malignancies, ovarian cancer responds best to chemotherapeutic regimens. A wide variety of antineoplastic drug regimens have been studied during the past two decades to determine the optimal choice of drugs, route, and timing of administration.

Currently, systemic chemotherapy with a platinum-based drug (cisplatin or its derivative, carboplatin) and paclitaxel is the most commonly used drug regimen in epithelial ovarian cancer. In patients with hypersensitivity to paclitaxel, an alternative drug like cyclophosphamide or topotecan is substituted.

Another modality being used in the first-line treatment of epithelial ovarian cancer is intraperitoneal chemotherapy. The rationale for intraperitoneal therapy is for the peritoneum, the primary site of ovarian cancer, to receive sustained exposure to the chemotherapeutic agent while sparing normal tissues such as the bone marrow. In optimally debulked stage III ovarian cancer patients, intraperitoneal and intravenous administration of paclitaxel/cisplatin has shown a statistically significant increase in survival when compared to administration of intravenous chemotherapy alone.

Treatment of malignant germ cells of the ovary are currently platinum-based chemotherapy combinations such as bleomycin, etoposide, and cisplatin (BEP). The treatment of refractory or recurrent ovarian cancer is not standardized. Patients that are resistant to platinum-based regimens are likely to be resistant to other drugs. Agents that have shown effects in these clinical situations include the topoisomerase I inhibitor topotecan, etoposide, the semisynthetic taxane docetaxel, liposome-encapsulated doxorubicin, and gemcitabine. In general, these drugs show a 13–26% clinical response rate in cisplatin-refractory and recurrent ovarian cancer.

ENDOMETRIAL CANCER

Chemotherapy in endometrial cancer is mainly confined to patients with advanced or recurrent metastatic disease. The most active single agents are doxorubicin, platinum-based regimens, and paclitaxel.

CERVICAL CANCER

Chemotherapy combined with concurrent radiation therapy (chemoradiation) is an important modality in the treatment of cervical cancer. The chemotherapeutic agents shown to be most effective are cisplatin or a combination of cisplatin and 5-FU. In a series of clinical trials, the combination of platinum-based chemotherapy with radiation showed increased survival rates in cervical cancer in early stage disease. Patients with bulky stage IB cervical cancer showed significantly prolonged survival and disease-free intervals when preoperative radiation was combined with cisplatin chemotherapy. Patients with locally advanced cervical cancer showed a 30% reduction in the risk of death for women receiving platinum-based chemoradiation compared with radiation therapy alone.

Current OB/GYN > Chapter 55. Infertility >

INFERTILITY: INTRODUCTION

The number of infertility visits has increased over the past decades. In some cases, couples have voluntarily delayed childbearing in favor of establishing careers and may experience an age-related decline in fertility. There have been significant advances in assisted reproductive technologies, from improved embryo culture media to intracytoplasmic sperm injection (ICSI) and preimplantation genetic diagnosis (PGD), which have resulted in remarkable increases in in vitro fertilization-embryo transfer (IVF-ET) pregnancy rates. This coupled with increasing public awareness and acceptance of assisted reproductive technology (ART) have spurred women or couples with infertility to seek medical care.

Definition

Infertility is defined as the inability of a couple to conceive within 1 year. Sterility implies an intrinsic inability to achieve pregnancy, whereas infertility implies a decrease in the ability to conceive and is synonymous with subfertility. Primary infertility applies to those who have never conceived, whereas secondary infertility designates those who have conceived at some time in the past.

Fecundity is the probability of achieving a live birth in 1 menstrual cycle. Fecundability is expressed as the likelihood of conception per month of exposure. Fertility, as well as infertility, of a woman or couple is best perceived as fecundability, as few infertile patients are sterile. It also allows for a direct comparison of treatment options over a more functional time frame.

Epidemiology

The prevalence of women diagnosed with infertility is approximately 13%, with a range from 7–28%, depending on the age of the woman. It has remained stable over the past 40 years; ethnicity or race appears to have little effect on prevalence. However, the incidence of primary infertility has increased, with a concurrent decrease in secondary infertility, most likely as a result of social changes such as delayed childbearing.

In normal fertile couples having frequent intercourse, the fecundability is estimated to be approximately 20–25%. Approximately 90% of couples with unprotected intercourse will conceive within 1 year. Sterility affects 1–2% of couples.

Etiology

Infertility can be due to either partner, or both. Overall, an etiology for infertility can be found in 80% of cases with an even distribution of male and female factors, including couples with multiple factors. A primary diagnosis of male factor is made in approximately 25% of cases. Ovulatory dysfunction and tubal/peritoneal factors comprise the majority of female factor infertility. In 15–20% of infertile couples, the etiology cannot be found and a diagnosis of unexplained infertility is made.

The success rates of treatment for infertility depends on a variety of factors, including cause of infertility, woman's age, duration of infertility, and treatment modality. Health insurance plans vary a great deal in the amount and type of infertility treatments that are covered. For those couples without infertility

coverage, treatment choices are dictated by medical and financial considerations. Not uncommonly, infertility treatment does not actually make the difference between conceiving and not conceiving, but allows for conception in the more immediate future rather than at a delayed point of time (increasing fecundability).

PSYCHOLOGIC ASPECTS

A diagnosis of infertility can be an assault on self-image, sexuality, and relationships. The emotional roller coaster ride begins with high hopes at the initiation of a cycle and culminates positively, but often negatively, on the day of the pregnancy test result. The couple may progress through stages as described by Kubler-Ross, including denial, anger, grief, and resolution. Recognition of these stages may assist the practitioner in providing appropriate support and counseling or referral for the additional therapy.

DIAGNOSIS

The armamentarium of diagnostic tests available for the evaluation of an infertile couple is large. Therefore, a clinician should be judicious in his/her use of tests. The history and physical exam shape the endocrinologic and radiologic testing algorithm specific to each patient. Other factors to consider include patient age, risks associated with the test, invasiveness, expense, and probabilities of significant findings (Table 55–1). The patient(s) should be included in the decision-making process.

Table 55–1. Causes of Infertility.

Male Factor	Peripheral defects
Endocrine disorders	Gonadal dysgenesis
Hypothalamic dysfunction (Kallmann's syndrome)	Premature ovarian failure
Pituitary failure (tumor, radiation, surgery)	Ovarian tumor
Hyperprolactinemia (drug, tumor)	Ovarian resistance
Exogenous androgens	Metabolic disease
Thyroid disorders	Thyroid disease
Adrenal hyperplasia	Liver disease
Anatomic disorders	Renal disease
Congenital absence of vas deferens	Obesity
Obstruction of vas deferens	Androgen excess, adrenal or neoplastic
	Pelvic Factor

Congenital abnormalities of ejaculatory system	Infection
Abnormal spermatogenesis	Appendicitis
Chromosomal abnormalities	Pelvic inflammatory disease
Mumps orchitis	Uterine adhesions (Asherman's syndrome)
Cryptorchidism	Endometriosis
Chemical or radiation exposure	Structural abnormalities
Abnormal motility	Diethylstilbestrol (DES) exposure
Absent cilia (Kartagener's syndrome)	Failure of normal fusion of the reproductive tract
Varicocele	Myoma
Antibody formation	Cervical Factor
Sexual dysfunction	Congenital
Retrograde ejaculation	DES exposure
Impotence	Müllerian duct abnormality
Decreased libido	Acquired
Ovulatory Factor	Surgical treatment
Central defects	Infection
Chronic hyperandrogenemic anovulation	
Hyperprolactinemia (drug, tumor, empty sella)	
Hypothalamic insufficiency	
Pituitary insufficiency (trauma, tumor, congenital)	

New Patient Assessment

The initial aspect of the interview includes discussion of the factors (ie, ovulation, sperm concentration, ovarian reserve, etc.) that affect fertility so that the patient(s) is aware of the potential etiologies. In this light, the physician can present an algorithm for the diagnostic evaluation that the patient will understand. This will help the patient grasp the peculiarities of the specific tests, such as timing the hysterosalpingogram to the day of the menstrual cycle, provide an opportunity for the patient(s) to ask fertility-related questions, and to address any information learned from friends, family, or the Internet.

The initial clinical assessment should begin with a thorough history of both partners. Factors to consider while obtaining the medical history are outlined in Table 55–2 for the female and in Table 55–3 for the male. The history should guide the physical examination beyond the general evaluation; for example, a rectovaginal exam to detect uterosacral ligament nodularity associated with endometriosis is indicated if a woman presents with a history of severe dysmenorrhea. However, a thorough physical exam may

divulge key information such as acanthosis nigricans and its association with insulin resistance.

Table 55–2. Medical History for Female Factor Infertility.

- In utero diethylstilbestrol (DES) exposure
- History of pubertal development
- Present menstrual cycle characteristics (length, duration, molimina)
- Contraceptive history
- Prior pregnancies, outcomes
- Previous surgeries, especially pelvic
- Prior infection
- History of abnormal Papanicolaou (Pap) smear, treatment
- Drugs and medications
- General health (diet, weight stability, exercise patterns, review of systems)

Table 55–3. Medical History for Male Factor Infertility.

- Congenital abnormalities
- Undescended testes
- Prior paternity
- Frequency of intercourse
- Exposure to toxins
- Previous surgery
- Previous infections, treatment
- Drugs and medications
- General health (diet, exercise, review of systems)
- Decreased frequency of shaving

The laboratory and radiologic tests assess four key aspects for fertility in a couple: the sperm (male factor), the oocyte (ovulatory factor and ovarian reserve), transport and implantation of ova (pelvic factor including fallopian tubes and uterus). In many cases, the couple will be attempting to absorb significant amounts of information, some of which may be highly technical, at a time of heightened emotion. It is therefore helpful to offer literature or a written summary of the discussion. Frequently, the

initial history will indicate a probable diagnosis or a contributing cause of infertility, but it is important to complete a basic evaluation of all of the major factors so a secondary diagnosis is not ignored.

Evaluation of Male Factors

Male factor is diagnosed in 25–40% of infertile couples. The majority of the diagnoses involve testicular pathology such as varicocele. Although validation is incomplete, there is a trend toward increasing use of molecular techniques to quantify the fertility potential of semen as our knowledge of fundamental molecular genetics expands. Experience and investigation have relegated several tests previously used to assess fertilization to historical interest. Beyond the history and physical exam, the initial evaluation of male factor is through semen analysis. If abnormal, the semen analysis should be repeated in 2–3 months to confirm findings.

SEMEN ANALYSIS

The male partner should abstain from coitus for 2–5 days before collecting the sample and the specimen should be received in the lab within 1 hour of collection. Table 55–4 lists normal sperm values. If fundamental parameters of count and motility are normal, the assessment of the morphology of the sperm becomes more critical. Specialized expertise in determining sperm morphology and strict application of criteria should be used before declaring the semen normal. The percent of sperm with normal morphology is the semen analysis parameter, which best correlates with pregnancy.

Table 55–4. Normal Semen Parameters.

Liquification	30 minutes
Count	20 million/mL or more
Motility	> 50%
Volume	2 mL or more
Morphology	≥ 30% normal
Strict criteria	> 14% normal
pH	7.2–7.8
White blood cell count	< 1 million/mL

The semen parameters in normal fertile males may vary significantly over time, and the first response to any abnormal result should be to wait an interval of several weeks to months and repeat the test. A normal semen analysis will usually exclude significant male factor. Although low counts, decreased motility, and increased numbers of abnormal forms are most frequently associated with infertility, unfavorable semen parameters may still be found in 20% of males undergoing vasectomy after having completed their families. If the semen analysis reveals abnormal or borderline parameters, the history should be reviewed for any proximate cause of an abnormality, keeping in mind that the cycle of spermatogenesis takes about 74 days. A male with less than 5 million sperm per milliliter warrants an endocrinologic evaluation including follicle-stimulating hormone (FSH), leuteinizing hormone (LH), and testosterone, or a karyotype in selected cases. The patient should be referred to an urologist with a special interest and expertise in infertility as indicated.

DNA ASSAYS

Several tests, including sperm chromatin structure assay (SCSA), comet, and terminal dUTP nick-end labeling (TUNEL), have been developed to quantify the damage to DNA or chromatin (packaged DNA). There is some evidence associating increased DNA damage as determined by these tests to poor fertility

outcome. The SCSA determines the percent of chromatin that is fragmented by exposing sperm DNA to acid denaturation (fragmented DNA is more vulnerable). Clinical experience has not matched initial expectations although the test may be useful for couples with unexplained infertility with repeated in vitro fertilization (IVF) failures. The comet assay consists of placing the sperm DNA on gel electrophoresis; DNA with increased strand breaks will be smaller and therefore travel further on the slide. The TUNEL assay identifies DNA strand breaks by their incorporation of labeled deoxyuridine triphosphate (dUTP). The comet and TUNEL assay are not in wide clinical use.

OTHER TESTS

More detailed assessment of sperm function may include postcoital test, antibody studies, a sperm penetration assay (hamster egg penetration assay). Such assessments are designed to investigate more subtle problems or abnormalities of function not revealed by the assessment of sperm number and motility. Although helpful in some cases, the sensitivity of these assays in detecting fertility is still uncertain and varies with the particular laboratory where the test is performed. Because no universal methodology has yet been accepted, the interpretation of these tests requires close communication with the laboratory selected.

Cervical mucus is a heterogeneous secretion containing more than 90% water. It has intrinsic properties including consistency, spinnbarkeit (stretchability), and ferning. When mucus is obtained from the cervical canal in the preovulatory phase, it normally exhibits a response to the high estrogen environment. The mucus is thin, watery, and acellular; it dries in a crystalline pattern (ferning), and acts as a facilitative reservoir for the sperm.

The functional sperm must interact normally with the egg and surrounding cells in the uterine tube. The normal migration of sperm is affected by attrition and filtering, and it is estimated that less than 1000 sperm will be found in the environment of the oocyte. The initial interaction of sperm and female genital tract can be determined by postcoital examination of the cervical mucus (Sims-Huhner test).

The purpose of the postcoital test is to determine the number of active spermatozoa in the cervical mucus and the length of sperm survival (in hours) after coitus. The test should be performed as close to ovulation as possible. The test involves aspirating cervical mucus with a syringe 6–8 hours after coitus and checking under a microscope for the number and the motility of the sperm; less than 10 motile sperm per high-power field is considered abnormal. The postcoital test is controversial and has limited use in the infertility work-up. Its value in assessing cervical hostility to sperm has never been proven.

Tests developed to predict the fertilizing ability of sperm include the zona-free hamster egg penetration test (the sperm penetration assay) and the hemizona test. These assays compare the ability of sperm to penetrate the zona-free hamster egg (a hamster egg in which the zona pellucida has been enzymatically digested) or to bind to human zona with sperm from a known fertile donor. The value of these tests remains controversial, and they are not in general clinical use.

Sperm possess antigens and semen may contain antibodies including sperm-agglutinating, sperm-immobilizing, or cytotoxic antibodies. The antibodies can be measured in semen or in serum. The immunobead test is the antibody assay used in most labs, and is considered positive when only 20% or more of motile spermatozoa have immunobead binding. However, the test is considered to be clinically significant when 50% of sperm are coated with immunobeads.

Evaluation of Female Factors

OVULATORY FACTOR

An ovulatory dysfunction is responsible for approximately 20–25% of infertility cases (~40% of female factor infertility). The problem should be investigated first by review of historical factors, including the

onset of menarche; present cycle length (intermenstrual interval); and presence or absence of premenstrual symptoms (molimina), such as breast tenderness, bloating, or dysmenorrhea. Signs and symptoms of systemic disease, particularly of hyperthyroidism or hypothyroidism, and physical signs of endocrine disease (ie, hirsutism, galactorrhea, and obesity) should be noted. The degree and intensity of exercise, a history of weight loss, and complaints of hot flashes all are clinical clues to possible endocrine or ovulatory dysfunction.

Follicular Pool

Early in gestation, the germ cells undergo mitosis to produce oogonia. The oogonia undergo meiosis in their transformation to oocytes but arrest at prophase of meiosis I until the time of ovulation. A layer of granulosa cells encircles the oocytes creating the follicle. A female will have the highest number of germ cells, approximately 6 million, in her ovaries at 20 weeks gestational age. Henceforth, atresia depletes the follicular pool at a brisk pace with only 1–2 million oocytes remaining at the time of birth. The ovaries contain approximately 500,000 oocytes at the time of first ovulation. Menopause signals the complete depletion of germ cells, with a woman having ovulated about 500 oocytes during her reproductive years.

Ovarian Reserve

An inverse relationship exists between fecundity and the age of the woman. The decline in fecundity is a result of progressive follicular atresia through apoptosis, which accelerates in the early thirties and progresses rapidly in the late thirties and early forties. Concomitantly, there is a decrease in follicular quality as a result of an increase in oocytes with chromosomal anomalies and progressive deletions in mitochondrial DNA. The concept of ovarian reserve represents the remaining follicular pool of the ovaries. As ovarian reserve decreases, the ovaries' responsiveness to gonadotropins decreases necessitating higher amounts of FSH to achieve follicular growth and maturation.

Ovarian reserve should be evaluated in women older than 35 years of age who are seeking fertility. Evaluation of the level of FSH and estradiol in the early follicular phase (cycle days 2–4) may provide helpful guidance in terms of the likelihood of achieving success, as mild elevations in either FSH or estradiol may precede overt ovulatory dysfunction but still indicate a poor prognosis for successful pregnancy. Use of the clomiphene challenge test has gone out of favor, while newer tests such as inhibin-B remain to be validated in large studies. The specific cause of oligo-ovulation or anovulation is determined by the history, the physical examination, and appropriate laboratory studies.

Confirmation of Ovulation

If the patient reports a history of mittelschmerz and/or regular menses with molimina (headaches, bloating, cramping, and emotional lability) and mild dysmenorrhea occur at intervals of 28–32 days, the likelihood of the patient having regular ovulatory cycles is very high. Otherwise, ovulation can be confirmed with a serum progesterone assay performed in the mid-luteal phase, or the third week of the cycle. Progesterone levels of 3 ng/mL or greater are consistent with ovulation.

Pelvic ultrasonography can provide evidence for ovulation. In the follicular phase, the developing follicle can be monitored to maturation and subsequent rupture. The disappearance of, or change in, the follicle and free fluid in the cul-de-sac can document ovulation.

To detect the LH surge, the patient can use commercially available urinary LH kits or serum LH assay. Ovulation occurs 24–36 hours after the onset of the LH surge and 10–12 hours after the peak of the LH surge. The kits can be used to time intercourse or intrauterine insemination.

The basal body temperature (BBT) is the temperature obtained in the resting state, and should be taken shortly after awakening in the morning after at least 6 hours of sleep and prior to ambulating. Progesterone has a central thermogenic effect; it elevates the BBT by an average of 0.8 °F during the

luteal phase. The luteal phase is thus characterized by a temperature elevation lasting about 10 days. When a biphasic monthly temperature pattern is recorded, it is confirmatory evidence of luteinization, but the absence of a biphasic pattern may be seen in ovulatory cycles.

The finding of secretory endometrium confirms ovulation. The use of an endometrial biopsy (EMB) near the end of the luteal phase can provide reassurance of an adequate maturational effect on the endometrial lining. Generally, the EMB is performed 2–3 days before the expected onset of menses. It should be within 1–2 days of the pathologically diagnosed cycle day determined by morphology of glands and stroma.

Within 48 hours of ovulation, the cervical mucus changes under the influence of progesterone to become thick, tacky, and cellular, with loss of the crystalline fernlike pattern on drying.

The only absolute documentation of release of an oocyte is pregnancy. In the case of oligomenorrhea, amenorrhea, short or very irregular menstrual cycles, or when ovulation is not confirmed, evaluation of the hypothalamic-pituitary-ovarian axis is warranted. A usual initial assessment includes the serum concentrations of FSH, estradiol, prolactin, and thyroid-stimulating hormone.

Luteal Phase Defect

The subject of the inadequate luteal phase remains an area of controversy. There is disagreement on how to make the diagnosis, when the diagnosis is significant, and how best to treat the problem if diagnosed. Luteal phase defect is a histologic diagnosis made when the endometrium lags 3 days or more behind the expected pattern at the time of EMB.

THE PELVIC FACTOR

The pelvic factor includes abnormalities of the uterus, fallopian tubes, ovaries, and adjacent pelvic structures. Factors in the history that are suggestive of a pelvic factor include any history of pelvic infection, such as pelvic inflammatory disease (PID) or appendicitis, use of intrauterine devices, endometritis, and septic abortion. Endometriosis is included as a pelvic factor in infertility and may be suggested by worsening dysmenorrhea, dyspareunia, or previous surgical reports. Any history of ectopic pregnancy, adnexal surgery, leiomyomas, or exposure to diethylstilbestrol (DES) in utero should be noted as possibly contributory to the diagnosis of a pelvic factor. A pelvic examination can be informative, yielding information such as a fixed uterus suggestive of adhesions, leiomyomas, or adnexal masses.

A transvaginal ultrasound examination can be an efficient means of supplementing information gained from the standard bimanual examination. Hydrosalpinges, leiomyoma, and ovarian cysts, including endometriomas, can often be observed, and the appropriate focused evaluations initiated.

A hysterosalpingogram (HSG) is a fluoroscopic study performed by instilling radiopaque dye into the uterine cavity through a catheter to determine the contour of the endometrial cavity and patency of the fallopian tubes. Sensitivity and specificity of an HSG are approximately 65% and 85%, respectively. Abnormal findings include congenital malformations of the uterus, submucous leiomyomas, intrauterine synechiae (Asherman's syndrome), intrauterine polyps, salpingitis isthmica nodosa, and proximal or distal tubal occlusion. The hysterosalpingogram can be obtained in an outpatient setting, with minimal analgesia consisting of premedication with a nonsteroidal anti-inflammatory drug (NSAID). The test is usually scheduled for the interval after menstrual bleeding and prior to ovulation. Either water- or oil-based dye may be selected; Table 55–5 summarizes the advantages and disadvantages of each. There is evidence for a fertility-enhancing effect of HSG using the oil-based dye.

Table 55–5. Comparison of Oil-Based versus Water-Based Dye Used in the Hysterosalpingogram.

Fertility enhancement	Oil: higher pregnancy rates
Patient discomfort	Water: less cramping
Image quality	Water: rugae seen Oil: better image
Embolization	Minimal risk with either dye
Granuloma	Greater risk for retained oil

Peritonitis is a risk of the procedure observed in up to 1–3% of patients; many clinicians use a short-course doxycycline during the immediate period before and after the procedure to minimize risk. A HSG is contraindicated in the presence of an adnexal mass or an allergy to iodine or radiocontrast dye.

A sonohysterogram, a transvaginal ultrasound of the uterus with instillation of saline into the uterine cavity, is a sensitive and specific test for the detection of intrauterine lesions, specifically space-occupying lesions. Hysterosalpingo contrast sonography, transcervical injection of sonopaque material during ultrasonography, is used to determine tubal patency as well as detect intrauterine defects; more commonly used in Europe, the procedure's sensitivity is comparable to HSG.

Laparoscopy with chromotubation (dye instillation) is the gold standard for the evaluation of tubal factor, and when performed in conjunction with hysteroscopy, information on uterine contour can be obtained simultaneously. Tubal abnormalities such as agglutinated fimbria or adhesions (which restrict motion of the tubes) or peritubal cysts may suggest tubal disease that would not necessarily be detected on hysterosalpingogram. The diagnosis of endometriosis is usually based on laparoscopic findings.

The necessity of laparoscopy in an infertility workup is controversial. There is significant evidence that pelvic pathology may exist in almost one-third of patients with normal HSG and ultrasound; consequently, some believe that with laparoscopy one can treat the pathology (such as adhesions) found at the time of procedure, or can spare a patient needless cycles of ovulation induction that are unlikely to succeed by providing knowledge of severe pelvic disease. Others believe that although pelvic disease may be present, a stepwise empiric approach is more cost-effective.

THE CERVICAL FACTOR

A cervical factor may be indicated by a history of abnormal Papanicolaou (Pap) smears, postcoital bleeding, cryotherapy, conization, or DES exposure in utero. The major evaluation of the cervical factor is by physical examination and properly timed postcoital test. In some cases of apparently normal cervical mucous that repeatedly fails to yield reassuring numbers of sperm, a crosscheck of donor sperm and donor mucous can be performed to determine the possible contribution of the cervical mucous as opposed to that of the sperm. The value of routine cervical cultures is controversial, and the role of infectious agents, such as *Chlamydia* and *Ureaplasma*, is not universally accepted, particularly when the organisms are identified in cervical or vaginal cultures.

Combined Factors & Unexplained Infertility

After the completion of the diagnostic workup, the findings should be reviewed with the patients and a treatment plan finalized based on guidance from the physician and input from the patient(s). In approximately 20% of couples, a combination of factors found may be suboptimal, and multiple therapies

may need to be instigated, either sequentially or simultaneously. For the couple with unexplained infertility, an empiric stepwise approach is an excellent option. However, depending upon the history, workup, and individual situation, additional test(s) including surgery should be discussed.

THERAPY FOR INFERTILITY

Male Factor Infertility

Treatment options progress from least to most invasive or use of donor sperm. Mild to moderate disease can be treated with intrauterine insemination (IUI). Prior to the insemination, the semen is prepared to select for highly motile sperm, concentrate sperm, and remove seminal fluid (with prostaglandins). The prepared sperm is transcervically injected into the uterus.

ICSI is used in conjunction with IVF for treatment of severe disease (< 2 million motile sperm). In this procedure, a sperm is individually injected into each oocyte. The sperm can be retrieved from the testes by microsurgical epididymal sperm aspiration (MESA) or testicular sperm aspiration (TESA); a minimum number of sperm are necessary.

Indications for ICSI include poor semen analysis parameters (low number of motile sperm, poor morphology), fertilization failure with standard IVF, and spermatozoal defects leading to poor fertilization. A decade of experience with the procedure has proven its overall safety. However, offspring conceived using ICSI may be at increased risk of imprinting disorders (eg, Angelman's syndrome), and male children are at risk for inheriting the genetic disorder (eg, Y chromosome microdeletions) that rendered their father infertile.

The initial evaluation of FSH, LH, testosterone, and prolactin helps to differentiate between obstructive defects, primary hypogonadism (testicular defect), and secondary hypogonadism (hypothalamic or pituitary). Obstructive defects may be addressed through surgical reanastomosis or through retrieval of sperm via MESA or TESA for use with ICSI. Retrograde ejaculation can be treated with alpha sympathomimetics or urine can be centrifuged to collect sperm for IUI. Patients with primary hypogonadism should have a karyotype, as Klinefelter's syndrome (47,XXY) is the most common etiology.

Secondary hypogonadism, or hypogonadotropic hypogonadism, may be a result of a pituitary lesion such as prolactinoma or a hypothalamic etiology such as Kallman's syndrome. Most prolactinomas respond to medical management. Pulsatile gonadotropin-releasing hormone (GnRH) administration with a pump or FSH replacement restores testosterone and sperm production in disorders leading to hypogonadotropic hypogonadism.

A varicocele is a dilatation of scrotal veins in the pampiniform plexus and is postulated to impair fertility through elevation of scrotal temperature. A clinical varicocele is one that is detected by examination and is present in 15% of men. Subclinical varicoceles can be detected by ultrasound or venography. There is contradicting evidence if ligation of clinical varicoceles leads to improved pregnancy rates; infertility is a questionable indication for the correction of subclinical varicoceles.

When male infertility is not amenable to therapy, donor sperm for insemination or IVF offers an opportunity for pregnancy. The use donor sperm is common in clinical practice and experience has lessened some of the medical, emotional, ethical, and legal issues. The American Society for Reproductive Medicine (ASRM) advocates use of frozen semen to reduce risk of transmission of infectious disease.

Female Factor Infertility

THE OVULATORY FACTOR

The treatment and success of specific ovulatory disorders is determined by the age of the patient and the etiology of the anovulation. A stepwise approach, from least to most invasive (and expensive), usually starts with clomiphene citrate and progresses to ovulation induction with gonadotropins and, ultimately, IVF. The risk to the patient, cost of therapy, and fecundability increase with each step closer to IVF. If premature ovarian failure or early menopause is the etiology, the options include oocyte or embryo donation.

Induction of ovulation can be accomplished in 90–95% of patients with chronic anovulation, normal ovarian reserve, and absence of other endocrine abnormalities (eg, hyperprolactinemia or hypothyroidism). Clomiphene citrate is the agent of choice for women younger than 36 years of age with oligomenorrhea or amenorrhea and normal FSH, including women with polycystic ovary syndrome (PCOS). Clomiphene citrate blocks the feedback inhibition of estradiol on the hypothalamus and pituitary leading to an increase in endogenous FSH. It is administered orally for 5 days starting on day 3 to 5 of the cycle; approximately half of the patients will ovulate at 50 mg/d and another 25% at 100 mg/d. Ultrasonographic and hormonal monitoring of follicular development is an option, which provides more information and allows greater control of the cycle. After a regimen has achieved ovulation, 3–4 cycles with timed intercourse should be attempted. Side effects with clomiphene are common, including hot flashes, emotional lability or depression, bloating, and visual changes; most are mild and all disappear with discontinuation of the drug. The incidence of twin gestation is 8% and triplets or higher-order multiple pregnancy (HOMP) is less than 1%.

A patient in whom there is no response to clomiphene, response to clomiphene but no pregnancy, pituitary insufficiency, or hypothalamic insufficiency should undergo ovulation induction with gonadotropins, often used in conjunction with IUI. Human menopausal gonadotropin (hMG) consists of FSH and LH isolated from the urine of postmenopausal women to various levels of purification (and LH content); recombinant FSH (rFSH) contains purely FSH. Gonadotropins are administered by subcutaneous (rFSH) or intramuscular injection (hMG) and the overall evidence indicates that the two preparations have similar efficacy.

Because of an increased risk of side effects such as multiple gestation and ovarian hyperstimulation syndrome, the use of gonadotropins requires close monitoring with ultrasonography and estradiol levels. Consequently, it is more time-consuming and expensive than clomiphene. The monitoring reveals both the number of developing follicles and their level of maturity. Mimicking the effects of the LH surge, human chorionic gonadotropins (hCG) is used to trigger ovulation. With perseverance, cumulative pregnancy rates of 45–90% can be achieved over 3–4 cycles with gonadotropin treatment; but even with careful monitoring there is a 25% risk of a multiple gestation. Ovarian hyperstimulation syndrome is a rare complication that occurs in less than 2% of cycles.

If pregnancy is not achieved with ovulation induction, IVF-ET is the next modality in the treatment algorithm. Development of the follicular cohort is induced with higher doses of FSH (hMG or rFSH). Follicular growth is monitored by ultrasonography and estradiol levels. When the leading follicles are mature, ovulation is triggered with hCG. The oocytes are retrieved from the follicles prior to ovulation by ultrasound-guided transvaginal aspiration of the follicular fluid. The oocytes are incubated with sperm for fertilization. Alternatively, ICSI is performed if male factor is also a concern. On average, several (from 1 to >3) embryos are transferred into the uterine cavity on day 3–5 after retrieval of the oocytes. Ovarian hyperstimulation syndrome (OHSS) is minimized by withholding hCG if there is a high number of follicles or elevated estradiol levels. Another option to limit the extent of OHSS is to cryopreserve the embryos for transfer at a later time, as pregnancy can prolong the course of OHSS.

When modification of lifestyle or body habitus does not successfully restore ovulation in the patient

diagnosed with hypothalamic insufficiency, pulsatile GnRH is another viable option with high likelihood of restoring normal ovulation. Normal fertility is then restored during cycles of treatment, and most pregnancies occur within 3–6 cycles.

Hypothyroidism and hyperprolactinemia can lead to ovulatory dysfunction. Primary hypothyroidism leads to elevated thyroid-stimulating hormone (TSH) levels, which is a secretagogue of prolactin. Elevated prolactin levels inhibit GnRH secretion, causing oligomenorrhea or amenorrhea. If elevated prolactin levels are detected in a woman with normal thyroid function, a full work-up including thorough history (to rule out drugs like psychotropics), physical exam (galactorrhea), and imaging (magnetic resonance imaging [MRI] to rule out a prolactinoma or other central nervous system [CNS] tumors) is likely to reveal the etiology. The elevated prolactin can be medically managed with dopamine agonist, leading to normalization of the cycle.

There is concern about a possible association between ovulation induction agents, specifically greater than 12 cycles of clomiphene citrate, and ovarian cancer. The possibility that ovulation induction increases the risk of ovarian cancer remains unproven. Primary infertility and endometriosis are independent risk factors for ovarian cancer. Although additional investigation is necessary, the low incidence of ovarian cancer makes it difficult to design an adequate study to detect an association of infertility drugs with ovarian cancer.

THE PELVIC FACTOR

Adhesions resulting from endometriosis or tubal occlusion after salpingitis are two of the most common problems confronting infertile couples. With increasing pregnancy rates, IVF represents improved fecundability and lower risk over surgical repair except in unique circumstances. The role of surgical treatment is mostly limited to what can be accomplished at the time of diagnostic laparoscopy. There is some evidence to suggest that resection of mild endometriosis results in improved pregnancy rates. Laparoscopic resection or ablation of moderate or advanced endometriosis enhances fecundity in infertile women for the period immediately following surgery. Reversal of tubal sterilization is indicated in young women with adequate residual tubal length. Tubal interruption or resection increases IVF pregnancy rates in women with hydrosalpinx.

The role of fibroids in infertility is unclear, and most surgeons reserve myomectomy for treatment of recurrent abortion, repeated implantation failure, or with distortion of the endometrial cavity by a submucosal leiomyoma. The fibroids which distort the endometrial cavity are considered to be significant. These may be diagnosed by hysterosalpingogram, sonohysterogram, hysteroscopy, or magnetic resonance imaging.

THE CERVICAL FACTOR

The absence of nurturing mucus at midcycle can be treated by bypassing the mucus with intrauterine insemination. When the cervical mucus appears to be affected by cervicitis and inflammatory changes, some physicians advocate empiric treatment of patient and partner with doxycycline. When the cervix is altered by congenital malformation or past surgical treatment that has rendered endocervical glands absent or nonfunctional, intrauterine insemination with washed sperm can be anticipated to result in pregnancy in 20–30% of patients per cycle in each of the first 3 cycles of treatment. Cervical factor patients who do not respond to these therapies can be offered IVF, gamete intrafallopian transfer (GIFT), or zygote intrafallopian transfer (ZIFT), although GIFT and ZIFT are now rarely used.

Unexplained Infertility

A diagnosis of unexplained infertility is assigned to couples with normal results of a standard infertility work-up. The main treatment options include expectant observation with timed intercourse, ovarian

stimulation with or without IUI, and IVF. Studies support the use of clomiphene with intrauterine insemination for up to 4 cycles. The next step is usually hMG with intrauterine insemination for 3 cycles; if unsuccessful, IVF should be considered. The rationale for treatment with superovulation in women with documented ovulation is that by increasing the number of oocytes available, the likelihood of pregnancy is increased. In instances in which unexplained infertility may be the result of a fundamental defect in fertilization or in embryo transfer to the uterus, IVF may play a role in treatment. Donor oocytes or donor sperm may be considered in couples with continued difficulties in achieving pregnancy. For many, the hardest course to contemplate is no therapy at all.

Current OB/GYN > Chapter 56. Amenorrhea >

AMENORRHEA: INTRODUCTION

Menstruation has long been an important societal marker of female sexual development, as well as one of the most tangible signs of female endocrine and reproductive tract maturation. Regular and spontaneous menstruation requires (a) an intact hypothalamic–pituitary–ovarian endocrine axis; (b) an endometrium competent to respond to steroid hormone stimulation; and (c) an intact outflow tract from internal to external genitalia.

The human menstrual cycle is susceptible to environmental influences and stressors. Thus, missing a single or occasional menstruation rarely reflects a significant pathology. However, prolonged or persistent absence of menses may be one of the earliest signs of neuroendocrine or anatomic abnormality.

DEFINITION & INCIDENCE

Amenorrhea is literally defined as the absence of menses. Primary amenorrhea, seen in approximately 2.5% of the population, is clinically defined as the absence of menses by age 13 years in the absence of normal growth or secondary sexual development; or the absence of menses by age 15 years in the setting of normal growth and secondary sexual development. Traditionally, evaluation was usually initiated by age 16 years if normal growth and secondary sexual characteristics were present, and at age 13 years if absent. However, because of secular trends toward earlier menarche over the past half century, the evaluation should begin at age 15 years, the age when more than 97% of girls should have experienced menarche. Certainly, the decision to evaluate should be made with a full understanding of the patient's clinical presentation. For example, evaluation should not be delayed in the setting of neurologic symptoms (suggestive of hypothalamic–pituitary lesion) or pelvic pain (suggestive of outflow obstruction). Secondary amenorrhea is clinically defined as the absence of menses for more than 3 cycle intervals, or 6 consecutive months, in a previously menstruating woman. The incidence of secondary amenorrhea can be quite variable, from 3% in the general population to 100% under conditions of extreme physical or emotional stress. Table 56–1 lists the most common causes of secondary amenorrhea.

Table 56–1. Causes of Secondary Amenorrhea.

Common

Pregnancy

Hypothalamic amenorrhea

Androgen disorders: polycystic ovarian syndrome, congenital adrenal hyperplasia

Galactorrhea-amenorrhea syndrome

Less Common

Premature ovarian failure

Asherman's syndrome

Sheehan's syndrome

Rare

Diabetes

Hyperthyroidism or hypothyroidism

Cushing's syndrome or Addison's disease

Cirrhosis

Tuberculosis

Malnutrition

Irradiation or chemotherapy

Surgery

Diagnosing and treating amenorrhea is important because of the implications for future fertility; risks of unopposed estrogen, including endometrial hyperplasia and neoplasia; risks of hypoestrogenism, including osteoporosis and urogenital atrophy; and impact on psychosocial development. Because of their significant overlap in etiology and treatment, primary and secondary amenorrhea are discussed collectively in this chapter.

ETIOLOGY & PATHOGENESIS

Pregnancy is the most common cause of amenorrhea and must be considered in every patient presenting for evaluation of amenorrhea. Amenorrhea caused by aberrations of the normal menstrual cycle is discussed in Chapter 6. Chapters 34 and 57 discuss developmental anomalies of the reproductive organs and masculinization, respectively. This chapter discusses amenorrhea associated with 46,XX and 46,XY karyotypes, anatomic defects, and defects in the hypothalamic–pituitary–ovarian axis, as well as systemic disorders that affect menstruation.

Hypothalamic Defects

Gonadotropin-releasing hormone (GnRH) secreting neurons of the hypothalamus originate in

the olfactory bulb and migrate along the olfactory tract into the mediobasal hypothalamus and the arcuate nucleus. Under normal physiologic circumstances, the arcuate nucleus releases pulses of GnRH into the hypophyseal portal system approximately every hour. Discharge of GnRH releases luteinizing hormone (LH) and follicle-stimulating hormone (FSH) from the pituitary; LH and FSH, in turn, stimulate ovarian follicular growth and ovulation. The ovarian hormones estradiol and progesterone stimulate the development and shedding of the endometrium, culminating in the withdrawal bleeding of menses. Anovulation and amenorrhea occur as a result of interference with GnRH transport, GnRH pulse discharge, or congenital absence of GnRH (Kallmann's syndrome). Any of these situations leads to hypogonadotropic hypogonadism.

DEFECTS OF GNRH TRANSPORT

Interference with the transport of GnRH from the hypothalamus to the pituitary may occur with pituitary stalk compression or destruction of the arcuate nucleus. Pituitary stalk transection from trauma, compression, radiation, tumors (craniopharyngioma, germinoma, glioma, teratomas), and infiltrative disorders (sarcoidosis, tuberculosis) may either destroy areas of the hypothalamus or prevent transport of hypothalamic hormones to the pituitary.

DEFECTS OF GNRH PULSE PRODUCTION

The metabolic consequence of any significant reduction in the normal GnRH pulse frequency or amplitude is that little or no LH or FSH can be released, with the result that no ovarian follicles develop, virtually no estradiol is secreted, and the patient is amenorrheic. This is the biochemical status in normal prepubertal girls and those with constitutional delayed puberty, such as in anorexia nervosa, severe stress, extreme weight loss, or prolonged vigorous athletic exertion, and in hyperprolactinemia. Amenorrhea on this basis may also be an idiopathic phenomenon.

Less-severe reductions in GnRH pulse amplitude and frequency result in diminished LH and FSH secretion with some follicular stimulation. The stimulation is insufficient to result in full follicular development and ovulation, but estradiol is secreted. This may occur with stress, hyperprolactinemia, as a result of vigorous athletic activity, or in the early stages of eating disorders. It may also be idiopathic.

Functional or hypothalamic amenorrhea results from abnormal hypothalamic GnRH secretion in the absence of pathologic processes. As a result, patients demonstrate decreased gonadotropin pulsations, absent follicular development and ovulation, and low estradiol secretion. Serum FSH levels are usually in the normal range; the setting of high FSH:LH ratio is consistent with prepubertal patterns. A number of environmental stressors are associated, including eating disorders and physical or psychological stress. Weight loss, especially to a level of at least 10% below ideal body weight, and excessive exercise are also associated with hypothalamic amenorrhea. The female athlete triad syndrome is defined by amenorrhea, eating disorder, and osteopenia or osteoporosis.

Congenital GnRH deficiency is called idiopathic hypogonadotropic hypogonadism when it occurs as an isolated phenomenon, and Kallmann's syndrome when it is associated with anosmia. These patients lack GnRH secretion, and express low, prepubertal levels of serum gonadotropins. Follicular recruitment and ovulation do not occur. Although more than 60% of cases are sporadic, congenital GnRH deficiency can also be inherited in an autosomal or X-linked pattern.

More common in boys with delayed puberty, constitutional delay of puberty is an uncommon etiology of primary amenorrhea in girls. Patients demonstrate delayed adrenarche and gonadarche, but ultimately go on to have normal, albeit delayed, pubertal development.

Pituitary Defects

Pituitary causes of amenorrhea are rare; most are secondary to hypothalamic dysfunction. However,

acquired pituitary dysfunction can ensue from previous local radiation or surgery. Excess iron deposition due to hemochromatosis or hemosiderosis may destroy gonadotropes.

CONGENITAL PITUITARY DYSFUNCTION

Congenital absence of the pituitary is a rare and lethal condition. Isolated defects of LH or FSH production do occur (rarely), resulting in anovulation and amenorrhea.

ACQUIRED PITUITARY DYSFUNCTION

Sheehan's syndrome, characterized by postpartum amenorrhea, results from postpartum pituitary necrosis secondary to severe hemorrhage and hypotension and is a rare cause of amenorrhea. Surgical ablation and irradiation of the pituitary as management of pituitary tumors also can cause amenorrhea.

Iron deposition in the pituitary may result in destruction of the cells that produce LH and FSH. This occurs only in patients with markedly elevated serum iron levels (ie, hemosiderosis), usually resulting from extensive red cell destruction. Thalassemia major is an example of a disease that causes hemosiderosis.

Pituitary microadenomas and macroadenomas also lead to amenorrhea because of elevated prolactin levels, but the mechanism(s) underlying this cause of amenorrhea are unclear. Isolated hyperprolactinemia in the absence of adenoma is an uncommon cause of primary amenorrhea. However, the diagnosis is strongly suggested by a history of galactorrhea. Diagnosis is readily made by evaluating a serum prolactin level. Hypothyroidism may also lead to elevated prolactin levels and thereby lead to amenorrhea.

Ovarian and Ovulatory Dysfunction

A variety of gonadal disorders can result in amenorrhea. The most common cause of primary amenorrhea is gonadal dysgenesis. This group of disorders is usually associated with sex chromosomal abnormalities, resulting in streak gonad development, premature depletion of ovarian follicles and oocytes, and absence of estradiol secretion. Patients usually present with hypergonadotropic amenorrhea regardless of degree of pubertal development. Primary ovarian failure is characterized by elevated gonadotropins and low estradiol (hypergonadotropic hypogonadism). Secondary ovarian failure is almost always caused by hypothalamic dysfunction and is characterized by normal or low gonadotropins and low estradiol (hypogonadotropic hypogonadism).

Table 56–2 lists the causes of primary ovarian failure.

Table 56–2. Causes of Primary Ovarian Failure (Hypergonadotrophic Hypogonadism).

Idiopathic premature ovarian failure
Steroidogenic enzyme defects (primary amenorrhea)
Cholesterol side-chain cleavage
3 β -ol-dehydrogenase
17-hydroxylase
17-desmolase
17-ketoreductase
Testicular regression syndrome
True hermaphroditism
Gonadal dysgenesis
Pure gonadal dysgenesis (Swyer's syndrome) (46,XX and 46,XY)
Turner's syndrome (45,XO)
Turner variants
Mixed gonadal dysgenesis
Ovarian resistance syndrome (Savage's syndrome)
Autoimmune oophoritis
Postinfection (eg, mumps)
Postoophorectomy (also wedge resections and bivalving)
Postirradiation
Postchemotherapy

OVARIAN DYSGENESIS

If the primitive oogonia do not migrate to the genital ridge, the ovaries fail to develop. Streak gonads, which do not secrete hormones, develop instead, and the result is primary amenorrhea. Cytogenetic abnormalities of the X chromosome account for the majority of abnormal ovarian development and function, and studies show that two intact X chromosomes are required to maintain normal oocytes. Fetuses with 45,X karyotype demonstrate normal oocyte number at 20–24 weeks' gestation, but there is rapid atresia resulting in absence of oocytes at birth. Similarly, women with deletions in either the long or short arm of one X chromosome also develop either primary or secondary amenorrhea.

Gonadal Dysgenesis with No Y Chromatin

Turner's syndrome (45,XO or 45,XO,XX mosaics) and 46,XX gonadal dysgenesis are the most common

karyotypes. Patients with Turner's syndrome usually present with primary amenorrhea. However, some patients with mosaic abnormalities may menstruate briefly and a few have conceived.

Gonadal Dysgenesis with Y Chromatin

Normal female sexual differentiation depends on testicular secretion of antimüllerian hormone (AMH) by Sertoli cells and testosterone by Leydig cells. AMH causes regression of müllerian structures, whereas testosterone and its metabolite dihydrotestosterone (DHT) promote differentiation of male internal and external genitalia, respectively. A variety of disorders can result in the presentation of amenorrhea in phenotypic females possessing Y chromatin material.

The vanishing testes syndrome occurs in 46,XY males with failed gonadal development. Although anorchia commonly occurs around 7 weeks' gestational age, the patient's presentation depends on the timing of gonadal regression. Failure occurring later in development might result in male genitalia at birth, but absence of puberty as a consequence of gonadal failure. On the other hand, typical early gonadal failure prior to testicular development would result absent secretion of testis-determining factor (TDF) and AMH. These patients would demonstrate feminization of internal and external genitalia, and primary amenorrhea.

Ullrich-Turner syndrome, which presents as a form of early onset vanishing testes syndrome, results from a deletion mutation in the TDF region of Y chromosome. These patients possess the 46,XY genotype but do not secrete testosterone or AMH, resulting in feminization of internal and external genitalia. Patients present with primary amenorrhea and gonadal failure. The syndrome is diagnosed by DNA hybridization studies showing abnormality in the short arm of the Y chromosome.

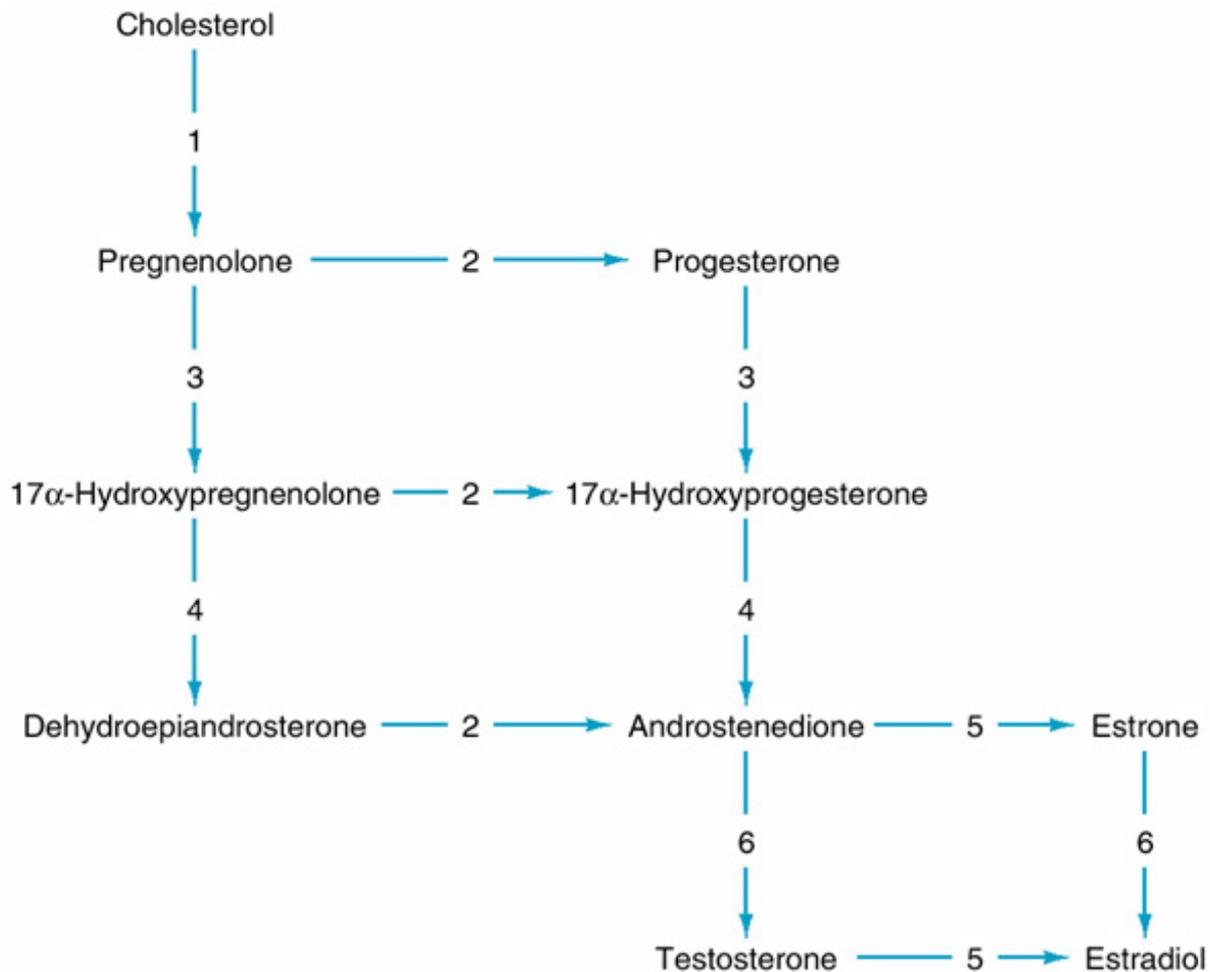

PREMATURE OVARIAN FAILURE

Menopause occurs when the ovaries fail secondary to depletion of ova. If this occurs before age 40 years, it is considered premature. It is marked by amenorrhea, increased gonadotropin levels, and estrogen deficiency.

STEROID ENZYME DEFECTS

Figure 56–1 depicts normal steroidogenesis in the ovary. Genetic females with defects in enzymes 1–4 have normal internal female genitalia and 46,XX karyotype. However, they cannot produce estradiol and thus they fail to menstruate or have breast development.

Figure 56–1.

Key to enzymes

1 = Cholesterol 20- and 22-desmolase and 20-hydroxylase

2 = 3 β -Hydroxysteroid dehydrogenase

3 = 17 α -Hydroxylase

4 = 17- and 20-Desmolase

5 = Aromatase

6 = 17-Hydroxysteroid dehydrogenase

Steroidogenesis in the ovary.

Congenital lipid adrenal hyperplasia describes one of fifteen known defects in the steroidogenic acute regulatory (STAR) protein, which facilitates cholesterol transport from the outer to the inner mitochondrial membrane. This enzyme catalyzes an early, rate-limiting step in tropic hormone-stimulated steroidogenesis. Patients thus present with hyponatremia, hyperkalemia, and acidosis in infancy. Both XX and XY individuals are phenotypically female. These patients can survive into adulthood given appropriate glucocorticoid and mineralocorticoid supplementation. XX patients may exhibit some secondary sexual characteristics at puberty, but present with amenorrhea and premature ovarian failure due to intraovarian accumulation of cholesterol.

OVARIAN RESISTANCE (SAVAGE'S SYNDROME)

Patients with this syndrome have elevated LH and FSH levels, and the ovaries contain primordial germ cells. A defect in the cell receptor mechanism is the presumed cause.

POLYCYSTIC OVARY SYNDROME

One of the most common causes of secondary amenorrhea is polycystic ovary syndrome (PCOS). PCOS is the most common cause of ovulatory dysfunction in reproductive-age women. Diagnosis is based on the presence of at least two of the following characteristics: (a) oligo- or anovulation; (b) clinical and/or biochemical signs of hyperandrogenism; (c) polycystic ovaries; and (d) exclusion of other etiologies (congenital adrenal hyperplasia, androgen-secreting tumors, Cushing's syndrome). Although the exact mechanism is unknown, it appears that insulin resistance and hyperinsulinemia play a permissive role. Abnormally elevated baseline insulin leads to increased androgens via decreased sex hormone-binding globulin, and stimulation of ovarian insulin and insulinlike growth factor-I (IGF-I) receptors. Increasingly, insulin-sensitizing agents such as metformin and rosiglitazone are used as a sole or adjuvant agent for ovulation induction in PCOS.

Anatomic Abnormalities Associated with Amenorrhea

See Chapter 34.

MÜLLERIAN DYSGENESIS

Müllerian dysgenesis is characterized by congenital absence of the uterus and the upper two-thirds of the vagina. Affected individuals have a 46,XX karyotype.

VAGINAL AGENESIS

Vaginal agenesis is characterized by failure of the vagina to develop.

TRANSVERSE VAGINAL SEPTUM

This anomaly results from failure of fusion of the müllerian and urogenital sinus-derived portions of the vagina.

IMPERFORATE HYMEN

If the hymen is complete, menstrual efflux cannot occur.

ASHERMAN'S SYNDROME

In Asherman's syndrome, amenorrhea is caused by intrauterine synechiae. The usual cause is a complicated dilatation and curettage (D&C) (eg, infected products of conception, vigorous elimination of the endometrium), but the syndrome can occur after myomectomy, cesarean section, and tuberculous endometritis.

Amenorrhea in Women with 46,XY Karyotype

The details of embryonic sexual differentiation are discussed in Chapter 4. Briefly, the sexually undifferentiated male fetal testis secretes müllerian-inhibiting factor (MIF) and testosterone. MIF promotes regression of all müllerian structures: the uterine tubes, the uterus, and the upper two-thirds of the vagina. Testosterone and its active metabolite DHT are responsible for embryonic differentiation of the male internal and external genitalia.

TESTICULAR FEMINIZATION

In testicular feminization, all müllerian-derived structures are absent. The external genital anlagen and mesonephric ducts cannot respond to androgens, because androgen receptors are either absent or defective. Affected individuals are therefore phenotypic females lacking a uterus and a complete vagina. They produce some estrogen, develop breasts, and are reared as girls, and therefore present with primary amenorrhea.

PURE GONADAL DYSGENESIS

If the primitive germ cells do not migrate to the genital ridge, a testis will not develop, and a streak gonad will be present. Affected individuals have normal female internal and external genitalia, as neither

MIF nor androgens are secreted by the streaks. Because these individuals produce no estrogen, they will not develop breasts. They are reared as girls and present clinically with either delayed puberty or primary amenorrhea.

ANORCHIA

If the fetal testes regress before 7 weeks' gestation, neither MIF nor testosterone is secreted, and affected individuals will present with a clinical picture identical to that of pure gonadal dysgenesis. Individuals whose testes regress between 7 and 13 weeks' gestation present with ambiguous genitalia.

TESTICULAR STEROID ENZYME DEFECTS

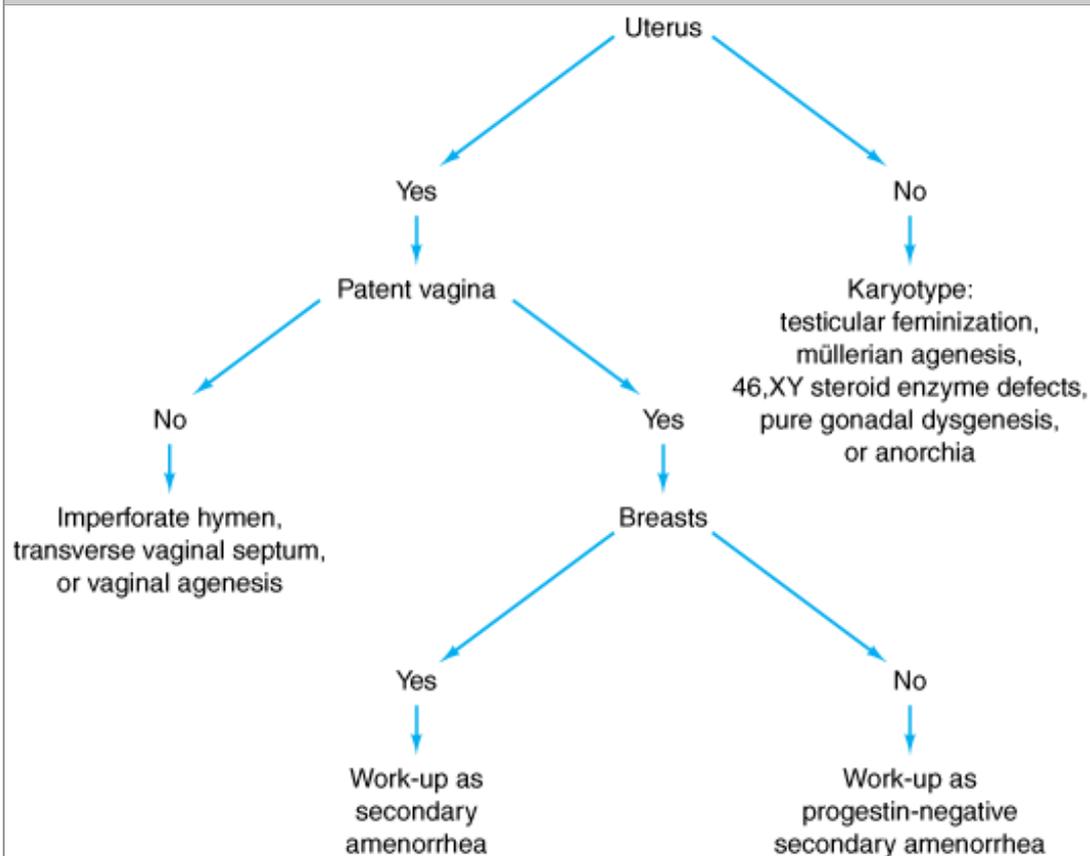

A testis with defective enzymes 1–4 will produce MIF but not testosterone (Fig 56–1). Affected individuals have female external genitalia and no müllerian structures. They will be reared as girls and present clinically with either delayed puberty or primary amenorrhea.

A defect in enzyme 6 (17-hydroxysteroid dehydrogenase) results in ambiguous genitalia and virilization at puberty.

DIAGNOSIS

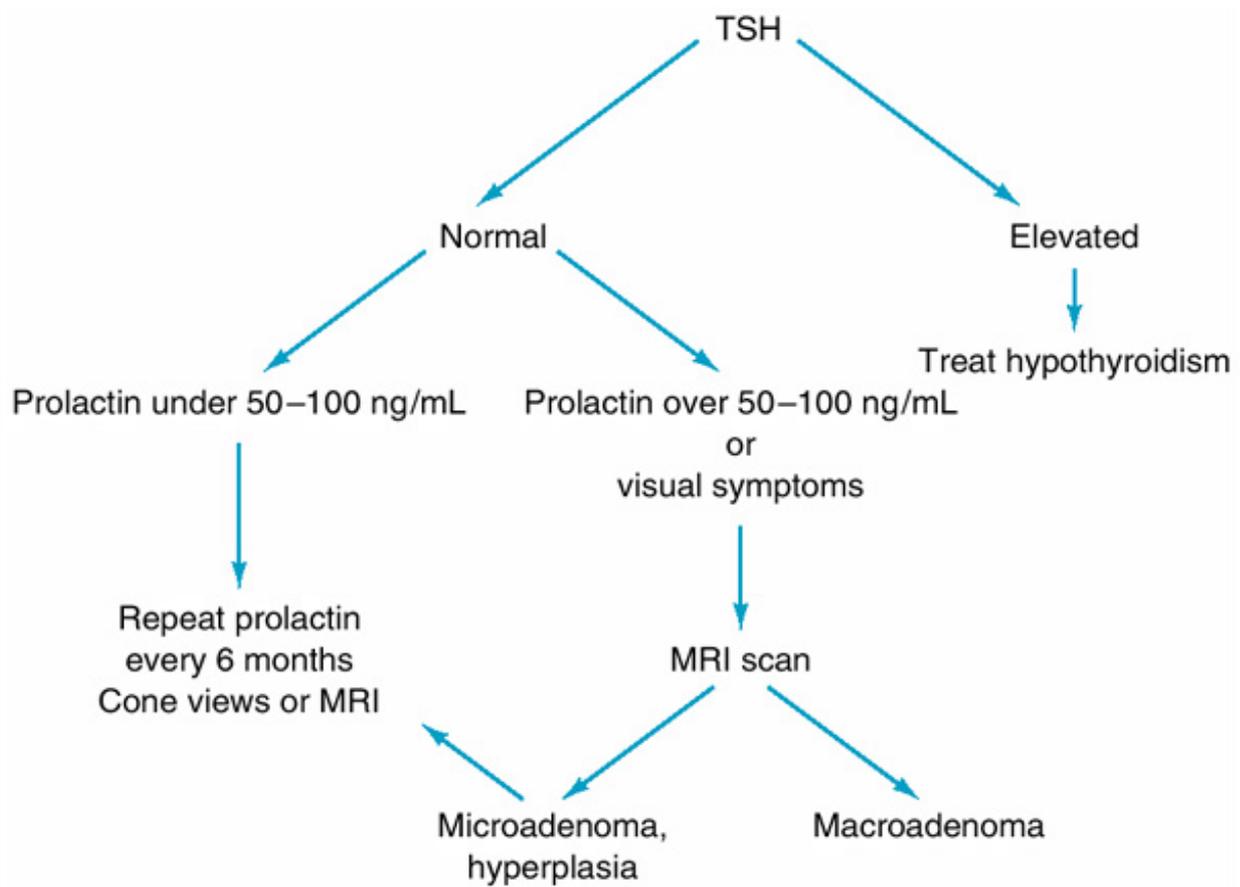

Figures 56-2, 56-3, and 56-4 summarize the diagnostic work-up for amenorrhea. It is important at the outset to determine which organ is dysfunctional and then to identify the exact cause. Once this has been done, specific therapy can be planned.

Work-up for patients with secondary amenorrhea.

Any patient with amenorrhea who has a uterus should be tested for pregnancy and for serum levels of thyroid-stimulating hormone (TSH) and prolactin. Galactorrhea should be identified or ruled out by physical examination.

Diagnosis of Primary Amenorrhea

Figure 56–2 outlines the diagnostic scheme for primary amenorrhea. Pelvic examination should be done to establish the presence of a vagina and uterus and no vaginal septum or imperforate hymen that might account for the failure of appearance of menses. Because pelvic examination of an adolescent girl may be difficult, pelvic ultrasound or examination under anesthesia may be required to establish the presence of a uterus.

If no uterus is present, serum testosterone levels should be measured and karyotyping done to differentiate between müllerian agenesis and testicular feminization.

Diagnosis of Amenorrhea Associated with Galactorrhea-Hyperprolactinemia

Figure 56–3 outlines the diagnostic work-up of patients with galactorrhea or hyperprolactinemia. Table 56–3 summarizes the differential diagnosis of galactorrhea-amenorrhea.

Table 56–3. Differential Diagnosis of Galactorrhea-Hyperprolactinemia.

Pituitary tumors secreting prolactin

Macroadenomas (> 10 mm)

Microadenomas (< 10 mm)

Hypothyroidism

Idiopathic hyperprolactinemia

Drug-induced hyperprolactinemia

Dopamine antagonists

Phenothiazines

Thioxanthenes

Butyrophenone

Diphenylbutylpiperidine

Dibenzoxazepine

Dihydroindolone

Procainamide derivatives

Catecholamine-depleting agents

False transmitters (α -methyldopa)

Interruption of normal hypothalamic–pituitary relationship

Pituitary stalk section

Peripheral neural stimulation

Chest wall stimulation

Thoracotomy

Chronic nipple irritation

Spinal cord lesion

Tabes dorsalis

Syringomyelia

Central nervous system disease

Encephalitis

Craniopharyngioma

Pineal tumors

Hypothalamic tumors

Pseudotumor cerebri

Patients with primary hypothyroidism have elevated thyroid-releasing hormone (TRH) levels. TRH acts to stimulate the release of prolactin and may thereby lead to galactorrhea-amenorrhea syndrome. TSH is also elevated and easier to measure and thus is the screening test for hypothyroidism.

Once hypothyroidism is adequately treated serum prolactin must be measured again after thyroid function has become normal. If prolactin remains elevated or is initially higher than 50–200 ng/mL, the patient should be further studied via cone view of the sella, or computed tomography (CT) or magnetic resonance imaging (MRI) scan of the sella, to rule out pituitary micro- or macroadenoma.

A meticulous history must be taken to ascertain whether the hyperprolactinemia is caused by ingestion of drugs. Prolactin secretion is inhibited by dopamine and stimulated by serotonin and TRH. Any drug that blocks the synthesis or binding of dopamine will increase the prolactin level. Prolactin is increased by serotonin agonists and decreased by serotonin antagonists. Pituitary macroadenoma should be ruled out if prolactin levels are higher than 50–100 ng/mL, even if the patient is taking drugs that lead to raised prolactin levels.

Diagnosis of Amenorrhea Not Associated with Galactorrhea-Hyperprolactinemia

These patients are studied according to the scheme outlined in Figure 56–4.

The first step is the progestin challenge, which indirectly determines whether the ovary is producing estrogen. If the endometrium has been primed with estrogen, exogenous progestin will produce menses. Give either medroxyprogesterone acetate, 10 mg orally daily for 5 days, or progesterone, 100–200 mg intramuscularly as a single dose. If vaginal bleeding follows, the ovaries are secreting estrogen. If it does not, it can be concluded that there is no estrogen or that the patient has Asherman's syndrome.

From a practical standpoint, if a patient has not had a D&C, it is virtually impossible for her to have Asherman's syndrome, so the diagnostic steps summarized in the following paragraphs can be disregarded.

Asherman's syndrome can be ruled out by administration of conjugated estrogen, 2.5 mg orally daily for 25 days, plus medroxyprogesterone acetate, 10 mg orally on days 16 through 25. Patients with Asherman's syndrome do not bleed following this regimen.

Asherman's syndrome can also be diagnosed by weekly serum progesterone tests. Any value in the ovulatory range (> 3 ng/mL) not associated with menses is indicative of Asherman's syndrome. Hysterosalpingography, sonohysterography, and hysteroscopy can also lead to a diagnosis of Asherman's syndrome.

In a patient who does not have Asherman's syndrome and who does not respond to the progestin challenge, ovarian dysfunction may be of hypothalamic or ovarian origin. The distinction is based on the FSH level. Primary ovarian dysfunction resulting in low estradiol secretion is associated with high serum FSH. Values vary in different laboratories, but in general an FSH level higher than 40 mIU/mL indicates primary ovarian failure.

Diagnosis of Amenorrhea Caused by Primary Ovarian Failure

Table 56–2 lists the causes of primary ovarian failure.

Karyotyping is indicated for all women who present with premature menopause, particularly if their amenorrhea is primary. Patients with primary amenorrhea may have a steroid enzyme defect. Autoimmune oophoritis is a reversible cause of ovarian failure that must be investigated.

Diagnosis of Amenorrhea Associated with Hypothalamic–Pituitary Dysfunction

Table 56–4 summarizes the differential diagnosis of hypoestrogenic amenorrhea. The category includes amenorrhea associated with athletic activity, weight loss, or stress. Differentiation of hypothalamic from pituitary dysfunction can be achieved by giving GnRH, but is generally not a worthwhile effort, as pituitary causes are rare and can often be diagnosed on the basis of the history. Moreover, in Kallmann's syndrome, a single bolus dose of GnRH may not elicit a normal response. Up to 40 doses of GnRH have been required to prime the pituitary so that it will respond normally. A GnRH pump also has been used.

Table 56–4. Differential Diagnosis of Hypoestrogenic Amenorrhea (Hypogonadotropic Hypogonadism).

Hypothalamic dysfunction

- Kallmann's syndrome
- Tumors of hypothalamus (craniopharyngioma)
- Constitutional delay of puberty
- Severe hypothalamic dysfunction
- Anorexia nervosa
- Severe weight loss
- Severe stress
- Exercise

Pituitary disorder

Sheehan's syndrome

Panhypopituitarism

Isolated gonadotropin deficiency

Hemosiderosis (primarily from thalassemia major)

If there is a significant history consistent with Sheehan's syndrome, pituitary function testing is indicated in order to determine the functional capacity of the gland—particularly the integrity of the pituitary–adrenal axis.

In girls with primary amenorrhea, observing the pattern of LH and FSH release after administration of GnRH will help to determine whether the patient is undergoing late pubertal changes.

Patients who bleed in response to the progestin challenge (ie, whose ovaries are secreting estrogen) fit into one of 4 categories: (a) virilized, with or without ambiguous genitalia; (b) hirsute, with polycystic ovaries, hyperthecosis, or mild maturity-onset adrenal hyperplasia; (c) nonhirsute, with hypothalamic dysfunction; or (d) amenorrheic secondary to systemic disease. Table 56–5 sets forth the differential diagnosis. Clinical examination and transvaginal ultrasound may be helpful in making the diagnosis of PCOS. However, 25% of normal patients have polycystic ovaries; consequently, ultrasound cannot be the sole criterion for diagnosis.

Table 56–5. Differential Diagnosis of Eugonadotropic Eugonadism (Progestin-Challenge Positive).

TREATMENT

Management of Patients Desiring Pregnancy—Ovulation Induction

Ovulation Induction in Patients with Amenorrhea-Galactorrhea with Pituitary Macroadenoma

Dopamine agonist drugs such as cabergoline and bromocriptine remain the first-line treatment of hyperprolactinemia of any cause, including macroadenomas. These drugs can decrease prolactin secretion and tumor size. Surgical therapy, transsphenoidal or frontal removal of the pituitary adenoma or the entire gland, may be required if tumor size or secretion are resistant to dopamine agonists; the lesion is rapidly enlarging or causing symptoms such as visual changes or headaches; or in women with giant adenomas (> 3 cm) who wish to discontinue agonist treatment for conception and the duration of pregnancy. About half of surgically treated patients will menstruate normally after this procedure.

Ovulation Induction in Patients with Amenorrhea-Galactorrhea Without Macroadenoma (Including Patients with Microadenomas)

These patients ovulate readily in response to dopamine agonist treatment, with dose titrated until serum prolactin is normal. Patients are maintained on the lowest dose necessary to maintain normal prolactin levels. Once pregnancy has been achieved, the agent can be discontinued. Patients with macroadenomas may need to continue therapy throughout pregnancy to avoid further growth of the lesion.

Patients taking drugs that raise the prolactin level should discontinue them if possible, but continued use of such drugs is not a contraindication to therapy.

Ovulation Induction in Patients with Hypothyroidism

Amenorrheic patients with hypothyroidism frequently respond to thyroid replacement therapy.

Ovulation Induction in Patients with Primary Ovarian Failure

According to Rebar and associates, patients with primary ovarian failure can be made to ovulate only under very rare circumstances. Patients with reversible ovarian failure include those with autoimmune oophoritis, who can be successfully treated with corticosteroids. Otherwise, almost all patients with primary ovarian failure fall into the category of idiopathic premature ovarian failure and cannot be made to ovulate. In vitro fertilization (IVF) with donor oocytes is the only way they can have children.

Any patient with a Y chromosome should undergo oophorectomy to prevent tumor development.

Ovulation Induction in Patients with Hypoestrogenic Hypothalamic Amenorrhea (Progesterin-Challenge Negative)

In these patients with low estrogen levels, the pituitary does not release high quantities of LH and FSH

(as would be expected with an intact, normally functioning, negative feedback mechanism). Therefore, even though clomiphene citrate (an antiestrogen) is unlikely to stimulate gonadotropin release, many reproductive endocrinologists treat such patients successfully with a single course of clomiphene citrate, 150 or 250 mg daily for 5 days, on the chance that ovulation will occur.

Injections of exogenous gonadotropins (human recombinant follicle-stimulating hormone [hrFSH] or human menopausal gonadotropin [hMG]) is usually first-line therapy. Patients showing some ovarian stimulation by clomiphene can be treated with a combination of clomiphene and hMG—the advantage being a reduction in the amount of hMG required and thus a substantial cost savings. Ovulation induction with gonadotropins must be carefully monitored with serial ultrasound and estradiol determinations to avoid hyperstimulation. Hyperstimulation is the stimulation of too many follicles, with associated ovarian enlargement and ascites, as well as other systemic abnormalities.

If a specific and potentially reversible cause of amenorrhea can be identified (eg, marked weight loss), it should be corrected.

Ovulation Induction in Patients Who Bleed in Response to Progestin Challenge

Virtually all of these patients respond to clomiphene citrate. The starting dose is 50 mg orally daily for 5 days. This can be increased to a maximum of 250 mg orally daily in 50-mg increments until ovulation is induced. Efficacy of clomiphene, however, plateaus at 100 mg/d. This medication is FDA-approved for use up to 150 mg/d. Ovulation occurs 5–10 days after the last dose. Patients with elevated androgens who do not respond to clomiphene citrate may respond to combined treatment with an oral hypoglycemic agent and clomiphene. If clomiphene therapy with or without oral hypoglycemic agents is ineffective, gonadotropin therapy may be attempted. Care must be taken in using FSH in these patients, as they are likely to become hyperstimulated.

Laparoscopic ovarian drilling (LOD) is a surgical method of ovulation induction in PCOS patients. LOD involves electrocautery or laser drilling of the ovarian cortex, with the goal of creating foci of laser or thermal damage in the cortex and ovarian stroma. In general, at least 6 puncture sites 2–4 mm in depth are made in the ovary away from the hilum. The mechanism of action is unknown, but may involve destruction of androgen-producing stromal cells, a sudden drop in ovarian androgen levels, improved follicular microenvironment, or increased gonadotropin secretion. This procedure may cause postoperative pelvic adhesions, resulting in tubal compromise.

Management of Patients Not Desiring Pregnancy

Patients who are hypoestrogenic must be treated with a combination of estrogen and progesterone to maintain bone density and prevent genital atrophy. The dose of estrogen varies with the age of the patient. Oral contraceptives are good replacement therapy for most women. Combinations of 0.625–1.25 mg of conjugated estrogens orally daily on days 1 through 25 of the cycle with 5–10 mg of medroxyprogesterone acetate on days 16 through 25 are a suitable alternative. Calcium intake should be adjusted to 1–1.5 g of elemental calcium daily.

Patients who respond to the progestin challenge require occasional progestin administration to prevent the development of endometrial hyperplasia and carcinoma. Oral contraceptive pills may be used to regulate the menstrual cycle. Oral contraceptives also help with management of hirsutism. Alternatively, medroxyprogesterone acetate, 10 mg orally daily for 10–13 days every month or every other month, is sufficient to induce withdrawal bleeding and to prevent the development of endometrial hyperplasia. Patients with hyperprolactinemia need periodic prolactin measurements and radiographic cone views of the sella turcica to rule out the development of macroadenoma.

COMPLICATIONS

The complications of amenorrhea can be numerous, including infertility and psychosocial developmental delays with lack of normal physical sexual development. Hypoestrogenic patients can develop severe osteoporosis and fractures, the most hazardous to life being femoral neck fracture (see Chapter 59). The complications associated with amenorrhea in patients who respond to progestin challenge are endometrial hyperplasia and carcinoma (see Chapter 50) resulting from unopposed estrogen stimulation.

PROGNOSIS

The prognosis for amenorrhea is good. It is not usually a life-threatening clinical event, as with proper evaluation, tumors can be recognized and treated. Many patients with hypothalamic amenorrhea will spontaneously recover normal menstrual cycles.

Virtually all amenorrheic women who do not have premature ovarian failure can be made to ovulate with a dopamine agonist, clomiphene citrate, insulin-sensitizing agents, and gonadotropins.

Current OB/GYN > Chapter 57. Hirsutism >

Definition

Hirsutism is defined as excessive growth of androgen-dependent sexual hair. This is most often manifested as increased "midline hair" on the upper lip, chin, ears, cheeks, lower abdomen, back, chest, and proximal limbs. The interpretation of what constitutes excessive growth is subjective and may range from an occasional hair on the upper lip to a full male-pattern beard. The psychological implications of hirsutism must not be underestimated. In Western society, excessive facial or body hair in women is unacceptable. Women who do not conform to a prevailing feminine ideal of physical appearance because of hirsutism may feel unattractive and suffer from low self-esteem, and such women may find social interactions difficult. Hirsutism is more than a cosmetic problem, however, because it usually represents a hormonal imbalance, resulting from a subtle excess of androgens that may be of ovarian origin, adrenal origin, or both.

Etiology

Excessive growth of sexual hair may be due to excessive production of androgens, increased sensitivity of the hair follicle to androgens, or increased conversion of weak androgens to potent androgens. Potential sources of increased androgens include the ovaries, the adrenal glands, exogenous hormones and other medications (Table 57–1).

Table 57–1. Differential Diagnosis of Hirsutism.

Ovarian nonneoplastic causes

- Polycystic ovary syndrome
- Stromal hyperplasia
- Stromal hyperthecosis
- Hyperandrogenism, insulin resistance, acanthosis nigricans (HAIR-AN)

Ovarian neoplastic causes

Idiopathic hirsutism

OVARIAN DISORDERS CAUSING HIRSUTISM

Nonneoplastic Disorders

The most common cause of hirsutism is polycystic ovary syndrome. Polycystic ovary syndrome is typically associated with menstrual irregularities, infertility, obesity, and hirsutism. The histologic changes seen in polycystic ovary disease include a thickened ovarian capsule and numerous follicular cysts surrounded by a hyperplastic, luteinized theca interna. The pathophysiology of this disease is not fully understood; proposed causes include ovarian dysregulation, a disturbance of the hypothalamic-pituitary axis, adrenal androgen excess, and increased insulin resistance. Regardless of the underlying defect, the degree of hyperandrogenism and the individual's sensitivity to androgens may result in the complaint of hirsutism in 80% of these patients.

Other nonneoplastic ovarian disorders associated with hirsutism include stromal hyperplasia and stromal hyperthecosis. Stromal hyperplasia results in the hypersecretion of androgens from hypertrophic ovaries. It has a peak incidence between 60 and 70 years of age and is usually associated with uniform enlargement of both ovaries. Stromal hyperthecosis is a proliferation of stroma with foci of luteinized thecal cells, and also results in bilateral ovarian involvement. It frequently results in the clinical manifestations of virilism, obesity, hypertension, and disturbances of glucose metabolism, with most patients showing histologic evidence of concurrent stromal hyperplasia. A syndrome known as *HyperAndrogenism, Insulin Resistance, Acanthosis Mgricans (HAIR-AN)* has also been described; however, this is thought to most likely represent a variation of one of the nonneoplastic disorders, rather than denoting a separate disease entity.

Neoplastic Disorders

Androgen-secreting ovarian neoplasms usually present with rapidly developing hirsutism, amenorrhea,

and virilization, and are rare causes of hirsutism. The most common androgen secreted by these tumors is testosterone, with serum testosterone levels usually in excess of 200 ng/dL. Most hormone-secreting neoplasms are palpable on pelvic examination and are unilateral.

Sertoli-Leydig cell tumors and hilar (Leydig) cell tumors are ovarian neoplasms typically associated with hirsutism and virilization. Sertoli-Leydig cell tumors constitute less than 0.5% of all ovarian tumors and occur mainly in young, menstruating females. Hilar cell tumors are rare neoplasms and are usually encountered in older women. Their presentation is often more indolent and less dramatic than that of Sertoli-Leydig cell tumors. Other ovarian neoplasms that may be associated with hirsutism are the gynandroblastomas, germ cell tumors, granulosa cell tumors, and gonadoblastomas. The latter occur mainly in male patients, with gonadal dysgenesis and resultant female phenotypes.

Ovarian tumors with functional stroma are categorized as germ cell tumors containing syncytiotrophoblast cells and idiopathic and pregnancy-related tumors (see below). In these tumors, the neoplastic cells do not secrete steroid hormones directly, but stimulate secretion by the ovarian stroma either within or immediately adjacent to the tumor. These tumors have been described in essentially all tumors that occur in the ovary, whether benign or malignant, metastatic or primary.

Pregnancy-Related Disorders

During pregnancy, elevated androgen levels that lead to severe hirsutism and virilization may be due to any of the above-mentioned conditions; however, pregnancy-specific disorders also exist. Theca lutein cysts (hyperreactio luteinalis) are benign neoplasms that can cause bilateral ovarian enlargement, hirsutism, and infrequently, virilization. These cysts occur almost exclusively in pregnancy and have an increased incidence in pregnancies complicated by gestational trophoblastic disease. Ovarian biopsy reveals cysts lined mostly with luteinized theca cells, but luteinized granulosa cells may also be present. Typically, resolution of the cysts occurs after pregnancy.

Luteoma of pregnancy is a benign human chorionic gonadotropin (hCG)-dependent ovarian tumor that may develop during pregnancy. High levels of testosterone and androstenedione are present, and virilization may occur in up to 25% of affected mothers and 65% of female fetuses. In most patients, spontaneous regression of the neoplasm and return of androgen levels to normal occur in the postpartum period.

ADRENAL DISORDERS CAUSING HIRSUTISM

Enzyme Deficiencies

Enzyme deficiencies affecting adrenal and ovarian steroidogenesis represent the second most common cause of hyperandrogenism in postmenarchal females and congenital adrenal hyperplasia (CAH) represents the most common disorder in this group. CAH is inherited as an autosomal recessive trait, and is present in 1–5% of women who complain of hirsutism. It results from mutations in enzymes required for adrenal steroidogenesis. The most common form of CAH is characterized by a deficiency of 21-hydroxylase with case reports of similar occurrences in patients with 3 β -hydroxysteroid dehydrogenase and 11 β -hydroxylase deficiencies. These defects prohibit cortisol synthesis from its precursor 17 β -hydroxyprogesterone. The expectant decrease in serum cortisol stimulates pituitary secretion of adrenocorticotrophic hormone (ACTH) in an effort to normalize cortisol levels. Higher levels of ACTH stimulate adrenal production of intermediates in the biosynthetic pathway of cortisol. Consequently, these intermediates cannot be used for cortisol production because of enzyme defects, and are instead shunted into the biosynthetic pathways for androgens, with resultant increases in testosterone and androstenedione.

Classical CAH is usually diagnosed in females during the neonatal period because of androgen-induced ambiguous genitalia (pseudohermaphroditism); however, a minor enzyme deficiency may go

unrecognized until puberty or later when hirsutism, amenorrhea, and virilization may occur. Such disease is termed acquired, late-onset, or adult-onset CAH.

Neoplastic Disorders

Adrenal tumors are a rare cause of hirsutism, although when present, symptoms may be acute and quite severe. The main androgen produced by adrenal neoplasms is dehydroepiandrosterone sulfate (DHEAS), with serum levels usually greater than 700–800 $\mu\text{g/dL}$. Rarely, adrenal neoplasms may secrete testosterone; when this occurs, testosterone values are usually higher than 200 ng/dL.

Cushing's Syndrome

Cushing's syndrome and the associated overproduction of cortisol may increase androgen levels and cause hirsutism. The syndrome has three known etiologies: (1) adrenal tumor, (2) ectopic production of ACTH by a nonpituitary tumor, or (3) excess production of ACTH by the pituitary (Cushing's disease). Since androgens are formed from intermediates in the synthesis of cortisol, increased serum and tissue levels of cortisol and its intermediates may result in hyperandrogenism and clinically present as hirsutism, regardless of the underlying cause of this syndrome.

Other Causes

Hyperprolactinemia has been shown to produce mild hirsutism. Several investigators have reported increased DHEAS levels with hyperprolactinemia. This likely results from adrenal stimulation after prolactin binds to its numerous receptors on the adrenal gland. Despite increased androgen secretion, clinical manifestations are mild or absent, due to the inhibitory effects of prolactin on the conversion of testosterone to dihydrotestosterone (DHT) and its metabolites.

The adrenal gland may be the source of excess androgen production in the absence of an identifiable cause. The cause of this adrenal hyperactivity is not clear, but mild enzyme deficiencies, stress and hyperfunctioning of the entire adrenal gland, have been postulated as probable causes.

IATROGENIC MECHANISMS CAUSING HIRSUTISM

Exogenous sources of androgens should also be considered as possible causes of hirsutism. Methyltestosterone, danazol, and anabolic steroids such as oxandrolone may lead to excessive hair growth. The 19-nortestosterones in low-dose oral contraceptives rarely cause hirsutism or acne.

IDIOPATHIC HIRSUTISM

Hirsutism that occurs without adrenal or ovarian dysfunction, in patients with normal menstrual cycles and in the absence of any exogenous source of steroid hormones is termed idiopathic hirsutism. The term idiopathic hirsutism is thought to be a misnomer, since a likely cause has been elucidated. When normal levels of testosterone, unbound testosterone, DHEAS, dihydrotestosterone, and androstenedione are present, increased 5 α -reductase enzyme activity appears to be the major mechanism of action. This enzyme converts testosterone to the more potent dihydrotestosterone in the hair follicle. Many patients with idiopathic hirsutism have an elevated level of plasma 3 α -androstanediol glucuronide, a metabolite of dihydrotestosterone, thought to reflect the increased peripheral androgen metabolism, which is responsible for the clinical manifestation of hirsutism.

In summary, hirsutism may result from an ovarian disorder, an adrenal disease, an iatrogenic cause, or an increase in peripheral androgen metabolism. Rarely, other endocrinologic disturbances such as hypothyroidism or acromegaly may be associated with excessive hair growth. An important clinical correlation is that hirsutism may be accompanied by infertility as a result of the underlying abnormality. Since infertility may be the inciting factor triggering a patient to seek medical care, questions regarding a history of hirsutism should be a part of any infertility work-up.

Physiology of Androgens

Androgens are steroids that stimulate the development of male secondary sex characteristics and consequently promote the growth of sexual hair. The major androgens are testosterone, dihydrotestosterone, androstenedione, dehydroepiandrosterone (DHEA), and DHEAS. In order to comprehend the role played by elevated levels of androgens in the development of hirsutism, one must understand the sources of androgens, their metabolic pathways and sites of action, and their interrelationship with other steroid hormones such as estrogens and corticosteroids.

PRODUCTION

All steroid hormone production begins with the two-stage rate-limiting step of cholesterol conversion to pregnenolone, which is regulated by trophic hormones. In the nonpregnant woman, androgens are produced by both the ovaries and the adrenals, as well as by peripheral conversion. The rate-limiting step in androgen formation is the regulation of P450c17 gene expression, which is dependent on the concentrations of luteinizing hormone (LH) in the ovary and ACTH in the adrenal cortex.

Ovarian Production of Androgens

Androgens are produced by the normal ovary as precursors in the synthesis of estrogens. When gonadotropin-releasing hormone (GnRH) is secreted in a pulsatile fashion, thecal cells are stimulated to secrete and bind LH. In response to ligand binding, the theca cells of the preantral follicle produce androstenedione, DHEA, and testosterone. In the normal female, follicle-stimulating hormone (FSH) secreted from granulosa cells stimulates the granulosa cells to aromatize these androgens to the estrogens, estrone and estradiol. This relationship produces a system of androgen anabolism and catabolism balanced and coordinated to meet the needs of the follicular cycle.

Adrenal Production of Androgens

Stimulation of the adrenal gland by ACTH results in androgen production in the zona reticularis and zona fasciculata of the adrenal cortex. The main androgen manufactured is DHEAS, with smaller amounts of DHEA and androstenedione. A phenomena called adrenarche occurs and is usually chronologically timed before menarche in females. During this period, the adrenal cortex has a significant increase in adrenal hormone production, as a result of increased responsiveness of androgens and their precursors to the circulating levels of ACTH. This results in adrenocortical secretion of DHEAS at a level similar to that of cortisol secretion. Controversy remains regarding the causative factors.

CIRCULATION

Testosterone

Testosterone, by virtue of its plasma concentration and its potency, is one of the major androgens. It is the second most potent androgen after dihydrotestosterone, and circulating levels are 20–80 ng/dL in adult women. The ovary and the adrenals contribute equally to testosterone production, with each supplying about 25% of the total circulating level. The other 50% of circulating testosterone is derived from peripheral conversion of androstenedione, although the ovarian contribution to testosterone levels may increase during the periovulatory portion of the menstrual cycle. Peripheral levels of testosterone display a slight diurnal variation that parallels that of cortisol. In normal women, 99% of testosterone is protein-bound, of which 80% is bound to sex hormone-binding globulin (SHBG) and 19% is loosely bound to albumin. The remaining 1% is free and unbound. The free and albumin-bound testosterone are the biologically active forms of circulating testosterone.

Dihydrotestosterone

Circulating levels of dihydrotestosterone, the most potent androgen, are 2–8 ng/dL or one-tenth those of testosterone. Although both the ovary and the adrenal gland secrete it, most dihydrotestosterone is produced by peripheral conversion of testosterone by 5 α -reductase.

Androstenedione

Androstenedione, one of the 17-ketosteroids, is not very potent, with only 20% of the effectiveness of testosterone. Synthesis and secretion occur mostly in the ovaries and adrenals in equal amounts, with the remaining 10% being produced peripherally. Androstenedione levels display a diurnal variation paralleling that of cortisol and may simultaneously increase by as much as 50% when cortisol levels rise. Moreover, periovulatory increases in androstenedione levels can also be observed. In contrast to testosterone, androstenedione is bound mainly to albumin and secondarily to SHBG.

DHEA and DHEAS

DHEA and DHEAS, both weak androgens, have approximately 3% of the effectiveness of testosterone, and are the other major precursors of 17-ketosteroids. DHEA is primarily produced by the adrenals (60–70%), with ovarian production and hydrolysis of DHEAS accounting for the remainder. DHEA has a large diurnal variation similar to that of cortisol. Conversely, DHEAS is derived almost entirely from the adrenal, has only slight diurnal variation, and circulates in high concentrations. The DHEAS level may provide a good clinical assessment of adrenal function.

ACTION

The skin and hair follicles are androgen-responsive and thus have the capacity to metabolize androgens. DHEA, androstenedione, and testosterone enter the target cell and are reduced to dihydrotestosterone by 5 α -reductase. Dihydrotestosterone is then bound to a cytoplasmic receptor protein that transports the androgen into the cell nucleus, where it is bound to chromatin and initiates transcription of stored genetic information. In the hair follicle, this promotes hair growth, leading to increased hair growth and initiating the conversion of vellus to terminal hair.

In females a certain amount of androgenic stimulation is expected, with the greatest levels noted at puberty, when these increased levels result in the clinical appearance of pubic hair and axillary hair. Similarly, androgens stimulate the facial pilosebaceous glands resulting in the pubertal development of acne.

Metabolic conversion of androgens to dihydrotestosterone may be accelerated. This results in irreversible conversion of vellus hair to terminal hair in areas of androgen-sensitive skin. Thus, in excess androgens are pathologic, and the clinical signs and symptoms of hirsutism and virilization result.

Physiology of Hair Growth

The hair follicle and its sebaceous gland together make up the pilosebaceous unit. The hair follicle begins to develop within the first 2 months of gestation, and by birth, a child possesses all of the hair follicles he or she will ever have. Hair first appears as vellus hair, which is fine, short, and lightly pigmented. During puberty, adrenal and ovarian androgen levels rise, converting vellus hair to terminal hair, which is coarse, long, and more heavily pigmented.

Hair growth is cyclic. The three phases of the cycle are (1) anagen (growth), (2) catagen (rapid involution), and (3) telogen (inactivity). The length of each hair is determined by the relative duration of anagen and telogen and varies with different locations on the body, although each hair follicle has its own growth cycle independent of adjacent hair follicles. Scalp hair has a long anagen, from 2 to 6 years, with a short telogen.

The growth and development of the hair follicle may be influenced by several factors. First, the pilosebaceous unit is sensitive to the effects of sex hormones, especially androgens. During puberty, adrenal and ovarian androgen levels rise, converting testosterone to dihydrotestosterone, which can initiate growth and increase both the diameter and pigmentation of hair. Although conversion of vellus hair to terminal hair is essentially irreversible, removal of the androgenic stimulus will slow hair growth

and stop the conversion of vellus to terminal hair. Conversely, estrogens can retard the growth rate and result in finer hair with less pigmentation.

Genetic factors may also influence the pilosebaceous unit. Although males and females are born with equal numbers of hair follicles, racial and ethnic differences are noted in the concentration of hair follicles; Caucasians have a greater number of hair follicles than African-Americans, who in turn have a greater number than Asians. Different ethnic groups within each race may also exhibit differences in hair follicle concentrations (eg, Caucasians of Mediterranean ancestry have a greater concentration of hair follicles than those of Nordic ancestry).

Understanding the role of exogenous factors on the pilosebaceous unit allows one to better understand how pathologic hirsutism develops, and what factors may affect the severity of the disease process.

Diagnosis & Clinical Findings

Appropriate questioning allows one to rule out any history of drug ingestion that might cause excessive hair growth, to determine the speed of onset of symptoms, and to correlate the timing of symptoms with age and puberty. Specific inquiry into the patient's menstrual history allows the classification of patients who are amenorrheic or oligomenorrheic, and to distinguish those whose pathology began with puberty from those with a later onset of hirsutism. Knowledge of a family history of hirsutism or of abnormal menstrual cycles may also be informative.

Finally, a physical examination should be performed to differentiate hypertrichosis from hirsutism and to evaluate for acanthosis nigricans or additional signs of virilization such as clitorimegaly, male pattern balding, deepening voice, or decreased breast contour. Particular attention should be paid to body habitus, hair distribution, and the pelvic examination. Employing the Ferriman-Gallwey grading system provides a subjective determination of the severity of hirsutism and may also be followed to determine treatment effectiveness.

SIGNS AND SYMPTOMS

Many of the disorders involving hirsutism have characteristic presentations that may aid in diagnosis. For example, in classical congenital adrenal hyperplasia, the stigmata are identified at birth and include clitorimegaly, labial fusion, and an abnormal urethral course. Hirsutism presenting in childhood may be due to androgen-producing tumors and usually presents with other pronounced signs of virilization and the presence of a pelvic mass. However, an androgen-producing tumor should also be suspected when a woman with a normal menstrual history presents with sudden onset of irregular menses followed by amenorrhea, hirsutism, and virilization. Genetic anomalies such as mosaic cells containing Y chromosomes or incomplete androgen insensitivity syndrome may produce signs of androgen stimulation associated with primary amenorrhea at puberty. Moreover, if a patient presents with a long history of irregular menses with slow onset of hirsutism beginning at puberty or in the early 20s, polycystic ovary syndrome or late-onset congenital adrenal hyperplasia are suggested. A higher index of suspicion for CAH should be considered in individuals with a genetic predisposition (Ashkenazi Jews and Eskimos), short stature, or a strong family history of hirsutism. Similarly, menstrual irregularities, in the presence of galactorrhea or visual changes, should cause suspicion of hyperprolactinemia. Hirsutism or virilization during pregnancy raises the suspicion of a luteoma of pregnancy or bilateral theca-lutein cysts. The physical signs of Cushing's syndrome, including centripetal obesity, wasting of the extremities, fat deposition in supraclavicular areas and in the neck and face, facial plethora, and wide cutaneous striae are usually apparent if this syndrome exists. When acromegaly is present, overgrowth of the viscera and soft body tissues, as well as enlargement of the bones of the hands, feet, and face can be seen. Finally, if hypothyroidism is present, thickening of the skin of the lips, fingers, lower legs, or lower eyelids may be present, along with complaints of lethargy, cold intolerance, constipation, and voice changes.

While the medical history, the menstrual history, and the physical examination are directive and informative, significant overlap exists and laboratory studies and sometimes imaging studies are needed before a diagnosis can be confirmed.

LABORATORY FINDINGS

Investigators disagree about which androgens should be measured in the evaluation of hirsutism. Laboratory evaluation should seek to identify life-threatening conditions associated with hyperandrogenism, such as Cushing's syndrome, congenital adrenal hyperplasia, and ovarian or adrenal tumors. Serum testosterone, DHEAS, and 17β -hydroxyprogesterone levels can be obtained for screening purposes.

Screening Tests

TESTOSTERONE

A serum testosterone level of less than 200 ng/dL will rule out almost all of the testosterone-secreting neoplasms. A total testosterone level higher than 200 ng/dL should be considered evidence of an ovarian tumor until proven otherwise; few adrenal tumors produce testosterone.

The presence of hirsutism in a patient with a normal testosterone level indicates increased androgen effects. In hirsute women, increased androgen levels may decrease production of SHBG by the liver, and the free, biologically active fraction of testosterone may increase 2–3%. Therefore, normal total serum levels of testosterone in a hirsute woman can reflect a decreased level of SHBG, with an increase in the free testosterone fraction. However, the determination of the serum free testosterone level is expensive and does not add any useful clinical information.

DHEAS

A normal or slightly elevated DHEAS level excludes significant adrenal pathology. Adrenal tumors usually produce DHEAS with plasma levels markedly elevated to greater than 700–800 μ g/dL. The plasma DHEAS level is reliable and convenient and has replaced 24-hour urine collection for measurement of 17-ketosteroids in most laboratories.

17α -HYDROXYPROGESTERONE

17α -Hydroxyprogesterone is the single most accurate diagnostic test for congenital adrenal hyperplasia due to 21-hydroxylase deficiency. It is a cost-effective screen for women whose history suggests CAH. 17α -Hydroxyprogesterone should be measured immediately upon awakening, in the morning, and only during the follicular phase of the menstrual cycle. Normal levels are less than 200 ng/dL. Levels ranging between 200 and 400 ng/dL warrant further evaluation. Levels greater than 400 ng/dL are virtually diagnostic of 21-hydroxylase deficiency.

Directed Tests

Further testing should be ordered based on history and physical examination. If a woman is oligo-ovulatory or anovulatory, determination of FSH, LH, thyroid-stimulating hormone (TSH), and prolactin levels is helpful. In patients with a mild enzyme deficiency or a partial block at the 21-hydroxylation step in the biosynthesis of cortisol, 17α -hydroxyprogesterone levels may not be elevated and ACTH stimulation may be required for diagnosis. If the DHEAS level is elevated or if Cushing's syndrome is suspected, then either an overnight dexamethasone suppression test or a 24-hour urinary free cortisol level should be obtained. If the above laboratory tests are normal in a hirsute female, the diagnosis of idiopathic hirsutism must be considered and an androstenediol glucuronide level may be evaluated.

FSH AND LH

An elevated level of LH, particularly when the LH:FSH ratio is 3 or higher, suggests polycystic ovary syndrome; however, this value is neither sensitive nor specific and is not required for the diagnosis. Newer diagnostic tests being employed include the evaluation of the glucose:insulin ratio and SHBG. Low

levels of these values indicate insulin resistance, which is often a contributing factor in the development of polycystic ovarian syndrome.

PROLACTIN

A mildly elevated prolactin level may be seen in patients with polycystic ovarian syndrome or those with increased adrenal stimulation. However, prolactin elevation above 200 μ g/dL usually suggests a prolactinoma.

TSH

An increased TSH level is strongly suggestive of hypothyroidism. A free T₄ and T₄ index should be obtained to confirm the diagnosis in these individuals.

ACTH STIMULATION TEST

The ACTH-induced increase in 17 α -hydroxyprogesterone is a sensitive diagnostic test for congenital adrenal hyperplasia. Generally, this test is reserved for individuals in high-risk populations, given the low prevalence of disease among hirsute women. For diagnosis, 17 α -hydroxyprogesterone is measured 30 minutes after an intravenous injection of 250 μ g of synthetic ACTH. Values rarely exceed 400 ng/dL in normal women and values above 1000 ng/dL are indicative of disease. Once the diagnosis is made, the nomogram by Marie New can be used to differentiate nonclassical and classical disease.

TESTS USED TO DIAGNOSE CUSHING'S SYNDROME

(1) Overnight dexamethasone suppression test—An overnight dexamethasone suppression test may be used as a simple outpatient screening test. A baseline morning plasma cortisol level is drawn, then dexamethasone, 1 mg orally, is given at 11:00 PM. A second plasma cortisol level is obtained at 8:00 AM the next morning. In normal patients, cortisol levels are suppressed to 5 μ g/dL, whereas in patients with Cushing's syndrome, cortisol levels fall but do not go below 5 μ g/dL. This test is easily performed on an outpatient basis, but may result in false-negative results, particularly in patients with mild disease. The false-positive rate is much higher in obese patients, chronically ill or depressed patients, and patients taking carbamazepine.

(2) 24-hour urinary free cortisol—The most accurate screening test for documentation of hypercortisolism is measurement of urinary free cortisol over a 24-hour period. Values greater than 100 ng/24 h are considered abnormal and further evaluation is warranted. Values greater than 250 ng/24 h are virtually diagnostic of Cushing's syndrome. The 24-hour urinary free cortisol determination is an excellent screening test because it has a low incidence of false-negative results; however, false-positive values may occur in the presence of depression, polycystic ovarian syndrome, carbamazepine therapy, or increased fluid intake.

(3) Low-dose dexamethasone suppression test—If the above screening tests yield equivocal results, the low-dose dexamethasone suppression test may be employed. Low-dose suppression of urinary free cortisol to less than 25 mg/24 h or 17-hydroxycorticosteroids to less than 3 mg/24 h after the administration of 0.5 mg of dexamethasone every 6 hours for 2 consecutive days rules out Cushing's syndrome. Unfortunately, this test also has remarkably low sensitivity and specificity, and some investigators question its benefit in patient evaluation.

(4) Additional tests—Alternatively, newer tests may be employed. These include (1) evaluation of late night plasma or salivary cortisol levels; (2) assessment of plasma cortisol after dexamethasone and corticotropin-releasing hormone are given; and (3) evaluation of ACTH after administration of intravenous and oral hydrocortisone. While all of the above tests may assist when verification of disease is required, the ideal test for evaluation has yet to be identified.

TESTS USED TO DIFFERENTIATE CUSHING'S DISEASE FROM CUSHING'S SYNDROME

(1) *High-dose dexamethasone test*—Once the diagnosis of Cushing's syndrome has been made, the etiology should be further elucidated. The high-dose dexamethasone test is usually used for this purpose, although it is currently being reevaluated. It requires 6 days of urine collection and the sensitivity and specificity are poor. Despite efforts by many investigators to improve this test, limitations continue to exist. When this test is used diagnostically, Cushing's disease is diagnosed when urinary free cortisol and 17-hydroxycorticosteroid are suppressed by 90%.

(2) *Corticotropin-releasing hormone (CRH) stimulation test*—Measuring plasma ACTH levels before and after the administration of CRH yields better results than the high-dose dexamethasone test; however, the diagnostic accuracy is no better than 85–90%. Therefore, the addition of imaging studies or inferior petrosal sinus sampling may be justified (see below).

ANDROSTANEDIOL GLUCURONIDE LEVELS

The measurement of serum androstanediol glucuronide has been proposed as a good marker of peripheral androgen production and activity in hirsutism. Serum androstanediol glucuronide may be elevated in idiopathic hirsutism as a result of altered metabolism or increased utilization of androgen in the skin and hair follicles. Although this test is useful for research, its clinical applicability remains limited. Because of high cost and limited usefulness, the test for androstanediol glucuronide levels is not currently recommended in the routine evaluation of hirsutism.

IMAGING STUDIES

Ultrasonography is usually reserved for patients suspected of having a pelvic mass contributing to their disease process. In general, pelvic examination reveals a palpable ovarian mass; however, if the examination is limited by the individual's body habitus, pelvic ultrasonography may help delineate an abnormal structure. Although patients with polycystic ovarian syndrome have characteristic small, peripheral ovarian follicles, the specificity of ultrasonography is extremely limited, since many individuals without this syndrome have been found to have polycystic ovaries. Hence, routine ultrasonography in the diagnosis of this syndrome is not a universal practice.

If the testosterone level is higher than 200 ng/dL and no ovarian mass is identified, computed tomography (CT) or magnetic resonance imaging (MRI) of the adrenal glands should be performed before laparotomy to rule out the rare testosterone-producing adrenal tumor. CT scan and MRI of the adrenal glands have proven to be sensitive diagnostic techniques that have generally replaced selective venous sampling and selective angiography. Selective bilateral venous catheterization of adrenal and ovarian veins has limited clinical usefulness, since it is technically difficult and hazardous to perform, and its diagnostic sensitivity is poor.

Primary adrenal disease is most often confirmed with adrenal CT scan. CT scan or MRI of the lung is indicated with ectopic ACTH secretion, since this is the most common site of ectopic ACTH production. Similarly, a CT scan or MRI of the sella turcica may be used to localize an ACTH-secreting tumor. Currently, MRI is the preferred study due to its increased sensitivity when enhancement and dynamic imaging are judiciously used. Still, detection of the more centrally located ACTH-secreting microadenomas is only about 45–71%, and only 40–50% of these lesions are visualized before surgical correction of the problem. Due to limitations in biochemical testing and conservative imaging studies for Cushing's disease, simultaneous bilateral inferior petrosal sinus sampling is usually necessary to confirm the disease and to localize the lesion. A petrosal sinus:peripheral venous ACTH ratio greater than 2 in the absence of CRH, or greater than 3 when CRH is administered, is diagnostic of Cushing's disease.

Differential Diagnosis

Hirsutism should be differentiated from both virilization and hypertrichosis, since the cause and treatment of these disorders may be different. Virilization is characterized by more extensive androgen-induced changes than hirsutism alone. These changes include acne, increased oiliness of the skin, temporal balding, clitorimegaly, deepening of the voice, development of male muscular pattern and body habitus (in extreme cases), and atrophy of the breasts.

Hypertrichosis is also characterized by excessive growth of hair, but the term denotes increased growth of nonsexual hair (eg, hair on the forehead, lower leg, or forearm). The hair is usually fine-textured and is not caused by androgen excess or abnormal androgen metabolism. Heredity, certain drugs, physical irritation (trauma to the skin), or even starvation may be responsible. However, drug ingestion is the most common cause. Phenytoin, diazoxide, and minoxidil are known to cause a generalized increase in hair growth. Penicillamine and streptomycin have been associated with increased hair growth in infants and children. In addition, inadvertent ingestion of the fungicide hexachlorobenzene has also caused hypertrichosis. Disorders such as porphyria, hypothyroidism, dermatomyositis, acromegaly, Hurler's syndrome, trisomy E, and Cornelia de Lange's syndrome may be associated with hypertrichosis.

Treatment

The selection of therapy for hirsutism depends on the physical and laboratory findings, as well as on the patient's desire for childbearing. After evaluation has ruled out neoplasm or a serious disease process, a mildly hirsute woman with normal menstrual cycles may require only reassurance. A moderately or severely hirsute woman with menstrual irregularities requires treatment. For women not desiring childbearing in the near future, medical therapy consisting of adrenal or ovarian suppression or the blocking of peripheral androgen effects is advised. If infertility is a major concern, ovulation induction with the appropriate drug (eg, clomiphene, bromocriptine, human menopausal gonadotropin [hMG], or gonadotropin-releasing hormone [GnRH]) is started after appropriate evaluation. In many patients, simultaneous use of mechanical depilators and rarely surgery may be necessary.

MEDICAL MANAGEMENT

The medical treatment of hirsutism is not completely successful. The response rate has been reported to be between 23% and 95%, depending on the drug and dosage used. The drugs most commonly used to treat hirsutism include oral contraceptives, GnRH analogs, androgen receptor antagonists, and corticosteroids.

All drug therapy should seek to alter at least one of the 5 major aspects of androgen metabolism: (1) decrease production; (2) increase the metabolic clearance rate; (3) inhibit androgen receptors; (4) inhibit the enzymes involved in the peripheral production of testosterone or dihydrotestosterone; or (5) increase SHBG.

Combination Oral Contraceptives

Oral contraceptives have been extensively used to treat hirsutism. Their effect is exerted through a wide range of actions. The combination pill contains both estrogen and progestins and prevents ovulation by inhibiting gonadotropin secretion. Inhibition of LH secretion is mainly accomplished by the addition of the progestational component. When adequate suppression of LH is achieved, ovarian steroidogenesis is suppressed, leading to decreased testosterone production by the ovary. A decline in plasma testosterone can be seen as early as 1 week after treatment has been started; levels may decrease to normal by 3 months. Hair growth is reportedly decreased 50–60% in patients taking combination birth control pills. This effect is seen with the administration of all combination oral contraceptives, regardless of the individual steroid concentrations. Use of a low-dose pill (less than or equal to 35 ng of estrogen) allows for suppression of testosterone production while minimizing estrogen-related side effects.

The estrogen component decreases the androgenic effects of plasma testosterone by increasing hepatic SHBG synthesis. Since only the unbound form of testosterone is available to initiate a biologic response, increasing the bound fraction of testosterone by increasing SHBG levels leads to a decrease in testosterone-mediated effects. However, this increase has not been shown to have a direct effect on hirsutism.

Several studies suggest that combination birth control pills may exert a significant suppressive effect on adrenal androgen synthesis. Although the mechanism of action is presently unclear, this effect is probably due (at least in part) to suppression of ACTH release. The ability of combination birth control pills to lower the serum levels of DHEAS has several therapeutic implications. First, although DHEAS is low in biologic potency, it can serve as a precursor for peripheral conversion to more biologically potent androgens, and elevated levels of DHEAS can therefore be clinically manifested as hirsutism. Second, the ability of combination birth control pills to suppress both adrenal and ovarian androgen production, resulting in a significant reduction of androstenedione, DHEAS, and testosterone, may make these pills an even more attractive therapeutic option.

Older combination pills contain progestins, which are derivatives of testosterone. These 19-nortestosterones have some androgenic properties, which may result in hirsutism, acne, or oily skin. However, newer generation oral contraceptives contain desogestrel, gestodene, norgestimate or drospirenone. These drugs have fewer androgenic side effects, but have not consistently been shown to be more beneficial in the treatment of hirsutism.

Gonadotropin-Releasing Hormone (GnRH) Agonists

GnRH analogs inhibit the secretion of gonadotropins from the pituitary gland, thereby inhibiting the secretion of androgens and estrogens from the ovary. Although GnRH agonists acutely stimulate ovarian production of androgens and estrogens, continued therapy causes a sustained decrease in ovarian steroid production compared with pretreatment levels. This suppression continues for the duration of GnRH agonist therapy. Significant decreases in serum levels of estradiol, testosterone, and androstenedione occur during treatment, although adrenal androgens are usually unaffected.

As a result of the hypoestrogenism associated with ongoing GnRH therapy, a potential risk of osteoporosis and menopausal symptoms exists with long-term therapy. However, concomitant use of estrogen and progesterone replacement therapy may counteract the adverse effects. Newer studies suggest that spironolactone may also simulate this effect.

Most studies have shown greater improvement of hirsutism with the use of GnRH agonists alone or in combination with oral contraceptives as compared with combination oral contraceptives alone; however, some studies show comparable efficacy.

Androgen Receptor Antagonists

There are four androgen receptor antagonists currently being used for the treatment of hirsutism. Despite proven efficacy in numerous clinical trials, none of these drugs has been approved by the U.S. Food and Drug Administration for this indication. Additionally, similar reported efficacy has been reported with all of these medications. Hence the agent of choice should be dictated by the individual's response, reported side effects, and known contraindications.

CYPROTERONE ACETATE

This potent agent was the first androgen receptor antagonist used to treat hirsutism and is widely prescribed in Europe to treat hirsutism. Antiandrogenic effects result from competitive displacement of dihydrotestosterone from its receptor and reduction of 5 α -reductase activity in the skin. Progestational activity results in gonadotropin suppression with subsequent suppression of ovarian testosterone

secretion. Cyclical administration of 50–100 mg on days 1–10 of the menstrual cycle combined with oral estrogen on days 1–21 produces therapeutic levels. Additionally, this method counters hypoestrogenism and irregular bleeding and prevents pregnancy and the potential teratogenic complications that may result. Although effective in 50–75% of hirsute women, significant side effects include decreased libido, mental depression, and hepatotoxicity, which is rarely seen when cyclic administration is performed. Clinical studies have shown efficacy equivalent to that of spironolactone, with the latter showing fewer side effects (see below). Currently, cyproterone acetate is not available in the U.S.

SPIRONOLACTONE

Spironolactone, an aldosterone antagonist traditionally used as a diuretic in the treatment of hypertension, is also used to treat hirsutism. It possesses antiandrogenic properties and exerts its peripheral antiandrogenic effects in the hair follicle by competing for androgenic receptors and displacing dihydrotestosterone at both nuclear and cytosol receptors. It also lowers testosterone levels by inhibiting the cytochrome P450 monooxygenases that are required for biosynthesis of androgens in gonadal and adrenal steroid-producing cells. Serum levels of SHBG, DHEAS, and DHEA are unaltered by treatment with spironolactone. The dosage used for treatment of hirsutism has varied between 50 and 200 mg/d. Serum androgen levels will drop within a few days of the start of treatment, and a clinical response can usually be seen within 2–5 months. Side effects are mild—transient diuresis and polydipsia have been noted in the first few days of treatment, and disturbances in the menstrual cycle, breast tenderness, and fatigue have also been reported, but no long-term problems have been encountered. Because spironolactone is a potent antiandrogen, all women using it should use effective contraception.

FLUTAMIDE

Flutamide is a potent, highly specific, nonsteroidal antiandrogen with no intrinsic hormonal or antigonadotropin activity. Although the exact mechanism of action is unknown, it competitively inhibits target tissue androgen receptor sites. Recent studies suggest that 250 mg 1–3 times daily is a highly effective treatment for moderate to severe hirsutism. Side effects include decreased appetite, amenorrhea, decreased libido, or dry skin. A rare but serious reported side effect is hepatotoxicity. Consequently, flutamide is usually reserved for resistant cases of hirsutism, and liver enzymes should be checked regularly in patients on the drug. Additionally, because of possible teratogenic effects, contraception must be used with this therapy.

FINASTERIDE

Finasteride is the newest antiandrogenic agent used for hirsutism. It is a selective type 2 5 α -reductase inhibitor that blocks the conversion of testosterone to dihydrotestosterone. It has proven efficacy in up to 86% of patients with a subjective improvement rate of 21–45% when 5 mg is administered orally over 3 months to 1 year. Side effects at this dosage are usually mild or absent and include headaches, transient gastrointestinal upset, and an unexplained increase in total testosterone.

Glucocorticoids

Dexamethasone is used mainly to treat hirsutism in patients with hyperandrogenism of adrenal origin. Chronic low-dose dexamethasone, 0.5–1 mg orally taken at bedtime, will provide adequate adrenal androgen suppression. Diminution of hair growth is reported in 16–70% of patients. Glucocorticoid therapy has fallen out of favor due to frequent side effects, potential for adrenal suppression, and evidence that these agents are less effective than antiandrogens, even when there is a clear adrenal cause of hyperandrogenism. However, their use may be justified in some patients, since recent data suggest that concomitant use of glucocorticoids with GnRH agonists may prolong the disease-free interval when therapy is discontinued. Moreover, glucocorticoids are the treatment of choice to decrease ACTH levels and thereby decrease formation of androgenic precursors of cortisol for patients with congenital adrenal hyperplasia.

Other

DOPAMINE

Dopamine is a centrally acting inhibitor of prolactin secretion and is frequently used in the treatment of hyperprolactinemia. Recently, hirsutism scores were shown to decrease significantly during dopamine treatment of hyperandrogenic women with hyperprolactinemia.

TROGLITAZONE

Troglitazone is an insulin-sensitizing agent of the thiazolidinedione class, which results in a dose-related decrease in androgen level in patients with polycystic ovarian syndrome. Additionally, it has been shown that the administration of 600 mg/d results in significant improvement of hirsutism in this population.

CIMETIDINE

Cimetidine, an H₂-receptor antagonist, has weak antiandrogenic properties. Recent studies show minimal or no beneficial effect in hirsutism.

KETOCONAZOLE

Ketoconazole is a synthetic imidazole derivative that blocks adrenal and gonadal steroidogenesis; it has been advocated by some as a treatment for hirsutism. However, serious side effects result in poor compliance and preclude long-term use. Its use should be avoided since safer therapeutic regimens exist.

MECHANICAL THERAPY

The goal of mechanical therapy is to limit new hair growth without affecting existing hair. For this reason, mechanical depilators such as lasers, electrolysis devices, creams, and waxes are often used as supplemental therapy. Recent technology has made this procedure faster, easier, less painful, and generally free of any serious adverse effects.

SURGICAL TREATMENT

In the minority of hirsute patients in whom a specific cause can be identified, therapy should be directed toward the underlying disorder. For example, ovarian and adrenal tumors should be surgically excised. Additionally, women with Cushing's disease are treated with transsphenoidal pituitary microsurgery. Alternatively, when Cushing's syndrome is caused by an adrenal tumor, simple adrenalectomy is sufficient. Finally, acromegaly can be treated by transsphenoidal hypophysectomy. For persistent disease, bilateral adrenalectomy or pituitary irradiation is appropriate.

Similarly, a minority of older women may fail to respond to medical management for hyperthecosis despite good compliance. For these women, bilateral oophorectomy may be justified as definitive therapy.

Although wedge resection of the ovary has been successfully used to induce ovulation, it is not recommended for the treatment of hirsutism. This surgical procedure exposes patients to the risks of both anesthesia and possible formation of adhesions. More importantly, this procedure results in only a transient decrease in androgen levels and has successfully reduced the rate of hair growth in only 16% of patients. Wedge resection should not be used as a treatment for hirsutism.

Complications & Prognosis

The treatment for hirsutism can be frustrating for both patient and physician because of the physiologic properties of hair itself. The growth cycle of hair is long, varying between 6 and 24 months, and the conversion of vellus hair to terminal hair is essentially irreversible. Also, once hair growth has been stimulated by excessive androgen levels, maintenance of that same growth rate requires much less androgen. Patients must be advised that a response to therapy may not be seen for 6–12 months and that although it is possible to prevent further conversion of vellus hair to terminal hair, little change will be seen in the total number of terminal hairs. Some patients may note lightening of hair color and a decrease in the diameter of the hair shaft with therapy. Cosmetic treatment of excess hair consists of shaving, plucking, bleaching, waxing, or use of depilatories; however, shaving and plucking may cause infection and scarring and are not recommended. Permanent hair removal may be accomplished only by electrolysis (electrocoagulation of the hair root, or papilla), which is costly and uncomfortable, or by depilation. Unless there is excessive hirsutism, electrolysis should be delayed until after 6–12 months of medical therapy have been completed.

Patients who exhibit progressive hirsutism while receiving hormonal therapy or patients whose circulating androgen levels fail to decrease as expected should undergo further evaluation. If androgen levels are not suppressed with appropriate therapy, the possibility of a slow-growing neoplasm should be considered. Levels of testosterone and DHEAS should be monitored and the adrenal glands and ovaries reevaluated.

When adequate suppression of DHEAS and testosterone has been maintained for 6–12 months but a satisfactory reduction in new hair growth has not occurred, several options are available. The dose of the current medication can be increased, a new medication can be substituted, or a new medication can be added. It is frequently impossible to increase the dose of the initial medication, since the incidence of side effects may increase as the drug dosage increases. Likewise, it is not always easy to switch medications, since choice of the initial drug may have been guided by specific therapeutic considerations (eg, hirsute women who desire contraception may be treated with combination contraceptive pills, whereas hirsutism associated with hypertension may be treated with spironolactone). Some authors have recommended adding a second medication to the treatment regimen for hirsutism unresponsive to therapy. Newer evidence suggests that combination drug treatment for hirsutism with concomitant use of drugs that act at different sites may produce the best results (eg, combination birth control pills that act chiefly through decreased production of ovarian steroids may be combined with spironolactone, which acts mainly at the peripheral androgen receptors).

Treatment for hirsutism must be individualized and based on the results of a thorough history, physical examination, and laboratory studies. After therapy has begun, the patient's progress can be monitored on the basis of both clinical appearance and laboratory values. The patient should be educated about her disorder in order to prevent unrealistic expectations of therapy and to make her aware of any side effects that might manifest during therapy. Adjunctive therapy is almost always necessary with any medical treatment for hirsutism. Depilatories and electrolysis are frequently needed to remove the terminal hair already present; these methods, when combined with medical therapy, offer the best cosmetic result.

Current OB/GYN > Chapter 58. Assisted Reproductive Technologies: In Vitro Fertilization & Related Techniques >

ASSISTED REPRODUCTIVE TECHNOLOGIES: IN VITRO FERTILIZATION & RELATED TECHNIQUES: INTRODUCTION

Assisted reproductive technologies (ART) include many techniques that allow gamete manipulation outside the body, and have evolved greatly over the past two decades.

IN VITRO FERTILIZATION

In vitro fertilization (IVF) involves the removal of eggs from the ovary, fertilizing them in the laboratory, and replacing them in the patient's uterus. The first live birth resulting from this technique occurred in June 1978. Since then, thousands of children have been born throughout the world.

Assisted reproductive techniques have come a long way with more programs reporting, an increasing number of cycles treated, an increasing pregnancy rate, and an increase in live births per cycle (from 6.6% in 1985 to 28% in 2003) for IVF. In 2003 there were 122,872 ART cycles (99.4% were IVF cycles and the rest were gamete intrafallopian transfer for fertilization (GIFT) and zygote intrafallopian transfer (ZIFT) cycles. Approximately half of the IVF cycles were IVF/ICSI. From all these cycles, 33,141 deliveries resulted in 45,751 babies. Among the ART cycles using fresh nondonor eggs or embryos, from 91,032 cycles that were started, there were 79,602 retrievals, 74,296 transfers, and 31,348 pregnancies, which resulted in 25,775 live births. The most important prognostic indicator for pregnancy rates is the age of the female partner. After age 43 years, the live birth rate with IVF is 2.4%.

Approximately 39% of patients who undergo egg retrieval will become pregnant with sonographic documentation of an intrauterine pregnancy (clinical pregnancy); 82% of these patients will carry to term. Many "biochemical pregnancies" occur, but these should not be included in pregnancy statistics. (A biochemical pregnancy is one in which serum levels of human chorionic gonadotropin [hCG] rise and then fall before sonographic detection of pregnancy is possible.) Eggs are almost always obtained by aspiration, and under ordinary circumstances, approximately 75% of eggs will fertilize and cleave. The clinical pregnancy rate of approximately 34% per embryo transfer per IVF cycle is greater than the 20–25% pregnancy rate per cycle observed in spontaneous conceptions in the general population.

The success rate in IVF has been improved by replacing more than 1 embryo, but doing so increases the likelihood of multiple gestations. Among the 31,348 pregnancies that resulted from fresh nondonor cycles in 2002, 54.1% were singletons, 28.1% were twins, and the rest were triplets or more. Although multiple gestations are often welcomed by the infertility couples, they are riskier pregnancies that often result in preterm births.

Indications

In vitro fertilization-embryo transfer (IVF-ET) bypasses the mechanical transport functions of the female reproductive tract. It was first developed for patients with severe tubal disease, and it clearly offers the only hope of conception to patients who have had a bilateral salpingectomy or whose tubes are so badly damaged that they cannot function. Subsequently, in vitro fertilization has been applied to a variety of other infertility problems. Indications for IVF include (a) male factor infertility, (b) tubal disease, (c)

decreased ovarian reserve, (d) endometriosis, (e) genetic diseases with need for genetic testing of the embryos, (f) need for third-party reproduction-donor eggs or gestational surrogate, and (g) unexplained infertility. When the probability of conception by IVF exceeds that of conception by conventional therapy, IVF appears to be the procedure of choice. Because of an increased incidence of infertility in our modern society in which women work earlier and conceive later and there is an increased awareness and availability of ART, the demand for these technologies has grown.

Although IVF is successful in treating many infertility problems, its success hinges on entry of sperm into the egg. It was initially hoped that routine IVF could be used to compensate for severe oligospermia (< 5 million sperm/mL). However, early results were highly variable. Advances in this area are now being applied in clinical practice. Modern microsurgical techniques permit placement of sperm directly into the cytoplasm of the oocyte. This is discussed in detail below. In addition to male factor issues, another barrier to success with IVF is hydrosalpinx (fluid collection in the fallopian tube). This condition may interfere with implantation and additional surgery may be needed so that implantation and pregnancy rates improve.

Technique

SUPEROVULATION

All ART programs use superovulation to stimulate production of several eggs and to improve timing of egg aspiration. The type of ovulation-induction therapy varies from group to group and is constantly changing. The following methods are used alone or in combination:

1. Clomiphene citrate;
2. Human menopausal gonadotropins—urinary or recombinant;
3. Follicle-stimulating hormone (FSH) products—urinary or recombinant; and
4. Leuteinizing (LH) agonists (mostly used in Europe).

Superovulation is carefully monitored with ultrasound scans to monitor the number and growth of follicles, as well as the uterine lining, and serum estradiol is drawn to assess the function of the follicles. At least 2 or 3 follicles should be developing before proceeding with egg aspiration; otherwise, the cycle is usually abandoned and an alternative stimulation regimen is selected for a subsequent cycle. Serum estradiol levels are complementary to ultrasonography in evaluating the maturation and growth of the developing follicles (200 pg/mL per mature follicle is expected). There is evidence that the pattern of serum estradiol may predict the cycles most likely to result in pregnancy. A declining estradiol level prior to hCG administration is associated with a lower pregnancy rate. hCG (either urinary or recombinant) is usually administered when the mature follicles have reached at least 17 mm in diameter to induce ovulation. Ovulation usually occurs 36 hours after hCG injection.

The introduction of gonadotropin-releasing hormone (GnRH) agonists or antagonists to superovulation regimens has drastically reduced the likelihood of a premature LH surge; consequently, they are used in the majority of IVF patients in the United States. The GnRH agonists are usually administered on day 21 or the previous cycle (long protocol) or at the beginning of menses, along with the addition of gonadotropins (short protocol), and they are continued until the day of hCG. When GnRH antagonists are used, treatment with antagonists begins after 5–6 days of gonadotropins or when the lead follicle is 13 mm. The antagonists have the advantage of requiring fewer injections; however, there may not be a difference in pregnancy rates when using the agonists versus the antagonists.

OOCYTE RETRIEVAL

Aspiration of the preovulatory follicles is performed approximately 34–36 hours after the hCG injection.

Egg aspiration is performed using either of two methods. Laparoscopy was the first method to be used and is rarely used today. The second method uses ultrasonography to direct transvaginal aspiration. In transvaginal aspiration, a needle is passed through the posterior vaginal fornix using a vaginal ultrasound probe and directed into the ovary. The advantage of ultrasound aspiration is that it can be performed on an outpatient basis, it is simpler, less invasive, and less expensive.

FERTILIZATION WITH CAPACITATED SPERM AND INTRACYTOPLASMIC SPERM INJECTION (ICSI)

Freshly ejaculated sperm cannot fertilize an egg; the sperm must be capacitated. Fortunately, capacitation is a very simple process in humans and involves only a short incubation period in a culture medium.

Because of the nature of the superovulatory process, eggs will be in different stages of maturation. Once the eggs have been identified, the embryologist classifies them as either mature (preovulatory) or immature. Mature eggs have an expanded cumulus oophorus, whereas immature eggs have a very compact cumulus. Mature eggs have undergone the first meiotic division and the first polar body is visible; immature eggs have not. Mature eggs are usually fertilized 5 hours after aspiration. Immature eggs can be incubated in the laboratory for up to 36 hours prior to fertilization. If sperm and eggs are mixed too early, fertilization and cleavage will not take place. Between 50,000 and 150,000 motile sperm are placed with each egg.

For male factor infertility (< 5 million total normal motile sperm/mL), intracytoplasmic sperm injection has emerged as an effective solution, resulting in higher fertilization rates and expanded possibilities for cryopreservation. In this procedure, 1 normal motile sperm is selected per oocyte and injected directly into the cytoplasm away from the polar body. Other indications for ICSI include surgically retrieved sperm (for men with azoospermia who need testicular or epididymal biopsy), cryopreserved oocytes, or cases in which preimplantation genetic diagnosis (PGD) is performed for single gene disorders.

EMBRYO CULTURE

Embryos are incubated in an atmosphere of \approx 5% carbon dioxide. Various culture media are used and are often supplemented with either the patient's serum or synthetic albumin as well as essential and nonessential amino acids and sugars. At various intervals after the attempted fertilization, the embryos are examined in order to identify pronuclei, which confirm fertilization, as well as the stage of cleavage.

EMBRYO TRANSFER

After 3–5 days of laboratory culture, the embryos are replaced into the patient's uterus, a procedure named *embryo transfer*. Prior to transfer, the embryos are graded from A to D depending on their appearance and on the degree of fragmentation. If day 5 or 6 transfers are performed, the embryos are at the blastocyst stage. The decision to transfer on day 3 or 5 depends on the success rates of the lab and the physicians. The decision of how many embryos to transfer is done by the patient in conjunction with the physician and the embryologist in conjunction with the American Society for Reproductive Medicine (ASRM) recommendations based on the patient's age (Table 58–1).

Table 58–1. Recommended Number of Embryos to Transfer

Age (years)	Number
< 35	2 (consider 1 if previous successful IVF cycle, great embryos, 1st IVF cycle)
35–37	2–3
38–40	3–4
> 40	5
Age independent	In some cases, such as previous failed IVF cycles or unfavorable prognosis, OK to transfer more

Most embryo transfers are performed under direct visualization with 2-dimensional (2-D) or 3-dimensional (3-D) ultrasounds. Before the embryo transfer is performed, the patient is usually asked to drink water so as to fill the bladder. A full bladder helps straighten the uterus as well as to improve visualization by ultrasound during the transfer. The embryologist prepares the best embryos by aspirating them into a small catheter with some media, and after the physician cleans the cervix with culture media and aspirates the extra cervical mucous, the catheter is passed transcervically into the uterus, and the embryos are injected into the uterine cavity under direct visualization. The probability of pregnancy after embryo transfer can be affected by the patient's age, the cause of infertility, the endometrial thickness, and the average embryo grade.

In some patients, assisted hatching or an opening in the zona is performed in order to improve implantation. This is thought to be beneficial in older patients (age 38 years and older) who have harder zonae; however, it is not routinely performed in all IVF centers.

LUTEAL PHASE SUPPORT

After embryo transfer is performed, progesterone supplementation is usually recommended by most physicians until approximately 7 weeks' gestation. Progesterone is usually administered by an intramuscular injection or by a vaginal suppository or gel.

Complications

Few risks are associated with ART. Some of the complications and drawbacks of ART are as follows:

1. Multiple gestations—Transferring more embryos does not necessarily lead to a greater IVF success rate. If embryos are left over, they can be either frozen for later use or be donated to another couple. A frozen embryo is thought to have one-half the potential for successful implantation of a fresh embryo. Recently, the methods for oocyte freezing have been improved as well, with some labs reporting comparable pregnancy rates in fresh or frozen cycles.
2. Ectopic and heterotopic pregnancies—Patients who undergo ART procedure are at twice the risk for having an ectopic pregnancy as the general population. Heterotypic pregnancies, which are rare but seen more commonly with ART, involve cases in which there is an intrauterine pregnancy and an ectopic pregnancy in the same patient.
3. Cost—Currently only a few states allow health insurance to cover infertility treatment, which leaves many couples with tremendous expenses (the estimated cost per delivery is \$66,667).
4. Preterm birth and low-birth-weight infants—These are higher in patients undergoing IVF.
5. Ovarian hyperstimulation syndrome—This syndrome is characterized by ovarian enlargement, ascites, and hemoconcentration. Risk factors include polycystic ovary syndrome, multiple follicles, and high estradiol levels. The prognosis is usually worse in patients who get pregnant and have this syndrome.

Patients with this syndrome may be at risk for blood clots.

6. Congenital abnormalities—The risk of congenital abnormalities may be slightly higher in patients who use ART; however, this concept is still controversial. In patients who have ICSI performed, the risk of imprinting disorders may be increased (such as Angelman's syndrome and Beckwith-Wiedemann syndrome).

OTHER TECHNIQUES RELATED TO IVF-ET

Ovum Donation

Embryos have been donated from one woman to another with many resultant live births. Women who receive donated embryos include those with ovarian failure or absence (eg, gonadal dysgenesis), diminished ovarian reserve, or genetically transmitted disorders.

Ovum donation can occur under either of two circumstances. One circumstance is the infertile patient who produces a large number of oocytes during her own IVF or GIFT cycle and elects to donate some of them to another woman who is otherwise incapable of producing eggs. The other, more common circumstance involves the recruitment of a woman who undergoes superovulation and oocyte retrieval purely for the purpose of donating her oocytes. The donor may be known to the patient (a family member or friend), or more commonly may be anonymous. Although the genetics of the resulting pregnancy are derived from the husband and the donor, the infertile woman incapable of producing her own eggs goes through the pregnancy. In these cases, the endometrium of the recipient must be primed with estrogen and progesterone prior to transfer of the donated embryos, and progesterone and estrogen supplementation must be maintained for at least 10 weeks. The number of embryos transferred is decided based on the age of the donor, not the age of the recipient.

Gestational Surrogacy

Sometimes a woman may be able to make eggs but may not be able to carry the gestation. These are women with certain medical conditions that are medically unfit to carry pregnancy or women who have no uterus, or have a uterus that is unsuitable for pregnancy. In these cases, a gestational surrogate may be used and transfer of the embryo is done into a uterus of a woman who has agreed to carry the pregnancy.

Gamete Intrafallopian Tube Transfer (GIFT)

GIFT is similar to IVF. It was first used in 1984 and the number of cycles in North America increased 75-fold from 75 in 1985 to 5767 in 1992, and the pregnancy rate rose from 4% to 29.5%. However with the improved pregnancy rates in IVF, GIFT procedures are rarely done now. Usual indications for GIFT nowadays include patients who have moral or religious objections to IVF and want to have fertilization in vivo rather than in vitro. As with IVF, superovulation is induced and the follicles are aspirated vaginally under ultrasound guidance. The eggs are then identified in the laboratory. Thereafter, sperm is collected and capacitated, and laparoscopy is performed. Sperm are then mixed with the eggs and drawn up into a catheter. The sperm and eggs can also be separated by an air bubble in the catheter, after which they are transferred into one of the fallopian tubes, permitting in vivo fertilization and cleavage. A 20–30% pregnancy rate per cycle has been reported for this technique.

Obviously, GIFT is useful only in patients who have normal tube function and are not of advanced age. It has been argued that the requirement of normal tubal function renders the direct comparison of IVF-ET and GIFT results impossible. Among proponents of each technique, there is vigorous ongoing debate as to the advantages of GIFT over IVF-ET.

In unexplained infertility, IVF-ET will differentiate the etiology of fertilization problems between egg and

sperm; GIFT will not. Additionally, GIFT exposes patients to the risks of general anesthesia and laparoscopy. GIFT is now rarely used.

Zygote Intrafallopian Transfer

ZIFT is a procedure that combines IVF and GIFT. Ovulation is induced and the oocytes are removed and fertilized in vitro. Soon thereafter the zygotes are placed into the fallopian tubes by laparoscopy similar to GIFT and the embryo travels to the uterine cavity. ZIFT also is now rarely used.

Preimplantation Genetic Diagnosis

PGD is a technology that has been around since early 1990. It allows many genetically heritable diseases to be identified using a variety of molecular biologic techniques. These techniques include but are not limited to polymerase chain reaction (PCR) and fluorescent in situ hybridization (FISH). Recent advances in embryo manipulation have made possible the removal of 1 or 2 cells, or blastomeres, from a developing 8-cell human embryo without harm to the embryo. Biopsy of the first and/or second polar bodies can also be done for several single-gene defects. In patients at risk of passing along a heritable genetic disease, PGD has made possible the identification of normal embryos (those with no risk of passing the heritable disease). These normal embryos are then transferred back to the patient. More than 1000 live births have been reported following application of these techniques. The number of centers performing these techniques are few but growing. PGD is also performed for patients with recurrent miscarriages, previous failed IVF cycles, aneuploidy diagnosis for patients with advanced maternal age, and for sex selection, but these indications are still controversial.

Cryopreservation

Cryopreservation is the process by which embryos or eggs are frozen to be used at a later time after thawing (unfreezing). Cryopreservation of embryos is very successful and has greatly improved since the first case in 1983. Survival rates of frozen embryos have been reported to be between 50% and 90%. Before thawing embryos, the patient's cycle is usually synchronized so that embryo transfer occurs during the implantation window of the uterus. Consequently, pretreatment with estrogen and progesterone is recommended. In 2003, the live birth rate per transfer of frozen embryos was 27%.

Cryopreservation of oocytes has been gaining attention and has improved over the past few years; however, it remains investigational. The same is true for ovarian cryopreservation and autologous transplantation (when the ovary is removed and transferred to a different location such as the forearm or abdomen).

Current OB/GYN > Chapter 59. Menopause & Postmenopause >

Menopause & Postmenopause: Introduction

According to the 2002 U.S. census, of the 144 million women in this country, 33 million were 55 years of age or older. Most of these women had or shortly would have their last menstrual period, thus becoming postmenopausal. As a woman at age 55 years can expect to live another 28 years, a large portion of the female population is without ovarian function and lives about one-third of their lives after this function ceases. Consequently, physicians caring for women must understand the hormonal and metabolic changes associated with the menopause, or "change of life," and the potential benefits and risks of hormone therapy (HT).

According to the Comité des Nomenclatures de la Fédération Internationale de Gynécologie et d'Obstétrique, the climacteric is the phase of the aging process during which a woman passes from the reproductive to the nonreproductive stage. The signals that this period of life has been reached are referred to as "climacteric symptoms" or, if more serious, as "climacteric complaints." Perimenopause, or menopausal transition, refers to the part of the climacteric before the menopause occurs when the menstrual cycle is likely to be irregular and when other climacteric symptoms or complaints may be experienced. The menopause is the final menstruation, which occurs during the climacteric. Postmenopause refers to the phase of life that comes after the menopause.

To develop a more functional staging system of reproductive aging, the Stages of Reproductive Aging Workshop (STRAW) was held in 2001. The specific goals of the workshop were to (a) develop a useful staging system, (b) revise nomenclature, and (c) identify knowledge gaps that should be addressed by the research community. According to STRAW, reproductive aging is divided into 7 stages (–5 to +2), with –5 beginning with menarche and +2 being defined as the late menopause. This staging system is not applicable to women who smoke, who are at the extremes of weight, who engage in heavy aerobic exercise, who have chronic menstrual irregularity, who have undergone hysterectomy, or who have abnormal uterine or ovarian anatomy.

The menopausal transition, or perimenopause, is divided into two stages—early (–2) and late (–1) and encompasses a wide age range. Both stages vary in length and both are characterized by an elevation in early follicular phase follicle-stimulating hormone (FSH). In stage –2, the menstrual cycles remain regular, but the cycle length changes by 7 days or more (ie, cycle length becomes 24 days instead of 31). Stage –1 (late menopausal transition) is characterized by two or more skipped menstrual cycles and at least one intermenstrual interval of 60 days or more. Many women begin to experience symptoms during this time which may include vasomotor symptoms, and sleep disturbance. The early postmenopausal period (stage +1) includes the first 5 years following the final menstrual period and the late postmenopausal period (stage +2) begins 5 years after the final menstrual period and continues until death.

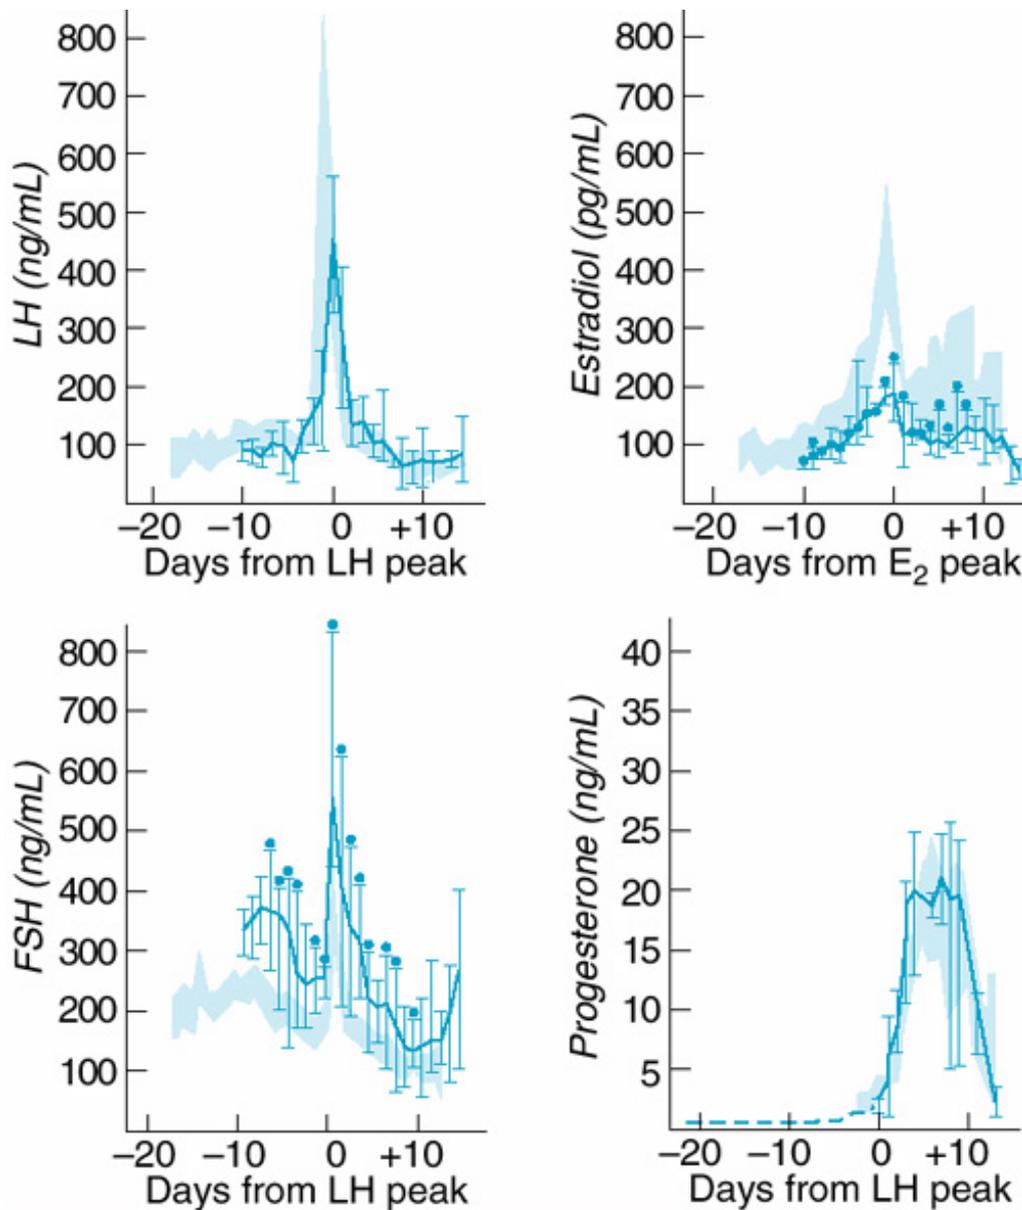

Etiology & Pathogenesis

PREMENOPAUSAL STATE

The decades of mature reproductive life are characterized by generally regular menses and a slow,

steady decrease in cycle length. Mean cycle length at age 15 years is 35 days, at age 25 years it is 30 days, and at age 35 years it is 28 days. This decrease is a result of shortening of the follicular phase of the cycle, with the luteal phase length remaining constant. After age 45 years, altered function of the aging ovary is detectable in regularly menstruating women (Fig 59–1). The mean cycle length is significantly shorter than in younger women and is attributable to a shortened follicular phase. The luteal phase is of similar length, and progesterone levels are no different from those observed in younger women. Estradiol levels are lower during portions of the cycle, including active follicular maturation, the midcycle peak, and the luteal phase. Concentrations of FSH are strikingly elevated during the early follicular phase and fall as estradiol increases during follicular maturation. FSH levels at the midcycle peak and late in the luteal phase are also consistently higher than those found in younger women and decrease during the midluteal phase. Luteinizing hormone (LH) concentrations are indistinguishable from those observed in younger women. The mechanism responsible for this early rise of FSH is probably related to inhibin. Inhibin is a polypeptide hormone that is synthesized and secreted by granulosa cells. It causes negative feedback on FSH release by the pituitary. As the oocyte number decreases, inhibin levels fall, resulting in a rise in FSH levels.

Mean and range of LH, FSH, estradiol (E_2), and progesterone levels in women over age 45 with regular menstrual cycles. Shaded area represents the mean (± 2 SEM) in cycles found in young women.

(Reproduced with permission from Sherman BM, Korenman SG: Hormonal characteristics of the human menstrual cycle throughout reproductive life. *J Clin Invest* 1975;55:699.)

The transition from regular cycle intervals to the permanent amenorrhea of menopause is characterized by a phase of marked menstrual irregularity. The duration of this transition varies greatly among women. Those experiencing the menopause at an early age have a relatively short duration of cycle variability before amenorrhea ensues. Those experiencing it at a later age usually have a phase of menstrual irregularity characterized by unusually long and short intermenstrual intervals and an overall increase of mean cycle length and variance.

The hormonal characteristics of this transitional phase are of special interest and importance. The irregular episodes of vaginal bleeding in premenopausal women represent the irregular maturation of

ovarian follicles with or without hormonal evidence of ovulation. The potential for hormone secretion by these remaining follicles is diminished and variable. Menses are sometimes preceded by maturation of a follicle with limited secretion of both estradiol and progesterone. Vaginal bleeding also happens after a rise and fall of estradiol without a measurable increase in progesterone, such as is seen during anovulatory menses.

From these findings, it is clear that the transitional phase of menstrual irregularity is not one of marked estrogen deficiency. During the menopausal transition, high levels of FSH appear to stimulate residual follicles to secrete bursts of estradiol. Occasionally, estradiol levels will rise to concentrations 2 or 3 times higher than is normally seen, probably reflecting the recruitment of more than 1 follicle for ovulation. This may be followed by corpus luteum formation, often with limited secretion of progesterone. Because the episodes of follicular maturation and vaginal bleeding are widely spaced, premenopausal women may be exposed to persistent estrogen stimulation of the endometrium in the absence of regular cyclic progesterone secretion.

MENOPAUSE

The two types of menopause are classified according to cause.

Physiologic Menopause

In the human embryo, oogenesis begins in the ovary around the third week of gestation. Primordial germ cells appear in the yolk sac, migrate to the germinal ridge, and undergo cellular divisions. It is estimated that the fetal ovaries contain approximately 7 million oogonia at 20 weeks' gestation. After 7 months' gestation, no new oocytes are formed. At birth, there are approximately 1–2 million oocytes, and by puberty this number is reduced to 300,000–500,000. Continued reduction of oocyte numbers occurs during the reproductive years through ovulation and atresia. Nearly all oocytes vanish by atresia, with only 400–500 actually being ovulated. Very little is known about oocyte atresia. Animal studies show that estrogens prevent the atretic process while androgens enhance it.

Menopause apparently occurs in the human female because of two processes. First, oocytes responsive to gonadotropins disappear from the ovary, and second, the few remaining oocytes do not respond to gonadotropins. Isolated oocytes can be found in postmenopausal ovaries on very careful histologic inspection. Some of them show a limited degree of development, but most reveal no sign of development in the presence of excess endogenous gonadotropins.

The average age at menopause in the United States is 50–51 years. There does not appear to be any consistent relationship between age at menarche and age at menopause. Marriage, childbearing, height, weight, and prolonged use of oral contraceptives do not appear to influence the age of menopause. Smoking, however, is associated with early menopause.

Spontaneous cessation of menses before age 40 years is called premature menopause, or premature ovarian failure. It appears that approximately 0.9% of women in the United States may experience this early cessation of function. Cessation of menstruation and the development of climacteric symptoms and complaints can occur as early as a few years after menarche. The reasons for premature ovarian failure are unknown.

Disease processes, especially severe infections or tumors of the reproductive tract, can occasionally damage the ovarian follicular structures so severely as to precipitate the menopause. The menopause can also be hastened by excessive exposure to ionizing radiation, chemotherapeutic drugs, particularly alkylating agents, and surgical procedures that impair ovarian blood supply. The possibility of associated endocrine or chromosomal abnormalities should also be considered.

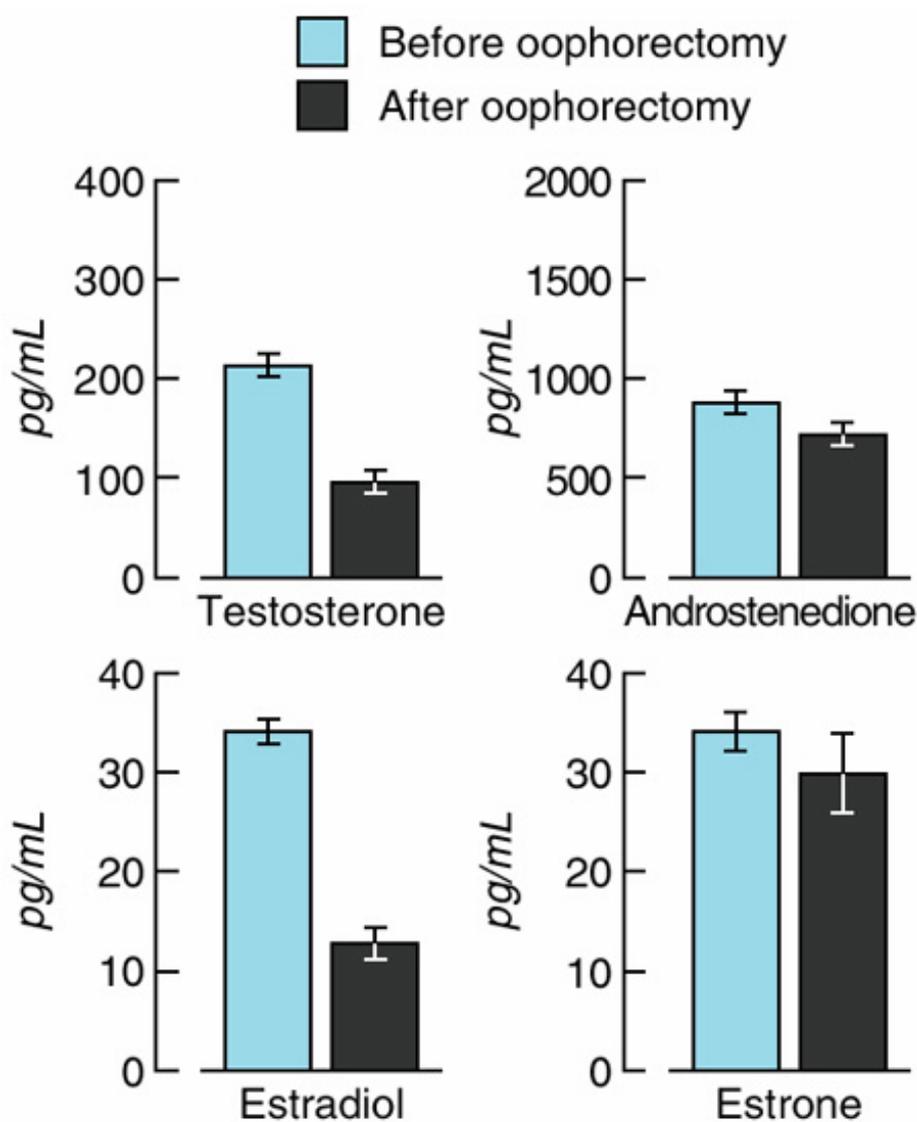

Artificial Menopause

The permanent cessation of ovarian function brought about by surgical removal of the ovaries or by radiation therapy is called an artificial menopause. Irradiation to ablate ovarian function is rarely used today. Artificial menopause is employed as a treatment for endometriosis and rarely may be used to treat estrogen-sensitive neoplasms of the breast and endometrium. More frequently, artificial menopause is a side effect of treatment of intra-abdominal disease; eg, ovaries are removed in premenopausal women because the gonads have been damaged by infection or neoplasia. When laparotomy is being performed for intra-abdominal or pelvic disease (ie, hysterectomy for leiomyomata), elective bilateral oophorectomy is sometimes employed to prevent ovarian cancer. In some women who are genetically predisposed to ovarian cancer, elective laparoscopic oophorectomy is also performed.

CHANGES IN HORMONE METABOLISM ASSOCIATED WITH THE MENOPAUSE

Following the menopause, there are major changes in androgen, estrogen, progesterone, and gonadotropin secretion, much of which occurs because of cessation of ovarian follicular activity (Fig 59–2).

Figure 59–2.

Serum androgen and estrogen levels in 16 postmenopausal women with endometrial cancer before and after oophorectomy.

(Reproduced with permission from Judd HL: Hormonal dynamics associated with the menopause. Clin Obstet Gynecol 1976;1:775.)

Androgens

During reproductive life, the primary ovarian androgen is androstenedione, the major secretory product of developing follicles. In postmenopausal women, there is a reduction of circulating androstenedione to approximately 50% of the concentration found in young women, reflecting the absence of follicular activity. In the year following the last menstrual period, the levels of this hormone are steady. In older women, there is a circadian variation of androstenedione, with peak concentration between 8:00 AM and 12 noon, and the nadir occurring between 3:00 PM and 4:00 AM. This rhythm reflects adrenal activity. The clearance rate of androstenedione is similar in pre- and postmenopausal women; therefore, the change in levels of circulating hormone reflects changes in production. Thus, the average production rate of androstenedione is approximately 1.5 mg/24 h in older women, a rate that is 50% of the rate found in premenopausal women. The source of most of this circulating androstenedione appears to be the adrenal glands, but continued secretion by the postmenopausal ovary accounts for approximately 20%.

For testosterone, the level found in postmenopausal women is only minimally lower than that found in premenopausal women before oophorectomy and is distinctly higher than the level observed in ovariectomized young women. There is also a prominent circadian variation of this androgen, with the highest levels occurring at 8:00 AM and the nadir at 4:00 PM. There is no difference in the clearance rate of testosterone before and after the menopause. Thus, the production rate in older women is approximately 150 µg/24 h, a rate that is only one-third lower than the rate seen in young women.

The source of circulating testosterone is more complex than that of androstenedione. Oophorectomy following menopause is associated with a nearly 60% decrease in testosterone. There is no change in the metabolic clearance rate of the androgen with oophorectomy; therefore, the fall in the circulating level reflects alterations of its production rate. Approximately 15% of circulating androstenedione is converted to testosterone. The small simultaneous fall of androstenedione after oophorectomy can only account for a small portion of the total decrease of testosterone. The remainder of the loss presumably represents loss from direct ovarian secretion of testosterone. Direct ovarian secretion in the postmenopausal ovary is larger than the amount secreted directly by the premenopausal ovary. Large increments in testosterone have been found in the ovarian compared with the peripheral veins of postmenopausal women. These increments are greater than those observed in premenopausal women, supporting the hypothesis that the postmenopausal ovary secretes more testosterone directly than the premenopausal ovary. Hilar cells and luteinized stromal cells (hyperthecosis) are present in most postmenopausal ovaries and have been shown to produce testosterone in premenopausal women. Presumably, these cells could do the same in postmenopausal subjects.

A proposed mechanism for increased ovarian testosterone production by postmenopausal ovaries is the stimulation of gonadal cells still capable of androgen production by excess endogenous gonadotropins, which, in turn, are increased because of reduced estrogen production by the ovaries. This increased ovarian testosterone secretion, coupled with a reduction of estrogen production, and decrease in sex hormone-binding globulin (SHBG) may partly explain the development of symptoms of defeminization, hirsutism, and even virilism occasionally seen in older women.

Levels of the adrenal androgens dehydroepiandrosterone (DHEA) and dehydroepiandrosterone sulfate (DHEAS) are reduced by 60% and 80%, respectively, with age. Whether these reductions are related to

the menopause or to aging has not been determined. Again, a marked circadian variation of DHEA has been observed. Whether a similar rhythm is present for DHEAS is unknown. As with younger subjects, the primary source of these two androgens is thought to be the adrenal glands, with the ovary contributing less than 15%. Thus, the marked decreases of DHEA and DHEAS reflect altered adrenal androgen secretion, and this phenomenon has been called the *adrenopause*. The mechanism responsible for it is unknown.

In premenopausal women, plasma androstenedione is approximately 1.5 ng/mL. Plasma testosterone is about 0.3 ng/mL. Mean DHEA and DHEAS levels are approximately 4 ng/mL and 1600 ng/mL, respectively, in samples drawn at 8:00 AM.

In postmenopausal women, the mean plasma androstenedione concentration is reduced by at least 50%, to approximately 0.6 ng/mL. Plasma testosterone levels are only slightly reduced (to about 0.25 ng/mL). Plasma DHEA and DHEAS levels are decreased to mean levels of 1.8 ng/mL and 300 ng/mL in women in their sixties and seventies.

Estrogens

After a woman has passed the menopause, there is good clinical evidence of reduced endogenous estrogen production in most subjects. When circulating levels have been assessed, the greatest decrease is in estradiol. Its concentration is distinctly lower than that found in young women during any phase of their menstrual cycle and is similar to the level seen in premenopausal women following oophorectomy. A decrease of this estrogen occurs up to 1 year following the last menstrual period. There does not appear to be a circadian variation of the circulating concentration of estradiol following the menopause. The metabolic clearance rate of estradiol is reduced by 30%. The average production rate is 12 µg/24 h.

The source of the small amount of estradiol found in older women has been established. Direct ovarian secretion contributes minimally, but the adrenal glands are the major source. Investigators who have examined the concentrations of estradiol in adrenal veins have reported minimal increments, arguing against direct adrenal secretion being a major contributor. Although both estrone and testosterone are converted in peripheral tissues to estradiol, it is conversion from estrone that accounts for most estradiol in older women.

After the menopause, the circulating level of estrone decreases—not as much as that of estradiol—and overlaps with values seen in premenopausal women during the early follicular phase in menstrual cycles. There is a circadian variation of circulating estrone, with the peak in the morning and the nadir in late afternoon or early evening. This variation is not as prominent as that observed for the androgens. In postmenopausal women, there is a 20% reduction of estrone clearance, and the average production rate is approximately 55 µg/24 h.

The adrenal gland is the major source of estrone. Direct adrenal or ovarian secretion is minimal. Most estrone results from the peripheral aromatization of androstenedione. The average percent conversion is double that found in ovulatory women and can account for the total daily production of this estrogen. Aromatization of androstenedione occurs in fat, muscle, liver, bone marrow, brain, fibroblasts, and hair roots. Other tissues may also contribute but have not been evaluated. To what extent each cell type contributes to total conversion has not been determined, but fat cells and muscle may be responsible for only 30–40%. This conversion correlates with body size, with heavy women having higher conversion rates and circulating estrogen levels than slender women.

During normal menstrual life, the mean plasma estradiol fluctuates from 50–350 pg/mL and estrone from 30–110 pg/mL. In postmenopausal women, the mean estradiol level is approximately 12 pg/mL, with a range of 5–25 pg/mL. The mean estrone level is approximately 30 pg/mL, with a range of 20–70 pg/mL.

Estradiol levels in normal young women do not overlap with those observed in postmenopausal subjects. The finding of estradiol levels below 20 pg/mL can be helpful in establishing the diagnosis of menopause, as the fall of this estrogen is the last hormonal change associated with loss of ovarian function. There is substantial overlap of estrone levels in younger and older women. Measurement of this estrogen is not helpful in determining the ovarian status of a patient.

Progesterone

In young women, the major source of progesterone is the ovarian corpus luteum following ovulation. During the follicular phase of the cycle, progesterone levels are low. With ovulation the levels rise greatly, reflecting the secretory activity of the corpus luteum. In postmenopausal women, the levels of progesterone are only 30% of the concentrations seen in young women during the follicular phase. Because postmenopausal ovaries do not contain functional follicles, ovulation does not occur and progesterone levels remain low. The source of the small amount of progesterone present in older women is felt to be caused by adrenal secretion, as dexamethasone suppresses its level, adrenocorticotrophic hormone (ACTH) increases its level, and human chorionic gonadotropin (hCG) administration has no effect.

In young menstruating women, the mean progesterone level is approximately 0.4 ng/mL during the follicular phase of the cycle, with a range of 0.2–0.7 ng/mL. During the luteal phase, progesterone levels rise and fall, reflecting corpus luteum function; the mean level is approximately 11 ng/mL with a range of 3–21 ng/mL. In postmenopausal women, the mean progesterone level is 0.17 ng/mL. To date, no clinical use has been established for the measurement of progesterone in postmenopausal women.

Gonadotropins

With the menopause, both LH and FSH levels rise substantially, with FSH usually higher than LH. This is thought to reflect the slower clearance of FSH from the circulation. The reason for the marked increase in circulating gonadotropins is the absence of the negative feedback of ovarian steroids and inhibin on gonadotropin release. As in young women, the levels of both gonadotropins are not steady, but instead show random oscillations. These oscillations are thought to represent pulsatile secretion by the pituitary. In older women, these pulsatile bursts occur every 1–2 hours, a frequency similar to that seen during the follicular phase of premenopausal subjects. Although the frequency is similar, the amplitude is much greater. This increased amplitude is secondary to increased release by the hypothalamic hormone gonadotropin-releasing hormone (GnRH) and enhanced responsiveness of the pituitary to GnRH because of low estrogen levels. Studies with rhesus monkeys suggest that the site governing pulsatile GnRH release is in the arcuate nucleus of the hypothalamus. The large pulses of gonadotropin in the peripheral circulation are believed to maintain the high levels of the hormones found in postmenopausal women.

During reproductive life, the levels of both FSH and LH range from 4–30 mU/mL except during the preovulatory surge, when they may exceed 50 mU/mL and 100 mU/mL, respectively. After the menopause, both rise to levels above 100 mU/mL, with FSH rising earlier and to higher levels than LH.

When contradictory or uncertain clinical findings make the diagnosis of the postmenopausal state questionable, measurement of plasma FSH, LH, and estradiol levels may be helpful. This situation occurs frequently in women following hysterectomy without oophorectomy. The findings of plasma estradiol below 20 pg/mL and elevated FSH and LH levels are consistent with cessation of ovarian function. In practical terms, it is not necessary to measure LH.

PHYSICAL CHANGES ASSOCIATED WITH THE MENOPAUSE

Reproductive Tract

Because estrogen functions as the major growth factor of the female reproductive tract, there are substantial changes in the appearance of all the reproductive organs. Most postmenopausal women

experience varying degrees of atrophic changes of the vaginal epithelium. The vaginal rugae progressively flatten and the epithelium thins. This may lead to symptomatic atrophic vaginitis (see Atrophic Vaginitis).

There are also atrophic changes of the cervix. It usually decreases in size, and there is a reduction of secretion of cervical mucus. This may contribute to excessive vaginal dryness, which may cause dyspareunia.

Atrophy of the uterus is also seen, with shrinkage of both the endometrium and myometrium. This shrinkage can be beneficial to women who enter the climacteric with uterine myomas. Reduction in size and elimination of symptoms frequently prevent the necessity for surgical treatment. The same applies to adenomyosis and endometriosis, both of which usually become asymptomatic following the menopause. Palpable and symptomatic areas of endometriosis generally become progressively smaller and less troublesome. With cessation of follicular activity, hormonal stimulation of the endometrium usually ceases. Endometrial biopsy may reveal anything from a very scanty, atrophic endometrium to one that is moderately proliferative. Spontaneous postmenopausal bleeding may occur in the presence of any of these patterns. Endometrial tissue revealing glandular hyperplasia (with or without uterine bleeding) is an indication of enhanced estrogenic stimulation from either endogenous estrogen production (eg, increased conversion of androgen), or from exogenous intake of estrogen.

The oviducts and ovaries also decrease in size postmenopausally. Although this produces no symptoms, the small size of the ovaries makes them difficult to palpate during pelvic examination. A palpable ovary in a postmenopausal woman must be viewed with suspicion, and the presence of an ovarian neoplasm must be considered.

The supporting structures of the reproductive organs suffer loss of tone as estrogen levels decline. Postmenopausal estrogen deficiency may lead to symptomatic progressive pelvic relaxation.

Urinary Tract

Estrogen plays an important role in maintaining the epithelium of the bladder and urethra. Marked estrogen deficiency may produce atrophic changes in these organs similar to those that occur in the vaginal epithelium. This may give rise to atrophic cystitis, characterized by urinary urgency, frequency, incontinence, and dysuria. Recurrent urinary tract infection may also develop in the setting of estrogen deficiency. Loss of urethral tone, with pouting of the meatus and thinning of the epithelium, favors the formation of a urethral caruncle with resultant dysuria, meatal tenderness, and occasionally hematuria. Treatment of symptomatic women involves topical vaginal estrogen (see Estrogen Therapy).

Mammary Glands

Regression of breast size during and after menopause is psychologically distressing to some women. For those who have been bothered by cyclic symptoms of breast pain and cyst formation, the disappearance of these symptoms postmenopausally is a great relief.

Clinical Conditions Associated with Menopause

ATROPHIC VAGINITIS

Pathogenesis

As the epithelium thins following menopause, the capillary bed shines through as a diffuse or patchy reddening. Rupture of surface capillaries produces irregularly scattered petechiae, and a brownish discharge may be noted. Further atrophy of the vaginal epithelium renders its capillary bed increasingly sparse, so that the hyperemic appearance gives way to a smooth, shiny, pale epithelial surface. The epithelium lacks glycogen which leads to a reduction in lactic acid production and an increase in the vaginal pH to 5.0–7.0. This is associated with disappearance of lactobacilli. Early in the process, local

bacterial invasion may initiate vaginal pruritus and leukorrhea. Vaginal burning, soreness, dyspareunia, and a thin watery or serosanguineous discharge may also occur. Minimal trauma with examinations or coitus may result in slight vaginal bleeding. Urinary complaints, including urinary frequency, urgency, dysuria, and urge incontinence, have also been described in association with atrophic vaginitis.

Diagnosis

There is no specific test that reliably quantifies the degree of atrophy. Clinical decision making is therefore generally based on patient symptomatology and findings on physical examination. However, vaginal cytology has been used to assist in the diagnosis of atrophic vaginitis. The degree of maturation of exfoliated vaginal epithelial cells, as revealed by stained vaginal smears, is an index of estrogenic activity. Among the various methods of assessing the smears, the following are most commonly used: the maturation index consists of a differential count of three types of squamous cells—parabasal cells, intermediate cells, and superficial cells, in that order—expressed as percentages (eg, 10/85/5); a greater percentage of parabasal cells reflects a greater degree of atrophy. The cornification count is the percentage of precornified and cornified cells among total squamous cells counted. This is actually a simplified maturation index, because this percentage is essentially the same as that of the superficial cells.

The assessment of exfoliated vaginal epithelial cells is influenced not only by the level of estrogenic activity, but also by other hormones (particularly progesterone and testosterone), local vaginal inflammation, local medication, vaginal bleeding, the presence of genital cancer, the location of the vaginal area sampled, and variations in end-organ (epithelial) responses to estrogenic influence. Thus, women with identical levels of circulating estrogens may have quite different cytograms.

The great variation in cytologic findings leads to the following conclusions regarding the use of smears in the clinical management of postmenopausal women: (a) The smear is only a rough measure of estrogenic status, and it may sometimes be grossly misleading. (b) The vaginal cytogram cannot predict whether or not an individual woman is experiencing menopausal signs and symptoms. (c) The smear cannot be used as the sole guide to steroid supplementation therapy; clinical signs and symptoms are more dependable for this purpose.

Treatment

Symptomatic atrophic vaginitis may be managed with water-soluble lubricants and/or topical vaginal estrogens, which are available in the form of creams, tablets, or estradiol-releasing rings (see Estrogen Therapy). Systemic estrogens may also be utilized in the treatment of atrophic vaginitis, but vaginal preparations are preferred when estrogen therapy is being utilized solely for the treatment of vulvovaginal atrophy.

HOT FLUSHES

General Considerations

The most common and characteristic symptom of the climacteric is an episodic disturbance consisting of sudden flushing and perspiration, referred to as a hot flash or flush. It is observed in approximately 75% of women who go through the physiologic menopause or have a bilateral ovariectomy. Of those having flushes, 82% experience the disturbance for more than 1 year and 25–50% complain of the symptom for more than 5 years. Most women indicate that hot flushes begin with a sensation of pressure in the head, much like a headache. This increases in intensity until the physiologic flush occurs. Palpitations may also be experienced. The actual flush is characterized as a feeling of heat or burning in the face, neck, and chest, followed immediately by an outbreak of sweating that affects the entire body but is particularly prominent over the head, neck, upper chest, and back. Less-common symptoms include weakness, fatigue, faintness, and vertigo. The duration of the whole episode varies from

momentary to as long as 10 minutes; the average length is 4 minutes. The frequency varies from 1–2 per hour to 1–2 per week. In women with severe flushes, the mean frequency is 54 minutes.

Investigators have characterized the physiologic changes associated with hot flushes and have shown that the symptoms result from true alterations in cutaneous vasodilation, perspiration, reductions of core temperature, and elevations of pulse rate. Fluctuations in electrocardiographic data probably reflect changes in skin conductance. Changes in heart rhythm and blood pressure have not been observed.

The patient's awareness of symptoms does not correspond exactly with physiologic changes. Women become conscious of symptoms approximately 1 minute after the onset of measurable cutaneous vasodilation, and discomfort persists for an average of 4 minutes, whereas physical changes persist for several minutes longer.

Pathogenesis

The exact mechanism responsible for hot flushes is unknown, but physiologic and behavioral data indicate that symptoms result from a defect in central thermoregulatory function. Several observations support this conclusion: (a) The two major physiologic changes associated with hot flushes—perspiration and cutaneous vasodilation—are the result of different peripheral sympathetic functions. Excitation of sweat glands results from sympathetic cholinergic fibers, and cutaneous vasodilation is under the control of tonic α -adrenergic fibers. It seems unlikely that any peripheral event could cause both cholinergic excitation of sweat glands and α -adrenergic blockade of cutaneous vessels, and it is well recognized that these are the two basic functions triggered by central thermoregulatory mechanisms that lower the central temperature. (b) During a hot flush, the central temperature decreases because of cutaneous vasodilation and perspiration. If hot flushes were the result of some peripheral event, the body's regulatory mechanisms would be expected to prevent such a decrease. (c) There is also a change in behavior associated with hot flushes. Women feel warm and have a conscious desire to cool themselves by throwing off the bedcovers, standing by open windows or doors, fanning themselves, or by other means. This behavior is observed even in the presence of a steady or decreasing central temperature.

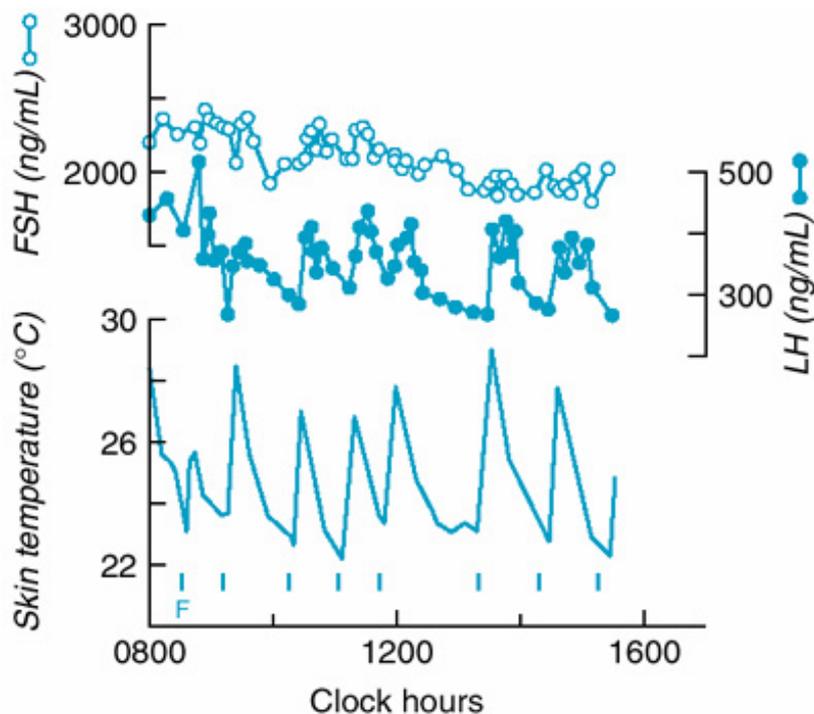

Most investigators believe the core temperature of the body is maintained near a central set point that is controlled by central thermoregulatory centers, particularly those in the rostral hypothalamus. This central set point temperature is analogous to a thermostat setting. Hot flushes appear to be triggered by a sudden lowering of the central hypothalamic "thermostat." As a consequence, heat loss mechanisms, both physiologic and behavioral, are activated so that the core temperature will be brought in line with the new set point; this results in a fall of central temperature.

Because hot flushes occur after the spontaneous cessation of ovarian function or following oophorectomy, it is presumed that the underlying mechanism is endocrinologic, related either to reduction of ovarian estrogen secretion or to enhancement of pituitary gonadotropin secretion. Low estrogen levels alone do not appear to trigger hot flushes; prepubertal children and patients with gonadal dysgenesis have low estrogen levels but not flushing. Patients with gonadal dysgenesis do experience symptoms if they are given estrogens that are later withdrawn. Thus, it appears that estrogen must be present and then withdrawn for hot flushes to be experienced.

Hot flushes appear to be related to gonadotropins. A close temporal association between the occurrence of flushes and the pulsatile release of LH has been demonstrated. The observation that flushes occur after hypophysectomy suggests that they are not directly caused by LH release (Fig 59–3). The appearance of hot flushes in women with defects in GnRH release or synthesis (Kallmann's syndrome) also suggests GnRH itself is not involved in the flushing mechanism. The absence of hot flushes in women with hypothalamic amenorrhea and hypoestrogenemia is intriguing. These women have defects in neurotransmitter or neurochemical input to their GnRH neurons. In particular, excessive endogenous

opioid and dopamine input to GnRH neurons may account for chronic suppression of GnRH release, leading to hypothalamic amenorrhea. The absence of hot flushes in these women suggests that altered afferent input of neurotransmitters or neurochemicals to the GnRH neuron that is secondary to hypogonadism leads to hot flushes. Two likely candidates are norepinephrine and endogenous opioids.

Skin temperature and LH and FSH levels in a woman with hot flushes. Note the close temporal relationship between the rises in skin temperature and the occurrence of pulsatile LH release.

(Reproduced with permission from Tatarzyn IV et al: LH, FSH, and skin temperature during the menopausal hot flash. *J Clin Endocrinol Metab* 1979; 49: 152.)

Hot flushes are a greater annoyance than most physicians recognize. Patients frequently complain of night sweats and insomnia. There is a close temporal relationship between the occurrence of hot flushes and nighttime awakening. Women with frequent flushes may experience flushes and awakening episodes hourly, which may cause a profound sleep disturbance that may, in turn, cause cognitive (memory) and affective (anxiety) disorders in some women.

Treatment

Estrogens are the principal medications used to relieve hot flushes. Estrogens block both the perceived symptoms and the physiologic changes. Their use also relieves some aspects of the sleeping disorder. Estrogen administration has been shown to enhance hypothalamic opioid activity in postmenopausal women. This increase of hypothalamic opiates may be involved in the relief of hot flushes with estrogen administration.

Progestins also block hot flushes and represent a reasonable form of substitutional therapy in women who can't take estrogens. Clonidine, a centrally acting alpha agonist, is more effective than a placebo but is associated with side effects. More recently, certain selective serotonin reuptake inhibitors

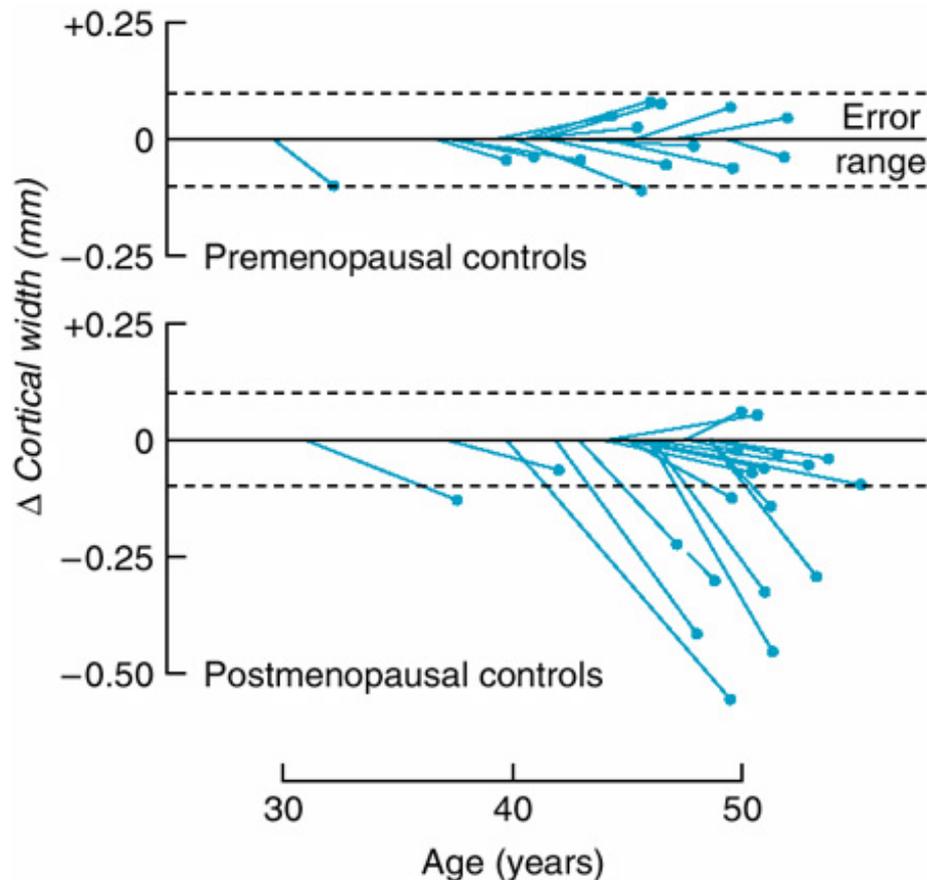

(SSRI s) have been shown to be effective in the treatment of hot flashes. Their side effects may limit their overall benefit, but they are one of the first alternative choices in women who are not taking estrogen. Black cohosh may have modest effects in decreasing hot flashes, but concerns remain regarding its potential to stimulate breast and uterine tissue. Gabapentin also decreases hot flashes. Tibolone is a synthetic steroid with estrogenic, progestogenic, and androgenic properties that alleviates menopausal symptoms and has been used in other countries for this purpose, as well as to preserve bone mineral density. However, its long-term safety profile with regard to breast and endometrial cancer remains controversial. Its mechanism of action would suggest that it is unlikely to increase the risk of breast cancer. This idea has been supported by results from studies showing that tibolone does not increase mammographic density. Furthermore, no increased risk of breast cancer has been observed in phase III/IV trials of tibolone. However, the Million Women Study reported an increased risk of breast cancer among participants using tibolone as compared to controls. Tibolone's action on the endometrium also suggests that it is unlikely to cause endometrial proliferation. This is supported by findings from studies demonstrating a low incidence of vaginal bleeding and an absence of endometrial hyperplasia on histology. However, rates of endometrial cancer were also increased in the Million Women's Study. Further study is required to ascertain whether tibolone can be used long-term without increased risks for breast and endometrial cancer. Tibolone's potential to modify risk for cardiovascular disease is also unknown. However, a recent study evaluating the effect of tibolone on myocardial blood flow demonstrated that tibolone improved myocardial blood flow in women with ischemic heart disease. Vitamins E and K, mineral supplements, and phytoestrogens have all been tried to alleviate menopausal symptoms, but have not been proven beneficial.

OSTEOPOROSIS

General Considerations

As defined by the Consensus Development Center in 1993, osteoporosis is a systemic skeletal disorder characterized by low bone mass and microarchitectural deterioration of bone tissue, with a consequent increase in fragility of bone and susceptibility to risk of fracture. This loss occurs primarily in trabecular bone and is therefore most noticeable in the vertebra and distal radius. Although gradual bone loss occurs in all humans with aging, this loss is accelerated in women after cessation of ovarian function. Following attainment of peak bone mass by age 25–30 years, bone loss begins, accelerates in women at menopause, and then slows again but continues into advanced years at a rate of 1–2% per year (Fig 59–4). Women can lose up to 20% of their bone mass in the 5–7 years following menopause.

Changes in metacarpal cortical width, as determined by sequential measurements in pre- and postmenopausal women, age range 30–50 years. Note bone loss in postmenopausal women.

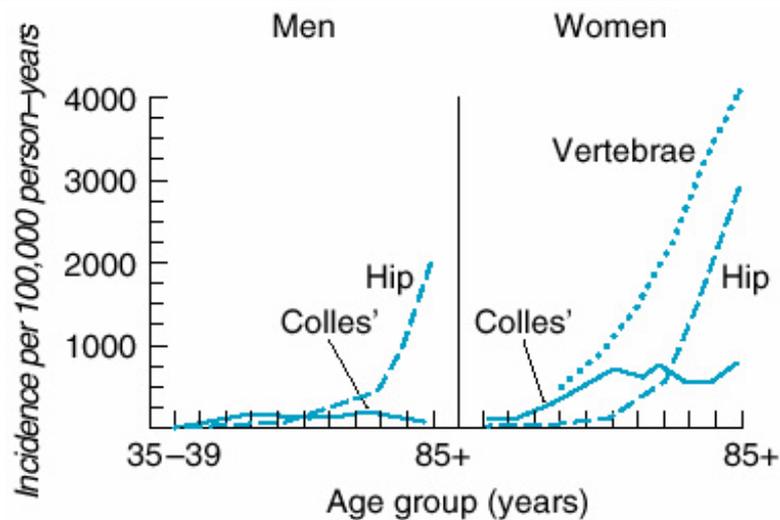

(Reproduced with permission from Nordin BEC et al: Postmenopausal osteopenia and osteoporosis. *Front Horm Res* 1975;3:131.)

Osteoporosis affects an estimated 10 million Americans 50 years of age or older, 80% of whom are women. Of Americans 50 years of age or older, 34 million are estimated to have low bone mass, placing them at increased risk for osteoporosis. Osteoporosis is most severe in women who have had early oophorectomy or premature ovarian failure, and in those with gonadal dysgenesis. Osteoporosis occurs most often in whites, followed by Asians, Hispanics and African Americans. Estrogen loss, smoking, family history, eating disorders, abnormal or absent menstrual periods, hyperthyroidism, excessive alcohol consumption, low lifetime calcium intake, vitamin D deficiency, use of certain medications (ie, corticosteroids, chemotherapy), slender body size, advanced age, and other chronic medical conditions are also risk factors.

Bone loss produces minimal symptoms, but leads to reduced skeletal strength. Thus, osteoporotic bones are more susceptible to fractures. The most common site of fracture is in the vertebral body; however, fractures also occur in the hip, upper femur, distal forearm, humerus and ribs (Fig 59–5). Recent figures from the National Osteoporosis Foundation show that osteoporosis is responsible for more than 1.5

million fractures per year, including 300,000 hip fractures, 700,000 vertebral fractures, 250,000 wrist fractures, and more than 300,000 fractures at other sites. Approximately 1 in 2 women older than the age of 50 years will have an osteoporosis-related fracture in her remaining lifetime. The incidence of hip fractures in women is 2–3 times that in men. The mortality rate associated with hip fractures is between 5% and 20% within 12 months following the injury. Of survivors, 15–25% are permanently disabled. The estimated cost for osteoporosis-related fractures in the United States totals more than \$17 billion per year.

Pathogenesis

Bone loss occurs because bone resorption is excessive, bone formation is decreased, peak bone mass is low or because of a combination of all three factors. Bone remodeling is regulated by many factors, including systemic hormones, local cytokines, prostaglandins, and local growth factors. Of the systemic hormones, sex steroids, parathyroid hormones, glucocorticoids, thyroid hormones, and growth hormone/insulinlike growth factors likely play a role. Ovarian estrogen and estrogen administered postmenopausally are protective against osteoporosis. The exact mechanisms by which estrogen regulates bone remodeling are incompletely understood. Estrogens likely modulate osteoclast and osteoblast function possibly via effects on cytokines and growth factors such as transforming growth factor- β (TGF β) and tumor necrosis factor- α (TNF α).

Interleukin-1 (IL-1) and TNF α derived from bone marrow macrophages stimulate bone resorption and may inhibit bone formation. There is evidence to suggest they may be regulated by estrogen as IL-1 activity in bone increases immediately after the menopause or oophorectomy. The levels remain increased in osteoporotic women, whereas they return to the premenopausal range after 2–3 years in those who do not develop the disease. Furthermore, it has been shown in animal models that inhibition of IL-1 and TNF α following ovariectomy attenuates bone loss. IL-6 and prostaglandins, especially

prostaglandin E₂ (PGE₂), are also involved in bone remodeling and are regulated by sex steroids. Other factors, such as insulinlike growth factor and fibroblast growth factor, also likely play a role in the pathogenesis of osteoporosis and may be regulated by sex steroids.

Androgens play a role in bone remodeling as androgen deficiency is associated with increased bone loss. The precise mechanism by which androgens alter bone remodeling is unknown.

Progestins may affect bone remodeling in a similar way to estrogens and androgens, but the mechanisms underlying these effects are not well understood.

Parathyroid hormone (PTH) also plays a role in bone remodeling. PTH stimulates bone resorption and absence of this hormone inhibits development of osteoporosis in animal and human studies. Thus far, it does not appear that PTH is elevated in most women with osteoporosis or that the sensitivity of bone to PTH is enhanced. It is interesting that the amino-terminus of PTH (1-34) inhibits bone resorption.

Growth hormone stimulates bone remodeling; however, studies evaluating the effect of exogenous growth hormone administration on established osteoporosis are inconclusive. Recently, new factors were discovered that are involved with the regulation of bone remodeling: osteoprotegerin, a naturally occurring protein, and RANKL (receptor activator of nuclear factor kappa beta ligand), both regulate osteoclastogenesis and bone resorption.

Genetic factors may also affect risk for osteoporosis. Variants in the estrogen receptors α and β expressed in bone are associated with altered risk for osteoporosis and fracture. Variants in the vitamin D receptor gene and bone morphogenetic protein 2 (BMP2) may also play a role in the pathogenesis of osteoporosis.

Diagnosis

Although much has been done to study urinary and serum factors as predictors of osteoporosis, the most predictive test remains bone densitometry. Several different types of densitometry are available. Single-photon absorptiometry can be used to measure appendicular bone mineral density (BMD). However, to measure axial bone, dual-energy x-ray absorptiometry is required for an accurate assessment. The variability of soft-tissue density around the spine and pelvis decreases the accuracy of single-photon testing. Results are given in grams or g/cm². In 1994, the World Health Organization created a clinically useful definition of osteoporosis. Bone mineral density results are reported using T and Z scores. The T score is the number of standard deviations (SD) above or below the mean bone mineral density for gender-matched young controls. The Z score compares the patient with a population adjusted for age, and gender. Normal bone density is defined as a T score greater than -1.0 SD. Osteopenic patients have T scores between -1.0 and -2.5, whereas osteoporotic patients have T scores below -2.5. In most studies, a decrease by 1 SD in mass increases the risk of fracture 2-3-fold.

Assessment of risk factors has not been nearly as predictive of fracture risk as density measurement. Assessment of serum osteocalcin and bone-specific alkaline phosphatase, markers of bone formation, or of urinary deoxypyridinoline (DPD) cross-links and serum/urinary cross-linked N-telopeptides (NTX) of type I collagen, markers of bone resorption, have not been shown to be useful for diagnosing osteoporosis but may give some indication of future risk for bone loss and/or be useful for monitoring response to antiresorptive therapy.

In 1998 the National Osteoporosis Foundation created a set of guidelines for the use and interpretation of measurement of bone mineral density. Measurements of bone mineral density are recommended for the following groups: (a) all postmenopausal patients younger than age 65 years who have one or more additional risk factors for osteoporosis (other than being white, postmenopausal, and female); (b) all women age 65 years and older regardless of additional risk factors; (c) postmenopausal women who

present with fractures; (d) women considering therapy for osteoporosis if testing would facilitate the decision; and (e) women who have been on hormone replacement therapy for prolonged periods.

Prevention and Treatment

All individuals at risk for or who have been diagnosed with osteoporosis should be advised to consume adequate calcium (minimum of 1200 mg elemental calcium per day) and vitamin D (400–800 IU/d). Smoking cessation, avoidance of excessive alcohol intake, and participation in regular weight-bearing exercise should be encouraged. Pharmacologic therapy should be strongly considered in women with BMD scores below -2.0 with no risk factors, and in women with BMD T-scores below -1.5 with 1 or more risk factors. Current pharmacologic therapy for osteopenia/osteoporosis, listed in alphabetical order, includes (a) bisphosphonates, (b) calcitonin, (c) estrogens (with or without progestogens), (d) parathyroid hormone, and (e) raloxifene.

Bisphosphonates are excellent choices for prevention and treatment of osteoporosis. They are potent antiresorptive agents that bind to hydroxyapatite crystals on the surface of bones, enter osteoclasts, and decrease resorptive actions by reducing the production of hydrogen ions and lysosomal enzymes. In addition, they have indirect effects, causing osteoblasts to produce substances that inhibit osteoclasts. They increase bone mineral density at the spine, wrist, and hip in a dose-dependent manner and decrease the risk of vertebral fractures by 30–50%. In addition, they reduce the risk of subsequent nonvertebral fractures in women with osteoporosis. There are three bisphosphonates currently available for oral administration. Alendronate is approved by the Food and Drug Administration for the prevention of osteoporosis (5 mg daily and 35 mg weekly) and for the treatment of established osteoporosis (10 mg daily or 70 mg weekly). Risedronate is approved by the FDA for prevention and treatment of postmenopausal osteoporosis. The recommended daily dose is 5 mg daily or 35 mg weekly. Ibandronate was recently approved for both prevention and treatment of postmenopausal osteoporosis. It has the advantage of being available in both a daily and monthly dosing regimen. The daily dose is 2.5 mg and the monthly dose is 150 mg. Intestinal absorption of bisphosphonates is poor and therefore these medications should be taken in the morning with 8 ounces of water, prior to consumption of any food or beverage. Nothing else should be taken by mouth for at least 30–60 minutes after oral dosing. The patient should also remain upright for 30 minutes after administration. The most common side effects of bisphosphonates are gastrointestinal. Pain in the joints, bone, and muscle may also occur. Risks include gastric and esophageal ulceration and, rarely, osteonecrosis of the jaw. Most cases of osteonecrosis of the jaw have been described in cancer patients being treated with intravenous bisphosphonates, but some cases have occurred in patients being managed for postmenopausal osteoporosis.

Calcitonin is a peptide hormone that inhibits osteoclast activity and therefore inhibits bone resorption. It demonstrates positive effects on bone mineral density at the lumbar spine, although less effectively than estrogen or bisphosphonates. Salmon calcitonin is the most potent form and is available for intranasal administration or as a subcutaneous injection. Calcitonin 100 IU is given subcutaneously daily or every other day; the intranasal calcitonin dose is 200 IU daily. The most frequent side effect with the intranasal route is rhinitis. Other antiresorptive therapies, such as bisphosphonates, are preferred over calcitonin, as they produce greater increases in bone mineral density. However, because of calcitonin's analgesic properties, calcitonin is the preferred therapy in patients with pain from vertebral fracture.

Until recently estrogen was the mainstay of therapy for prevention and treatment of postmenopausal osteoporosis. However, with the findings from the Women's Health Initiative (WHI) trial demonstrating overall greater health risks than benefits from hormone therapy, it is no longer first-line therapy for prevention of osteoporosis. Osteoporosis prevention does remain an FDA-approved indication for estrogen therapy, however. It is best used in women who would otherwise use estrogen/hormone

therapy for management of menopausal symptoms, or in women who cannot tolerate alternate antiresorptive therapies.

In observational studies, estrogen decreases the risk of hip fractures by 25–50%, of vertebral fractures by approximately 50%, and reduces the risk of other fractures. Daily dosages of 0.3–0.625 mg of conjugated estrogens, 0.5–1 mg micronized estradiol, 1.25 mg piperazine estrone sulfate, 0.025–0.05 mg of transdermal estradiol, and a new low dose (0.014 mg) of transdermal estradiol all are appropriate for the prevention of osteoporosis. The lower doses (ie, 0.3 mg conjugated equine estrogens) are not as effective as higher doses but do prevent bone loss. For best results, therapy should begin soon after the menopause.

Parathyroid hormone, teriparatide (PTH [1-34]) has been approved by the FDA for use in women and men who are at high risk for fracture, including those with previous fracture, multiple risk factors for fracture, and previous failed treatment. Despite its potential deleterious effect on bone, intermittent administration of recombinant PTH stimulates bone formation and clinical trials support its use in the treatment of osteoporosis. It should only be used in high-risk patients because of its high cost, the need for daily injection, and a possible risk for osteosarcoma.

Selective estrogen receptor modulators (SERMs) are nonhormonal agents that bind to estrogen receptors and may exhibit either estrogen agonist or antagonist activity. Currently, there are three SERMs approved for use in humans (tamoxifen, toremifene, and raloxifene); however, raloxifene is the only SERM approved for the prevention and treatment of osteoporosis. It exhibits estrogen agonist properties in the bone (inhibits osteoclast function) and the liver (decreases low-density lipoprotein cholesterol), and acts as an antagonist in the breast and uterus. Raloxifene 60 mg daily for 24 months is associated with a 1–2% increase in lumbar spine and hip bone density.

Other therapies have been proposed for osteoporosis treatment and prevention, some without proven benefit. Progestins decrease biochemical markers of bone resorption and preserve bone density. When used as monotherapy for osteoporosis, they may be more effective at preserving bone in the wrist than in the spine.

Fluoride has been used in Europe and the United States and is associated with a marked increase in trabecular bone, but did not improve fracture rates, and in some studies fracture rates were increased. This may be a result of a lack of increase in cortical bone. Sodium fluoride is generally not recommended for the treatment of osteoporosis.

Phytoestrogens are plant-derived compounds that have weak estrogenlike effects. Although some animal studies are promising, no effects on the incidence of fractures in humans have been shown.

Tibolone (see Hot Flushes) also increases lumbar spine and femoral neck bone density. Its effects on bone are comparable to those of estrogens. As discussed previously, however, issues regarding long-term safety are currently being evaluated.

SEXUAL DYSFUNCTION

The determinants of sexual behavior are complex and interrelated. Sexual function is believed to be regulated by three general components: the individual's motivation (also called desire or libido), endocrine competence, and social-cultural beliefs. Decreased libido is reported with increasing age. However, the relative contributions of the primary decrease in desire, anatomic limitations to sexual function, or beliefs that sexual behavior is inappropriate in older women to this decreased libido are unknown.

The hypoestrogenemic state leads to atrophy of the internal genitalia. Although dyspareunia is the most

obvious symptom of vaginal atrophy, suboptimal sexual functioning can occur without frank dyspareunia. Diminished genital sensation (and therefore decreased sensory output in the arousal phase), lessened glandular secretions, less vasocongestion, and decreased vaginal expansion may not be perceived as discrete symptoms by the postmenopausal female, but may influence her perception that she is less responsive.

Genital atrophy, one cause of postmenopausal sexual dysfunction, responds to estrogen therapy. The specific impact of estrogen on libido has been difficult to determine. Improved anatomy may also have a positive psychologic impact and may indirectly encourage sexual motivation. The role of androgen therapy in female sexual dysfunction is an active area of investigation.

Common Clinical Conditions of the Aged, Postmenopausal Woman: Controversial Role of Estrogens

CORONARY HEART DISEASE (CHD)

Heart disease affects approximately 6 million women in the United States. Deaths caused by CHD in women number more than 230,000 per year. The incidence of death from CHD increases with age in all populations and both sexes. Substantially more heart disease is seen in younger men, with the onset of cardiovascular problems occurring an average of 10 years later in women. Before the age of menopause, very few women die of a heart attack. After the menopause, a woman's risk increases progressively such that CHD rates in women after menopause are 2–3 times those of women of the same age before menopause. Statistics such as these, indicating a role for both gender and menopause on the development of CHD, have led to the suggestion that estrogen deficiency that occurs following menopause is at least partially responsible for the increased risk of CHD in postmenopausal women.

Until recently, two types of studies have attempted to ascertain whether cessation of ovarian function is associated with an increased incidence of heart disease. The first examined the relationship between the menopause and carefully defined cardiovascular disease in an entire population. For example, the Framingham study, in which nearly 3000 women were examined biennially, revealed that following the menopause, there is indeed an increased incidence of heart disease that is not just age-related. In this study, the impact of the menopause was abrupt, and further (age-related) increases in incidence occurred only slowly, if at all. In the Nurses' Health Study cohort of 121,700 women, after controlling for age and cigarette smoking, women who had a natural menopause had no appreciable increase in risk compared to that of premenopausal women. However, women who underwent a bilateral oophorectomy and no estrogen replacement had an increased risk (relative risk [RR] 2.2) compared with that seen in premenopausal women.

In the second type of investigation, case-control studies were performed comparing the degree of coronary heart disease or the incidence of myocardial infarction in women who had undergone early oophorectomy with age-matched premenopausal controls. Most of these studies revealed an increased risk of cardiovascular disease after ovarian excision. All these reports have been criticized because of patient selection bias, particularly of the controls.

Numerous case-control and large-cohort studies have been published, with most showing a beneficial impact of estrogens. A meta-analysis found that estrogen use provided a 50% decrease in risk of mortality from heart disease. Although the magnitude of change and the consistency of results appear compelling, it must be recognized that all these studies are observational, and that the choice of controls has been questioned. In particular, women who take estrogens are more health conscious and must see a doctor regularly to receive their medication, whereas women who don't take estrogens may or may not receive regular medical checkups. Thus, some or all of the apparent benefits of estrogens on heart disease may have been a consequence of these other considerations.

Based on these observational/case-controlled studies suggesting a beneficial effect of estrogens, numerous experimental studies were performed attempting to elucidate the mechanism(s) by which estrogens could prevent coronary heart disease. Evidence for both an indirect effect on circulating lipids and a direct action on the vascular system was found. For years, the greatest emphasis of research had been to study the impact of estrogens on lipoproteins. Orally administered estrogens influence hepatic lipid metabolism and raise high-density lipoprotein (HDL) cholesterol and triglycerides and lower low-density lipoprotein (LDL) cholesterol. The impact of nonorally administered estrogens is of lesser magnitude and takes longer to become apparent. The Lipid Research Clinic study suggested that approximately 50% of the benefit of estrogen on heart disease was elicited through the action of estrogens on lipoproteins, whereas the remainder was through other mechanisms.

The PEPI (Postmenopausal Estrogen Progestin Intervention) Trial showed that there is a significant lowering of LDL cholesterol with oral conjugated equine estrogens (CEEs), even with the addition of medroxyprogesterone acetate (MPA) or micronized natural progesterone. Of the four regimens studied, continuous CEE 0.625 mg without the addition of progestin had the most favorable effect on lipid profiles. All active HT regimens lowered LDL cholesterol and fibrinogen levels.

Numerous studies show that estrogen and progesterone receptors are present in the heart and aorta. Thus, the subcellular components necessary for hormonal action exist in these tissues. Studies in castrated cynomolgus monkeys given atherogenic diets have shown estradiol administered by subcutaneous pellets prevents coronary atherogenesis in the absence of any measurable change in circulating lipoproteins. Endothelial cells of the arteries produce factors in response to estrogen. One of the most potent of these is believed to be nitric oxide (NO). NO exerts several effects on the arterial wall. It increases intracellular cyclic guanosine monophosphate in the arterial smooth muscle, which results in vasodilation. It also inhibits platelet adhesion and aggregation, as well as monocyte adherence to the arterial endothelium. Estrogen appears to increase NO production. Basal release of NO is greater in intact female rabbits than in either male rabbits or castrated females. Acetylcholine is known to stimulate vasodilation of the coronary arteries of humans and monkeys. This effect is dependent on an intact vascular endothelium and mediated via NO. It has been theorized that estrogens may increase muscarinic receptors on endothelial cells, leading to acetylcholine-induced, endothelial-dependent, NO-mediated vasodilation, which may be important in preventing vasospasm. Estrogen has also been shown in an animal model to prevent two of the earliest steps in the atherogenic process—adhesion and migration of monocytes. Estrogens also likely have adverse effects on the vessel wall. Estrogens lead to a hypercoagulable state which may increase the risk of coronary events. Although these mechanisms are only partially understood, they emphasize the importance of studying the direct effects of estrogen on the vascular system.

Interestingly, use of estrogen had been widespread for many years, yet it was not until recently that large-scale, prospective, randomized, placebo-controlled studies evaluating the effect of hormone therapy on relevant clinical endpoints in humans were performed. One of the first of these studies was the Heart and Estrogen/Progestin Replacement Study (HERS) which studied the use of estrogen and progestin in the secondary prevention of coronary events in women with known coronary heart disease. HERS showed that treatment with oral conjugated equine estrogen (CEE) plus medroxyprogesterone acetate (MPA) did not reduce the overall rate of coronary heart disease events in postmenopausal women with established heart disease. In addition, there was an early increased risk of CHD events within the first year of starting HT. In addition, the ERA (Estrogen Replacement and Atherosclerosis) Trial, which was the first randomized angiographic end point trial to test the effect of HT on the progression of atherosclerosis in postmenopausal women with documented coronary stenosis, showed no benefit of CEE either alone, or in combination with MPA, on angiographic progression of disease. Consequently, it is

suggested that physicians not prescribe estrogen therapy (ET)/HT for the sole purpose of *secondary* prevention of coronary events.

The primary prevention of CHD by HT also had not been evaluated in a prospective, randomized fashion until recently. The WHI, a large, multicenter, prospective, randomized, placebo-controlled trial of primarily healthy postmenopausal women, was initiated to assess the effects of a specific regimen of CEE alone or in combination with MPA on several health-related outcomes, including CHD. The combined estrogen/progestin portion of the study was stopped after 5.2 years as overall health risks exceeded benefits. The increased risks included a greater number of cardiovascular events. Although the absolute risk of harm was small, the authors concluded that this regimen of HT should not be initiated or continued for the primary prevention of CHD. The estrogen-only arm of the study was continued for approximately 7 years. This arm of the study was stopped early because of an increased risk of stroke. Overall, there was no reduction in the risk of coronary events. Interestingly, there appeared to be a trend toward a decreased risk of coronary events in the younger subset of postmenopausal women. This finding was confirmed in a subanalysis of the data for the 50–59-year-old age group where the investigators reported a lower relative risk for the combined end points of myocardial infarction, coronary death, coronary revascularization, and confirmed angina among women ages 50–59 years using estrogen alone.

There were several limitations of the WHI study. It did not assess different dosages, types of estrogens and progestogens, nor different routes of administration (ie, transdermal vs. oral). Finally, many of the subjects had become menopausal several years before entry into the study. Consequently, it was not possible to precisely ascertain whether starting HT with the onset of menopause, when initiation or more rapid acceleration of atherosclerosis may take place, is beneficial. Because estrogen has been shown in experimental models to prevent the very earliest steps in atherogenesis, but to raise cardiovascular risk in the setting of established atherosclerosis (possibly via increases in clotting factors), it is possible that the adverse cardiovascular effects seen in this study may have been a result of the possibility that many women started HT following the onset of menopause when subclinical atherosclerotic changes and irreversible endothelial damage may have already set in. In support of this concept, a recent analysis from the ongoing Nurses Health Study, a long-term prospective observational study, demonstrated that women who used HT had a decrease in the risk of CHD relative to women who did not use HT. The majority of these women started HT/ET close to menopause. This is in contrast to the WHI where the majority of women started HT/ET remote from menopause. This emphasizes the importance of continuing to study the effects of estrogen, particularly in younger, recently postmenopausal women. Additional studies are currently underway to assess whether estrogen administration to younger, healthy, recently postmenopausal women is safe from a cardiovascular standpoint.

The decision to use HT should be based primarily on the proven benefits of ET/HT on other systems, the potential risks of therapy, and patient preference. Short-term use of HT for relief of postmenopausal symptoms is still an option for women without contraindications.

MOOD DISORDERS

Studies assessing the effects of estrogen on depression and other mood disorders are conflicting. Although some studies suggest beneficial effects of estrogen, others, including the recent WHI, do not. Early cross-sectional surveys of community or large, general, medical practice-based populations attempted to measure the temporal association of depression and irritability to the cessation of menses. Some reports indicated an increased incidence of minor symptoms such as irritability, dysphoria, and nervousness early in the menopausal transition.

Reports from community-based cohort studies have refined knowledge in the area of mood, mentation,

and menopause. The initial longitudinal report of the U.S. cohort found an increase in overall nonspecific symptom reporting at the menopause. Depression for more than two interviews was noted in 26% of the cohort. Perceived health, rather than menopause or coincident life stresses, was most related to depression in this study. These findings are consistent with the concept of variability in a woman's response to the menopause; individual characteristics and self-perceptions appear to be important determinants of each woman's experience of the climacteric.

Hypotheses as to the etiology of the affective complaints at the menopause also include a primary biologic cause (eg, an alteration in brain amines). Studies using the opioid antagonist naloxone have demonstrated that estrogen deficiency is associated with low levels of endogenous opioid activity and that estrogen supplementation increases opioid activity. These findings suggest that central neurotransmitters may contribute to the etiology of affective and cognitive complaints. Sociologic factors postulated to cause psychological symptoms, such as negative cultural values attached to aging, may also promote a negative climacteric experience.

Double-blind studies have found improvements in self-reported irritability, mild anxiety, and dysphoria in women treated with estrogen alone or when combined with progestin. Improvement of the Beck depression score in women without hot flushes indicates that estrogens likely have direct effects on brain function.

Depression and other quality of life outcomes were studied in the Women's Health Initiative trial. Overall, conjugated equine estrogen alone, or in combination with medroxyprogesterone acetate, did not improve depressive symptoms amongst postmenopausal women ages 50–79 years after 1 and 3 years. In a subgroup analysis of 50–54-year-old women experiencing hot flashes, estrogen plus progestin improved hot flashes and sleep disturbance, but no other quality-of-life outcomes. In the estrogen-alone group, there was a slight improvement in sleep disturbance and social functioning, but no other quality-of-life outcomes measured. Therefore, a role for HT/ET in improving depressive symptoms following the menopause remains unproven.

COGNITIVE DECLINE

As life expectancy in women has risen, there has been more research regarding the effects of estrogen on cognitive functioning in postmenopausal women. Research indicates that estrogen influences areas of the brain known to be important for memory. However, recent data from the WHI suggests that estrogen alone or in combination with progestin does not decrease, and in fact may increase, the risk of cognitive decline in women older than 65 years of age.

SKIN AND HAIR CHANGES

With aging, noticeable changes occur in the skin. There is generalized thinning and an accompanying loss of elasticity, resulting in wrinkling. These changes are particularly prominent in the areas exposed to light (ie, the face, neck, and hands). "Purse-string" wrinkling around the mouth and "crow's feet" around the eyes are characteristic. Skin changes on the dorsum of the hands are particularly noticeable. In this area, the skin may be so thin as to become almost transparent, with details of the underlying veins easily visible.

Histologically, the epidermis is thinned, and the basal layers become inactive with age. Dehydration is typical. Reduction in the number of blood vessels to the skin is also seen. Degeneration of elastic and collagenous fibers in the dermis also appears to be part of the aging process.

These skin changes are of cosmetic importance and are of great concern to many women. It is unclear if these changes are primarily caused by the menopause, aging, or a combination of both factors. It is commonly stated that women undergoing estrogen replacement look younger, and the cosmetic industry

has been putting estrogens in skin creams for years for precisely this reason.

The possibility that estrogens may have effects on skin was suggested by the demonstration of estrogen receptors in skin. The number of receptors is highest in facial skin, followed by skin of the breasts and thighs. This gives credence to the hypothesis that estrogens affect the skin.

Skin circulation is decreased in women after oophorectomy. Radiolabeled thymidine incorporation (an index of new DNA metabolism) is reported to decrease during the several months following oophorectomy. In some animal studies, estrogens increase the mitotic rate (a reflection of growth) of skin. Estrogens may alter the vascularization of skin. They also change the collagen content of the dermis, as reflected by mucopolysaccharide incorporation, hydroxyproline turnover, and alterations of the ground substance. In addition, dermal synthesis of hyaluronic acid and dermal water content are enhanced.

Skin collagen content and thickness have been studied in postmenopausal women. Decreases of both have been observed at a rate of 1–2% per year. The losses correlated with the number of years since the menopause, but not with chronologic age. Estrogen replacement prevents these losses or restores both parameters to premenopausal values. The greatest recovery is observed in women who began with low values. These data were interpreted to indicate that estrogen can prevent loss in women with high skin collagen levels, whereas it can restore content as well as prevent further loss in women with low collagen levels. Although these results are promising, it remains unclear whether they are clinically relevant. Estrogen should not be prescribed to improve the appearance of skin.

After the menopause, most women note some change in patterns of body hair. Usually there is a variable loss of pubic and axillary hair. Often there is loss of lanugo hair on the upper lip, chin, and cheeks, together with increased growth of coarse terminal hairs; a slight moustache may become noticeable. Hair on the body and extremities may either increase or decrease. Slight balding is seen occasionally. All of these changes may be partly a result of reduced levels of estrogen in the face of fairly well-maintained levels of testosterone.

MISCELLANEOUS SYMPTOMS

Many other symptoms are attributed to the endocrine changes of the postmenopausal state, but a direct cause-and-effect relationship has not been established for them. Some of these so-called climacteric symptoms are so common that they deserve brief mention.

Symptoms possibly related to specific autonomic nervous system instability—but equally attributable to anxiety or other emotional disturbances—are paresthesia (pricking, itching, formication), dizziness, tinnitus, fainting, scotomas, and dyspnea. Symptoms clearly not of endocrine origin are weakness, fatigue, nausea, vomiting, flatulence, anorexia, constipation, diarrhea, arthralgia, and myalgia.

Many women erroneously believe that the endocrine changes accompanying menopause will produce a steady weight gain. Women and men do tend to gain weight at this time of life, but the cause is usually a combination of decreased exercise and possibly increased caloric intake. There may be some redistribution of body weight occasioned by the deposition of fat over the hips and abdomen. Perhaps this is partly an endocrine effect, but more likely it is the result of decreased physical activity, reduced muscle tone, and other effects of aging.

Many of the previously mentioned symptoms occasionally respond promptly to administration of estrogen. This should not mislead physicians into assuming a specific endocrine action for what is actually a placebo effect.

Differential Diagnosis of Common Signs and Symptoms during Menopause

Signs and symptoms similar to those of the climacteric can be caused by a variety of other diseases. In general, seeing the entire clinical picture is helpful in establishing the proper diagnosis. The absence of evidence of other disease points to cessation of ovarian function, whereas the presence of prominent features of other conditions, in the absence of other climacteric symptoms, suggests a nonclimacteric origin.

AMENORRHEA

By definition, the primary symptom of the menopause is the absence of menstruation. Amenorrhea can occur for many reasons, of which physiologic menopause is only one. Cessation of ovarian function is by far the most common reason for amenorrhea to occur in women in their forties or early fifties. Persistent amenorrhea in younger women may be a result of premature cessation of ovarian function, but must be differentiated from other causes. Obvious features of specific disease often suggest the proper diagnosis (eg, extreme weight loss in anorexia nervosa, galactorrhea in hyperprolactinemia, hirsutism and obesity in polycystic ovarian disease).

HOT FLASHES

Several diseases can produce sensations of flushing that may be misinterpreted as hot flashes. Notable are hyperthyroidism, pheochromocytoma, carcinoid syndrome, diabetes mellitus, tuberculosis, and other chronic infections. None of these disorders produces the specific symptoms associated with the climacteric (ie, short duration and specific body distribution). Moreover, the absence of other signs or symptoms of the climacteric suggest some other cause of the flushes should be sought.

ABNORMAL VAGINAL BLEEDING

Prior to the menopause, irregular vaginal bleeding is expected and does not necessitate a diagnostic work-up in many cases. However, organic disease can occur at this time, and some patients require evaluation. If a woman is in her forties or fifties and experiences an increase in cycle length and a decrease in the quantity of bleeding, menopausal involution can be presumed and endometrial sampling is usually not necessary. However, if menses become more frequent and heavier, spotting between menses occurs, or any pattern of irregular bleeding persists, assessment of the endometrium should be performed. The usual procedure is an endometrial biopsy or dilatation and curettage (D&C) to rule out endometrial hyperplasia or cancer. The disadvantage of the former is that entry into the endometrial cavity may not be accomplished in the setting of a stenotic os, and the drawbacks of the latter are greater expense, risk and need for anesthesia.

It is most unusual for a woman to experience vaginal bleeding because of ovarian activity by 6 months after the menopause. Thus, postmenopausal bleeding is much more ominous and necessitates evaluation each time it occurs. The only exception to this rule is the uterine bleeding associated with estrogen replacement therapy. Other guidelines are recommended for this type of bleeding (see Estrogen Therapy).

Organic disease is commonly associated with postmenopausal bleeding. Endometrial polyps may be found, which can be resected via the hysteroscope. Endometrial hyperplasia may be discovered, frequently in obese women. This can be treated by the periodic administration of progestin or by hysterectomy. If hyperplasia develops in a woman taking estrogens, the addition of progestins should be considered. If hyperplasia develops unrelated to hormone replacement, surgery should be considered if the patient is a good surgical risk or is not reliable in taking progestins. The finding of endometrial cancer necessitates appropriate therapy depending on the stage and grade of the tumor.

VULVOVAGINITIS

Many specific vulvar and vaginal diseases (eg, trichomoniasis and candidiasis) may mimic the atrophic vulvovaginitis of estrogen deficiency. Their special clinical characteristics usually suggest more specific

diagnostic testing. When pruritus and thinning of the vaginal epithelium or the vulvar skin are the only manifestations, therapeutic testing with local applications of estrogen may help to establish the diagnosis of vulvovaginitis. When any whitening, thickening, or cracking of vulvar tissues is present, biopsy to rule out carcinoma is mandatory. Raised or erosive lesions should also be sampled. Biopsy to rule out carcinoma is also necessary for suspicious looking vaginal or cervical lesions.

BACK PAIN

Occasionally, the pain of vertebral compression from osteoporosis may mimic that of gastric ulcer, renal colic, pyelonephritis, pancreatitis, spondylolisthesis, acute back strain, or herniated intervertebral disk.

Prevention of Menopause

Nothing can prevent the physiologic menopause (ie, ovarian function cannot be prolonged indefinitely), and nothing can be done to postpone its onset or slow its progress. However, artificial menopause can often be prevented. When ionizing radiation is used for the treatment of intra-abdominal disease, incidental ablation of ovarian function often cannot be avoided. In such cases, if an operation will serve equally well to treat intra-abdominal disease, it should be used in preference to radiation therapy in order to preserve the ovaries.

Elective removal of the ovaries to prevent ovarian cancer is frequently performed at laparotomy or laparoscopy in premenopausal women, with deliberate acceptance of artificial menopause. This form of therapy, however, remains controversial.

Estrogen Therapy

Every woman with menopausal symptoms deserves an adequate explanation of the physiologic event she is experiencing, so as to dispel her fears and address symptoms such as hot flashes and sleep disturbance. Reassurance should be emphasized. Specific reassurance about continued sexual activity is important.

As long as ovarian function is sufficient to maintain some uterine bleeding, no treatment is usually required. Occasionally, women complain of hot flashes while menstrual function is still present. Treatment with low-dose oral contraceptive pills, if no contraindications exist, will relieve these symptoms and help to regulate menstrual cycles during the menopausal transition.

INDICATIONS

Estrogen therapy has been used for many years for a variety of symptoms and conditions seen in the aged female population. However, despite suggestions from observational and experimental studies that estrogens prevent many common conditions of aging, such as Alzheimer's disease and CHD, estrogen therapy has only been proven to be effective in the prevention of osteoporosis, treatment of vasomotor symptoms, and treatment of vulvovaginal atrophy. Results from the WHI further call into question the degree to which estrogen can act as a "cure-all" for the common conditions of aging, particularly those affecting the brain and heart. Benefits beyond those already established are still possible, but await proof in large-scale studies in humans. Therefore, use of estrogens should be limited to the currently approved Food and Drug Administration (FDA) indications: prevention of osteoporosis, treatment of vasomotor symptoms, and treatment of vulvovaginal atrophy (see Management Guidelines for Estrogen Therapy).

COMPLICATIONS

Before discussing the management of estrogen replacement, it is necessary to review the complications of and contraindications to this type of therapy. These play an important role in the ultimate decision regarding treatment for all patients.

Endometrial Cancer

The role of estrogen therapy in the development of endometrial cancer is one of the most highly charged issues related to the menopause. Current concerns are based on several lines of investigation. The scope of investigative efforts lead to the conclusion that estrogen stimulation of the endometrium, unopposed by progesterone, causes endometrial proliferation, hyperplasia, and, finally, neoplasia. Consequently, it is recommended that a progestin be added to ET to reduce the risk of endometrial hyperplasia or carcinoma.

The reports of estrogen replacement and endometrial carcinoma have received the greatest attention. In most studies, a strong association has been found, with 2- to 8-fold overall risk ratios. High dosage and prolonged treatment increase the risk. Disease is local in most cases, although more widespread invasive tumors have been reported. Concerns have been raised about these studies, particularly regarding the selection of controls. In most studies, controls had not undergone sampling of the endometrium to rule out asymptomatic endometrial cancer. Thus, debates persist, and prudent physicians should discuss the risks with their patients and employ preventive measures.

Breast Cancer

Early age at menarche and older age at menopause are known risk factors for breast cancer, and early oophorectomy is known to give protection against this disease. Ovarian activity is an important determinant of risk, thus estrogen may play a role in the development of breast cancer. Studies in rodents support that view. More than 30 epidemiologic studies have been published since 1974 to determine the possible link between postmenopausal estrogen use and breast cancer. In general, the later studies have had better design, quality, and analytic strategies. The number of subjects in more recent studies has also been larger. At least 6 meta-analyses of this topic also have been conducted. These results have not always agreed. The recent prospective, randomized Women's Health Initiative trial also addressed this issue. In this study there was an increased risk of invasive breast cancer in the estrogen/progestin arm. However, in the estrogen-alone arm, the risk of breast cancer was not increased compared to controls.

Despite this inconsistency in studies, some trends have been observed: (a) The overall risk of breast cancer with estrogen use has not uniformly been shown to be increased. (b) Long-term use (ie, 4–10 years) has been associated with mild increased risk (RR 1.2–1.5) in some of the meta-analyses and the Women's Health Initiative. (c) The addition of a progestin does not appear to decrease risk and may increase risk. (d) Finally, risk does not vary in strata of family history of breast cancer or with benign breast disease.

It must be remembered that all women are at risk for breast cancer. Thus, instructions for breast self-examination, a careful breast assessment, and routine screening mammography should be a part of the medical care of all older women.

Thromboembolic Disease

Use of oral contraceptives increases the risk of overt venous thromboembolic disease and subclinical disease extensive enough to be detected by laboratory procedures such as ¹²⁵I fibrinogen uptake and plasma fibrinogen chromatography. The risk of venous thromboembolic disease was also increased among users of ET/HT in the WHI, as well as among users of HT in the HERS trial.

The effects of estrogen on the clotting mechanism may contribute to or be responsible for a generalized hypercoagulable state. Oral estrogens affect synthesis of coagulation factors through a first-pass effect in the liver, an effect associated with an increased risk of thromboembolic disease. The risk for thromboembolic events with use of ET/HT is also likely further increased amongst patients with inherited thrombophilias.

Use of transdermal estrogens is probably associated with a lowered risk for thromboembolic events as compared to use of oral estrogens. However, randomized trials are needed to better characterize the effects of transdermal estrogens on risk for clinical thromboembolic events.

Stroke

Several recent studies suggest that hormone therapy is associated with an increased risk of stroke. In the combined HT arm of the WHI, there was an increased risk of ischemic stroke amongst those using combined HT when compared to the placebo. In the estrogen alone arm of the WHI, there was also a statistically significant increased risk of stroke after approximately 7 years of follow-up, and this outcome led to the trial being terminated.

Uterine Bleeding

If patients are given sequential estrogen and progestins, the majority will experience some uterine bleeding, particularly soon after initiation of therapy. This bleeding can occur during the treatment-free interval (scheduled bleeding) or while the medications are being administered (unscheduled bleeding). Hyperplastic endometrium can develop with this type of therapy. If the bleeding is heavy or prolonged, a biopsy should be performed. In women using a combined continuous regimen of estrogen and progestin, bleeding is common in the first several months of therapy and usually doesn't indicate endometrial pathology. However, if bleeding persists in these patients, or is prolonged or heavy at any time, endometrial sampling should be performed. If endometrial hyperplasia is present, the medications can be discontinued, progestin dose can be increased or a progestin can be given each day of estrogen administration. Whichever approach is adopted, a repeat biopsy should be performed to make certain that the hyperplastic endometrium has resolved. The cost-effectiveness ratio for periodic biopsy in women who do not bleed or bleed only during the medication-free interval is poor and indicates that such biopsy is probably unnecessary.

In women taking estrogen only, the incidence of endometrial hyperplasia can be as high as 25% after only 12 months of therapy. Hyperplasia occurs in women who do not experience vaginal bleeding, bleed only during the medication-free interval, or bleed during drug administration. Thus, a pretreatment biopsy and yearly endometrial biopsies are necessary in all women receiving estrogens alone to assess for the presence of hyperplasia. Again, estrogen withdrawal or combined estrogen-progesterone therapy may be employed to treat the hyperplasia. The incidence of endometrial cancer will likely be reduced if the programs discussed above are instituted.

Gallbladder Disease

An increased incidence of gallbladder disease has been reported following estrogen replacement therapy. Estrogens cause increased amounts of cholesterol to collect in bile. Two primary bile salts, cholate and chenodeoxycholate, are produced by liver cells. In women taking estrogen, decreased levels of chenodeoxycholate and increased levels of cholate are found in bile. Chenodeoxycholate inhibits activity of the enzyme β -hydroxy- β -methylglutaryl-CoA reductase, which regulates cholesterol synthesis, and a decrease in chenodeoxycholate may therefore cause increased activity of β -hydroxy- β -methylglutaryl-CoA reductase, leading to increased synthesis of cholesterol. Bile normally has a 75–90% saturation in cholesterol, and even small increases of this substance can initiate cholesterol precipitation and stone formation. Three-fourths of gallstones are composed predominantly of cholesterol.

Lipid Metabolism

Estrogen replacement also has an impact on circulating lipids. As discussed above, many of these effects are favorable. However, others may pose increased risk. Most lipids are bound to proteins in the blood, and the concentrations of the various types of lipoproteins are associated with varying risks of heart disease. Lower levels of HDL cholesterol and higher concentrations of total cholesterol, LDL cholesterol,

very-low-density lipoprotein (VLDL) cholesterol, and triglycerides are associated with increased risk of atherosclerosis and coronary artery disease. Estrogen replacement decreases LDL cholesterol and increases HDL cholesterol and triglycerides. Use of conjugated estrogens, 0.625 mg/d or less, causes approximately a 10% increase in HDL cholesterol. Much attention has been focused on the impact of estrogens on lipoproteins to explain what appeared to be a beneficial effect of HT on heart disease in earlier observational studies of younger postmenopausal women. The impact of estrogen-induced increases in triglycerides on cardiovascular risk is unclear. In patients with familial defects of lipoprotein metabolism, estrogen replacement therapy is associated with massive elevations of plasma triglycerides, leading to pancreatitis and other complications. However, this is a very unusual complication of estrogen replacement. Transdermal estrogens are probably less likely to raise triglyceride levels and thus are preferred in women with an elevation in triglyceride levels.

Miscellaneous

Other side effects of estrogen therapy include uterine bleeding, generalized edema, mastodynia and breast enlargement, abdominal bloating, signs and symptoms resembling those of premenstrual tension, headaches (particularly of a "menstrual migraine" type), and excessive cervical mucus. These side effects may be dose related or idiosyncratic, and are managed by lowering the dosage, by use of another agent, or by discontinuation of the medication.

CONTRAINDICATIONS TO ESTROGEN REPLACEMENT THERAPY

Contraindications to estrogen therapy are as follows: (a) Undiagnosed abnormal vaginal bleeding; (b) known, suspected or history of cancer of the breast; (c) known or suspected estrogen-dependent neoplasia; (d) active deep vein thrombosis, pulmonary embolism, or a history of these conditions; (e) arterial thromboembolic disease (myocardial infarction, stroke); and (f) liver dysfunction or disease. In general, estrogen therapy should be avoided in patients with a diagnosis of endometrial cancer. Estrogen therapy may stimulate growth of malignant cells remaining after treatment of breast or endometrial carcinoma and may thus hasten the recurrence of cancer. Therefore, it is prudent to avoid systemic estrogen therapy in breast cancer patients and most endometrial cancer patients. Recently, it was suggested that women with early (stage 1) and well-differentiated (grade 1) endometrial cancer can be administered estrogens following primary treatment of the cancer. Care must be exercised in following this recommendation until it has been properly studied. Any decision to use ET/HT following a diagnosis of endometrial cancer should be made in consultation with the patient's oncologist. Patients who have had estrogen receptor-positive malignant tumors of the breast probably should not receive systemic estrogen supplements. Topical vaginal estrogens to treat symptoms of urogenital atrophy in breast/endometrial cancer patients might be acceptable, but should first be discussed with the patient's oncologist. A history of treated carcinoma of the cervix or ovary is not a contraindication to estrogen therapy. Estrogens may have undesirable effects on some patients with preexisting seizures, hypertension, fibrocystic disease of the breast, uterine leiomyoma, collagen disease, familial hyperlipidemia, diabetes mellitus, migraine headaches, chronic thrombophlebitis, and gallbladder disease. At the low dosages recommended for replacement therapy, increased growth of uterine myomas, endometriosis, or chronic cystic mastitis is rarely a concern.

MANAGEMENT GUIDELINES FOR ESTROGEN THERAPY

General

Only general guidelines can be offered, because risks and benefits must be evaluated for each patient. Numerous formulations of estrogen and estrogen plus progestin are available (Table 59–1). Current indications for estrogen therapy are relief of menopausal symptoms (including hot flashes and vaginal atrophy) and prevention of osteoporosis. Caution should be exercised in providing therapy for other conditions until more definitive studies have been performed. If symptoms of hot flashes and vaginal

atrophy are moderate to severe, therapy may be used for the shortest duration possible; minimal or no symptoms may not require hormones.

Table 59–1. Preparations of Estrogens and Progestins Available in the United States for Hormone Therapy.

Agent	How Supplied	Special Features
Oral estrogens		
Conjugated equine estrogens	0.3 mg, 0.45 mg, 0.625 mg, 0.9 mg, 1.25 mg tablets	Well studied, well tolerated; approved for prevention of osteoporosis, 0.625 mg dose used in WHI study
Estradiol	0.5 mg, 1 mg, 2 mg tablets	Well tolerated; approved for prevention of osteoporosis
Piperazine estrone (estropipate)	0.75 mg, 1.5 mg tablets	
Synthetic conjugated estrogens	0.3 mg, 0.45 mg, 0.625 mg, 0.9 mg, 1.25 mg tablets	Not approved for prevention of osteoporosis
Transdermal estrogens		
Estradiol patch (mg/day)	0.014 mg, 0.025 mg, 0.0375 mg, 0.05 mg, 0.06 mg, 0.075 mg, 0.1 mg patches	Well tolerated, 10% skin rash, available in weekly and biweekly formulations; approved for prevention of osteoporosis; new low dose (0.014 mg) also approved for prevention of osteoporosis
Estradiol gel	0.06% gel	Not approved for prevention of osteoporosis
Vaginal estrogens		
<i>Creams</i>		
Conjugated equine estrogens	0.625 mg/g cream	Not approved for prevention of osteoporosis
Estradiol	0.1 mg/g cream	Not approved for prevention of osteoporosis
<i>Tablets</i>		
Estradiol	0.025 mg tablet	Not approved for prevention of osteoporosis
<i>Rings</i>		
Estradiol	0.05 mg/day, 0.1 mg/day	Remains in place for 3 months; not approved for prevention of osteoporosis
Oral Progestogens		
Medroxyprogesterone acetate	2.5 mg, 5 mg, 10 mg tablets	Well tolerated, well studied
Micronized progesterone	100 mg, 200 mg capsules	Well tolerated, possible somnolence

Agent	How Supplied	Special Features
Megestrol acetate	20 mg, 40 mg scored tablets	Not used routinely for postmenopausal hormone therapy
Norethindrone	0.35 mg tablets	Available as contraceptive "minipill"
Norethindrone acetate	5 mg scored tablets	Dosage probably too large for routine hormone therapy
Intrauterine Progestin		
Levonorgestrel releasing IUD	20 µg/day	Not routinely used for postmenopausal hormone therapy, approved for use as contraceptive; remains in place for 5 years; may prevent endometrial hyperplasia with fewer side effects but not approved for this use.
Estrogen/Progestogen Combination Formulas		
<i>Oral</i>		
Conjugated equine estrogens (CEE)/medroxyprogesterone acetate (MPA)	0.3 mg CEE/1.5 mg MPA; 0.45 mg CEE/1.5 mg MPA; 0.625 mg CEE/2.5 mg MPA; 0.625 mg CEE/5 mg MPA; 0.625 mg CEE days 1–14, then 0.625 mg CEE/5 mg MPA days 15–28	Well tolerated, well studied, approved for prevention of osteoporosis, 0.625 mg/2.5 mg preparation used in WHI study
Estradiol/norethindrone acetate	1 mg estradiol/0.5 mg norethindrone	Approved for prevention of osteoporosis
Estradiol/norgestimate	1 mg estradiol × 3 days, alternating with 1 mg estradiol/0.09 mg norgestimate × 3 days	Intermittent progestin; approved for prevention of osteoporosis
Ethinyl estradiol/norethindrone acetate	2.5 µg ethinyl estradiol/ 0.5 mg norethindrone; 5 µg ethinyl estradiol/1 mg norethindrone	Approved for prevention of osteoporosis
Esterified estrogens/methyl testosterone	0.625 mg esterified estrogens/1.25 mg methyl testosterone; 1.25 mg esterified estrogens/2.5 mg methyl testosterone	Not approved for prevention of osteoporosis
<i>Transdermal patches</i>		
Estradiol/norethindrone acetate	0.05 mg estradiol/0.14 mg norethindrone per day; 0.05 mg estradiol/0.025 mg norethindrone per day	Not approved for prevention of osteoporosis
Estradiol/levonorgestrel	0.045 mg estradiol/0.015 mg levonorgestrel per day	Not approved for prevention of osteoporosis

In women who require pharmacologic intervention for prevention of osteoporosis, estrogen may be used. However, estrogen therapy for osteoporosis prevention is generally reserved for those women who

are otherwise using estrogen for menopausal symptoms and/or who cannot tolerate other antiresorptive therapies. Lower dosages of estrogen are being increasingly used for prevention of osteoporosis so as to minimize the risks of estrogen therapy. There are several options available for use of estrogen or estrogen plus progestin for prevention of osteoporosis (Table 59–1). In the past, standard doses included 0.625 mg of conjugated equine estrogens, 0.05 mg of transdermal estradiol, and 1 mg of micronized estradiol. However, 0.3 mg of conjugated equine estrogens, 0.5 mg of micronized estradiol, and 0.025-mg transdermal patches also prevent bone loss, although not as well as higher doses. A new low-dose (0.014 mg/d) transdermal formulation of estradiol was recently FDA approved for prevention of osteoporosis. Early commencement of prophylaxis following cessation of ovarian function will maintain the highest bone density. Initiation of HT well after the menopause will stop bone loss, but will not return bone density to that which was present at the time of the menopause.

For women with hot flashes, a standard dosage of estrogen, such as 0.3–0.625 mg of conjugated equine estrogens, 0.025 mg transdermal estradiol, or 0.5 mg oral estradiol should be given daily (Table 59–1). Higher doses may be necessary to relieve hot flashes. Progressive reduction of dosage should be attempted as soon as feasible. Additional formulations containing estradiol, synthetic estrogens and estrogens plus progestins are also available (Table 59–1).

In women who are suffering from atrophic vaginitis, vaginal preparations can be used and are preferred over systemic estrogens. These preparations are available in the form of creams (ie, conjugated equine estrogens or estradiol 0.25–2 g given nightly for 2 weeks, followed by twice weekly), tablets (25 µg estradiol given nightly for 2 weeks, followed by twice weekly), and rings (estradiol releasing rings which remain in place for 3 months at a time) (Table 59–1). With the tablets, rings, and lowest-dose creams, endometrial proliferation is rare. However, higher doses, presence of vaginal bleeding, or other risk factors may necessitate periodic endometrial biopsy or ultrasound to assess the endometrial thickness. Progestins may be necessary to prevent endometrial proliferation in some cases.

Progestogen-Estrogen Therapy

One of the most serious concerns about estrogen replacement is the occurrence of endometrial hyperplasia or cancer. Progestins oppose the action of estrogen on the endometrium. Progestins reduce the number of estrogen receptors in glandular and stromal cells of the endometrium. These agents also block estrogen-induced synthesis of DNA, and they induce the intracellular enzymes estradiol dehydrogenase and estrogen sulfotransferase. The former reduces estradiol to the much less potent estrone, whereas the latter converts estrogen to estrogen sulfates for rapid elimination from endometrial cells. In addition, full secretory transformation occurs if the progestin is given at a large enough dosage for a sufficient length of time.

Progestins reduce the occurrence of endometrial cancer. Epidemiologic studies show significant reduction of the occurrence of endometrial cancer with estrogen plus progestin compared with estrogen alone. One study indicated use of the progestin for more than 10 days a month reduced the occurrence more than use for a shorter interval. In treating women with hormones, a more practical concern is the prevention of endometrial hyperplasia. Initially, British investigators showed that high-dose estrogens (1.25 mg or greater of conjugated equine estrogens) resulted in 32% hyperplasia, whereas low doses (0.625 mg or less) stimulated 16% hyperplasias in women followed for 15 months. In women given estrogen plus progestins, the occurrence of hyperplasia was 6% and 3%, respectively. In comparing length of therapy, 7 days of progestin reduced the occurrence of hyperplasia to 4%, 10 days reduced it to 2%, and 12 days eliminated hyperplasia. Direct comparisons in drug trials have also shown reductions of hyperplasia in women given estrogens and progestins compared with those given estrogen alone. It should be pointed out that the majority of endometrial lesions observed in women in these trials were either cystic or

simple hyperplasias, which could be reversed by giving a progestin or discontinuing the estrogen.

One option is to administer a progestin such as medroxyprogesterone acetate at a dosage of 5–10 mg/d for 12–14 days each month (see Table 59–1). If this is accomplished, 80–90% of women will experience some vaginal bleeding monthly toward the end of or after the progestin is administered. An alternative is to prescribe a lower dosage, 2.5 mg, continuously. Many newer formulations of hormone therapy contain both estrogen and progestin (Table 59–1). The combined, continuous administration of estrogen plus progestin is the most common mode of administration today. This regimen promotes endometrial atrophy and results in amenorrhea in 70–90% of women who use continuous therapy for more than 1 year. The remainder will bleed occasionally, with the bleeding usually being less frequent, shorter, and lighter than with sequential therapy.

Administration of progestins can be associated with other uncomfortable side effects including fatigue, depression, breast tenderness, bloating, menstrual cramps, and headaches. It is also important to keep in mind that it was a progestin-containing regimen that was used in the WHI trial that was discontinued largely because of a trend toward an increased risk of breast cancer. In the estrogen-only arm, breast cancer rates were not increased over control levels. This raises concerns about the potential role of progestogens in increasing breast cancer risk. This concern combined with potential progestogen side effects may lead to elimination of or nonstandard progestogen administration. If lower dosages or shorter duration of progestogens are used, endometrial sampling to diagnose the development of hyperplasia or cancer should be performed. Use of locally administered progestins through the use of the levonorgestrel intrauterine device is also being considered as an alternative strategy to minimize systemic side effects and risks while maintaining endometrial protection.

Prognosis

The prognosis for the postmenopausal woman who does not develop clinically manifest estrogen deficiency includes only the ordinary hazards of disease and aging. For the woman who does develop signs of estrogen deficiency, hormone therapy can correct physical symptoms and signs, and prevent the development of osteoporosis. Correction of minor distressing symptoms and signs can improve the general well-being of the postmenopausal woman and help her to pursue a vigorous life. However, hormone therapy for the postmenopausal woman who does not need it serves no purpose and can cause unpleasant side effects and impose unnecessary risks to her health.

Current OB/GYN > Chapter 60. Critical Care Obstetrics >

CRITICAL CARE OBSTETRICS: INTRODUCTION

Critical care medicine has increasingly become an area of interest to the obstetrician-gynecologist. Pregnancy complications such as shock, thromboembolism, acute respiratory distress syndrome (ARDS), and coagulation disorders can lead to significant morbidity. Furthermore, the approach to these patients can be influenced by a variety of physiologic changes that are unique to pregnancy. This chapter provides a basic approach to some of the common clinical problems that often require complex multidisciplinary care and a knowledge of invasive hemodynamic monitoring.

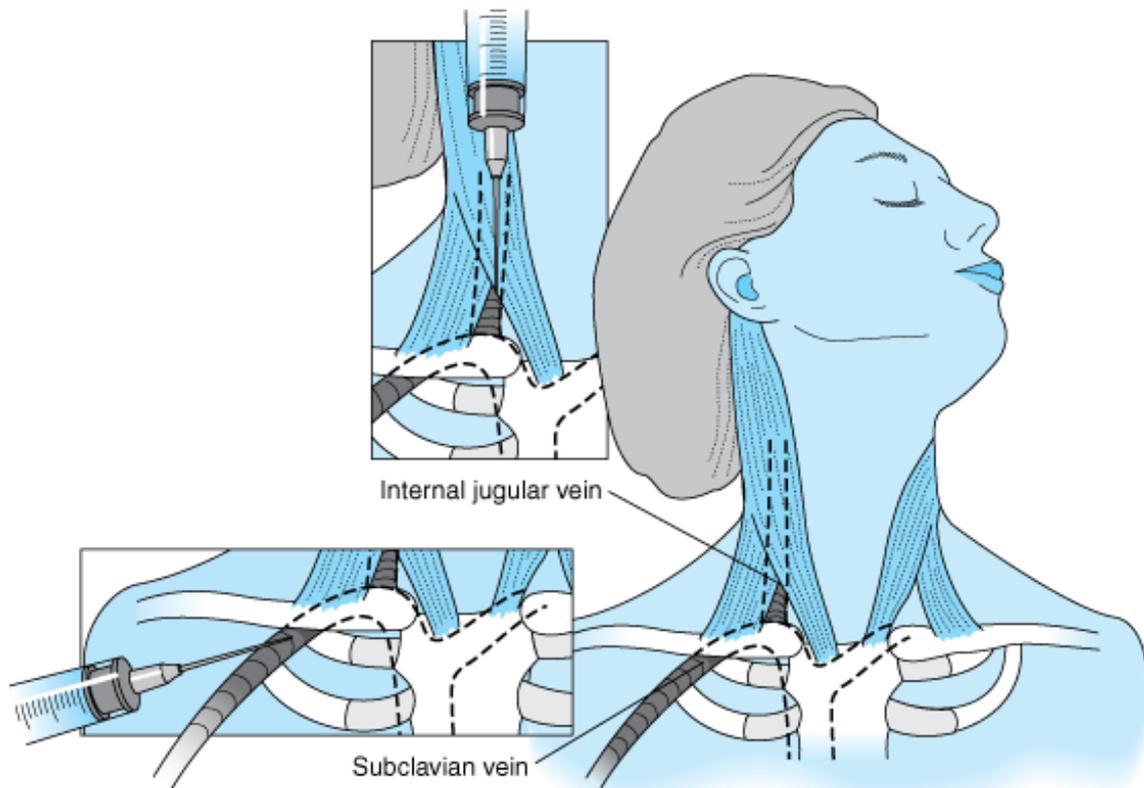

PULMONARY ARTERY CATHETERIZATION

The flow-directed pulmonary artery catheter has been a major addition to the clinician's armamentarium because of its applicability to a wide range of cardiorespiratory disorders. The catheter allows simultaneous measurement of central venous pressure (CVP), pulmonary artery pressure (PAP), pulmonary capillary wedge pressure (PCWP), cardiac output, and mixed venous oxygen saturation. The pulmonary artery catheter is a 7F triple-lumen polyvinyl chloride catheter with a balloon and thermodilution cardiac output sensor at the tip. The distal port is used to measure PAP when the balloon is deflated and PCWP when inflated. A proximal lumen is present 30 cm from the balloon tip; this can be used to monitor the CVP and to administer fluids and drugs. Both ports can be used to withdraw blood. Oximetric catheters also have 2 optical fibers that permit continuous measurement of mixed venous oxygen saturation by reflection spectrophotometry.

Insertion Technique

A 16-gauge catheter is used to gain access to the internal jugular or subclavian vein (Fig 60–1). Pertinent anatomic landmarks for the internal jugular vein approach are shown in Figure 60–2. A guidewire is then introduced into the vein through the catheter, and the 16-gauge catheter sheath is removed. A pulmonary artery catheter is inserted over the guidewire, and the guidewire is removed. The central venous and pulmonary artery ports are connected to a pressure transducer, so that the characteristic waveforms of the various heart chambers can be identified as the catheter is advanced (Fig 60–3). When the catheter is in the superior vena cava, the balloon is inflated with 1–1.5 mL of air, and the catheter is advanced forward into the main pulmonary artery. Table 60–1 shows the average distance in centimeters the catheter must be advanced from various insertion sites. From the main pulmonary artery, the flow of blood moves the catheter into a branch of the pulmonary artery, where it wedges and records the PCWP.

Changes in waveforms observed during placement of a pulmonary artery catheter. RA, right atrium; RV, right ventricle; PA pulmonary artery; PAW, pulmonary artery wedge.

(Reproduced, with permission, from Rosenthal MH: Intrapartum intensive care management of the cardiac patient. Clin Obstet Gynecol 1981;24:796.)

Table 60–1. Distance to Right Atrium from Various Sites of Insertion in Pulmonary Artery Catheterization.

Vein	Distance to Right Atrium ¹ (cm)
Internal jugular	15
Subclavian	15
Right antecubital	40
Left antecubital	50
Femoral	30

¹Distance from right atrium to pulmonary artery is 8–15 cm.

Criteria for verification of the true PCWP include (1) x-ray confirmation of catheter placement, (2) characteristic left atrial waveform configuration, (3) mean PCWP lower than mean PAP, (4) respiratory variation demonstrated by fluctuation of the PCWP waveform baseline with inspiration and expiration, and (5) blood samples showing higher oxygen tension and lower CO₂ tension than in arterial blood.

After deflation of the balloon, the pulmonary artery waveform should again be visualized. Fiberoptic catheters allow verification of PCWP by showing a sudden increase in mixed venous saturation to 95% or greater.

Indications for Invasive Monitoring

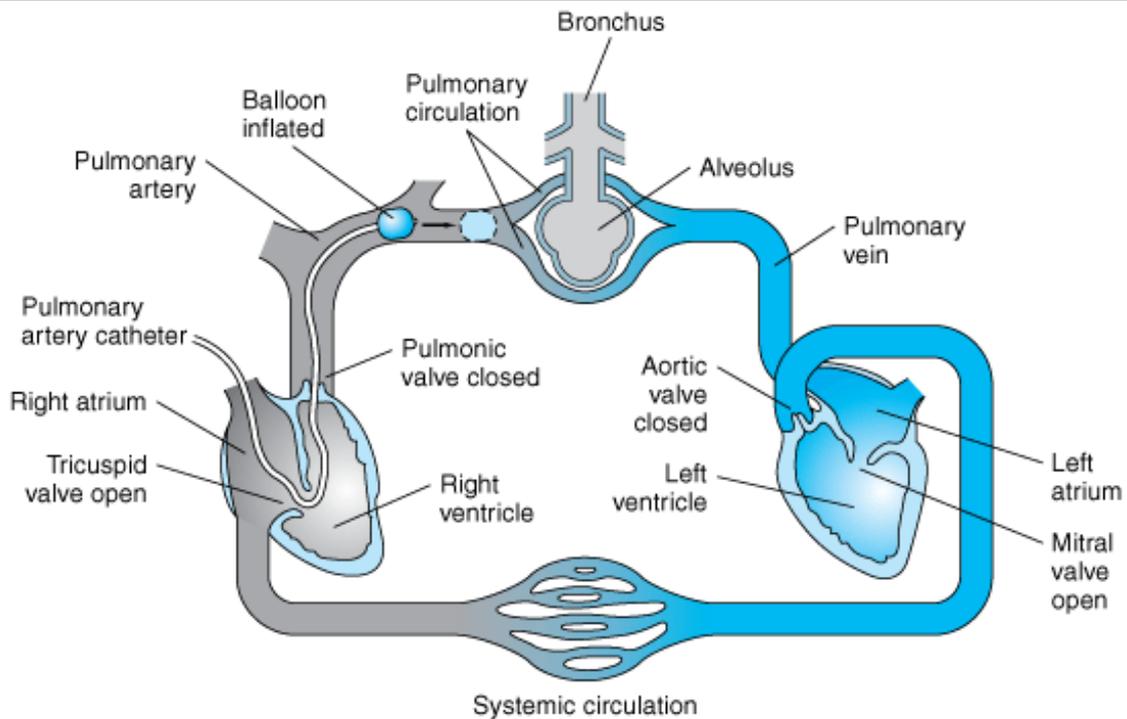

According to the American College of Obstetricians and Gynecologists, invasive hemodynamic monitoring may provide useful information for critical conditions during pregnancy such as:

- Shock (septic, hemorrhagic, cardiogenic, unexplained).
- Pulmonary edema (eg, severe pregnancy-induced hypertension [PIH], congestive heart failure [CHF], unexplained or refractory).
- Severe PIH with persistent oliguria unresponsive to fluid challenge.
- ARDS.
- Severe cardiac disease.

Hemodynamic Parameters Available with Pulmonary Artery Catheterization

During the diastolic period of the cardiac cycle, the left ventricle, left atrium, and pulmonary vascular bed essentially become a common chamber (Fig 60–4). In a normal cardiovascular system, the left ventricular end-diastolic pressure (LVEDP), left atrial pressure, and PCWP are essentially interchangeable. A disparity may develop between PCWP and LVEDP when LVEDP is greater than 15 mm Hg; however, for clinical purposes, the PCWP provides a fairly accurate index of LVEDP, especially if the "a" wave (caused by retrograde transmission of the left atrial contraction) can be identified in the wedge tracing. The relationships described earlier can be substantially altered by mitral or aortic valvular disease.

CARDIAC OUTPUT

The thermal sensing device in the tip of a pulmonary artery catheter allows for rapid determination of cardiac output by the thermodilution method. Five milliliters of 5% dextrose in water is injected through the central venous port at a constant distance from the thermistor tip. The use of this solution at room temperature can minimize sources of potential error associated with inaccurate temperature measurements and catheter warming. The change in pulmonary artery temperature is detected by the thermistor. The cardiac output is inversely proportional to the fall in temperature and is computed by planimetric or computerized methods. The average of 3 values within 10% of each other is typically utilized to calculate cardiac output.

SYSTEMIC VASCULAR RESISTANCE

Systemic vascular resistance (SVR) represents the total resistance to forward flow of blood through the body's vascular tree. SVR is calculated as follows:

$$SVR = \frac{[(MAP - CVP)] \times 80}{CO}$$

During pregnancy, this parameter is usually in the range of 800–1200 dynes · s · cm⁻⁵. Depending on the clinical condition, a reduction or increase in SVR may be desirable in the presence of normal blood pressure (eg, septic shock), in which a very low SVR may be seen despite normal or low blood pressure. In order to maintain vital organ perfusion, vasopressor therapy may be indicated to increase SVR.

PULMONARY CAPILLARY WEDGE PRESSURE

The PCWP provides important information on 2 basic parameters of cardiopulmonary function: (1) pulmonary venous pressure, which is a major determinant of pulmonary congestion; and (2) the left atrial and left ventricular filling pressures, from which ventricular function curves can be constructed.

Pulmonary capillary wedge pressure can be reliably assessed by CVP monitoring only in the absence of significant myocardial dysfunction. The measurement of PCWP has certain advantages over measurement of CVP alone. A disparity between right and left ventricular function may be seen in conditions such as myocardial infarction, valvular disease, sepsis, and severe PIH. Under these circumstances, the management of fluid therapy based on CVP alone could have adverse results. Additionally, cardiac output and mixed venous oxygen tension cannot be determined with a simple CVP catheter.

VENTRICULAR FUNCTION CURVES

Myocardial performance is best interpreted in terms of left ventricular function curves (ie, the Frank-Starling relationship). The cardiac output and PCWP are used to construct the ventricular function curve by plotting the ventricular stroke work index against the mean atrial pressure or ventricular end-diastolic pressure (usually the PCWP). The left ventricular stroke work index is calculated by the following formula:

$$\text{LVSWI} = \text{SVI} \times (\text{MAP} - \text{PCWP}) \times 0.0136$$

(LVSWI = left ventricular stroke work index [g-m/m²]; SVI = stroke volume index [mL/beat/m²]; MAP = mean arterial pressure [mm Hg]; PCWP = pulmonary capillary wedge pressure [mm Hg]).

Ventricular function curves provide a useful index of cardiovascular status to guide inotropic and vasoactive drug therapy. Evaluation of myocardial contractility by ventricular function curves allows one to obtain optimal filling pressures and stroke volume index in critically ill patients. The effects of therapy (eg, diuretics, antihypertensive agents, or volume expanders) can be evaluated on the basis of performance. Under normal conditions, a small rise in filling pressure is accompanied by a rapid rise in stroke work. Unfavorable conditions such as hypoxia or myocardial depression produce a shift in the curve to the right and downward such that lower stroke work indices are seen at higher filling pressures.

MIXED VENOUS OXYGEN SATURATION

The mixed venous oxygen saturation (SvO₂) reflects the body's capacity to provide adequate tissue oxygenation. This parameter is affected by cardiac output, hemoglobin concentration, arterial oxygen saturation, and tissue oxygen consumption. An SvO₂ of 60–80% usually indicates normal oxygen delivery and demand with adequate tissue perfusion. An SvO₂ greater than 80% reflects increased oxygen delivery and decreased oxygen utilization. This situation may be seen in patients with hypothermia or sepsis who are receiving supplemental oxygen. A high SvO₂ may also provide confirmatory evidence that the pulmonary artery catheter is in the wedge position. Finally, a low SvO₂ (< 60%) indicates increased oxygen demands with decreased oxygen delivery due to anemia, low cardiac output, or decreased arterial oxygen saturation.

Measurement of SvO₂ allows for continuous monitoring of cardiorespiratory reserve by providing an index of tissue oxygen delivery and utilization. Changes in SvO₂ will be apparent with infusion of vasoactive drugs, volume loading, or afterload reduction. While many intensive care units rely on direct measurement of cardiac output alone, this parameter does not always accurately reflect tissue oxygenation. For instance, normal cardiac output might not be adequate to meet increased oxygen requirements in malignant hyperthermia or thyroid storm.

MATERNAL OXYGEN CONSUMPTION

Mixed venous oxygen saturation results can be used with arterial blood gas analysis to provide useful information about the metabolic status of the critically ill obstetric patient. Resting maternal oxygen consumption progressively increases during pregnancy. Occasionally, one needs to pay particular attention to the metabolic status of critically ill women or those with ARDS. Factors such as tachycardia or fever that are associated with increased oxygen consumption should be minimized under these circumstances.

The Fick relationship:

$$CO = \frac{Vo_2}{Avo_2 \text{ diff.}} \times 100$$

provides a method for calculating oxygen consumption (Vo_2), if the cardiac output (CO) and systemic arteriovenous oxygen (Avo_2) concentration difference is known. The Avo_2 difference can be calculated by subtracting the oxygen content of desaturated mixed venous blood from that of arterial blood that passes through the pulmonary artery catheter. For example, a patient with a cardiac output minus Avo_2 difference of 5 mL would have an oxygen consumption (Vo_2) of 300 mL.

$$6000 \text{ mL min}^{-1} \times 5 \text{ mL per } 100 \text{ mL blood}$$

$$Vo_2 \text{ } 100 = 300 \text{ mL min}^{-1}$$

An understanding of these relationships will allow the clinician to better understand how to use physiologic variables for interpreting the hemodynamic and pulmonary condition of critically ill patients.

COLLOID OSMOTIC PRESSURE

The plasma colloid oncotic pressure (COP) is another measurement that can be useful in critical care (Table 60–2). Plasma COP is the pressure exerted by certain plasma proteins that hold fluid in the intravascular space. Albumin accounts for 75% of the oncotic pressure of plasma, with the rest coming from globulin and fibrinogen. It has been demonstrated in dogs that iatrogenic reduction in plasma proteins resulted in pulmonary edema with only minimal increases in left atrial pressure. Subsequent studies in humans identified cases of pulmonary edema in which normal or slightly elevated PCWP was present. From these studies, the important concept of a COP-PCWP gradient evolved. It appears that when the COP-PCWP gradient is less than 4 mm Hg, the likelihood of pulmonary edema is increased, although not all patients with a decreased gradient will develop pulmonary edema. The determination of COP and its relationship to the PCWP can play a crucial role in the detection of patients likely to develop pulmonary edema in the face of normal left-sided filling pressures.

Table 60–2. Serum Colloid Oncotic Pressure during Pregnancy.

	Normotensive (mm Hg)	Hypertensive (mm Hg)
Antepartum (term)	22.4 ± 0.5	17.9 ± 0.7
Postpartum (first 24 hours)	15.4 ± 2.1	13.7 ± 0.5

Studies of pregnant women have demonstrated that patients with certain conditions in which the risk of pulmonary edema is markedly increased tend to have lowered COP (eg, hypovolemic shock, severe PIH, prolonged tocolytic therapy, and frank pulmonary edema).

Complications

The most common complication associated with pulmonary artery catheter placement is dysrhythmia.

More serious complications also include pulmonary infarction, thromboembolism, balloon rupture with air embolism, pulmonary artery or valve rupture, catheter knotting, infection, arterial puncture, thromboembolism, pneumothorax, and pulmonary hemorrhage. Table 60–3 summarizes the complication rates for pulmonary artery catheterization.

Table 60–3. Complications of Pulmonary Artery Catheterization.¹

Complication	Incidence (%)
Premature ventricular contractions	15–27
Arterial puncture	8
Superficial cellulitis	3
Thromboembolism	?
Pneumothorax	1–2
Balloon rupture	< 1
Pulmonary infarction/ischemia	1–7
Pulmonary artery rupture	< 1
Catheter knotting	< 1
Catheter-related sepsis	1

¹Reproduced, with permission, from Hankins GDV, Cunningham FG: Severe preeclampsia and eclampsia: Controversies in management. Williams Obstetrics 1991; 18(suppl): 11. Appleton & Lange.

DYSRHYTHMIA

Premature ventricular contractions may transiently occur as the catheter tip enters the right ventricle. However, they usually resolve following advancement of the catheter into the pulmonary artery. If the dysrhythmia is refractory to lidocaine, 50–100 mg given intravenously, the catheter should be withdrawn from the cardiac chambers.

PULMONARY INFARCTION

Pulmonary infarction may occur when the catheter migrates distally and wedges spontaneously for a prolonged period. This complication, as well as thromboembolism, may be avoided by monitoring the PCWP at regular intervals and by using a continuous heparinized flow system.

BALLOON RUPTURE

Balloon rupture can be avoided by limiting the number of balloon inflations and by inflating only to the smallest necessary volume. Inflation of the balloon beyond 2 mL of air is unnecessary and may be harmful. To avoid rupture of a pulmonary artery branch, inflation of the balloon should be stopped immediately when the wedge tracing is seen.

CATHETER KNOTTING

Catheter knotting is usually the result of advancing the catheter 10–15 cm farther than is necessary to reach the right ventricle or pulmonary artery. Withdrawing the catheter while the balloon is still inflated may cause tricuspid rupture or chordae tendineae tears.

INFECTION AND PHLEBITIS

Infection and phlebitis can be minimized by using aseptic technique. The risk of associated sepsis is related to excessive catheter manipulation and the duration of catheterization.

NONINVASIVE MONITORING FOR CRITICALLY ILL PATIENTS

Pulse oximetry is a simple tool that can be used with invasive monitoring for patients with cardiovascular or respiratory compromise. The correlation between pulse oximetry and direct blood oxygen saturation is excellent when oxygen saturation is greater than 60%. Factors adversely affecting the accuracy of pulse oximetry include movement, peripheral vasoconstriction, hypotension, anemia, hypothermia, intravascular dye, and possibly nail polish.

OBSTETRIC SHOCK

Shock may be defined as an imbalance between oxygen supply and demand. The basic underlying defect is a significant reduction in the supply of oxygenated blood to various tissues due to inadequate perfusion. In obstetrics, this reduction often results from hemorrhage, sepsis, or pump failure. The physiologic compensation common to all shock states involves tachycardia and peripheral vasoconstriction to maximize cerebral and cardiac perfusion by way of the sympathetic nervous system. Failure of these compensatory mechanisms will lead to a predominance of anaerobic metabolism and lactic acidosis, which can be potentially devastating to the patient and fetus. Cardiogenic shock may be seen in pregnant women with cardiac dysrhythmias, congenital heart disease, peripartum cardiomyopathy, and congestive heart failure. The following discussion will focus on 2 of the more common shock syndromes complicating pregnancy—those related to hemorrhage and sepsis.

Hypovolemic Shock

Essentials of Diagnosis

- Recent history of acute blood loss or excessive diuresis.
- Hypotension, tachycardia, tachypnea, and oliguria with progression to altered mental status.
- Precipitous drop in hematocrit.

General Considerations

Hypovolemic shock is a leading cause of maternal mortality in the U.S. and is most commonly associated with obstetric hemorrhage. Bleeding severe enough to cause hemorrhagic shock may result from a wide variety of conditions, including ruptured ectopic pregnancy; abruptio placentae; placenta previa; placenta accreta; rupture, atony, or inversion of the uterus; surgical procedures; obstetric lacerations; or retained products of conception.

Pathophysiology

During normal pregnancy, the blood volume expands by approximately 1500 mL. This hypervolemia results from hormonal alterations and may be considered protective against peripartum bleeding. During acute hemorrhage, the body responds to volume loss by hemodynamic, volume-altering, and hormonal mechanisms.

Hemodynamic adjustments result from activation of the sympathetic nervous system. These changes include vasoconstriction of arteriolar resistance vessels, constriction of venous capacitance vessels, and redistribution of blood flow away from peripheral organs to preserve adequate cerebral and cardiac blood flow.

Volume adjustments occur from extravascular fluid shifts into the intravascular compartment. The rate of plasma refill depends on the magnitude of volume depletion.

If these mechanisms are insufficient to restore circulatory function, other compensatory effects, such as secretion of antidiuretic hormone (ADH), cortisol, aldosterone, and catecholamines will occur.

Epinephrine, in addition to causing peripheral vasoconstriction, will have inotropic and chronotropic effects on the heart. ADH, cortisol, and aldosterone will help conserve water and salt, which may then result in reduced blood flow to the kidneys and decreased urine output.

These homeostatic mechanisms serve to maintain adequate tissue perfusion until approximately 25–30% of the circulating blood volume is lost. Inadequate tissue perfusion and oxygenation will then lead to anaerobic metabolism and lactic acidosis. Over a prolonged period of vasoconstriction, there may be decompensation of the peripheral vasculature leading to damaged or leaky capillaries. Observations of blood flow regulation during pregnancy suggest that uterine arteries have limited capacity to autoregulate fetoplacental perfusion. Thus uteroplacental blood flow is critically dependent upon systemic maternal cardiac output.

Clinical Findings

The clinical manifestations of hemorrhagic shock depend on the quantity and rate of volume depletion. Orthostatic signs and symptoms may be masked by the hypervolemia of pregnancy, especially if a source of bleeding is not evident. Obvious hypotension and tachycardia in the presence of external bleeding should alert the clinician to the possibility of shock. A careful physical examination will identify decreased tissue perfusion in several different organ systems, including the heart, brain, kidneys, lungs, and skin. Altered mental status, dizziness, diaphoresis, and cold, clammy extremities, as well as a fast, "thready" pulse are common findings in significant hemorrhagic shock. Oliguria (< 30 mL/h), CVP of less than 5 cm H₂O, and PCWP of less than 5 mm Hg are all consistent with significant volume depletion. The identification of intra-abdominal bleeding may require culdocentesis or peritoneal lavage. Fetal heart monitoring may reveal bradycardia or late decelerations.

Differential Diagnosis

Hypovolemic shock should be differentiated from other shock syndromes resulting from sepsis or heart failure. Usually, there is a history of profound bleeding. Since shock may affect several organ systems, it is essential that its underlying cause be identified. Patients with septic shock will tend to be febrile, with associated abnormal white blood cell counts and clinical evidence of infection. Cardiogenic shock may be associated with clinical and radiographic evidence of pulmonary congestion or a previous history of heart disease.

Complications

Electrolyte imbalance, acidosis, acute tubular necrosis, stress-induced gastric ulceration, pulmonary edema, and ARDS are common complications associated with hemorrhagic shock. Myocardial infarction is a rare complication in the obstetric population.

Treatment

The treatment of hemorrhagic shock should be directed toward replacing blood volume and optimizing cardiac performance. The source of bleeding should be controlled. Uterine atony that is unresponsive to massage and oxytocin may benefit from methylergonovine (0.2 mg intramuscularly), or 15-methyl prostaglandin F₂ (0.25 mg intramuscularly). Persistent bleeding may require uterine artery ligation, hypogastric artery ligation, or even cesarean hysterectomy. Decisions regarding blood and fluid replacement should be guided by central pressures and urine output, although pulmonary artery catheterization is rarely necessary. Military antishock trousers (MAST) suit will mobilize blood pooled in the lower body and return it to the central circulation, improving systemic cardiac output and organ perfusion. Supplemental oxygen will minimize tissue hypoxia and fetal acidosis.

Initial rapid volume replacement with crystalloid solution given through a large-bore intravenous site is a

temporizing measure until blood replacement is possible. Typically, 1–2 L of lactated Ringer's solution can be administered as rapidly as possible. Compared with normal saline, the electrolyte composition of lactated Ringer's solution more closely approximates plasma, and the metabolism of lactate to bicarbonate provides some buffering capacity for acidosis.

Guidelines for perioperative transfusion of red blood cells have been defined by the National Institutes of Health. Initial treatment of hemorrhagic shock should involve volume replacement by crystalloid or colloid solutions that do not carry risks for disease transmission or transfusion reaction. The use of perioperative red blood cell transfusion should not rely solely upon the dogma of "transfusing to a hematocrit above 30%" as the sole criterion since there is poor evidence supporting its usefulness. The decision whether or not to transfuse red cells should also take into account other factors such as patient age, hemodynamic status, anticipated bleeding, and medical or obstetrical complications. If it is necessary to transfuse large amounts of blood, it is important to note and correct the presence of electrolyte imbalances, acid-base abnormalities, hypothermia, and the dilution of platelets and coagulation factors, which may require the transfusion of other blood products.

The risk of posttransfusion hepatitis has been dramatically decreased by testing blood products with a commercially available hepatitis C assay. The test is a qualitative, enzyme-linked immunosorbent assay (ELISA) for the detection of antibody to hepatitis C virus (anti-HCV) in human serum or plasma. The ELISA test has a specificity of 99.84% in a low prevalence population. A supplemental assay, the recombinant immunoblot assay (RIBA), can be performed on blood that has a repeat reactive anti-HCV.

Fluid balance from intravenous infusions or urine output should be meticulously recorded with daily weights. Oliguria refractory to volume loading may be improved by the addition of intravenous dopamine in low doses (2–5 µg/kg/min) to improve renal perfusion. A diuretic such as bumetanide 0.5–1 mg IV, not to exceed 10 mg/day, should be considered for patients with prolonged oliguria despite normal elevated pulmonary capillary wedge pressures.

Blood tests should include complete blood count, serum electrolytes, creatinine, arterial blood gas analysis, and coagulation profile. Urinalysis is also important. A baseline chest radiograph and electrocardiogram are desirable. Typed and cross-matched transfusion products should be available from the blood bank. One to two ampules of sodium bicarbonate (50–100 mEq) can be administered intravenously to correct acidosis (pH < 7.20). Frequent serial hematocrits may provide an index of acute blood loss. A baseline hematologic profile (PT, partial thromboplastin time [PTT], fibrinogen, platelets) is necessary to evaluate the possibility of coagulopathy.

Prognosis

Maternal and fetal survival rates are directly related to the magnitude of volume depletion and length of time the patient remains in shock. If the hemorrhage is controlled and intravascular volume is restored within a reasonable interval, the prognosis is generally good in the absence of associated complications. However, the return of fetal blood flow may lag behind correction of maternal flow.

Septic Shock

Essentials of Diagnosis

- History of recent hospitalization or surgery.
- Pelvic or abdominal infection with positive confirmatory cultures.
- Temperature instability, confusion, hypotension, oliguria, cardiopulmonary failure.

General Considerations

Septic shock is a life-threatening disorder secondary to bacteremia. The American College of Obstetricians and Gynecologists defines septic shock as sepsis with hypotension despite adequate fluid resuscitation, with the presence of perfusion abnormalities including (but not limited to) lactic acidosis and oliguria. The incidence of bacteremia in obstetric patients has been estimated to be between 0.7% and 10%. Although gram-negative bacteria are usually responsible for most of these infections, septic shock may also result from infection with other bacteria, fungi, protozoa, or viruses. The most common cause of obstetric septic shock is postoperative endometritis (85%). Other commonly associated conditions include antepartum pyelonephritis, septic abortion, and chorioamnionitis.

Pathophysiology

Sepsis may lead to a systemic inflammatory response that can be triggered not only by infections but also by noninfectious disorders, such as trauma and pancreatitis. However, there is strong evidence to support the concept that endotoxin is responsible for the pathogenesis of gram-negative septic shock. *Escherichia coli* has been implicated in 25–50% of cases of septic hypotension, but a variety of other organisms may be causative, including *Klebsiella*, *Enterobacter*, *Serratia*, *Proteus*, *Pseudomonas*, *Streptococcus*, *Peptostreptococcus*, *Staphylococcus*, *Fusobacterium*, *Clostridium*, and *Bacteroides*. The gram-negative endotoxin theory does not explain gram-positive shock, although an understanding of the proposed mechanisms will serve to exemplify the multisystemic effects of this disorder.

Endotoxin is a complex lipopolysaccharide present in the cell walls of gram-negative bacteria. The active component of endotoxin, lipid A, is responsible for initiating activation of the coagulation, fibrinolysis, complement, prostaglandin, and kinin systems. Activation of the coagulation and fibrinolysis systems may lead to consumptive coagulopathy. Complement activation leads to the release by leukocytes of mediators that are responsible for damage to vascular endothelium, platelet aggregation, intensification of the coagulation cascade, and degranulation of mast cells with histamine release. Histamine will cause increased capillary permeability, decreased plasma volume, vasodilatation, and hypotension. Release of bradykinin and β -endorphins also contributes to systemic hypotension. Early stages of septic shock involve low SVR and high cardiac output with a relative decrease in intravascular volume. Late or cold shock subsequently involves an endogenous myocardial depressant factor that has not been isolated. This factor is associated with decreased cardiac output and continued low SVR in the absence of pressor agents. Recent studies suggest that tumor necrosis factor (TNF) may lead to depressed myocardial function during septic shock. Monocytes and macrophages incubated with endotoxin produce this 17-kDa polypeptide within 40 minutes. Direct injection of TNF into animals leads to many of the changes seen in endotoxic shock. Other possible factors include IL-1, IL-6, IL-8, interferon gamma, and granulocyte stimulating factor.

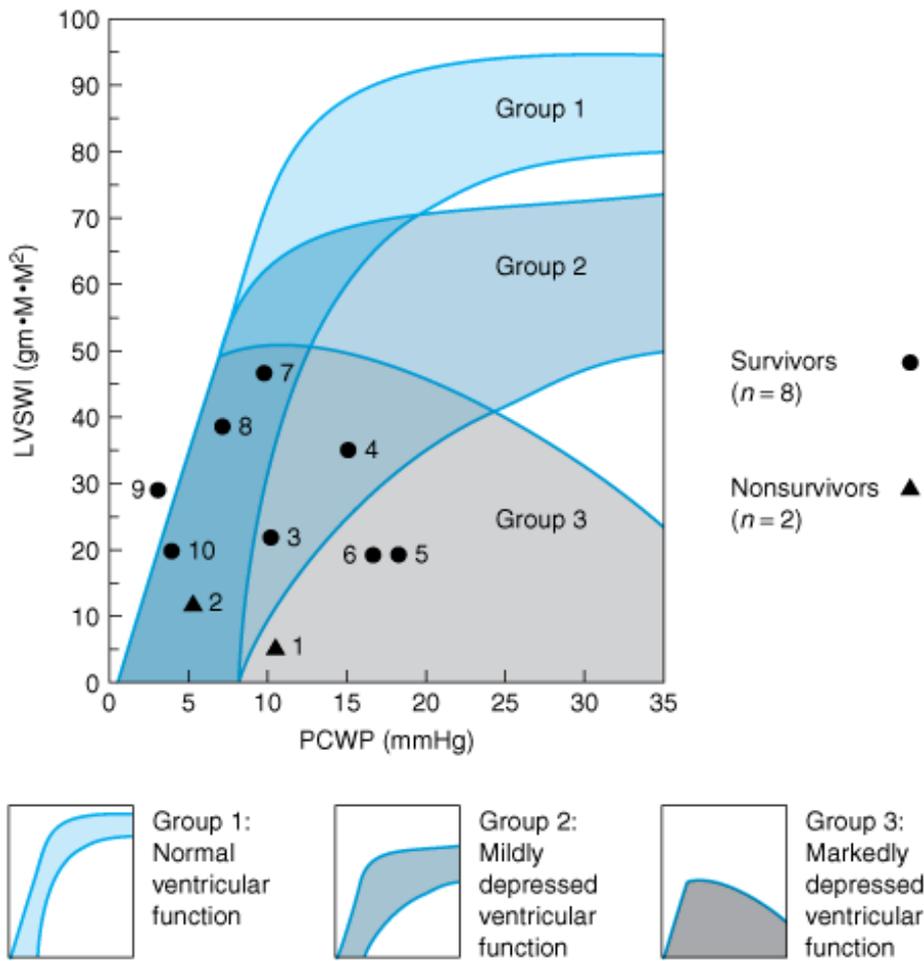

Clinical Findings

SYMPTOMS AND SIGNS

Septic shock can be divided into 3 stages: preshock, early shock (warm shock), and late (or cold) shock. In preshock, patients present with tachypnea and respiratory alkalosis. Their condition is best described as a moderate hyperdynamic state, with elevated cardiac output, decreasing SVR, and normal blood pressures. Response to therapy will be greatest at this stage. Early shock is a more hyperdynamic state. Blood pressure drops (SBP < 60 mm Hg), and SVR decreases dramatically (< 400 dynes \cdot s \cdot cm⁻⁵). Altered mental status, temperature instability, and sinusoidal fluctuations in arterial blood pressure may be seen at this stage. As this condition progresses into late shock, activation of the sympathetic nervous system with release of catecholamines will lead to intense vasoconstriction, which serves to shunt blood from the peripheral tissues to the heart and brain (cold shock). The compensatory vasoconstriction results in increased cardiac work. Lactic acidosis, poor coronary perfusion, and the influence of

myocardial depressant factor may also contribute to poor cardiac performance (Fig 60–5). The fetus is more resistant to the effects of endotoxin than the mother; however, alterations in uteroplacental flow can lead to hypoxia, acidosis, placental abruption, intracranial hemorrhage, and fetal demise.

Presenting left ventricular function of 10 pregnant women with septic hypotension. LVSWI, left ventricular stroke work index; PCWP, pulmonary capillary wedge pressure.

(Reproduced, with permission, from Lee W et al: Septic shock during pregnancy. *Am J Obstet Gynecol* 1988; 159: 410.)

The clinical manifestations of septic shock depend on the target organs affected (Table 60–4). The most common cause of death in patients with this condition is respiratory insufficiency secondary to ARDS.

Table 60–4. Effects on Target Organs in Septic Shock.¹

Organ System	Clinical and Laboratory Findings
Brain	Confusion, obtundation
Hypothalamus	Hypothermia, hyperthermia
Cardiovascular	Myocardial depression, arrhythmias, tachycardia, hypotension
Pulmonary	Tachypnea, arteriovenous shunting, hypoxemia
Gastrointestinal	Vomiting, diarrhea
Hepatic	Increased AST (SGOT) and bilirubin
Kidneys	Oliguria, renal failure
Hematologic	Hemoconcentration, thrombocytopenia, leukocytosis, coagulopathy

¹Adapted and reproduced, with permission, from American College of Obstetricians and Gynecologists: Septic shock. ACOG Technical Bulletin No. 75, March 1984.

LABORATORY FINDINGS

Complete blood cell count, serum electrolytes, urinalysis, baseline arterial blood gases, chest radiograph, and a coagulation profile are laboratory studies important in the management of these patients. Hematologic findings may include significant anemia, thrombocytopenia, and leukocytosis. Serum electrolytes are often abnormal because of acidosis, fluid shifts, or decreased renal perfusion. Urinalysis permits evaluation of renal involvement. In addition to urine cultures, aerobic and anaerobic blood cultures may be helpful to confirm the diagnosis and guide antibiotic therapy.

Arterial blood gas measurements and a chest radiograph will facilitate clinical assessment of the ventilatory and oxygenation status. Early stages of septic shock will be associated with respiratory alkalosis, which later progresses to metabolic acidosis.

A baseline electrocardiogram (ECG) should be performed to rule out myocardial infarction or cardiac dysrhythmia. Abdominal radiographic studies may be useful to rule out other intrapelvic or intra-abdominal sources of obstetric sepsis (eg, bowel perforation, uterine perforation, tubo-ovarian abscess). Significant disseminated intravascular coagulation (DIC) will be identified by abnormal PT, PTT, or fibrinogen levels.

Differential Diagnosis

The differential diagnosis should include other hypovolemic and cardiogenic shock syndromes. Additional causes of acute cardiopulmonary compromise include amniotic fluid embolism, pulmonary thromboembolism, cardiac tamponade, aortic dissection, and diabetic ketoacidosis. The history, physical examination, and laboratory studies will usually be sufficient to distinguish between these diagnoses.

Complications

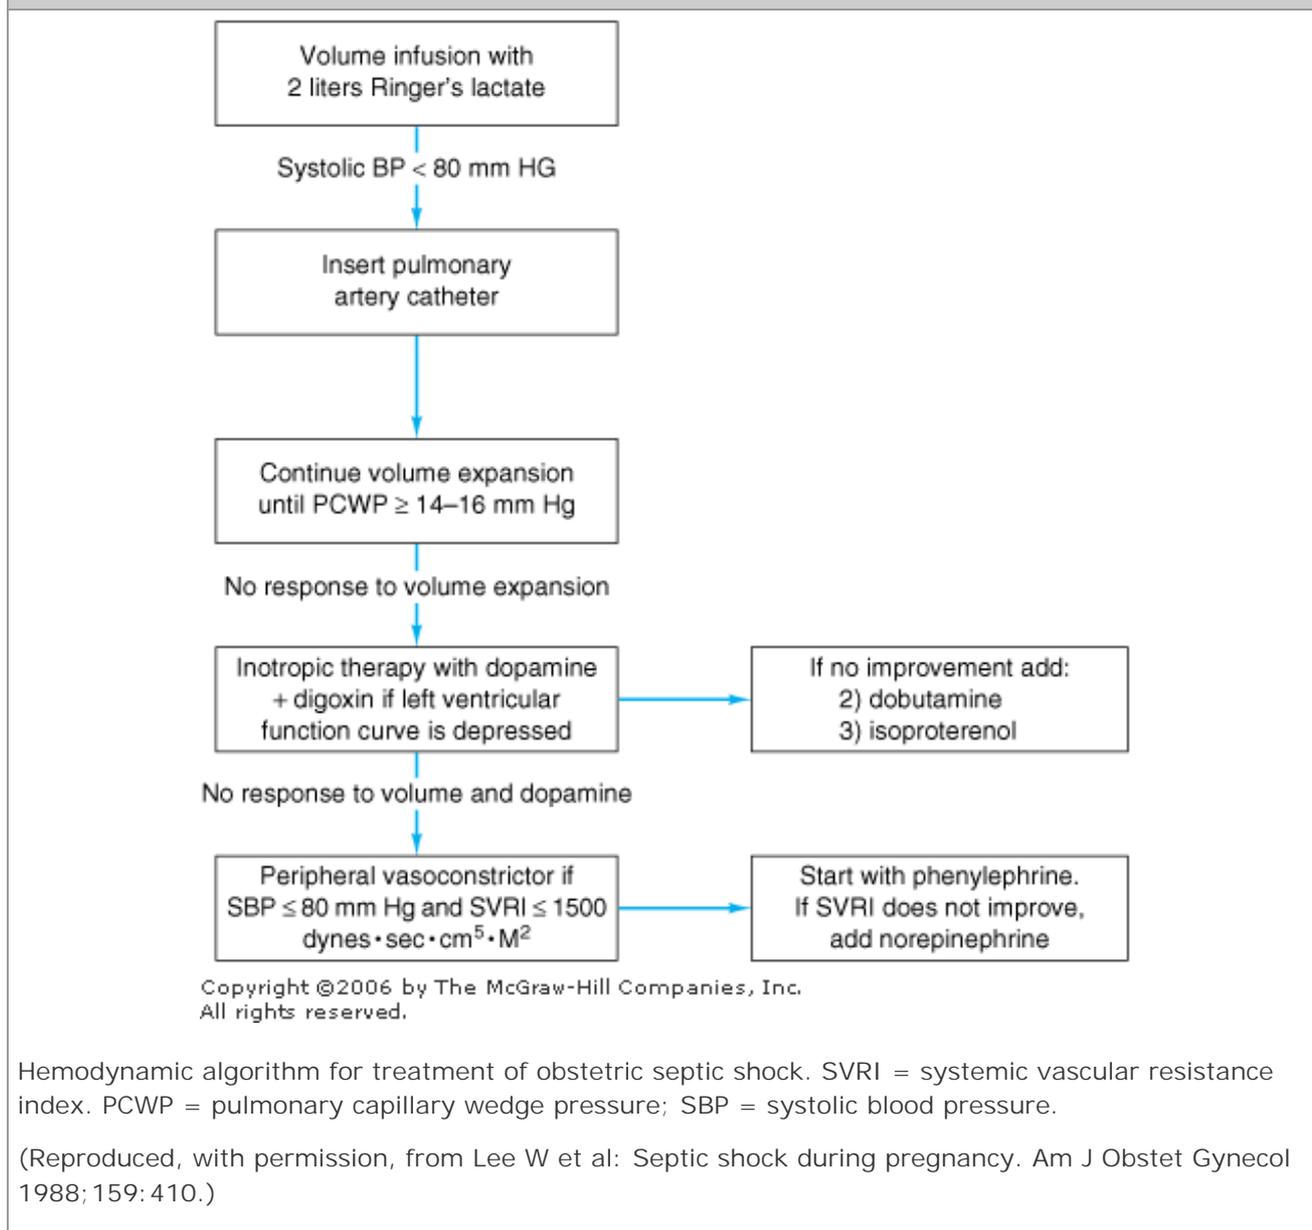

Numerous complications may occur with septic shock, depending on the target organs involved. Aside from ARDS, some of the more serious complications include congestive heart failure and cardiac dysrhythmias. Systemic hypotension and ischemic end-organ damage can lead to hepatic failure or renal insufficiency. Fetal or maternal demise are the most dire outcomes.

Treatment

Successful management of obstetric septic shock depends on early identification and aggressive treatment focused on stabilization of the patient, removal of underlying causes of sepsis, broad-spectrum

antibiotic coverage, and treatment of associated complications. Febrile patients with mild hypotension who respond rapidly to volume infusion alone do not require invasive monitoring. In other cases, the pulmonary artery catheter should be used to guide specific therapeutic maneuvers for optimizing myocardial performance and maintaining systemic cardiac output and blood pressure. A hemodynamic approach for stabilizing pregnant women with septic shock should include (1) volume repletion and hemostasis; (2) inotropic therapy with dopamine on the basis of left ventricular function curves; and (3) addition of peripheral vasoconstrictors (phenylephrine first, then norepinephrine) to maintain afterload (Fig 60–6).

Figure 60–6.

GENERAL MEASURES

Septic shock during pregnancy should be treated with a broad-spectrum antibiotic regimen such as ampicillin, gentamicin, and clindamycin. Aminoglycoside maintenance doses should be titrated in relation to serum peak and trough levels or a 24-hour dosing regimen may be used. Newer antibiotics such as imipenem, cilastatin, vancomycin, and the extended spectrum penicillins (eg, ticarcillin) are also proving

to be effective therapies. There must be a careful search for infected or necrotic foci that can result in persistent bacteremia, and surgical intervention may be necessary. In one study, 40% of septic obstetric patients required surgical removal of infected products of conception, and all survived. If chorioamnionitis is present in the septic obstetric patient, prompt delivery is necessary. However, if the pregnancy is not the cause of infection, immediate delivery is usually not required. Supportive care should also include control of fever with antipyretics, hypothermic cooling blankets, or both. Correction of maternal acidosis, hypoxemia, and systemic hypotension will usually improve any abnormalities in the fetal heart tracing.

CARDIOVASCULAR SUPPORT

Aggressive treatment of obstetric septic shock must rapidly and effectively reverse organ hypoperfusion, improve oxygen delivery, and correct acidosis. Priority should be given to cardiopulmonary support with the additional understanding that other major organ systems can also be severely affected.

A sequential hemodynamic approach for stabilizing obstetric septic shock with volume repletion, inotropic therapy, and peripheral vasoconstrictors is recommended. Volume therapy initially begins with 1–2 L of lactated Ringer's solution infused over approximately 15 minutes. However, it is important that volume infusion not be withheld in a hypotensive patient pending placement of a pulmonary artery catheter. The total amount of crystalloid administered should be guided by the presence or absence of maternal hypoxemia secondary to pulmonary edema and left ventricular filling pressures, as estimated by PCWP.

In general, myocardial performance will be optimized according to the Starling mechanism at a PCWP of 14–16 mm Hg. Such preload optimization is mandatory prior to the initiation of inotropic therapy. Blood component therapy can also be an important adjunctive measure if the patient has experienced significant hemorrhage and has developed an associated coagulopathy.

If the shock state persists despite volume replacement and adequate hemostasis, efforts should be directed toward improving myocardial performance and vascular tone. Inotropic agents such as dopamine, dobutamine, or isoproterenol are excellent choices for improving myocardial contractility in an obstetric patient with a failing heart (Table 60–5). We recommend dopamine as the first-line drug of choice for treating septic hypotension when inotropic therapy is indicated. This substance is a chemical precursor of norepinephrine that has alpha-adrenergic, beta-adrenergic, and dopaminergic receptor stimulating actions. The dopamine infusion is initiated at 2–5 $\mu\text{g}/\text{kg}/\text{min}$ and titrated against its effect on improving cardiac output and blood pressure in patients with obstetric septic shock. At low doses (0.5–5.0 $\mu\text{g}/\text{kg}/\text{min}$), this sympathomimetic amine acts primarily on the dopaminergic receptors, leading to vasodilation and improved perfusion of the renal and mesenteric vascular beds. Higher dopamine doses (5.0–15.0 $\mu\text{g}/\text{kg}/\text{min}$) are associated with predominant effects on the β receptors of the heart. The beta-adrenergic effects are responsible for improved myocardial contractility, stroke volume, and cardiac output. Much higher dopamine dosages (15–20 $\mu\text{g}/\text{kg}/\text{min}$) will elicit an alpha-adrenergic effect, similar to a norepinephrine infusion, and result in generalized vasoconstriction. Vasoconstrictive action associated with high doses of infused dopamine can actually be detrimental to organ perfusion and will rarely be useful under these clinical circumstances. Although myocardial performance after dopamine therapy is best evaluated by ventricular function curves, it is reasonable to maintain a systemic cardiac index above 3 L/min/m².

Table 60–5. Sympathomimetic and Vasopressor Drugs Useful for Therapy of Obstetric Septic Shock.

Agent	Maintenance Dose Range ¹	Therapeutic Goals
Inotropic		
Dopamine	2–10 µg/kg/min	Cardiac index \geq 3 L/min/m ² SBP \geq 80 mm Hg
Dobutamine	2–10 µg/kg/min	Optimize left ventricular function curves
Isoproterenol	1–20 µg/min	
Vasopressors		
Phenylephrine	1–5 µg/kg/min	SVRI \geq 1500 dynes · s · cm ⁻⁵ · m ²
Norepinephrine	1–4 µg/min	

¹Drug dosages that are administered by µg/kg/min can be prepared by the following method:

1.5 mg × body weight (kg) = total mg in 250 mL 5% dextrose in water

10 mL/h = 1 µg/kg/min

20 mL/h = 2 µg/kg/min

If satisfactory ventricular function is not achieved with dopamine, a second inotropic agent such as dobutamine (2–20 µg/kg) should be added to the dopamine regimen. Dobutamine is a direct myocardial β_1 stimulant that increases cardiac output with only minimal tachycardia. Isoproterenol should be considered a third-line agent, which can be titrated at 1–20 µg/min. This drug acts primarily on beta-adrenergic receptors to increase contractility and heart rate. However, potential side effects may include ventricular ectopy, excessive tachycardia, and undesired vasodilatation. Digoxin is commonly added to the previously described regimen to improve the force and velocity of myocardial contraction. This agent is given in a loading dose of 0.5 mg IV, followed by 0.25 mg every 4 hours for a total dose of 1.0 mg. Intravenous digoxin should be given under continuous ECG monitoring with special attention to serum potassium levels. The usual maintenance dosage during pregnancy is 0.25–0.37 mg/dL depending on plasma drug levels.

A peripheral vasoconstrictor may be initiated if there is a reduced systemic vascular resistance index (SVRI; less than 1500 dynes · s · cm⁻⁵) accompanied by a systolic blood pressure of less than 80 mm Hg despite inotropic therapy. It should be emphasized that maintenance of afterload appears to be a major hemodynamic determinant associated with maternal survival. Because of its pure alpha-adrenergic activity (which increases SVR), phenylephrine (1–5 µg/kg/min) is the initial drug of choice.

Norepinephrine is only indicated for septic shock patients with decreased afterload who do not respond to volume loading, inotropic therapy, and phenylephrine. This drug is a mixed adrenergic agonist with a primary effect on the alpha receptors, which leads to generalized vasoconstriction and increased SVR. Although the therapy of septic shock should focus primarily on stabilization of maternal factors, vasopressor agents should be administered cautiously during pregnancy since they have been reported to decrease uterine blood flow in animals with experimentally-induced spinal hypotension.

Some investigators have advocated large doses of corticosteroids for the acute management of septic shock, but human clinical trials have failed to demonstrate any conclusive benefit.

Newer investigational agents include corticosteroids and antiendotoxin therapy. Multicenter trials of endotoxin antibodies have suggested a possible improvement in mortality rate and organ failure in some subgroups of nonpregnant septic patients.

Prognosis

Despite all medical and surgical therapeutic options, the overall maternal mortality rate in septic shock is approximately 50%. The prognosis is worsened by the presence of ARDS or preexisting medical problems.

AMNIOTIC FLUID EMBOLISM

Essentials of Diagnosis

- Sudden, unexplained peripartum respiratory distress, cardiovascular collapse, and coagulopathy.
- Bleeding secondary to coagulopathy or uterine atony (common).
- Amniotic fluid debris in right side of the heart on autopsy.

General Considerations

Amniotic fluid embolism is a rare but potentially devastating complication of pregnancy that often results in poor obstetric outcome. Most of the information about amniotic fluid embolism has been derived from clinical reports, because the rarity of the disorder does not allow for clinical trials, and no suitable animal model exists. The first major review of the literature regarding this condition was by Morgan in 1979. This evaluated 272 cases. Since that time, a national registry was initiated by Clark. The incidence of amniotic fluid embolism is difficult to estimate, and may be anywhere from 1:8000 to 1:30,000.

Pathophysiology

The basic mechanism of disease is related to the effects of amniotic fluid on the respiratory, cardiovascular, and coagulation systems. One of the classic theories hypothesized that the following 3 primary acute events occur: (1) pulmonary vascular obstruction, leading to sudden decreases in left ventricular filling pressures and cardiac output; (2) pulmonary hypertension with acute cor pulmonale; and (3) ventilation-perfusion inequality of lung tissue, leading to arterial hypoxemia and its metabolic consequences.

Only a small volume of amniotic fluid (1–2 mL) is transferred to the maternal circulation during normal labor. Thus, enhanced communication between the amniotic fluid sac and the maternal venous system is necessary for amniotic fluid embolism to occur. Sites of entry may include endocervical veins lacerated during normal labor, a disrupted placental implantation site, and traumatized uterine veins. Squamous cells and trophoblastic tissue are often found in the maternal pulmonary vasculature of patients who underwent pulmonary artery catheterization. However, one must see more specific material like mucin, fetal debris, vernix, lanugo, and squamous cells coated with white blood cells and granular debris to confirm the diagnosis. If meconium is present, a more dramatic response is seen. Fetal demise has also been shown to worsen this condition. Once amniotic debris enters the venous system, it travels rapidly to the cardiopulmonary circulation, leading to shock and arterial hypoxemia. Myocardial dysfunction may result from ischemic injury or right ventricular dilatation. Some experimental evidence suggests that amniotic fluid may have a direct myocardial depressant effect. Endothelin, a vasoconstrictive peptide found in vascular endothelial cells, has been implicated. Other factors that may play a role include proteolytic enzymes, histamine, prostaglandins, complement, and biogenic amines (eg, serotonin). These mediators are seen in other shock states like sepsis and anaphylaxis, leading Clark to suggest that amniotic fluid embolism be termed "anaphylactoid syndrome of pregnancy." The effects of systemic

hypotension and hypoxemia may lead to cardiopulmonary collapse, renal insufficiency, hepatic failure, seizures, and coma.

Amniotic fluid embolism is almost always associated with some form of DIC. The etiology of coagulopathy associated with amniotic fluid embolism is incompletely understood, but it is known that amniotic fluid has potent total thromboplastin and antifibrinolytic activity, both of which increase with advancing gestational age. Once clotting is triggered in the pulmonary vasculature, local thrombin generation can cause vasoconstriction and microvascular thrombosis.

Limited hemodynamic observations with pulmonary artery catheterization suggest that in humans with amniotic fluid embolism, left ventricular dysfunction is the only significant hemodynamic alteration that is consistently documented. The response to amniotic fluid embolus in humans may be biphasic, initially resulting in intense vasospasm, severe pulmonary hypertension, and hypoxia. The transient period of right heart failure with hypoxia is later followed by a secondary phase of left heart failure, as reflected by elevated pulmonary artery pressure with subsequent return of right heart function. This biphasic theory may account for the extremely high maternal mortality rate within the first hour (25–34%) and explains why pulmonary hypertension can be difficult to document in patients with this disorder.

Clinical Findings

SYMPTOMS AND SIGNS

In his classic review of 272 patients with amniotic fluid embolus, Morgan characterized the main presenting clinical features: 51% presented with respiratory distress and cyanosis, 27% with hypotension, and only 10% with seizures. The Clark national registry noted 30% of patients presented with seizures or seizure-like activity, 27% with dyspnea, 17% with fetal bradycardia, and 13% with hypotension. Between 37% and 54% of patients exhibited an associated bleeding diathesis. Risk factors identified in the Morgan study included multiparity, tumultuous labor, or tetanic uterine contractions. Other studies have noted risk factors including advanced maternal age, use of uterine stimulants, cesarean section, uterine rupture, high cervical lacerations, premature separation of the placenta, and intrauterine fetal demise. Clark, however, was unable to identify any notable risk factors. Other presenting signs that have been described include tachypnea, peripheral cyanosis, bronchospasm, and chest pain.

LABORATORY FINDINGS

Arterial blood oxygen tension typically indicates severe maternal hypoxemia. This hypoxemia may result from ventilation-perfusion inequality with atelectasis and associated pulmonary edema. The diagnosis of significant coagulopathy is manifested by the presence of microangiopathic hemolysis, hypofibrinogenemia, prolonged clotting times, prolonged bleeding time, and elevated fibrin split products. The chest radiograph is nonspecific, although pulmonary edema is often noted. The ECG typically reveals unexplained tachycardia, nonspecific ST- and T-wave changes, and a right ventricular strain pattern. Lung scans occasionally identify perfusion defects resulting from amniotic fluid embolism even though chest radiographic findings are normal.

Differential Diagnosis

Many conditions may mimic the effects of amniotic fluid embolism on the respiratory, cardiovascular, and coagulation systems. Pulmonary thromboembolism can result in severe hypoxemia with pulmonary edema. In contrast to amniotic fluid embolism, chest pain is a relatively common finding. Congestive heart failure due to fluid overload or preexisting heart disease may mimic the cardiorespiratory compromise observed during amniotic fluid embolism. Hypotension may result from several disorders, including septic chorioamnionitis or postpartum hemorrhage. Pulmonary aspiration (Mendelson's syndrome) is associated with tachycardia, shock, respiratory distress, and production of a frothy pink

sputum, but is usually also associated with bronchospasm and wheezing. Other conditions in the differential diagnosis include air embolism, myocardial infarction, anaphylaxis, placental abruption, eclampsia, uterine rupture, transfusion reaction, and local anesthesia toxicity.

Treatment

Amniotic fluid embolism remains one of the most devastating and unpreventable conditions complicating pregnancy. Therapeutic measures are supportive and should be directed toward minimizing hypoxemia with supplemental oxygen, maintaining blood pressure, and managing associated coagulopathies. Patients with poor oxygenation often require intubation and positive end-expiratory pressure. Adequate oxygenation will minimize related cerebral and myocardial ischemia and acidosis-induced pulmonary artery vasospasm. Pulmonary artery catheterization should be considered in the absence of coagulopathy to guide inotropic therapy with dopamine. If invasive hemodynamic monitoring is not available, rapid digitalization should be considered. Finally, the development of consumptive coagulopathy may require replacement of depleted hemostatic components in cases with significant uncontrollable bleeding or abnormal clotting parameters.

Prognosis

Maternal mortality rates range from 60–80%; however, a recent study quoted a 26.4% mortality rate. Of those patients who do not survive, 25% die within the first hour, and 80% within the first 9 hours. Correspondingly high perinatal morbidity and mortality rates would be expected.

PULMONARY THROMBOEMBOLISM

Essentials of Diagnosis

- Unexplained chest pain and dyspnea (most frequent presenting symptoms).
- History of pulmonary embolism, deep venous thrombosis, prolonged immobilization, or recent surgery.
- Physical examination: usually nonspecific, depending on extent of cardiopulmonary involvement, but may include tachycardia, wheezing, pleural friction rub, and pulmonary rales.
- Laboratory evaluation: decreased arterial blood oxygen tension to less than 90 mm Hg in the sitting position.
- Diagnostic studies: pulmonary radionuclide ventilation-perfusion scanning, spiral CT, and angiography.

General Considerations

Pulmonary thromboembolism is a rare complication of pregnancy (0.09%) but is a significant cause of maternal morbidity and mortality. Mortality has been documented as 12.8% if untreated, and 0.7% if therapy is instituted. The diagnosis of deep venous thrombosis (DVT) occurs in the antepartum period approximately half the time, and is evenly distributed throughout each trimester. Pulmonary embolism has a higher incidence in the postpartum period. Predisposing factors commonly include advanced maternal age, obesity, traumatic delivery, abdominal delivery, thrombophlebitis, and endometritis. Patients with underlying thrombophilias or previous thrombotic events are at greater risk for this condition.

Pathophysiology

More than 100 years ago, Virchow postulated that the basic mechanism of thrombus formation is related to a combination of vessel injury, vascular stasis, and alterations in blood coagulability. Venous thrombi consist of fibrin deposits and red blood cells with varying amounts of platelet and white blood cell

components. In most cases, lower extremity and pelvic thrombi are responsible for the pathologic sequelae.

Ordinarily, the vascular endothelium does not react with either platelets or the blood coagulation system unless it is disrupted by vessel injury. Such injury exposes subendothelial cells to blood elements responsible for activation of the extrinsic coagulation cascade. Disruption of the vascular endothelium may occur during traumatic vaginal delivery or cesarean section.

Pregnancy is also associated with venous stasis, especially in the lower extremities, because the enlarging uterus reduces blood return to the inferior vena cava by direct mechanical effects. Hormonal factors may contribute to venodilatation and stasis during pregnancy. Stasis prevents the hepatic clearance of activated coagulation factors and minimizes mixing of these factors with their serum inhibitors. In this manner, venous stasis becomes another predisposing factor for the formation of thrombi. Stasis secondary to prolonged bedrest for medical or obstetric complications will predispose a pregnant woman to increased venous stasis and formation of vascular thrombi. The period of greatest risk for thrombosis and embolism appears to be the immediate postpartum, especially after cesarean delivery.

The maternal circulation becomes hypercoagulable from alterations in the coagulation and fibrinolytic systems. Serum concentrations of most coagulation proteins, such as fibrinogen and factors II, VII, VIII, IX, and X, increase during pregnancy. These changes are also associated with decreased fibrinolytic activity, which is responsible for the conversion of plasminogen to the active proteolytic enzyme plasmin.

Women with congenital or acquired thrombophilias are at increased risk for thrombosis; in fact, up to half of women who have these events in pregnancy may have an underlying disorder. The most commonly recognized thrombophilia in the Caucasian population is factor V Leiden mutation (5%). Other less common but significant disorders include: prothrombin gene mutation G20210A (2–4%), antithrombin III deficiency (0.02–0.2%), protein C deficiency (0.2–0.5%), protein S deficiency (0.08%), and hyperhomocysteinemia (1%). The antiphospholipid antibody syndrome also significantly increases maternal risk.

Once a venous thrombus is formed, it may dislodge from its peripheral vascular origin and enter the central maternal circulation. Propagation of the original venous clot or recurrent pulmonary emboli are possible. DVTs limited to the calf rarely embolize, but approximately 20% extend to the proximal lower extremity.

Clinical Findings

SYMPTOMS AND SIGNS

The subsequent cardiopulmonary effects of pulmonary embolus will depend on the location and size of thrombi in the lung. A patient with a large embolus affecting the central pulmonary circulation may present with acute syncope, respiratory embarrassment, and shock. Smaller emboli may not have significant clinical sequelae.

No single symptom or combination of symptoms is specific for the diagnosis of pulmonary embolus. Classic triads (hemoptysis, chest pain, and dyspnea; or dyspnea, chest pain, and apprehension) are rarely seen (Table 60–6). Chest pain and dyspnea were the most common symptoms in patients with angiographically documented pulmonary emboli (over 80%). Physical findings include tachycardia, tachypnea (rate > 16/min), pulmonary rales, wheezing, and pleural friction rub.

Table 60–6. Symptoms and Signs in 327 Patients with Pulmonary Embolus Confirmed by Angiography.¹

Symptom or Sign	Frequency (%)
Chest pain	88
Pleuritic	74
Nonpleuritic	14
Dyspnea	84
Apprehension	59
Cough	53
Hemoptysis	30
Sweating	27
Syncope	13
Respiration more than 16/min	92
Pulmonary rales	58
Pulse more than 100/min	44
Fever (> 37.8 °C [99.7 °F])	43
Phlebitis	32
Heart gallop	34
Diaphoresis	36
Edema	24
Heart murmur	23
Cyanosis	19

LABORATORY FINDINGS

There are no specific routine laboratory findings associated with the diagnosis of pulmonary embolus, although arterial blood gas measurements will often reveal significant hypoxemia. In the upright position, almost all healthy young pregnant women will have an arterial blood oxygen tension greater than 90 mm Hg. An alveolar-atrial (A-a) gradient of greater than 20 is suspicious for pulmonary embolus. The ECG may reveal unexplained tachycardia associated with cor pulmonale (right axis deviation, S wave in lead I, Q wave plus T wave inversion in lead III). A chest roentgenogram may be normal or may show infiltrates, atelectasis, or effusions. Thirty percent of patients with a pulmonary embolus will have a normal chest x-ray.

It is generally accepted that a normal radionuclide perfusion study can effectively rule out pulmonary embolus. Perfusion studies are occasionally equivocal, and ventilation scanning may be required to clarify the diagnosis. Ventilation scanning will improve the specificity of the perfusion study, since this will rule out airway disorders that may be responsible for reduced pulmonary perfusion. The radiation exposure is minimal (< 0.1 rad). Unfortunately, a V/Q scan can only confirm a diagnosis if it is normal or indicates high probability of embolus. Therefore, 40–60% of patients will require further testing.

Spiral computed tomography is a newer form of imaging that has a sensitivity and specificity of 94% in the nonpregnant patient. Spiral CT may also be helpful in detecting other abnormalities causing pulmonary symptoms (eg, pleural effusions, consolidation, emphysema, pulmonary masses). However, this study may miss emboli below the segmental level. Magnetic resonance imaging has limited value in pregnancy because it has not been well studied.

If the above studies are equivocal, pulmonary angiography should be considered. Subsequent exposure of the fetus to the relatively low levels of ionizing radiation from angiography can be minimized with appropriate pelvic shielding and selective angiography on the basis of prior radionuclide scanning.

Noninvasive Doppler should be considered as an initial diagnostic test for suspected DVT involving the lower extremities. Compression ultrasound uses firm compression with the transducer probe to detect intraluminal filling defects. Imaging is most useful for the distal iliac, femoral, and popliteal veins. Doppler is also useful for the proximal iliac veins. Sensitivity is 95%, with a 96% specificity. Impedance plethysmography measures impedance flow with pneumatic cuff inflation. Sensitivity and specificity are 83% and 92%, respectively. Compression of the inferior vena cava by the gravid second- or third-trimester uterus may cause false-positive results.

If the above noninvasive tests are inconclusive, it may be helpful to confirm the extent of the original thrombotic event by venography with pelvic shielding. The soleal calf sinuses and the valves involving the popliteal and femoral veins are the sources of most deep venous thrombi. Venography is associated with induced phlebitis in approximately 3–5% of procedures performed. Radiofibrinogen methods to detect thrombus formation will result in placental transfer of radioactive iodine and are contraindicated in pregnant or nursing women.

Differential Diagnosis

Any condition potentially related to cardiopulmonary compromise during pregnancy should be included in the differential diagnosis. This includes amniotic fluid and air emboli, spontaneous pneumothorax, septic shock, and preexisting heart disease.

Treatment

PREVENTIVE TREATMENT

Once predisposing risk factors to pulmonary embolus are identified, it is important to minimize the possibility of further complications. In patients at higher risk for DVT, prophylactic measures should be directed toward preventing venous stasis that leads to clot formation. Mechanical maneuvers such as raising the lower extremities 15 degrees above the horizontal, keeping the legs straight rather than bent at the knees when sitting, or performing calf flexion exercises may be useful, as may external pneumatic compression. One method used to prevent perioperative thrombophlebitis includes minidose heparin prophylaxis, 5000 U subcutaneously 2 hours before surgery and every 12 hours until routine ambulation is achieved. Minidose heparin prophylaxis significantly decreases not only the incidence of DVT but also the incidence of fatal pulmonary emboli. Subcutaneous minidose heparin may be reinstated approximately 6 hours after delivery. Postpartum or postoperative ambulation is important in minimizing thromboembolic complications during this high-risk period. Some women may require therapeutic anticoagulation during pregnancy to prevent a thromboembolic event. Included in this category are women with artificial heart valves, antithrombin III deficiency, antiphospholipid antibody syndrome, history of rheumatic heart disease and atrial fibrillation, homozygosity for factor V Leiden or prothrombin gene mutation, and recurrent thromboembolic disease. Therapeutic anticoagulation can be achieved by using subcutaneous heparin 2–3 times a day, adjusting for a PTT of 2.0–3.0 times normal. Low molecular weight heparin (LMWH) can also be used. LMWH does not cross the placenta, and it has been shown to

be relatively safe in pregnancy. In addition, complications of heparin therapy (osteoporosis, thrombocytopenia) are not seen with this medication, and dosing in pregnancy usually does not require many adjustments. The PTT does not need to be followed; instead, peak antifactor Xa levels can be checked every 4–6 weeks. It is controversial whether other disorders, like protein C or S deficiency, or a family history of thrombophilias, require anticoagulation therapy. These patients may benefit from minidose heparin prophylaxis.

TREATMENT OF DOCUMENTED PULMONARY EMBOLISM

Once pulmonary embolism is documented, therapeutic intervention should be directed to correction of arterial hypoxemia and any associated hypotension. Other measures should prevent clot propagation or recurrent emboli. Supplemental oxygen should be given to achieve an arterial oxygen tension of at least 70 mm Hg. A loading dose of 5000–10,000 U of heparin should be given intravenously by continuous infusion, followed by a maintenance dose of approximately 1000 U/h. The PTT should be maintained at 1.5–2.5 times control values. Other investigators recommend the use of heparin levels for monitoring anticoagulation therapy. Heparin levels may be measured on the third or fourth day and should be about 0.2 µg/mL, not to exceed 0.4 µg/mL. Leg elevation, bedrest, and local heat will be beneficial to patients who have associated DVT. Intravenous morphine may be helpful in alleviating anxiety and ameliorating chest pain.

Intrapartum care of pulmonary embolus is complicated, and individual treatment approaches may vary. Selected patients with recent pulmonary thromboembolism, iliofemoral DVT, or heart valve prosthesis should probably continue full anticoagulation with high-dose heparin during labor or surgical procedures. Under these circumstances, the risk for potential bleeding complications from anticoagulant needs to be balanced against the risk of thromboembolism. Although there is a higher incidence of wound hematomas associated with peripartum anticoagulation, there is no clear evidence that this regimen is associated with excessive postpartum hemorrhage after normal vaginal delivery.

Postpartum patients receiving heparin may be switched over to warfarin once oral intake is tolerated. Heparin should be continued for the first 5–7 days of warfarin therapy. By the time heparin is discontinued, the international normalized ratio (INR) should be 2.0–3.0 times the normal value. Alternatively, it may be desirable to continue moderate doses of subcutaneous heparin (10,000 U twice daily), especially in nursing mothers. Postpartum anticoagulation should be continued for at least 3 months if the patient developed pulmonary embolus in the third trimester.

COMPLICATIONS OF TREATMENT

The major complication of anticoagulant therapy is maternal or fetal hemorrhage. Heparin does not cross the placenta due to its large molecular weight, but it has been associated with maternal thrombocytopenia and osteoporosis. These effects can be avoided with low molecular weight heparin. Warfarin is known to cross the placental barrier, and its use in the first trimester has been associated with embryopathy (nasal hypoplasia and stippled epiphyses). Fetal nervous system abnormalities (eg, hydrocephalus) have also been noted with the use of warfarin during pregnancy.

A small percentage of patients will experience recurrent pulmonary emboli despite full anticoagulation. These patients may be candidates for vena caval ligation by a transabdominal approach under general or regional anesthesia. If the pelvis is suspected as the source of embolus, the right ovarian vein should also be ligated. It has been estimated that approximately 95% of patients with pulmonary embolism massive enough to cause hypotension eventually die. In this context, pulmonary artery embolectomy may be life-saving.

Placement of a vena caval umbrella via the internal jugular vein is an option for unstable patients with recurrent emboli who would not be prime surgical candidates. Although abdominal radiography is

required for this procedure, placement of the umbrella filter does not require general anesthesia. This strategy will prevent larger emboli from reaching the pulmonary circulation.

Prognosis

Pulmonary embolus, with a mortality rate of 12–15% if left untreated, will develop in approximately one-fourth of untreated patients with antenatal DVT. In a review of pregnancies complicated by DVT treated with anticoagulant therapy, the incidence of pulmonary embolus was 4.5% of patients, with a maternal mortality rate of less than 1%.

DISSEMINATED INTRAVASCULAR COAGULATION (DIC)

Essentials of Diagnosis

- History of recent bleeding diathesis, especially concurrent with placental abruption, amniotic fluid embolism, fetal demise, sepsis, preeclampsia-eclampsia, or saline abortion.
- Clinical evidence of multiple bleeding points associated with purpura and petechiae on physical examination.
- Laboratory findings classically include thrombocytopenia, hypofibrinogenemia, and elevated PT, elevated D-dimer, and fibrin split products.

General Considerations

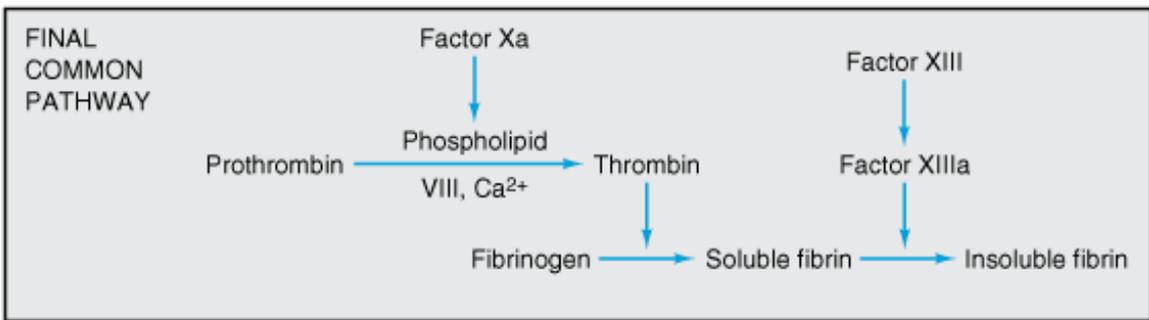

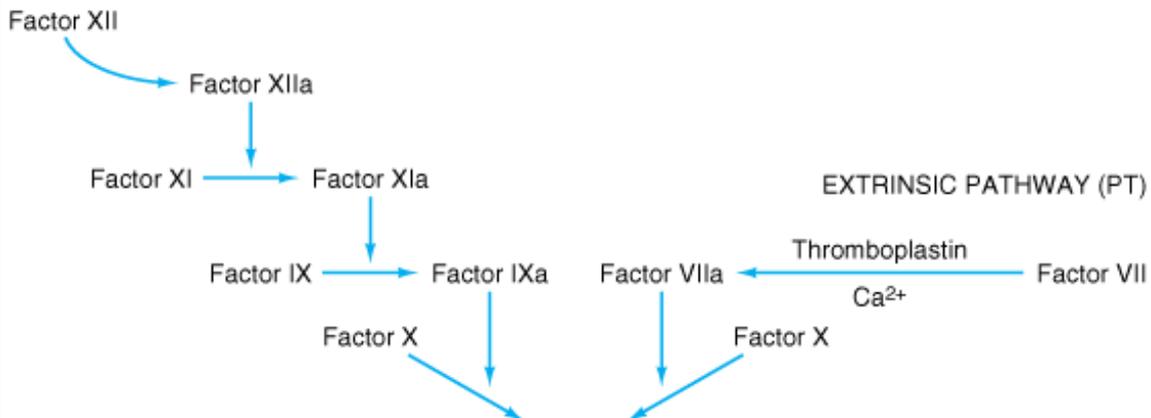

DIC is a pathologic condition associated with inappropriate activation of coagulation and fibrinolytic systems. It should be considered a secondary phenomenon resulting from an underlying disease state. The most common obstetric conditions associated with DIC are intrauterine fetal death, amniotic fluid embolism, preeclampsia-eclampsia, HELLP (hemolysis, elevated liver enzymes, and low platelet count syndrome), placenta previa, and placental abruption. Saline-induced abortion is also a cause.

Pathophysiology

The most widely accepted theory of blood coagulation entails a "cascade theory" (Fig 60–7). Basically, the coagulation system is divided into intrinsic and extrinsic systems. The intrinsic system contains all the intravascular components required to activate thrombin by sequential activation of factors XII, XI, IX, X, V, and II (prothrombin). The extrinsic system is initially activated by tissue thromboplastin, leading to sequential activation of factors VII, X, V, and prothrombin. Both the intrinsic and extrinsic pathways converge to activate factor X, which subsequently reacts with activated factor V in the presence of calcium and phospholipid to convert prothrombin to thrombin.

Figure 60–7.

INTRINSIC PATHWAY (PTT)

Coagulation cascade mechanism.

Thrombin is a proteolytic enzyme responsible for splitting fibrinogen chains into fibrinopeptides, leading to the formation of fibrin monomer. This central enzyme is capable of activating factor XIII to stabilize the newly formed fibrin clot and will enhance the activity of factors V and VIII.

Activation of the coagulation system also stimulates the conversion of plasminogen to plasmin as a protective mechanism against intravascular thrombosis. Plasmin is an enzyme that inactivates factors V and VIII and is capable of lysing fibrin and fibrinogen to form degradation products. Thus, the normal physiologic hemostatic mechanism represents a delicate and complex balance between the coagulation and fibrinolytic systems.

Pregnancy is considered to represent a hypercoagulable state. With the exception of factors XI and XIII, there is an overall increase in the activity of coagulation factors. Fibrinogen rises as early as 12 weeks' gestation and reaches a peak level of 400–650 mg/dL in late pregnancy. The fibrinolytic system is depressed during pregnancy and labor but returns to normal levels within 1 hour of placental delivery. The early puerperium is accompanied by a secondary rise in fibrinogen, factors VIII, IX, X, and antithrombin III; a return to nonpregnant levels occurs by 3–4 weeks postpartum.

The complex pathophysiology of DIC is characterized by (1) procoagulant system activation; (2) fibrinolytic system activation; (3) inhibitor consumption; (4) cytokine release; (5) cellular activation; and (6) resultant end-organ damage. DIC occurs as a secondary event in a wide variety of illnesses associated with excess production of circulating thrombin. The pathophysiologic factors responsible for inappropriate activation of the clotting mechanism include endothelial cell injury, liberation of

thromboplastin from injured tissue, and release of phospholipid from red cell or platelet injury. All these mechanisms may contribute to development of a bleeding diathesis resulting from increased thrombin activity. Additionally, widespread DIC will cause increased platelet aggregation, consumption of coagulation factors, secondary activation of the fibrinolytic system, and deposition of fibrin into multiple organ sites, which can result in ischemic tissue damage. The associated thrombocytopenia and presence of fibrin split products will impair hemostasis.

Specific obstetric conditions associated with DIC include the following.

PLACENTAL ABRUPTION

DIC may occur in placental abruption involving liberation of tissue thromboplastin or possible intrauterine consumption of fibrinogen and coagulation factors during the formation of retroplacental clot. This leads to activation of the extrinsic coagulation mechanism. Placental abruption is one of the most common obstetric causes of DIC.

RETAINED DEAD FETUS SYNDROME

Another cause of DIC is retained dead fetus syndrome involving liberation of tissue thromboplastin from nonviable tissue. This cause is less common in recent years due to advanced ultrasound technology and the earlier detection of this condition.

AMNIOTIC FLUID EMBOLISM

This involves not only the release of tissue thromboplastin but also the intrinsic procoagulant properties of amniotic fluid itself. It is likely that the associated hypotension, hypoxemia, and tissue acidosis will encourage the activation of coagulation factors.

PREECLAMPSIA-ECLAMPSIA

This condition is associated with chronic coagulation abnormalities that may lead to thrombocytopenia and elevation of fibrin degradation products. It is uncertain whether endothelial damage activates procoagulant proteins and platelets or the reverse, although the former is more likely. Eclampsia is associated with DIC 11% of the time; with HELLP syndrome this increases to 15%. Preeclampsia together with placental abruption also significantly increases this association.

SALINE OR SEPTIC ABORTION

Saline-induced abortion has been associated with subclinical DIC. Severe cases of DIC have occurred in 1:400–1:1000 cases. Disease may be related to the release of tissue thromboplastin from the placenta. Septic abortion may also cause release of tissue thromboplastin or release of bacterial endotoxin (phospholipids).

OTHER

Other triggers of DIC include septicemia, viremias (eg, HIV, varicella, CMV, hepatitis), drugs, and acidosis.

Clinical Findings

SYMPTOMS AND SIGNS

Acute clinical manifestations of DIC are variable and include generalized bleeding, localized hemorrhage, purpura, petechiae, and thromboembolic phenomena. Also, fever, hypotension, proteinuria, hypoxia, hemorrhagic bullae, acral cyanosis, and frank gangrene have been described. Widespread fibrin deposits may affect any organ system, including the lungs, kidneys, brain, and liver. Chronic DIC (eg, fetal demise) is associated with slower production of thrombin and may be associated with minimal or absent clinical signs and symptoms.

LABORATORY FINDINGS

Although histologic diagnosis of fibrin deposits is the only definitive manner by which DIC may be confirmed, there are a host of indirect tests suitable for the clinical evaluation of coagulopathy.

Platelets

Platelets are decreased ($< 100,000/\mu\text{L}$) in more than 90% of cases. In the absence of other causes, spontaneous purpura usually does not occur when platelet counts are greater than $30,000/\mu\text{L}$.

Prothrombin Time (PT)

PT measures the time required for clotting by the extrinsic pathway and is dependent on the ultimate conversion of fibrinogen to fibrin. It is prolonged in only 50–75% of patients with DIC. The explanations for the normal PTs are, first, the presence of circulating activated clotting factors like thrombin or factor Xa, that accelerate the formation of fibrin; and second, the presence of early degradation products, which are rapidly clottable by thrombin; these may cause the test to register a normal or fast PT.

Partial Thromboplastin Time (PTT)

PTT is frequently normal in DIC (40–50% of the time) and is not as helpful for establishing the diagnosis. This test measures the function of the intrinsic and final common pathways of the coagulation cascade.

Thrombin Time (TT)

TT is elevated in 80% of patients with DIC. It is affected only by the amount of circulating fibrinogen or the presence of thrombin inhibitors such as fibrin degradation products and heparin. This test specifically measures the time necessary for conversion of fibrinogen to fibrin.

Fibrinogen

Fibrinogen is often decreased, with approximately 70% of patients with DIC having a serum level less than 150 mg/dL. The normal physiologic increase of serum fibrinogen levels during pregnancy may mask a pathologic decrease in this parameter.

Fibrin Split Products

Values greater than $40 \mu\text{g/mL}$ are suggestive of DIC. These are elevated in 85–100% of patients with DIC. These degradation products are diagnostic of the plasmin biodegradation of fibrinogen or fibrin, so indicate only the presence of plasmin.

Clotting Time and Clot Retraction

Observation of clotting time and ability of the clot to retract can be performed by using 2 mL of blood in a 5-mL glass test tube. These are relatively simple bedside tests that can provide qualitative evidence of hypofibrinogenemia. When the clot forms, it is usually soft but not reduced in volume (adding celite will hasten this reaction). Over the next half hour, the clot should retract, with the volume of serum exceeding that of the formed clot. If this phenomenon does not occur, low serum fibrinogen levels can be suspected.

Peripheral Blood Smear

A peripheral blood smear reveals schistocytes in approximately 40% of patients with DIC.

Bleeding Time

The time required for hemostasis after skin puncture will become progressively prolonged as the platelet count falls below $100,000/\mu\text{L}$. Spontaneous continuous bleeding from puncture sites may develop if the platelet count falls below $30,000/\mu\text{L}$.

Newer Tests

Several of these laboratory findings are more reliable than the classic studies.

D-DIMER

This is a neoantigen formed as a result of plasmin digestion of cross-linked fibrin when thrombin initiates

the transition of fibrinogen to fibrin, and activates factor XIII to cross-link the fibrin formed. The test is specific for fibrin (not fibrinogen) degradation products, and is abnormal in 90% of cases.

ANTITHROMBIN III LEVEL

This is abnormal in 89% of cases.

FIBRINOPEPTIDE A

This is abnormal 75% of the time.

Differential Diagnosis

Most acute episodes of generalized bleeding in obstetric patients will be related to pregnancy, but other rare causes of congenital or acquired coagulopathies need to be considered. These include idiopathic thrombocytopenic purpura, hemophilia, and von Willebrand's disease. Placental abruption is often associated with uterine tenderness, fetal bradycardia, and uterine bleeding. DIC associated with fetal demise usually does not become apparent until at least 5 weeks after the absence of heart tones has been documented. Amniotic fluid embolus is typically associated with acute onset of respiratory distress and shock. Preeclampsia is characterized by hypertension and proteinuria, which may lead to eclamptic seizures.

Complications

In addition to the potential complications of uncontrolled hemorrhage previously discussed, widespread fibrin deposition may affect any major organ system. This may include the liver (hepatic failure), kidneys (tubular necrosis), and lungs (hypoxemia).

Treatment

Although individual measures will be dictated by the specific obstetric condition, the primary, most important treatment of pregnancy-related DIC is correction of the underlying cause. In most cases, prompt termination of the pregnancy is required. Moderate or low-grade DIC may not be associated with clinical evidence of excessive bleeding and often will require close observation but no further therapy.

Supportive therapy should be directed to the correction of shock, acidosis, and tissue ischemia. Cardiopulmonary support, including inotropic therapy, blood replacement, and assisted ventilation, should be implemented with the patient in close proximity to a delivery suite. Fetal monitoring, careful recording of maternal fluid balance, and serial evaluation of coagulation parameters are extremely important. If sepsis is suspected, antibiotics should be employed. Central monitoring with a pulmonary artery catheter is relatively contraindicated due to potential bleeding complications. Vaginal delivery, without episiotomy if possible, is preferable to cesarean section. Failure of improvement in the coagulopathy within several hours after delivery suggests sepsis, liver disease, retained products of conception, or a congenital coagulation defect.

Blood component therapy should be initiated on the basis of transfusion guidelines reported by the National Institutes of Health. Criteria for red cell transfusions were discussed earlier (see Hypovolemic Shock). Fresh-frozen plasma has only limited and specific indications, which include massive hemorrhage, isolated factor deficiencies, reversal of warfarin, antithrombin II deficiency, immunodeficiencies, and thrombocytopenic purpura. Although most cases of severe obstetric hemorrhage will lead to laboratory evidence of coagulation abnormalities, transfusion of fresh-frozen plasma may not always benefit these patients; the amount transfused is usually insufficient for replacing coagulation factors lost by dilution or clot formation. Even with massive obstetric hemorrhage, most procoagulant levels are above 30% of normal values, which is sufficient for maintaining clinical hemostasis in most patients. Specific replacement of fibrinogen should be accomplished by cryoprecipitate. Each unit of cryoprecipitate carries approximately 250 mg of fibrinogen. Platelets should

only be administered in the face of active bleeding with a platelet count $< 50,000/\mu\text{L}$ or prophylactically with platelet count 20–30,000/ μL or less or following massive transfusion (> 2 times blood volume). Platelets should be transfused on the basis of 1 U/10 kg body weight to raise the cell count above 50,000/ μL . However, it should be noted that clotting factors containing fibrinogen may be associated with enhanced hemorrhage and also with thrombosis when given to patients with DIC. For this reason, they should be administered with extreme caution. Obstetricians should remember that Rh immune globulin should be given to Rh-negative recipients of platelets from Rh-positive donors.

Subcutaneous low-dose heparin or low molecular weight heparin may be effective in treating the intravascular clotting process of DIC. Heparin acts as an anticoagulant by activating antithrombin III but has little effect on activated coagulation factors. Anticoagulation is contraindicated in patients with fulminant DIC and central nervous system insults, fulminant liver failure, or obstetric accidents. The one instance, however, in which heparin has been demonstrated to benefit pregnancy-related DIC is in the case of the retained dead fetus with an intact vascular system, where heparin may be administered to interrupt the coagulation process and thrombocytopenia for several days until safe delivery may be implemented.

Prognosis

Most cases of obstetric DIC will improve with delivery of the fetus or evacuation of the uterus. The maternal and fetal prognosis will be more closely related to the associated obstetric condition than to the coagulopathy.

ACUTE RESPIRATORY DISTRESS SYNDROME (ARDS)

Essentials of Diagnosis

- History of gastric aspiration, infection/sepsis, preeclampsia-eclampsia, seizures, hemorrhage, coagulopathy, or amniotic fluid embolism.
- Progressive respiratory distress with decreased lung compliance.
- Severe hypoxemia refractory to oxygen therapy.
- Diffuse infiltrates on chest roentgenogram.
- Normal PCWP, with absence of radiographic evidence of congestive heart failure.

General Considerations

ARDS is a severe form of lung disease with acute onset, characterized by bilateral infiltrates on chest X-ray, no evidence of intravascular volume overload (PCWP no greater than 18 mm Hg), and severely impaired oxygenation, demonstrated by a ratio of arterial oxygen tension (PaO_2) to the fraction of inspired oxygen (FIO_2) of less than 200 mm Hg. ARDS appears to occur more commonly in obstetric patients than in the general population. Its incidence in the nonpregnant population is 1.5 per 100,000, but it has been estimated to occur in between 1:3000 and 1:10,000 pregnant patients. ARDS has many causes, including gastric aspiration, amniotic fluid embolism, sepsis, coagulopathy, massive blood transfusion, and shock. It can be easily confused with cardiogenic pulmonary edema secondary to alterations in preload, myocardial contractility, or afterload. A basic understanding of the differences between cardiogenic and noncardiogenic pulmonary edema is essential before rational therapeutic intervention may be implemented.

Pathophysiology

The basic underlying pathologic change responsible for ARDS is lung injury that results in damage to the pulmonary epithelium and endothelial tissue. This, in turn, leads to enhanced vascular permeability.

Factors determining the net flux of lung fluid between the capillary lumen and interstitial space are quantitatively related by the Starling equation:

$$\text{Net fluid flux} = k[(P_{\text{cap}} - P_{\text{is}}) - (\pi_{\text{cap}} - \pi_{\text{is}})]$$

(k = filtration coefficient, P_{cap} = pulmonary capillary hydrostatic pressure, P_{is} = interstitial space hydrostatic pressure, π_{cap} = pulmonary capillary serum colloid osmotic pressure, π_{is} = interstitial space fluid colloid osmotic pressure)

Normally, fluid flows from the capillary system to the interstitial space and is returned to the systemic circulation by the pulmonary lymphatic system. An increase in left atrial pressure is observed when the left ventricle is unable to pump all the returning blood into the left atrium. Accordingly, the pulmonary capillary hydrostatic pressure increases, facilitating net movement of lung fluid into the interstitial space. When capillary fluid efflux into the interstitial space exceeds lymphatic resorption, the clinical presentation of pulmonary edema will occur. Although colloid osmotic pressure in the interstitial space and serum also plays a role in pulmonary edema, the most common factor is increased capillary hydrostatic pressure secondary to increased preload (fluid overload), afterload (severe hypertension), and decreased myocardial contractility (postpartum cardiomyopathy).

Capillary membrane permeability plays a much larger role in the genesis of noncardiogenic pulmonary edema (ARDS). Such injury due to hypoxic ischemia, vasoactive substances, chemical irritation, or microthrombi facilitates further efflux of capillary fluid and plasma proteins into the interstitium. This increase in permeability acutely produces atelectasis and diminished compliance of the lung, and damage is usually non-uniform. As the functional capability of atelectatic bronchioles diminishes, shunting and hypoxemia develop.

Maternal physiologic changes can contribute to the severity of ARDS. It has been suggested that decreased extrathoracic compliance, decreased functional residual capacity, higher oxygen deficit, limited cardiac output increases, and anemia may adversely affect the clinical presentation and course of ARDS during pregnancy.

Clinical Findings

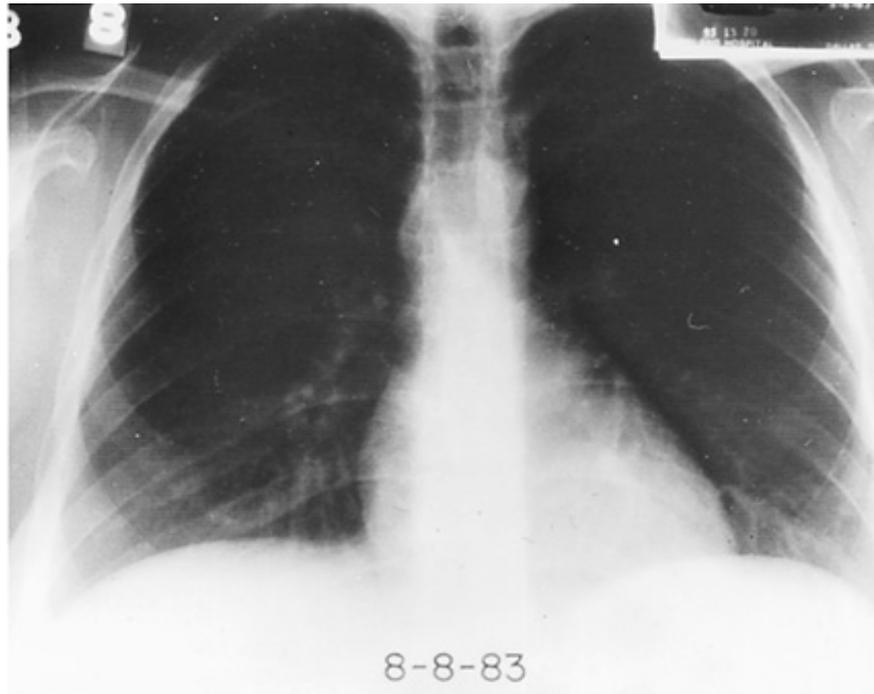

SYMPTOMS AND SIGNS

Classic signs of respiratory distress are tachypnea, intercostal retractions, and even cyanosis, depending on the degree of hypoxemia. Fetal tachycardia or late decelerations may reflect maternal hypoxemia and uteroplacental insufficiency. Pulmonary rales in noncardiogenic pulmonary edema will be indistinguishable from those of cardiogenic pulmonary edema, but physical findings consistent with the cardiogenic disorder (ventricular gallop, jugular venous distention, and peripheral edema) are not typical features of ARDS. Unfortunately, the physiologic changes of pregnancy may mask the significance of these physical findings during the more subtle stages of respiratory distress.

LABORATORY FINDINGS

Arterial blood gas determinations will reveal a progressive moderate to severe hypoxemia despite oxygen therapy. Depending on the obstetric cause of ARDS, other laboratory findings will be variable or nonspecific. The initial chest roentgenogram will often be normal, even in the presence of clinically significant respiratory distress. Within the next 24–48 hours, patchy or diffuse infiltrates will progress to prominent alveolar infiltrates (Fig 60–8). Unlike in cardiogenic pulmonary edema, the heart will most likely be of normal size in a patient with ARDS. PCWP measured by right heart catheterization is the procedure most helpful in differentiating ARDS and pulmonary edema. The PCWP is elevated (> 20 mm Hg) in cardiogenic pulmonary edema but is often normal in ARDS.

Sequence of chest radiographs from a 21-year-old woman during her first pregnancy with antepartum pyelonephritis and ARDS. A: Normal chest film. B: Bilateral patchy pulmonary densities have developed consistent with the diagnosis of ARDS. Much of the apparent increase in heart size is related to shallow inspiration and supine technique. C: ARDS has improved dramatically with only minimal residual pulmonary densities.

Measurement of endobronchial fluid COP has also been utilized to differentiate capillary permeability-induced pulmonary edema from hydrostatic or cardiogenic pulmonary edema. In pulmonary edema secondary to capillary permeability, the COP of endobronchial fluid obtained from endotracheal tube suctioning is usually greater than 75% of the simultaneously obtained plasma COP. In cardiogenic pulmonary edema, the COP of the endobronchial fluid is usually less than 60% that of plasma.

Histopathologically, idiopathic pulmonary fibrosis and ARDS are remarkably similar. Both show evidence of acute alveolar injury, which is characterized by interstitial inflammation, hemorrhage, and edema. This is followed by a hypercellular phase, loss of alveolar structure, and pulmonary fibrosis.

Differential Diagnosis

ARDS should be differentiated from infectious pneumonitis and cardiogenic causes of pulmonary edema. Cardiogenic pulmonary edema will usually respond more rapidly to diuretic therapy than will ARDS, in which abnormalities in capillary membrane permeability are not quickly resolved by such intervention.

Treatment

Therapy should be directed toward the prevention of hypoxemia, correcting acid-base abnormalities, removal of inciting factors, and hemodynamic support appropriate for the specific cause (eg, amniotic fluid embolus, DIC). Cardiogenic pulmonary edema is usually treated with a combination of diuretics, inotropic therapy, and afterload reduction. If a hemodynamic profile is not immediately available by pulmonary artery catheter, the clinician may elect to begin oxygen and furosemide (20 mg IV) for the presumptive diagnosis of cardiogenic pulmonary edema. By contrast, it should be apparent that the basic therapy for ARDS is supportive. Endotracheal intubation with mechanical ventilation is almost always required. The pulmonary artery catheter will be helpful in guiding fluid management and optimizing cardiac performance. Additionally, mixed venous oxygen saturation from the distal port of the pulmonary

artery catheter will provide an index of oxygen utilization.

In obstetric patients, reasonable therapeutic goals for cardiorespiratory support include a mechanical ventilator tidal volume of less than 10 mL/kg, PCWP 8–12 mm Hg, arterial blood oxygen tension greater than 60 mm Hg, and mixed venous oxygen tension greater than 30 mm Hg. If unable to maintain PaO₂ of at least 60 mm Hg on 50% or less inspired oxygen, positive end-expiratory pressure (PEEP) in amounts of up to 15 cm H₂O may be helpful. However, it is important to avoid barotrauma to the remaining functional alveolar units, so high tidal volumes and pressures should be avoided. If the mixed venous tension is low, transfusion of red blood cells or inotropic therapy may improve oxygen transport and delivery.

Since the presence of capillary membrane abnormalities in ARDS is associated with rapid equilibration of proteinaceous material between the capillaries and interstitial spaces, intravenous colloid replacement should be discouraged in lieu of crystalloid resuscitation. A policy of relative fluid restriction should be followed, but only if the following criteria are met: stable fetus, no evidence of metabolic acidosis, normal renal function, and no need for vasopressor therapy or PEEP. Sedation and pain relief should be used liberally, and may help to decrease oxygen consumption. Nutritional support for patients on prolonged mechanical ventilation must be considered; enteral feeding is preferred as it may reduce the translocation of gut bacteria into the body. Prospective controlled studies have not demonstrated the benefit of steroid therapy for ARDS. Once therapy for cardiopulmonary support has been implemented, a thorough search for predisposing factors to ARDS must be identified for specific intervention.

Potential future therapies for ARDS include high frequency ventilation, extracorporeal membrane oxygenation (ECMO), intravenous oxygen, inhaled nitric oxide, surfactant replacement, oxygen-free radical scavengers, arachidonic acid metabolite inhibitors, antiprotease agents, antiendotoxin antibodies, anti-tumor necrosis factor antibodies, and other immunologic therapies for sepsis.

The timing of delivery in these patients is unclear from the literature. Based on the high rates of fetal death, preterm labor, fetal heart rate abnormalities, and perinatal asphyxia, most authorities recommend delivery after a gestational age of 28 weeks. In one review, only 10 of 39 patients with antepartum ARDS were discharged undelivered, and all had pyelonephritis or *Varicella*. Cesarean section should be reserved for standard obstetrical indications.

Prognosis

Older series suggested a mortality rate as high as 50–60% for patients with ARDS. More recent reviews show rates of 39–44%. One study of 41 patients demonstrated a 24.4% mortality rate; this has been attributed to possible differences in patient population as well as improvements in critical care. Many affected patients developed pulmonary complications that included barotrauma and pneumothorax. Fortunately, survivors of ARDS usually do not demonstrate permanent long-term pulmonary dysfunction.

CARDIOPULMONARY RESUSCITATION DURING PREGNANCY

Many of the critical conditions discussed in this chapter can lead to cardiopulmonary arrest. Cardiopulmonary resuscitation should follow standard protocols, with some modifications for the pregnancy. It may be difficult to perform cardiac compressions due to a large uterus and engorged breasts. Compressions should not be performed in the supine position, as the gravid uterus may cause aortocaval compression, diminished venous return, and subsequent decreased cardiac output. Patients should be positioned with a left lateral tilt before compressions are applied. This can be accomplished using a moving table, a wedge, or with manual displacement of the uterus. Defibrillation and cardioversion been successfully used during pregnancy without disturbance of the fetal cardiac conduction system. It is important, however, to remove fetal monitors to prevent arcing. Finally, the decision to perform a perimortem cesarean section should be made rapidly, within 4–5 minutes of cardiac arrest. This extreme measure can maximize maternal survival by relieving aortocaval compression and increasing blood flow return back to the heart.

[Current OB/GYN > Chapter 61. Psychological Aspects of Obstetrics & Gynecology > Psychological Aspects of Gynecology >](#)

PSYCHOLOGICAL ASPECTS OF GYNECOLOGY: INTRODUCTION

Human sexual behavior and reproduction have long been influenced by culture, taboos, religion, and civil forces. For this reason, the psychological aspects of obstetrics and gynecology deserve special consideration. Recent changes in gynecologic practice and the growing number of female practitioners have greatly influenced women's care. This chapter addresses normal and pathologic psychological issues that are seen in the scope of obstetric and gynecologic practice.

Gynecologists care for women throughout their life cycle—from menarche through adolescence, young adulthood, pregnancy, menopause, and old age. Thus it is critical that they understand the psychosexual and physical development of women. The obstetrician and gynecologist will often fill the role of a general physician, surgeon, sexual counselor, educator, and confidant. Gynecologists must be sensitive to their own attitudes, values, prejudices, and personality style, as these tendencies will influence their practice and their patients' willingness to work collaboratively with them.

THE DOCTOR–PATIENT RELATIONSHIP IN GYNECOLOGY

Traditionally, doctors and patients related to each other in accordance with a model in which a compliant patient viewed the doctor as omnipotent. Today, many women reject this model and demand a more active role in making health care decisions. Health and disease-related information are widely available. Thus, patients are often better informed than they have been in the past. However, there are many sources of misinformation. The lay media can confuse patients by oversimplifying the data or jumping to conclusions. Pharmaceutical advertisements are often biased. A patient may arrive at a first visit with a physician having preconceived ideas about what her diagnosis is and how it should be treated. However, there are still many women who do not want to participate in decisions about health care and who view their physicians as an all-knowing protector. Although these beliefs may be flattering to the physician, unrealistic expectations often lead to anger and disappointment on the part of the patient.

The doctor–patient relationship is an essential part of the therapeutic process and can lead to healthy compliance with medical and surgical regimens. To achieve this relationship, it is essential to have some understanding of the personality style of each patient and her approach to thinking about her body and medical interventions. The collaborative model of doctor–patient interaction is usually most effective for both doctor and patient. The patient interview is the place to begin this collaboration and to evaluate the woman's personality.

The Patient Interview

The first task of any physician is to take the patient's history. The more comfortable the patient feels, the more personal and detailed information she will give. The clinician must use both direct and indirect methods in history taking. It is important to actively listen, noting not only the words, but also the affect and the nonverbal cues. Facial expressions, body posture, gestures, voice quality, and tears are examples. The physician also needs to learn why the patient is seeking help with her problem at this time. Did the patient recently undergo a hardship, did the condition worsen, or did she lose her ability to

cope with a preexisting problem?

It is most useful to start with open-ended questions, followed by more specific ones. For example, in interviewing a woman with pelvic pain, it is better to ask the open-ended question, "What is the pain like and what is it associated with?" than the close-ended question, "Does the pain hurt badly, and does it happen in the morning or at night?" Psychological symptoms, such as problems with sleep or eating, fatigue, libido, and anxiety, may relate to physical disorders. If open-ended questions are asked, the interviewer gleans a better understanding of all the factors that play a role in the patient's complaint.

Understanding a patient's social context can also shed light on the medical issues at hand. It may be difficult for the patient to bring up these topics. In these circumstances, it is often best to ask personal questions in a direct way that demonstrates that the interviewer is comfortable discussing the topic. For example, instead of assuming a patient is in a monogamous relationship, ask her if she has intimate sexual relations with men, women, or both. You will likely get to the core of the issue by using this technique when discussing personal topics.

Personality Style

The following personality styles are commonly seen across the scope of medical practice. These descriptions are rather extreme, but are useful outlines. The insightful physician will consider how each patient copes with illness and relate to her in a way that benefits that patient.

THE DEPENDENT PERSONALITY

These patients have a lack of self-confidence and require significant reassurance. This patient becomes increasingly dependent on the physician, calls frequently and often creates frustration. The physician needs to set limits, but with some concessions such as telling the patient she can call at specific times. Interviews can be limited in frequency and duration. The dependent patient can make the physician angry by venting hostility in an indirect way. Illness is seen as a threat of abandonment. Assuring her of continued care that has definite limits is helpful.

THE OBSESSIVE OR ANXIOUS PERSONALITY

These patients have an unusual need for control. They tend to employ the defense mechanisms of isolation and intellectualization. This patient seeks copious medical information and is particularly active in medical decision making. Illness is seen as a punishment for letting things get out of control. Her participation in the management of her illness will likely help.

THE HISTRIONIC OR DRAMATIC PERSONALITY

These patients are dramatic and attention seeking. They are often flirtatious and can be quite emotional. A caring physician with a firm professional manner is ideal for this patient. She needs support, but not overly detailed explanations.

BORDERLINE PERSONALITY DISORDER

This patient poses one of the most difficult personality types for physicians. Borderline patients suffer from an unstable self-image. As a result they have unstable moods and often alternate between kindness and volatility. They tend to identify some medical staff as "good" and others as "bad." They come across as unpredictable and manipulative. These patients possess deep loneliness and impulsivity. Not uncommonly, they self-mutilate or attempt suicide. Physicians often need to manage these patients in conjunction with a psychiatrist.

THE PARANOID PERSONALITY

This patient is suspicious, blaming, hypersensitive and is threatened by intimacy. A respectful distance is necessary to help this individual. Illness is viewed as an annihilating assault coming from outside the self. Helpful techniques include honest, simple explanations and assuring her that the medical team is there to

help her.

THE SCHIZOID PERSONALITY

This patient is remote, unsociable, and uninvolved. She may be very eccentric or have an unusual style of dress. These patients are often in denial of their illness and present late. Illness is viewed as a force that threatens to invade her privacy. It is important to screen for a more serious psychiatric illness, such as schizophrenia. A respect for privacy and distance is helpful.

PSYCHOLOGICAL ASPECTS OF SPECIFIC GYNECOLOGIC PROBLEMS

Acute Gynecologic Emergency

When urgent medical or surgical care is needed, the relationship with the patient changes to one that requires submission of the patient to the physician. In these cases the patient has likely never met the physician. This role may be one the physician is comfortable with, but that terrifies the patient. Once the emergency has passed, it is essential to help the patient gradually resume a role in her care.

Prolongation of the dominant role by the physician may easily lead to continued dependency after its justification has ceased. The patient recovering from surgery or a serious illness must not be suddenly abandoned to her own devices as long as she needs her doctor's help and support. Every effort should be made to hasten her return to full health without dependency on her doctor.

Emergent care for the sexual-assault survivor deserves special mention. In this circumstance, the care provider needs not only to be concerned with patient care, but also with obtaining important legal evidence. Many states require that at least the physician, a police representative, and a patient advocate be present during the interview and examination. It is essential to be familiar with your local government's guidelines and to take appropriate steps to ensure proper data collection. Obviously, sedatives and narcotic medications should only be used once the patient has given a full, recorded statement. Counseling services should be arranged.

Chronic Pelvic Pain

Chronic pelvic pain (CPP) is generally defined as pelvic pain that persists for at least 6 months. The pain cannot be limited to the dysmenorrhea, although an exacerbation of baseline pain during this time is consistent with the diagnosis. This is a diagnosis of exclusion and is made once another etiology cannot be identified. Between 3.8% and 14.7% of women suffer from this syndrome. In primary care practices, 39% of women complain of CPP. The differential diagnosis for CPP is broad. The most likely gynecologic causes of CPP are endometriosis, masses, and infection. Neoplasia and less-common diagnoses should be ruled out with imaging and biopsy when indicated. Other common causes of CPP are irritable bowel syndrome (up to 79%), urinary tract complaints, and musculoskeletal pain. CPP can be extremely frustrating for the patient and her physician, as a clear etiology cannot be identified. It is important to remember that there are at least three reasons why women complain of pain in the apparent absence of organic pelvic disease: (a) Disease processes are present but have not been detected; (b) pain may be associated with disorders that are not accompanied by objective evidence (migraine variant, neurologic problem, limited medical technology, chronic/episodic syndrome); and (c) complaints may be psychogenic or a manifestation of a somatization disorder.

The gynecologic work-up includes a careful history that allows the patient to explain the course of her symptoms. The timing of symptom onset and exacerbation should be noted. The severity of pain is best assessed by pain scales. Visual analogue scales, or a 0–10 scale, is useful in tracking pain fluctuation. Pretreatment assessments (like the one provided by the International Pelvic Pain Society) are often used in research to quantify pain and identify response to treatment. The nature and quality of the pain may give a clue to the source of the pain. Somatic pain (musculoskeletal, cutaneous) is sharp and usually

localized. Visceral pain (intraperitoneal, upper reproductive tract) is vague, aching, and difficult to isolate and describe. Obstetrical, surgical, menstrual, and sexual histories often give important clues to the etiology. The perception of pain can be influenced by several psychosocial variables. Examples include the anxiety that accompanies pain, childhood experiences with pain and punishment, the ability of an individual to control pain by cognitive and behavioral means, experiences with physical and sexual abuse, previous painful illnesses, the patient's current psychic state, and the patient's cultural expression of pain. These patients often have histories of childhood and adult sexual abuse. Patients with chronic pelvic pain are more often found to be depressed and suffer from substance abuse, sexual dysfunction and somatization disorders.

Women without a clear cause of their pain are often labeled as having psychiatric problems. In such cases, pain is seen as a result of emotional conflicts or a depression. Despite our limited understanding of the mechanism of pelvic pain, the syndrome has been included as a psychiatric diagnosis in the *Diagnostic and Statistical Manual of Mental Disorders, 4th edition (DSM-IV)*. This is a very controversial classification. The fact that CPP pain patients are more likely to suffer from psychiatric conditions leads many to suspect the conditions are part of one syndrome. This finding neither clarifies that they are part of one syndrome nor whether there is a causal relationship between the conditions. Sadly, patients with pain syndromes and depression are less likely to have their depression identified and treated. One should determine which organic and psychiatric disorders are present and treat distinct symptoms. Research suggests that depression and pain share neurotransmitters and biologic pathways that may shed light on how these conditions interact.

The management of chronic pain and somatization requires a complete evaluation of possible etiologies, psychological assessment (and treatment), and a multidisciplinary approach that incorporates specialists. Unnecessary surgery should be avoided, and psychological treatments along with suitable medications are helpful. Narcotics should be used as appropriate, usually in conjunction with the care of a pain specialist. Biofeedback, relaxation training, hypnosis, and psychotherapy can be helpful. Antidepressants have been used with good results. Advances in this field will come from research that integrates the biologic, psychological, and cultural approaches. A multidisciplinary approach appears to be the most effective in managing intractable pelvic pain syndromes.

Eating Disorders

Eating disorders are 10 times more likely to occur in women than men. The incidence of eating disorders is believed to have increased in recent years, although changing diagnostic criteria makes these conditions difficult to track. Anorexia, bulimia, and obesity are heterogeneous conditions with biologic, psychological, and social dimensions. For each patient being evaluated particular attention should be paid to history of the eating problem, weight history, physical examination, and family dynamics, including affective mental disturbances in the family, personality style, substance abuse, physical abuse, and cultural background. Life changes (ie, pregnancy, relationship trouble) can trigger recurrence of an eating disorder. Although these patients present to the OB/GYN, psychiatric consultation should be obtained.

ANOREXIA NERVOSA

Ninety-five percent of patients are female, and occurrence is rare in heterosexual males. Its prevalence is 0.13–1% in females 12–18 years old. Usually these patients are in their teens with the overwhelming majority being younger than age 30 years. Anorexia nervosa is a disorder characterized by refusal to maintain a body weight within 85% of ideal body weight for age and height. Firm control over one's diet distinguishes this disorder from the others. Generally, anorexia is seen in the cultural context of a society where food is abundant and thinness is desirable. The fact that minority women are more likely to develop an eating disorder the more assimilated they are into American society supports this assertion.

Anorexia is characterized by markedly decreased food intake, a preoccupation with a fear of becoming obese, a distorted body image, and often by amenorrhea for at least 3 consecutive menstrual cycles. The subtypes include restricting (food avoidance) and binge eating/purging. Although the weight loss is generally dramatic, the patient does not consider it concerning. Because these patients are secretive and in denial of their problem, experts suspect the incidence of anorexia is higher than reported. These patients often come to the attention of the gynecologist for evaluation of amenorrhea, infertility, or other endocrine disorders. Associated physiologic signs may include hypothermia, bradycardia, hypotension, edema, lanugo, and other metabolic changes. Not uncommonly, these patients develop osteopenia during the important years of bone deposition. Anorexics are 2.9 times more likely to suffer a fracture than controls.

Typically, anorexia nervosa presents in early adolescence or the early twenties. The course may be episodic or chronic: Approximately 40% of patients recover, 30% significantly improve, 20% remain ill, and death occurs in more than 5%. Family patterns demonstrate that these disorders are more prevalent in sisters and mothers of affected individuals. Other family members may have a history of major depression or bipolar affective disorder. The onset may or may not coincide with a stressful life event. The associated family model has included parental pressure for the child to be perfect (perceived), poor communication within the family, and a devalued mother role. Research does not clearly demonstrate that this is the case.

Management consists of referral to specialists trained in the treatment of this disorder, usually as a team with behavioral medicine specialists and nutritionists. Hospital treatment is indicated for severe cases. Inpatients should be managed by specialists, as they can develop complicated medical problems. The primary physician should remain involved throughout each phase of treatment to provide continuity of care. Better prognosis is associated with earlier age of onset and poor prognosis with premorbid obesity, bulimia, vomiting, and laxative abuse.

BULIMIA

The estimated incidence of bulimia nervosa is 1–1.5%. Bulimia is characterized by recurrent bouts of rapid consumption of large amounts of food in a short time. This behavior alternates with self-induced vomiting, use of laxatives and diuretics, dieting, fasting, and/or vigorous exercise. These behaviors are all intended to keep weight down. The subtypes include purging (eg, laxative, vomiting) and nonpurging type (fasting, excessive exercise). They are generally accompanied by depression, anxiety, lack of control over the eating, low self-esteem, and/or social isolation. Preoccupation with food, weight, and body shape are common. The diagnosis is made when there are at least 2 large binge-eating episodes per week for at least 3 months. The food eaten is usually high in calories and eaten secretly. The binge may be followed by abdominal pain, distention, and vomiting. The individual may be obese, thin, or of normal weight. Stress or eating itself may precipitate binges.

Many bulimics are depressed or are afflicted with other affective disorders. Alcohol or drug abuse is often associated with bulimia and often involves sedatives, amphetamines, and cocaine. A variety of personality types, including those with borderline personality disorders, develop this condition. Subjective complaints may include lethargy, impaired concentration, and abdominal pain. Dehydration and electrolyte disturbances (ie, hypokalemia, metabolic alkalosis, hypochloremia, and, rarely, metabolic acidosis) may result from fasting, diuretic use, and acute diarrhea. Arrhythmias may result from significant electrolyte disturbances. Other complications are gastric rupture, salivary gland swelling (usually the parotid), and dental problems including decalcification of teeth that result from frequent vomiting. The neuroendocrine abnormalities include blunted thyroid-stimulating hormone response to thyroid-releasing hormone (TRH) administration, increase in growth hormone following TRH or glucose

administration, and elevated basal serum prolactin. Menstrual dysfunction may be due to disturbed gonadotropin production.

An exact etiology is unknown, but associated factors include a history of traumatic events, especially separation or loss and a history of being overweight. The mild form of bulimia is fairly common among women in college (one study of college freshmen reported 4.5% of women and 0.4% of men). The course is chronic and intermittent over many years. The differential diagnosis must include schizophrenia, certain neurologic diseases such as central nervous system tumors, and epileptic equivalent seizures. A history of sexual assault is common. A recent survey of girls demonstrated that sexual assault survivors were three times more likely to binge and purge than girls who did not report a history of sexual abuse.

Eating Disorder (Not Otherwise Specified)

Between 3% and 5% of women between 15 and 30 have an unspecified eating disorder. They can have any of the complications that anorexics and bulimics have. They also need a complete evaluation to determine any precipitating causes or stressors along with a psychiatric consultation.

Binge Eating Disorder

Binge eating disorder (BED) is a new diagnosis that is characterized by rapid binge eating to the point of discomfort and self-disgust. It is identified in 3% of people in a community population, but up to 30% in obese patients in the weight-loss clinic population. Men are much more likely to have this condition than any other eating disorder.

For each of these conditions management and treatment begin with a very careful history of eating patterns, stressors, and screening for mental disorders, substance abuse and physical/sexual abuse. Behaviors to inquire about include binge eating and use of diuretics, laxatives, diet pills, and enemas. The next step is careful physical examination including a neurologic work-up, noting the state of hydration, teeth, salivary glands, and cardiac function. Minimal laboratory work should include plasma glucose, complete blood count, liver function tests, thyroid function, brain imaging (if needed), and an amenorrhea work-up if indicated. Hospitalization may be necessary for cardiac complications (heart failure, arrhythmia), severe electrolyte disturbances, seizures, gastrointestinal bleeding, and initiating feeding in severe anorexia. Psychological approaches are usually cognitive-behavioral therapy, group therapy, family counseling, and nutrition education. This requires continuity of care and a multidisciplinary approach. Drug treatment consists of antidepressants/antianxiety medications, anticonvulsants, and appetite suppressants.

Sleep Disorders

A national survey indicates that one-third of the U.S. population has some degree of sleep disturbance. Over the course of a woman's life she goes through different hormonal and physiologic phases that may affect sleep (ie, puberty, pregnancy, postpartum, menopause). Sleep disturbance is not only uncomfortable, but also associated with affective disorders. Complaints are frequently presented to gynecologists and may represent a minor problem or exist as part of a more serious physical or psychiatric disorder. Considerable diagnostic and treatment options are available.

Recent advances in the study of sleep have related sleep physiology and the stages of the sleep cycle. Stage 0 is wakefulness with closed eyes, high muscle tone, and some eye movement. Stages 1–4 are non-REM (rapid eye movement) sleep in humans and are characterized by specific encephalographic changes. REM, or "desynchronized," sleep is characterized by extreme hypotonia, rapid eye movements, blood pressure and heart rate variability, muscle twitches, and nocturnal penile tumescence. There is high dream recall if one awakens during REM sleep. Sleep cycles vary with age, sex, and numerous other influences. In an ordinary 8-hour period of sleep, a 25-year-old adult will go through 4–6 cycles, with the

average cycle taking 90 minutes with REM 15-minute periods.

Sleep and arousal problems have been classified into 4 groups. (a) The insomnias are disorders of initiating and maintaining sleep. They are a heterogeneous group associated with organic and psychiatric conditions. A history of the sleep–wakefulness pattern helps with diagnosis. A disturbance in falling asleep may be caused by anxiety or worry. Staying asleep or early morning awakening is often seen in depressive illness. Myoclonus or central apnea can disturb sleep. (b) Disorders of excessive somnolence can be caused by narcolepsy, obstructive airway syndrome, depression, substance abuse, and other conditions. (c) Disorders of the sleep–wake schedule are those in which there is a misalignment between the individual's usual sleep–wake cycle and the internal circadian rhythms (eg, jet lag). (d) Parasomnias are a group of clinical conditions that happen during sleep, sleep stages, and partial arousals. Examples include somnambulism (sleep walking) and asthma (which may get worse during sleep). They are manifestations of atypical central nervous system activation during sleep with discharge into skeletal muscle or into channels of autonomic activity.

Women have fluctuations in the quality and quantity of sleep that associate with their life phases. For example, sleep disturbance is reported in 16–42% of premenopausal, 39–47% of perimenopausal, and 35–60% of postmenopausal women. Of women in the third trimester of pregnancy, 66–97% suffer from insomnia. Very little is known about how the changing hormone environment affects sleep. For example mood changes, fetal movement, raised body temperature (luteal phase), caring for a newborn at night, hot flashes, and the stress that can accompany life changes are some of the main causes of the sleep disorders. Subjective and objective measures of sleep correlate poorly, making it difficult to study sleep.

Treatment of sleep problems requires an accurate diagnosis. After ruling out medical problems that contribute to sleep disturbances behavior modification (sleep hygiene) should be the next step in treatment. Sleep hygiene generally includes curtailing excess sleep; maintaining regular awake and bed times; regular exercise; maintaining a quiet sleep environment; avoiding hunger, caffeine, smoke, and alcohol. Relaxation techniques are also useful. Hypnotic drugs are among the most widely used drugs in the United States. The three most commonly used groups are the barbiturates, the benzodiazepines, and nonbarbiturate nonbenzodiazepines (eg, chloral hydrate, methaqualone). It is essential to be familiar with their pharmacology, action, potential for addiction or use for suicide, and teratogenicity before prescribing these drugs. Hormonal therapies have not been clearly shown to alleviate sleep disturbances. Insomnias that do not respond to treatment with relaxation techniques, sleep hygiene methods, and a short course of medication should be referred to a sleep specialist for diagnosis and treatment.

Premenstrual Syndrome and Premenstrual Dysphoric Disorder

Premenstrual syndrome and premenstrual dysphoric disorder are psychoneuroendocrine disorders that accompany the menstrual cycle. A complete discussion is found in Chapter 35.

PSYCHOLOGICAL ASPECTS OF GYNECOLOGIC SURGERY

Most people are afraid of the prospect of surgery. There are several sources of fear: the unknown, separation from family, forced dependency, and injury or death. It is not abnormal to have a recurrence of childhood fears. Patients often experience these as punishment or abandonment and may exhibit aggressive and controlling behaviors. Patients who have a clear understanding of why they are having surgery, the risks of surgery, appropriate expectations about outcome, motivation to be healthy, and a lack of psychiatric conditions cope best with the stress of the perioperative period.

Preoperative Preparation

Patients who are well prepared for surgery show less postoperative pain, use fewer pain medications, and have shorter hospital stays. Preparation means more than reassurance. It includes a careful description

of the indications for surgery and an explanation of the preferred surgical approach. A clear preoperative discussion about patient preferences and concerns may prevent a great deal of anxiety, miscommunication, and dissatisfaction after the procedure.

It is ideal to review these topics while obtaining informed consent. Informed consent occurs when the patient agrees to certain procedures after a complete discussion with the physician delineating the risks, benefits, and alternatives to the procedures. The process of obtaining consent allows the patient to make an informed decision about whether she understands and accepts the medical implications of the surgery. When the physician and patient sign the document, it serves as a legal statement of the patient's permission to proceed. Answering all of the patient's questions is a necessary component of informed consent. Patients often have strong feelings about their preferred surgical approach; for example, where the incision should be made. Such issues should be discussed and documented before the patient has received any sedating or antianxiety medications.

Because patients who are anxious do not assimilate information well, it is necessary to communicate effectively with the patient. Consideration of a patient's social context and personality type may help the physician navigate this communication successfully. It can be helpful to have a family member or friend assist the patient in asking questions and assimilating information. A representative of the professional staff or translation services (24-hour availability via telephone services) should be used for translation whenever possible. The physician cannot be sure that his or her words are being properly communicated by the patient's family or friends.

Postoperative Preparation

Patients need a clear explanation of their procedure and potential postoperative outcomes. They also need to know what to expect in the hospital and how to transition once home. Anticipatory guidance includes a brief orientation to hospital procedures, rehabilitation, medication instructions, follow-up arrangements, expectations about pain management and activity limitations. They should also understand how their body will change. For example, the possibility of hormone replacement after oophorectomy should be discussed preoperatively.

Hysterectomy: A Special Case

It is important to remember that hysterectomy has not been shown to cause psychopathology. New evidence actually suggests it improves quality of life in patients with appropriate indications for hysterectomy.

This being said, many women are afraid that removing their reproductive organs will divest them of their womanhood. For some this may be because they consider menstruation an important confirmation of their feminine identity. For others, the reproductive years represent sexuality and vitality. Of course cultural influences affect how one interprets the significance of hysterectomy. The prospect of having a hysterectomy may bring sadness to an infertile patient who held onto hope or to someone who places religious importance on childbearing. A woman who views the world from a more analytical or medical perspective may feel liberated after hysterectomy, knowing her symptoms will not return or that her risk of cancer has been lowered. A woman's adaptation to hysterectomy is related to her age, stage of development, personality, style of coping, ideas regarding fertility, sexuality, experiences with surgery, and the rapport she establishes with medical personnel.

Preoperatively, it is helpful to inquire about attitudes toward femininity, prior losses, attitudes and expectations about surgery, baseline sexual functioning, and past history of anxiety or depression. Patients at high risk for psychological difficulties after hysterectomy are those who seek surgery without a clear indication, suffer from chronic pelvic pain, have a psychiatric history, have conflicts over

sexuality/childbearing, have inappropriate levels of preoperative anxiety, and who do not want surgery. Of course, surgery should be avoided unless a clear indication exists and the patient desires surgery. In the operating room, patients may perceive comments made despite being under anesthesia. Care should be taken when conversing in the operating room, even when the patient is thought to be unconscious.

Postoperatively the surgeon may note that a previously high-functioning patient has developed delirium. This is a transient form of encephalopathy that is characterized by an alteration in consciousness, disorientation, perceptual abnormalities, and agitation or withdrawal. An excess of pain medications and electrolyte imbalances can also create an altered mental state. Other postoperative syndromes include tremors, postoperative depression or psychosis, and excessive pain.

Sexual function is a common concern for patients undergoing gynecologic surgery. It is important to address concerns directly and to reassure patients that sexual function is minimally altered by hysterectomy. The best predictor of sexual functioning postoperatively is a patient's level of sexual functioning preoperatively. Patients who had bothersome pelvic symptoms before hysterectomy often have improved sexual functioning. Patients complaining of a worse sexual functioning after hysterectomy should be encouraged to consider other contributing factors, such as changes in relationship, body image, age, medications, libido, and stress.

Gynecologic Oncology

The improved prognosis for many cancers makes quality of life an increasingly important issue in the management of malignancy. The physician who cares for patients with gynecologic cancer needs to be familiar with the most current technical data, and must be able to respond to the patient with empathy and understanding at all stages of the illness. A multidisciplinary team of physicians, social workers, nurses, research coordinators, and counselors may be required at times along the course of disease. Sometimes the patient's family members also need counseling. Suffering should be minimized and a lower threshold for prescribing medications and work-release may be appropriate.

With the diagnosis there is often a grief response characterized by shock, disbelief, anger, and fears of death, pain, losing a body part, and abandonment. This can occur even when the malignancy is treatable. A discussion of the treatment plan should cover expected functional losses, side effects of treatment, and effects on sexual functioning. Psychiatric disorders that may occur in the course of malignant disease (eg, organic brain syndromes, depressive syndromes, and anxiety syndromes) need recognition and treatment. When the physician suspects a patient is not going to survive her cancer, she should be informed and allowed to make the necessary adjustments in her and her family's life.

SEXUALITY IN GYNECOLOGIC PRACTICE

The most available resource for the woman with sexual difficulties is her gynecologist or family physician. Thus, a sexual history is part of every gynecologic history. The gynecologist should be familiar with the sexual response cycle, taking a sexual history, the ability to make diagnoses of the most common sexual disorders, the effects of organic problems and drugs on sexuality, and the kind of sexual therapies that are available. Most sexual problems are managed by education, corrections of organic problems, and reassurance. More serious psychological problems should be managed by gynecologists with added training in sexual therapy. Certain common dimensions of sexual identity warrant discussion for those providing primary sexual counseling. Sexuality and reproduction are central to one's identity as a male or female, whether or not one wants children. The sexual identity can be described along three major dimensions: gender identity, sexual orientation, and sexual intention.

Gender identity is the earliest aspect of sexual identity to form. Core gender identity is the sense one has of being male or female. It develops in the second year of life and is the result of (a) biologic factors

originating in fetal life and with the organization of the fetal brain; (b) sex assignment at birth by parents and medical staff; (c) parental attitudes; (d) conditioning and imprinting; and (e) development of body ego and body image, which comes in part from sensations from the genitals and other body parts. Masculinity and femininity are those behaviors that a person, parents, society, or the culture define as male or female. These may change from time to time. While many children show some evidence of gender confusion, 90% develop a core gender identity consistent with their biologic sex. Gender role is the sum of what one does that indicates to others the degree of maleness or femaleness. Gender identity continues to be influenced by identification with important adults as the child grows to adulthood.

Sexual orientation refers to the sex of the person in fantasy or reality that causes sexual arousal. Heterosexual individuals are sexually aroused by persons of the opposite sex, homosexual individuals by persons of the same sex, and bisexual individuals by persons of both sexes. There is increasing evidence of biologic contributions to sexual orientation, but further research is needed in this area.

Sexual intention refers to what a person wants to do with his or her sexual partner, eg, kissing, caressing, or intercourse. There are two dimensions: fantasy and real-life behavior. The usual intention is giving and receiving pleasure. Some examples of abnormal sexual intention related to aggression are sadism, exhibitionism, rape, and pedophilia.

The ability to function sexually in adulthood is formed at birth with the earliest parent–infant bonds. The loving care a person receives in infancy and childhood prepares him or her for intimate relationships in adult life.

Phases of the Sexual Response Cycle*

Stages in the sexual response cycle are described below. A more detailed description can be found in the classic work of Masters and Johnson, *Human Sexual Response*.

*This section contributed by Ralph Benson.

EXCITEMENT PHASE

In the woman, arousal in the excitement phase is associated with vaginal lubrication. This lubrication, previously thought to be of uterine or cervical origin, has been demonstrated by Masters and Johnson to be a "sweating reaction" of the vagina; it is probably a true transudation that continues throughout sexual excitement. Coalescence of droplets provides a lubricating film. Later in the response cycle, Bartholin's glands make a small contribution. The glans clitoridis swells, often to almost double its size, as a result of engorgement. The degree of enlargement is apparently unrelated either to the woman's capacity for sexual response or to her ability to achieve orgasm. The shaft of the clitoris also increases in diameter. Engorgement of the glans clitoridis and shaft occur most rapidly with direct manual stimulation of the glans clitoridis and the mons veneris.

Breast changes in the sexually aroused woman consist of nipple erection and, later in the excitement phase, an increase in total size of the breasts. The labia majora, which in a resting state meet in the midline of the vagina, gape slightly and may be displaced toward the clitoris. In nulliparous women, the outer labia may also thin out and flatten against the surrounding tissue. In multiparous women, they may extend and be engorged to an exaggerated degree. The labia minora also swell. The vagina, which is in a collapsed state normally, now begins to expand in the inner two-thirds of the vaginal canal, alternating with a tendency to relax. As excitement increases, progressive distention of the vagina occurs. The vaginal walls also "tent" in response to upward and backward posterior movement of the cervix and uterus, so that the inner portion of the vagina swells dramatically. Engorgement changes the color of the vaginal wall to dark purple and causes the vaginal rugae to become smooth.

In both men and women, erotic tension causes increased muscle tone accompanied by tachycardia and blood pressure elevation. A "sex flush" begins over the upper abdomen and later spreads over the breasts as a morbilliform rash; this occurs in approximately 75% of women and 25% of men before orgasm.

Early sexual arousal in the male, whether initiated by tactile, visual, or psychic stimuli, results in engorgement and erection of the penis and an increase in penile size and in the angle of protrusion from the body. In the late phase, the man experiences shortening of the spermatic cords and retraction of the testes. The scrotum thickens and is flattened against the body.

THE PLATEAU PHASE

The delineation between the excitement and the plateau phases is imprecise. Ordinarily, the penis is completely erect in the first phase. In the plateau phase, there is usually a slight increase in the diameter of the coronal ridge and, in some men, a deepening of color of the glans to reddish-purple. Progressive excitement may increase testicular size by approximately 50%; at this point, the man is very close to orgasm and approaches an inevitable stage. In the late plateau phase, respiratory rate, muscle tone, pulse rate, and blood pressure changes intensify, and muscle tension increases in the buttocks and anal sphincter. A few drops of fluid may appear in the male urethra from the bulbourethral (Cowper's) gland. Although this is not semen, it can contain large numbers of active sperm, which means that impregnation is possible before ejaculation.

In the woman, the "orgasmic platform" is formed by increased engorgement and swelling of the tissues of the outer third of the vagina, which reduces its interior diameter by 30–50%, tightening the grip on the penis and indicating that she is rapidly approaching orgasm. Elevation and ballooning of the inner two-thirds of the vagina increase, as does the size of the uterus (especially in multiparous women). The clitoris, now erect, rises from its position over the pubic bone, and retracts into its hood, shortening by approximately 50%. In this position, the clitoris continues to respond to either manual stimulation or penile thrusts. Engorgement of the labia continues until they take on a deep wine color, indicating that climax is imminent.

ORGASMIC PHASE

Orgasm consists of rhythmic contractions (1 per second) of pelvic musculature, uterine and vaginal contractions, and increased lubrication, all accompanied by pleasurable feelings. Because of the connection between brain and spinal cord centers for orgasm, learned inhibition can occur as with other reflexes. Orgasm is under voluntary control so there may be neural connections between the orgasm center and the voluntary motor perception areas of the brain. Occasionally, rhythmic contractions in the anal sphincter occur. The reflex centers are close to those for bowel and bladder control, so that injuries to the lower cord may affect all three functions.

In the man, the rhythmic contractions stimulate a discharge in the perineal floor, particularly in the bulbocavernosus muscle. Just before orgasm, increasing tension in the seminal vesicles causes the semen to empty into the bulbous urethra. Simultaneously, the prostate begins to contract, expelling fluid and distending the bulbous portion of the urethra as semen and prostatic fluid mingle. A series of rhythmic contractions at the bulb now eject the semen. A series of minor contractions persists in the urethra for several seconds, continuing even after complete expulsion of the semen.

Changes in pulse rate, blood pressure, and respiratory rate reach a peak and quickly dissipate, but for both the man and the woman the height of orgasm is marked by generalized muscle tension. The facial muscles tighten, and the muscles of the neck, extremities, abdomen, and buttocks are strongly contracted. There may be grasping movements by both partners, followed by clutching and even carpedal spasm. A fleeting period occurs in which each individual withdraws psychologically,

concentrating almost solely on genital sensation.

RESOLUTION PHASE

Muscle tension is released and engorgement subsides in the genitals and skin. The "sexual flush" slowly fades and perspiration may occur. In some women, perspiration appears uniformly over the entire body, whereas men frequently perspire on the soles and palms. In either case, the amount of perspiration is unrelated to the degree of muscular effort expended before or during orgasm.

In the woman, the clitoris promptly returns to its unstimulated state but will not reach normal size for 5–10 minutes. Relaxation of the orgasmic platform then occurs, and the diameter of the outer third of the vagina increases. Vaginal ballooning diminishes, the uterus shrinks, and the cervix descends into its normal position. The slight enlargement of the cervical canal is maintained. Total resolution time varies; as much as 30 minutes may elapse before the woman is in a truly unstimulated state.

In men, loss of erection occurs in two stages: In the first, most of the erectile volume is lost; the second is a refractory stage during which he is unable to be aroused again, and the remainder of the shrinkage occurs. In young men, the refractory period may be very short, but it lengthens with age. In most men it will last for several minutes; in others it may last for hours, or even days. Women are generally capable of multiple orgasms.

Sexual History Taking

A sexual history should be part of every gynecologic examination. This history provides information that may relate to a patient's medical problem, identifies high-risk sexual practices, provides an opportunity to discuss contraception, gives insight into a patient's domestic situation, and provides a forum for the patient to bring up her personal concerns. Sexual dysfunction is very common, and patients usually appreciate suitable inquiry.

A physician's own anxiety may get in the way of adequate questioning. The sexual history belongs in the review of systems. Language should begin with biologic terms and then move to simpler terms. General questions precede more specific ones. The physician should maintain a positive, empathetic, and professional manner with a patient and ask questions in a logical sequence. The sexual history can cover (a) areas of the sexual response cycle: sexual desire, sexual arousal (erection in males, lubrication in females), orgasm, and satisfaction; (b) concerns about gender identity and sexual orientation; (c) classification of problems: onset, course, best and worst functioning, frequency of sexual behaviors, and relationship of sexual behaviors to other life circumstances (ie, relationships, losses, financial problems, illness, medication, surgery, family difficulties, infertility, and contraception).

Sexual history taking should include the following information:

1. Identifying data
 - a. Patient: age, sex, number of pregnancies and marriages
 - b. Parents and family
 - c. Partner
 - d. Children
2. Childhood sexuality

a. Family and religious attitudes toward sex

b. Sexual learning

c. Childhood sexual activity

d. Childhood sexual abuse or incest

3. Adolescence

a. Preparation for menses

b. Menarche

c. Masturbation

d. Consent to sexual activity

e. Intercourse

f. Gender issues

4. Adolescence and adulthood

a. Sexual fantasies

b. Sexual orientation (heterosexual, homosexual)

c. Partner choice

d. Sexual activity

e. Sexual deviations

f. Sexual orientation

g. Sexual function and dysfunction

h. Contraception

5. Recent life changes

- a. Losses
- b. Moves
- c. Pregnancy
- d. Other

Validated questionnaires and scales are available for screening and determining a patient's baseline and posttreatment level of functioning (eg, pain or sexual function).

Sexual Dysfunction

In the past, women had been so inhibited by their culture that some had lived through courtship, marriage, childbearing, and menopause without ever experiencing or feeling comfortable with sexual arousal, orgasm, or a sense of sexual freedom. Although more women are comfortable exploring their sexual side, sexual dysfunction does persist. Considerable advances in the knowledge of female sexuality have occurred in the past decade. The major contributions of researchers William Masters and Virginia Johnson to the physiology and psychology of sexuality are well recognized. Sexual dysfunction includes psychogenic and organic causes of decreased sexual desire, arousal, orgasm, and pain causing personal distress. Table 61–1 lists the most common types of female sexual dysfunction. When evaluating these patients, it is important to determine if the problem is lifelong or acquired; generalized or situational; and organic, psychogenic, mixed, or unknown. It is important to remember that many drugs contribute to sexual dysfunction, such as antihypertensives, gastrointestinal agents, chemotherapy, anticonvulsants, antipsychotic drugs, antidepressants, sedatives, anxiolytics, cannabis, alcohol, and heroin.

Table 61–1. Classification of Female Sexual Dysfunctions.

Component	Symptom	Term
Desire	Decreased interest in sex	Inhibited sexual desire (ISD)
Excitement or arousal	Decreased lubrication	Excitement-phase dysfunction
Orgasm	No orgasm	Orgasmic dysfunction
Satisfaction	Decreased satisfaction	—
Other	Pain with intercourse	Dyspareunia
	Spasm of circum-vaginal musculature	Vaginismus
	Fear of sex; fear of penetration	Sexual phobias
		Sexual panic

All: Primary or secondary, situational or absolute.

INHIBITED SEXUAL DESIRE

This condition may be lifelong (primary) or occur after a period of normal functioning (secondary). Its presence does not necessarily imply a lack of ability to respond physiologically. Many women with primary inhibited sexual desire come from very sexually repressive backgrounds, have been sexually traumatized in childhood or adolescence, or have a poor partner relationship. They may avoid relationships in order to avoid sex. Treatment consists of behavioral and psychological methods.

Secondary inhibited sexual desire often develops after problems with a partner, physical or emotional traumas, physical illnesses, drug or alcohol abuse, surgery, or psychological depression. A careful history will usually reveal recent life changes, losses, and medical or drug problems. Other contributions to difficulties in sexual desire come from concern about pregnancy, partners with very different sexual appetites, and changes in body image. A dramatic change in libido should be evaluated by a physician.

Sexual phobias occur in many women who then develop patterns of avoidance and are thought to have low desire. The thought of sex arouses panic and anxiety. There may be avoidance of any mention of sex and social isolation. Treatment consists of education, support, psychotherapy, medications, and behavioral desensitization.

AROUSAL DISORDERS

Arousal disorder represents an inability to achieve or maintain satisfactory sexual excitement. They are often caused by vasomotor phenomena or inadequate lubrication. Nitric oxide contributes to the engorgement of the genitals and many medical and herbal therapies aim to increase local production of nitric oxide. Any process that contributes to small vessel disease or neuropathy also impedes the arousal response.

ORGASMIC DISORDER

Orgasmic problems are very common. Approximately 8–10% of adult women in the United States have never been orgasmic; another 10% may achieve orgasm with fantasy alone. Most women fall somewhere in between these two extremes, demonstrating a variety of responses. Women with primary orgasmic problems have never experienced orgasm in any situation, even after prolonged and effective sexual stimulation. Those with secondary orgasmic problems have had periods of normal functioning. In both primary and secondary cases, the women may lubricate easily, enjoy lovemaking, and feel satisfaction. Somehow, they get "stuck" in the plateau phase of the sexual-response cycle. Some women are not sure if they have reached orgasm; others regularly "fake" orgasm in order to please their partner or live out their own fantasies. A number of women are orgasmic with clitoral stimulation but not during intercourse; this is a normal variant. For others, the presence of the penis or other erotic stimulus is necessary for orgasm.

There are innumerable orgasmic variations. Theories that labeled vaginal orgasms mature and clitoral orgasms immature have been laid to rest. The goal of any treatment is to help the individual achieve her first orgasm, often without a partner present. Although most women are physiologically capable of having an orgasm, the focus that our culture places on the achievement of orgasm may actually inhibit a woman's ability to reach orgasm. Pressure may also come from partners who insist that a woman's lack of orgasm is because of her partner's failure.

Treatment is aimed at enhancing sensory stimulation and extinguishing the woman's involuntary inhibitions. The therapist's first task is to make certain that the woman understands that sufficient clitoral stimulation is required and is able to communicate her needs to her partner. She needs to know that it is normal to be sexual. Sometimes these educational techniques alone are enough to overcome the problem. Barbach's book *For Yourself* has been very helpful to many women.

A woman with primary orgasmic dysfunction needs to learn what it feels like to have an orgasm. She may have to disregard her obsessive thoughts and distractions and focus on the erotic thoughts and premonitory feelings that directly precede orgasm. The use of fantasy can be very helpful. Women with very religious backgrounds may find the idea of erotic fantasy (ie, thinking of other partners and being overcome by a loving partner) more guilt-provoking than sex itself. Self-stimulation is often recommended as a means of learning what feels good and helps the woman become sexually aroused. The long-standing prohibition against masturbation in her value system may be difficult to overcome.

She may prefer to masturbate in private, rather than with a partner. Some women have marked success with a vibrator, at first alone and then possibly with the partner. In addition to mastering the physical aspects of achieving orgasm, women need to address their fears. Many patients find it helpful to join a women's discussion group. Besides discussing educational issues, members are assigned specific sexual tasks to do at home alone. Tasks are performed in privacy and responses are later shared with the group members. They may also be able to share fantasies and give one another support.

Transferring orgasmic achievement to a partner situation is the final step in most treatment situations. Heterosexual women are encouraged to heighten arousal before penetration. They learn the clitoris may be stimulated by indirect friction of the hood being pulled back and forth over this organ, eg, during penile thrusting. Each woman needs to learn the most effective means of increasing her own pleasure, eg, active thrusting and use of pelvic and thigh musculature, avoidance of distracting thoughts, and free use of erotic and exciting fantasies. When there is a beloved, trusted partner, the prognosis is good.

DYSPAREUNIA

Pain during sexual intercourse can be especially distressing. After the pain has subsided the memory of pain may persist and interfere with pleasure. Some women with no background of trauma or major inhibitions may assume that sex will be painful because they associate menstruation and childbirth with pain. Inadequate lubrication (45% of women) is one of the main sources of dyspareunia. Low estrogen states, such as the postpartum and menopausal stages, is often to blame. Luckily, estrogen replacement (transdermal, oral, vaginal) is usually very helpful. A careful history and physical examination are essential. Table 61–2 lists the physical reasons for dyspareunia. Management consists of treating the specific problem.

Table 61–2. Some Physical Reasons for Dyspareunia.

Vaginal opening
Hymen—rare
Tender episiotomy scar
Aging—with decreased elasticity
Labia—Bartholin's gland abscess
Other lesions
Clitoris
Irritation
Infections
Vagina
Infections
Sensitivity reactions
Atrophic reactions
Decreased lubrication
Uterus, uterine tubes, ovaries

Endometriosis
Pelvic inflammatory disease
Ectopic pregnancy
Numerous others

VAGINISMUS

Vaginismus is the painful, involuntary reflex spasm of the pubococcygeal muscles that occurs in anticipation of vaginal penetration. It occurs most often in young women. Some patients may have been subjected to rape or incest as children or adults. Severe pain secondary to trauma, surgical procedures, or medical disorders in the vaginal area may sometimes cause the problem. Insufficient lubrication from lack of arousal or sexual phobias may also cause pain with intercourse and vaginismus.

Vaginismus must be diagnosed by history and physical examination. Gynecologists often institute a program of gradual vaginal dilatation using dilators or the patient or her partner's finger. Not all women will respond to this prescription. Some may have more serious problems that require psychotherapy. It is not unusual for a woman who has overcome her difficulty to find that her partner has developed erectile problems. This finding supports the belief that sexual problems are rarely limited to one partner.

Male Sexual Dysfunction

The term impotence used to refer to most male performance problems. Today, the word has an imprecise meaning as there has been a great increase in knowledge about sexual dysfunction and classification based on the physiology of the sexual response cycle (Table 61–3). The term impotence usually refers to erectile problems or the inability to sustain an erection for the time necessary for a desired sexual act. Erectile problems are common and increase with age.

Table 61–3. Classification of Male Sexual Dysfunctions.

Component	Symptom	Term
Desire	Decreased interest in sex	Inhibited sexual desire (ISD)
Arousal of excitement	Difficulty with erection	"Impotence," erectile difficulty
Orgasm	No ejaculation	Premature ejaculation, inhibited orgasm, retrograde ejaculation
	No emission	
Satisfaction	Decreased satisfaction	—

All: primary or secondary, situational or absolute.

Male sexual dysfunctions have been classified on the basis of an understanding of the sexual response cycle. The classification includes (a) problems of desire—diminished or excessive; (b) problems with arousal, ie, erectile difficulties; and (c) problems with orgasm—premature ejaculation, inhibited orgasm, or retrograde ejaculation. These conditions may be caused by psychogenic, organic, or mixed psychogenic and organic factors. Performance anxiety leads to "spectatoring" in which a person becomes preoccupied in watching his or her own sexual responses. They may be primary (present all of one's life) or secondary (having developed after a period of normal functioning). The history should focus on the

stage of life of the man, the quality of his sexual desire, the role of his partner, and significance of early and past life experiences. Organic contributions are more common than was previously thought and are related to illness, surgery, medication, drugs, alcohol, vascular disorders, and neuropathies.

Psychological causes include performance anxiety, fear of women and intimacy, relationship problems, and depression or other mental illnesses. The purely psychogenic dysfunctions show more variability in erectile responses and are associated with normal nocturnal tumescence studies. An evaluation by a urologist knowledgeable about sexual function is often indicated.

Treatment is based on etiology. Organic causes need treatment if possible. The psychogenic forms of dysfunction are best managed by behavioral treatment approaches. Partners are seen together and their relationship helped with improved communication as well as special techniques for specific problems.

Sexual Activity with Aging

Generally, the sexual response diminishes with age. Older women may have less sexual desire, with fewer sexual fantasies and a slower and lessened lubrication response to arousal. The vaginal walls are thinner and less pliable. Orgasm may be less intense, with weaker muscle contractions, and may be uncomfortable. Atrophic skin changes and altered peripheral nerve endings may diminish sensory perceptions. The gynecologist can help the aging couple by educating them about normal changes and alternative techniques. Estrogen and progesterone replacement (when indicated) may diminish vaginal discomfort. Estrogen and testosterone therapy may increase a woman's libido.

Men show decreased sexual activity with aging. By age 60 years men have about 1 erection a week. Sexual desire may diminish and erections take longer, require more stimulation, and are less firm. Ejaculation takes longer, with the feeling of ejaculatory inevitability less pronounced. There is less ejaculate, and the refractory period is longer.

Despite these normal changes with aging, the capacity for sexual activity and enjoyment persists. Many couples, freed from the worries of pregnancy, feel more able than ever to have the pleasure of an active sex life. Noncoital sexual activity may be a very satisfying form of intimacy and pleasure for some couples. However, 30–78% of 60-year-olds are sexually active. Never make an assumption regarding a patient's sexual activity.

PSYCHOLOGICAL ASPECTS OF OBSTETRICS: INTRODUCTION

A woman's psychology cannot be understood without considering the stage she is in the course of her reproductive life. Pregnancy affects nearly all aspects of her life. Her body, family, relationships, job, financial status, and life plans are all impacted by pregnancy. Changes in our modern social structure also influence psychological aspects of pregnancy. Many women now work outside the home, are single or divorced, or are having first babies in the teenage years or after age 35 years. Women have more knowledge about their bodies, and most want to participate in important decisions regarding fertility, pregnancy, delivery, and infant care. Many men want a greater part in sharing their partner's pregnancy. Finally, the legal climate has greatly affected medical practice. These alterations significantly influence the practice of obstetrics and gynecology. Indeed, the clinician is faced with new challenges and stresses in caring for women from diverse ethnic, economic, and social backgrounds.

Good obstetric and gynecologic care requires the consideration of each woman as an individual. To establish an effective working alliance with women who seek treatment, the clinician must not only be knowledgeable in medicine but also be a good observer and an able communicator. With a biopsychosocial approach, the clinician sees a person and not a disease. Objectivity, compassion, and a nonbiased approach are essential principles that foster appropriate care. Often a multidisciplinary

approach is useful in evaluating and managing patients when psychological issues are intertwined with their medical problems. This involves employing physicians along with nurses, social workers, and psychiatrists or psychologists in the process of evaluation and treatment.

This section presents an overview of the important normal and abnormal psychological aspects of pregnancy and the puerperium, and describes some of the syndromes and clinical situations that tend to affect female patients. It is important to remember that many women only see physicians during their pregnancies. They may lack insurance, time, or interest, and may not seek medical care outside of pregnancy. Every effort should be made to screen for medical, social, and psychiatric problems that need attention after pregnancy.

MOTIVATIONS FOR PREGNANCY

Pregnancy may be a welcomed and fulfilling experience for many women, but not for all. Motivations for pregnancy are varied and complex, and only some of them are conscious. The desire for a pregnancy is not always the same as the wish for a child. For example, a pregnancy may be wanted to confirm one's sexual identity or to give proof of one's reproductive integrity and capability. Desire for a pregnancy may also be a response to loss or feelings of loneliness. A woman may have a child so that she will always have someone to love who will love her in return. She may wish to preserve a relationship with a partner or she may be responding to family or cultural pressures to have a baby. In adolescents, peer pressure, rebellion against family, and feelings of depression are frequent motivations for pregnancy. Toward the end of their reproductive years, women may feel pressured to conceive before their personal and professional lives are ready to incorporate a child. Many of these feelings also exist in men. In some cultures, children represent immortality for parents, and it is natural as they grow older for many people to hope that some part of them will live on in future generations. Regardless of the multifactorial forces that play a role in women's reproductive choices, many women face similar stresses as the stages of pregnancy unfold.

Pregnancy as a Developmental Transition

Pregnancy is a major developmental step in the lives of women, often providing fulfillment of deep and powerful wishes that allow creativity, self-realization, and an opportunity for new growth. Although pregnancy may bring a sense of joy and well-being, it is also a stressful experience. Conflicts may arise. How a woman responds to pregnancy is related to her early childhood experiences, coping mechanisms, personality style, life situation, emotional supports, and physical problems.

The father-to-be is also presented with challenges and conflicts. Men may have unusual symptoms during their partner's pregnancy and visit physicians more often with complaints reflecting their own anxieties and concerns about their new role. Infidelity often manifests when the female partner is pregnant. Men may envy their partner's new condition, have conflicts with sexuality and pregnancy, or may feel threatened by the baby's potential to replace them as the mother's focus of attention.

Although prenatal classes, friendships, and office visits are useful ways for patients to learn about the process of pregnancy and alleviate fears, professional consultation may be necessary. With a full understanding of the psychological aspects of pregnancy, an insightful physician will be able to identify these issues and help a patient navigate through this developmental stage.

Normal Psychological Processes during Pregnancy and the Puerperium

The basic developmental and psychological tasks of pregnancy vary with the stage of pregnancy. During the first trimester, a woman tends to incorporate the fetus as an integral part of her body and self. Ultrasonography has led to earlier maternal and paternal bonding. In the second trimester, with recognition of fetal movement, it is necessary to perceive the fetus as a separate entity and to begin to

visualize the fetus as a baby with needs of its own. In the third trimester and postpartum, the patient comes to see herself as a mother and begins to establish a nurturing relationship with the infant. She may have to resolve some lingering conflicts with her own parents. Her relationship with her partner may also change for better or worse.

FIRST TRIMESTER

The diagnosis of a wanted pregnancy is usually accompanied by a sense of excitement and anxiety. Even the most wanted pregnancy may cause ambivalence on the part of both parents because of the recognized major life transition. An unplanned pregnancy is not necessarily unwanted and may be readily accepted. However, the woman and her partner need time to process their feelings and thoughts. If a termination is being considered, counseling should begin as soon as possible and without ambivalence on the part of the professional staff. Such counseling should allow the woman, and her partner if possible, to understand the implications of each of their possible choices and to weigh the risks, benefits, and alternatives before making a decision. If a physician is unable to provide an unbiased approach to counseling, the patient should be referred for appropriate counseling.

The first trimester, with its attendant fatigue, breast tenderness, nausea, and urinary frequency, is often accompanied by an increased preoccupation with self and with the growth of the fetus. There may be a sense of fulfillment and well-being, but emotions may be labile. Sexual interest may decline, while a desire for affection may increase. Concern about weight gain may manifest. Apprehension concerning miscarriage, the baby's health, and changing roles is common. Interestingly, even the most educated individuals may harbor superstitious beliefs that serve to help patients understand or feel control over the process of pregnancy.

SECOND TRIMESTER

During the second trimester, there is an increased sense of well-being and the resumption of outside interests. Fetal movement, commencing at approximately 16–18 weeks, often results in a greater sense of reality about the pregnancy. The fetus is perceived as a separate entity, and the parents fantasize about how the baby will look. The mother may experience increased feelings of dependency; sexual desire varies greatly, and changes in body image may be distressing.

THIRD TRIMESTER

During the latter part of pregnancy, fear or anxiety about labor and delivery may increase. Concerns arise about pain, injury, and the baby's health; about being a responsive mother; and about how relationships may be changed. Sleep is often disturbed, and somatic preoccupations may increase.

Childbirth education is invaluable. Ideally, the woman will be in a setting where she and her partner feel free to ask questions, regardless of how inconsequential she may think they are. Questions to the mother-to-be should be open-ended, not "yes" or "no" questions. For example, "What worries or concerns are you having?" is far more likely to evoke a meaningful response than "Is everything going well?" In high-risk pregnancies, a patient should have realistic expectations about her options and their implications before entering the labor and delivery floor.

There is an increasingly high parental expectation that modern obstetric technology will prevent anything untoward from disrupting their expectation of a positive birth experience. Because patients think of childbirth as a natural process, patients often have a limited understanding of the inherent dangers involved. For these reasons it is essential to obtain informed consent before performing procedures. Obtaining informed consent not only offers an opportunity for physicians to explain all of the risks, benefits, and alternatives to procedures, but it also allows patients to discuss their concerns and make their preferences clear. It is important to respect a patient's wishes and incorporate her desired approach whenever possible. Good communication is essential for an informed exchange. Patience in listening is an

invaluable aid to lessening patient anxiety and fear and improving the chance of successful communication.

LABOR AND DELIVERY

Each woman has a different experience on labor and delivery. The professional support team's goals are to enhance the health and safety of mother and infant while fostering a fulfilling experience. The emphasis today is on active family involvement in the birth experience. Women differ in their interest in obtaining medical information and even in making decisions about labor or pain management. Fear and unfamiliarity can increase tension and pain. Generally, fear can be minimized by educating patients about what to expect. Childbirth education classes, relaxation techniques, knowledge of both usual and unusual obstetric procedures, and familiarity with hospital facilities and delivery rooms can alleviate some fear. Some difficulties arise when a woman does not fulfill her own expectations concerning birth options and delivery methods. For example, she may feel like a failure if she requires anesthesia or surgical intervention during labor and delivery. Prospective discussion of these issues may prevent the patient from placing value judgments on treatment options. It is essential to remind patients that the ultimate goal is having a healthy baby and a healthy mother.

The presence during the labor of the partner, a close friend, or a family member offers invaluable support to the mother. Even having a doula (professional labor coach) improves a woman's birth experience and is associated with decreased epidural use. It is important to remember that each person has a different pain tolerance level. The perception of pain can be influenced by fear, past experiences, personality, style of expression, and cultural factors. The reassuring presence of a labor companion and childbirth preparation classes can help the mother handle the pain of labor and delivery.

The patient's attitude during pregnancy may *not* be a good predictor of her emotional state in labor. Some women report that the loss of unity (the "oneness" with the child) is a stressor that saddens them. Fears exist about death, bodily injury, loss of adequacy or control, and, especially, about exposing bodily functions. Other women feel the pressure of the importance of their labor for their family. Often family members insist on being present at the delivery and are convinced that the patient is comforted by their presence. This may not be the case. Care givers should ask the patient if she prefers privacy in labor. It is appropriate for the medical professional to request that guests vacate the labor room, as the patient is often uncomfortable doing so.

Although the safety of mother and infant must be the first concern, hospitals should strive to provide a more homelike and less institutional atmosphere for the birthing experience. The number of home births in the United States remains low. The major concern is that there may be complications that require hospital-level care. One-third of infants requiring immediate intensive care after home deliveries have been products of normal pregnancies. Electronic fetal monitoring during labor is now commonly employed. Some patients find this practice intrusive, whereas others find it reassuring. Women who have experienced prior fetal loss are more accepting of its presence and find it reduces their anxiety. However, highly technical equipment does not eliminate the possibility of complications, nor is it a replacement for human skill. Patients may need to be reminded that though birth is a beautiful process, it can be a dangerous process.

PUERPERIUM

Attachment between mother and infant begins long before birth. The term bonding refers to a sensitive period after birth, during which interactions between mother and infant facilitate a powerful connection. The attachment direction is from mother to infant, making her a more effective parent. Early visual and physical contact between mother and baby facilitates the attachment. Attachment behaviors include fondling, kissing, cuddling, breastfeeding, and gazing—practices that maintain contact between mother

and infant. Factors that can interfere with early bonding include lack of instinctual response, psychological problems, inadequate preparation, unrealistic scheduling, physical illness in mother or baby, and hospital practices that separate mother and infant. To facilitate early bonding, sedation and separation should be minimal. Separation may have physical, biologic, and emotional consequences. However, a mother should not believe she will be a failure because something has interfered with her earliest contact with her infant. There is evidence that later bonding is also successful.

Bonding is especially important for women and infants who may have attachment problems. Some of these high-risk individuals are mothers who are very young, ill, or ambivalent about pregnancy, or who have suffered child abuse, have relational difficulties with their partner, or have a psychiatric disorder. Intervention includes recognition of the problem and referral to an appropriately trained mental health professional or support services.

The father's presence in the labor and delivery room contributes to earlier father–infant bonding, but fathers must be prepared for attending the delivery and should have a role in it (eg, coaching the mother's efforts). Whether the father will be present when complications occur or when operative delivery is required should be discussed in advance.

TRANSITION TO MOTHERHOOD

Mothering has instinctual roots, but it is largely a learned behavior. A mother's early experiences with a loving caregiver in her own infancy strengthen her capacity for mothering. Mothers of young infants in our culture are often isolated from family and friends, which makes the early days even more difficult. During this stressful time, the new mother needs supportive individuals in her environment. It is helpful if the professional staff knows about unusual home circumstances. Indeed, an evaluation of this environment should be part of discharge planning. Will this new mother be alone or with numerous relatives? Are there religious or cultural practices that will interfere with sexuality, reproduction, nursing, or motherhood? Will this woman be returning to work? If so, when? Finally, have her personality and coping ability undergone abrupt changes?

Breastfeeding has many advantages, but once a woman decides to bottle-feed her decision should be supported.

It is helpful for a woman to review her labor and delivery experience with her physician. She just completed one of life's greatest challenges and may need a forum to process her feelings. Such communication may be encouraged by asking the woman, "How do you feel about your labor and delivery?" Often patients have expectations for the perfect labor and may not realize that some procedures are normal. Clarification can put a patient at ease.

Sources of Stress in Pregnancy and the Puerperium

Endocrinal, psychological, and body changes contribute to making pregnancy and the puerperium times of stress. The confirmation of pregnancy may be thrilling for some but devastating for others. Indeed, some degree of ambivalence is probably the usual response. Anticipatory guidance can assist the new mother in navigating the coming challenges.

Women with preexisting health problems may be concerned about withstanding the physical demands. Most healthy women have some physical distress from the discomforts of abdominal enlargement, nausea, heartburn, musculoskeletal pain, and urinary frequency. Most women also experience psychological distress from worries about body image, genetic problems, and role changes, as well as the effect of the pregnancy on her partner, career, education plans, finances, or her ability to be a mother. A worry often not voiced, especially by a primigravida, is "Can I do this?"

Interpersonal relationships with the patient's partner, mother, coworkers, and friends change during and after the pregnancy. Her partner's sexual satisfaction may decline during pregnancy. Women who are sexually responsive are more likely to enjoy sex during pregnancy. Pregnancy is a public statement of a woman's sexual activity, which may be a source of pride or embarrassment.

Although anxiety, emotional lability, and worries are normal during this time, the ability to cope depends on each woman's life experiences, personality style, social supports, and the care and technical expertise of the obstetric staff.

DENIAL OF PREGNANCY

Good prenatal care improves pregnancy outcome. Early recognition of pregnancy by a woman and her family leads her to seek prenatal health care, take extra care of herself, eat well, and get sufficient rest. Denial of pregnancy may interfere with the patient obtaining proper care. The woman most prone to denial of pregnancy may be psychotic, have borderline personality, or be from an extremely rigid background. The denial is usually an unconscious process in which the individual keeps the unpleasant reality of an unwanted pregnancy out of her awareness. She is often joined in this negativity by family and, on rare occasions, by physicians. She may go through an entire pregnancy forgetting missed periods, and unaware of breast changes, abdominal enlargement, or fetal movements. She may present in the emergency room in labor or deliver the infant at home. With the birth, a psychotic reaction may occur. These neonates are at higher risk for injury or death. Obviously, these women need extra support in the postnatal period and, if identified during the course of pregnancy, may benefit from psychological assistance.

SEXUALITY

There are many variations in sexual functioning during pregnancy and the puerperium. In general, women note a decrease of sexual interest during the first trimester, which is related to fatigue, nausea, and a feeling of turning inward. Women without a history of miscarriage, genital bleeding, or dyspareunia need not fear that intercourse will harm the fetus. In the second trimester there is often an increased interest and desire for sexual activity. Many women have an increased wish to be held or to masturbate. Some become orgasmic for the first time, possibly because of increased pelvic vasocongestion.

In the third trimester, sexual interest and performance are even more variable. The woman may feel awkward and have increased fears of harming the fetus. If there are no obstetric complications or physical discomfort, intercourse is not contraindicated; there is no evidence that intercourse precipitates premature labor, although orgasm does cause uterine contractions. Some men lose their sexual interest during their partner's pregnancy, or they fear harming the fetus. Noncoital techniques can be satisfying to the couple. Couples should be told that oral-genital sex must not include air blown into the vagina as this practice may cause an air embolism, which is potentially fatal to mother and fetus.

Sexual desire postpartum may not return for many weeks or months. This may be a consequence of new interest in the baby, fatigue, depression, hormonal status, pain, or concerns about body image. Breastfeeding may alter sexual feelings in the new mother or her partner. Fathers may feel excluded. The obstetrician can be helpful to a couple by discussing changes in sexuality with them.

VOMITING IN PREGNANCY

Vomiting in pregnancy can have several causes: the same as those seen in the nonpregnant state (eg, viral, dietary, drug reactions); hormonal changes in the first trimester (which affect approximately 80% of pregnant women); preeclampsia, liver disease, or other obstetric complication; or hyperemesis gravidarum (pernicious vomiting of pregnancy).

Hyperemesis gravidarum is a severe form of nausea that may occur at any time during pregnancy. The

woman may become severely dehydrated, lose weight, and have metabolic disturbances and electrolyte imbalances. The incidence in the United States is 1 in 1000 pregnancies. Biologic, psychological, and social etiologies have been suggested for hyperemesis gravidarum. Disturbances in the endocrine, metabolic, or immune system likely play a role. There is some support for an association with multiple birth and past pregnancy loss. Treatment may require rehydration, hospitalization, and correction of electrolyte imbalance. Antiemetics are the most effective treatment. In fact, hyperemesis gravidarum is one of the only approved indications for droperidol. Ginger, steroids, antihistamines, vitamin B₆ (pyridoxine), and acupuncture may be helpful. It is important to review the teratogen risk before prescribing medications in pregnancy.

At times this condition may represent a somatization disorder in which dysphoric feelings or psychic conflicts are expressed via physical symptoms. There is often a history of early life experience colored by abdominal pain and nausea. The condition is not related to any one psychiatric diagnosis, although more severe psychiatric illness may be present. Social stress may contribute to its severity. Many practitioners believe that the most effective aspect of hospitalization is actually isolating the patient from the stressors of her life at home. A good response has been noted with hypnosis and relaxation techniques. Identification of stress in the individual's life and help with stress reduction are often useful.

SLEEP IN PREGNANCY AND THE PUERPERIUM

Sleep disturbances during pregnancy and the puerperium are common. There is often increased sleepiness in the early prepartum period associated with high levels of estrogen and progesterone. In the postpartum period, a demanding infant together with decreased ovarian hormone levels may lead to sleep deficiency. During pregnancy and the puerperium, sleep latency, the frequency of awakening, and stage 0 sleep are increased; REM sleep is decreased. Hormonal fluctuations are related to sleep pattern changes. Medication should be used cautiously. Developing a routine for baby and mom is useful. Often the patient's partner needs education as well. Family meetings may be necessary for both parents to fully understand the impact of the patient's inadequate sleep on the family and to develop a schedule.

ADOLESCENT PREGNANCY: PSYCHOLOGICAL ISSUES

Approximately 1 million adolescents 15–19 years old (10% of all women in this age range in the United States) become pregnant each year. Half of them will give birth. This high teenage pregnancy rate is a result of many factors, including a subculture in which there is glorification of sexual activity without education of young people regarding its consequences. Other motivations for pregnancy in adolescence may be related to peer pressure, rebellion, keeping a relationship, and desiring more emotional intimacy. Unfortunately, teen pregnancy is associated with many bad outcomes. These include premature birth, infant homicide, domestic violence, substance abuse, low maternal educational achievement, low socioeconomic status, and maternal depression. Interestingly, the teen pregnancy rate has declined over the last 50 years (89.1/1000 vs. 45.9/1000 in 1960 vs. 2001). This trend is seen across age groups and races. As a result, the abortion rate has also dropped. Access to birth control appears to be the most important factor.

Half of all teen pregnancies are conceived within 6 months of first intercourse. Because the average delay between intercourse and initiation of contraception is 6–18 months, contraception counseling is essential whenever caring for a teen. Psychological traits associated with contraceptive use in adolescents are high self-esteem, an orientation toward the future, feelings of control over life, and acceptance of the sexual self.

Three psychological subsets of adolescent mothers have been described. "Problem-prone" adolescents are those who use alcohol or drugs, are truant from school, and get poor grades. They act on impulse and are often part of a peer counterculture that rejects conventional values. The adequate copers are

those who are competent and open to alternative lifestyles but characteristically go through life transitions at an earlier age than their peers. The depressed or lonely adolescents are those who idealize pregnancy as a way of dealing with their feelings of loss, sadness, and emptiness. It is useful to distinguish among these three groups and to offer assistance in response to their various needs.

Adolescents often strain the patience of health care personnel because they may be difficult to talk with, have values very different from those of the staff, arrive late for prenatal care, or be noncompliant. If the physician understands adolescent development and sexuality well, adolescent care can be extremely gratifying. The importance of taking a responsible approach to prenatal care should be stressed. Counseling adolescents requires an ability to educate and communicate with them while offering privacy and confidentiality. Many states consider a pregnant adolescent to be an emancipated minor. It is important for practitioners to be familiar with the laws in their state.

PSYCHIATRIC DISORDERS OF PREGNANCY AND THE PUERPERIUM

Pregnancy and the puerperium are emotionally stressful periods for many women. Mood swings are commonly manifested by emotional lability, weepiness, irritability, and feeling blue or high. Prenatal assessment for psychological difficulties should include the following:

- (1) Prior personal or family history of psychiatric illness.
- (2) Psychiatric disorder.
- (3) Psychological problems that accompanied maturational periods, eg, puberty.
- (4) History of early maternal deprivation or mother's death.
- (5) Difficulty separating from parents.
- (6) Conflicts about mothering.
- (7) Marital or family difficulties, including separation.
- (8) Past difficulty with pregnancy, delivery, or postpartum depression.
- (9) Recent death of family member or close friend.
- (10) Familial or congenital disorders.
- (11) History of infertility.
- (12) History of repeat abortion.
- (13) History of pseudocyesis or hyperemesis.
- (14) Prior fetal death, miscarriage, or congenital abnormality.
- (15) History of sexual, physical, or emotional abuse, current or past.
- (16) History of premenstrual syndrome.

Psychiatric disorders during pregnancy and in the puerperium have been described throughout history, although there is disagreement as to whether these disorders are the same or different from those occurring at other times. Because untreated maternal mental illness is associated with deleterious effects on maternal–infant attachment and synchrony in child development, it is essential to diagnose and appropriately treat psychological disorders. Although some psychotropic medications appear to be safe when used in breastfeeding mothers, few randomized controlled trials have been performed. For this reason, it is important to involve a pediatrician in the infant's care when treating a breastfeeding mother with psychotropic medications.

Depressive Disorders

Depressive symptoms are part of human experience and relate to sadness, frustration, discouragement, and feeling "down." Many women experience such moods in the weeks following delivery. The symptom can be related to another illness such as alcoholism, pain, or a worsening medical condition. A syndrome, such as major depression, is characterized by a specific set of mood symptoms that persists and is severe enough to interfere with activities of daily living. A wide range of mood changes occur during the postpartum period. The severity can vary considerably from a transient period of feeling blue to major clinical depression with thoughts of infanticide.

POSTPARTUM BLUES

This condition (also called 3-day blues or baby blues) is a transitory mood disturbance following delivery (within 2 weeks) and usually occurs at the height of hormonal changes. It is frequent, occurring in approximately 50–85% of women. It is characterized by irritability, feeling trapped, sensitivity to criticism, despondence, anxiety, sadness, anger, guilt, or elation. It is unrelated to the health of mother or baby, obstetric complications, hospitalization, social class, or breastfeeding. However, any of these factors can affect the patient's mood. It occurs cross-culturally, but is less noticeable in cultures where emotions are expressed freely and when relatives and friends surround the new mother, offering care and support. It may last a few days to 2–3 weeks. Although it is generally self-limited, 20% of women who suffer from this disorder will go on to develop depression in the first postpartum year. Treatment consists of support from family, health care providers, and other mothers.

MAJOR DEPRESSION

Major depression is a depressive syndrome (without psychosis) that can occur during pregnancy or the postpartum period. It is estimated that this syndrome develops at the following rates during each phase of pregnancy: 7.4% first trimester, 12.8% second trimester, 12.0% third trimester, 10–20% postpartum. Its symptoms include change in mood, sleep patterns, eating, mental concentration, and libido, and may involve somatic preoccupations, phobias, and fear of harming self or infant. Diagnosis is best made through standardized self-report or physician screens. The syndrome is profoundly under diagnosed (< 15%) and often left untreated. Postpartum depression is likely to go undiagnosed because the syndrome develops weeks to months after delivery when the patient is not under the routine medical care.

Clear risk factors for pregnancy-associated depression include a history of depression, a family history of depression, prior pregnancy-associated depression. Precipitating factors such as ambivalence about pregnancy, marital problems, financial problems, and limited social support may contribute. Postpartum depression has a high rate of recurrence in subsequent pregnancies. Treatment may include psychotherapy, antidepressant medication, support groups, and the involvement services that take some of the child care burden off of the patient. Suicidal or homicidal patients should be immediately referred to a mental health professional. Of course they should not be left alone. Hospitalization may be necessary.

Initiating a conversation regarding a patient's depressive symptoms may be difficult. It may be useful to start by acknowledging that the transition to motherhood is difficult for most parents. Next the physician should ask more specific questions, aimed at screening for depression. To elicit suicidal or homicidal ideas, the physician might ask "Have you felt so overwhelmed or that you might hurt yourself or your baby?" Patients tend to view parenting as a process that should come naturally. They often underestimate the challenges and pressure that accompanies a new baby. They should be reminded that they are under more stress than they realize and that it is acceptable to ask for help. The mother of today generally has more responsibility than raising children. Many balance careers and/or single parent. Often simply redistributing child care responsibilities or adjusting the patients work responsibilities can

relieve tremendous pressure.

Postpartum Psychoses

A woman is more likely to suffer from new-onset psychosis during the postpartum period than during any other time of her life. Interestingly, the antenatal period is not associated with increased risk of psychosis. Psychosis is a severe mental illness characterized by a false reality and can be associated with fear and impulsivity. Patients usually require admission to mental hospitals for delusions and the concern that the woman may harm herself or the infant. Psychosis is most frequently associated with depressive illness (70–80%) but must be differentiated from bipolar disorder, schizophrenia, drugs and organic brain disease. Contributing factors include a family history of mental illness, past psychiatric disorders, marital and family problems, recent stressful life situations, and a lack of social supports, although none of these risk factors may be present. These individuals appear to be biologically vulnerable to mental disease. Risk of recurrence in subsequent pregnancies may be as high as 20–30%.

Symptoms develop most commonly from a few days to 4–6 weeks postpartum, although a careful history may reveal that the illness began in the third trimester of pregnancy. The woman may become restless, unable to sleep, irritable, have pressured speech, unusual behavior, obsessional or delusional thinking, or become very withdrawn. Drug-dependency, endocrinopathies, such as thyroid diseases, and other neurologic disorders must be ruled out. Infant injury or infanticide by the mother is rare but does occur. Treatment of affective disorders is with antidepressant drugs or lithium and care in a psychiatric care facility.

Schizophrenia is a psychiatric disorder of at least 6 months' duration, characterized in its acute phase by delusions, hallucinations, incoherent speech, catatonia, or flat affect. Generally, the level of the individual's function declines, with withdrawal and social isolation. The onset is usually during adolescence or young adulthood. Genetic as well as environmental and psychological factors are involved. Schizophrenic women may have exacerbations during pregnancy and the puerperium and should be carefully monitored. Delusions in pregnancy often relate to bodily changes and fetal movements. The disease is considered to have an organic basis with biochemical abnormalities, and drug treatment is usually with neuroleptic antipsychotics such as phenothiazines, butyrophenones, and thioxanthenes. A psychiatric referral is indicated. Suicidal risk should be assessed.

Organic brain disease (delirium, organic brain syndrome) is often confused with acute psychosis. Toxic states, drugs, metabolic disorders, infection, and hemorrhage can cause neurodysfunction. There may be impairment of orientation, memory, intellectual function, and judgment, as well as emotional lability. The individual is usually conscious and symptoms fluctuate. A neuropsychiatric consultation is indicated. It is best to avoid sedative drugs until an evaluation and diagnosis are made and treatment of the underlying disorder is begun.

In-hospital management includes keeping the surroundings familiar, the room well lit, and the woman oriented by using her name. The clinician must be alert to changes in mood, behavior, and thinking.

Psychoses require specialized psychiatric care. If a patient becomes acutely disturbed or confused, she requires emergency management until the psychiatric consultation can be performed. Such patients can be divided into five categories according to the following features:

(1) Acute psychoses with disordered thought, hallucinations, and fear, possibly caused by psychotic illness or drug reaction.

(2) Delirium caused by an underlying medical problem with fluctuating disorientation to time, place, and person.

- (3) Severe anxiety with somatic symptoms.
- (4) Anger and belligerence with or without alcohol or drug abuse.
- (5) Depression with suicidal ideas.

A medical and drug history should be obtained from relatives or friends. Accuracy in diagnosis is essential (eg, insulin shock in a diabetic may be confused with psychogenic seizures). If possible, a blood sample should be drawn for drug and toxicity screening. The patient is calmed, and a relative or friend may remain with her unless she becomes violent. In such instances, security personnel should be alerted and the patient transferred to a psychiatric care facility as quickly as possible. Haloperidol may be given orally or parenterally to facilitate immediate management.

Anxiety Disorders in Pregnancy

Anxiety during pregnancy and the puerperium is normal; its total absence is as pathologic as is its excess. When anxiety increases enough to be considered a disorder, there are two major classifications: phobic disorders and anxiety state disorders. Phobic disorders include persistent and irrational fear of a specific object, activity, or situation that may lead to avoidance. In pregnancy, irrational fears are often related to the fetus (eg, unsubstantiated worries about food that might harm the fetus). Treatment ranges from simple reassurance to behavior modification to medication.

Anxiety states are divided into three categories. Panic disorders include recurrent attacks of anxiety with sudden onset of intense fear and apprehension. There may be physical symptoms such as dyspnea, chest pains, palpitations, choking, and dizziness. Attacks may last minutes to hours with anxiety between attacks. They are thought to have a biochemical basis, but there is often a precipitating event. Panic disorders may be part of the syndrome of depression. Generalized anxiety disorders last a month or more with signs of motor tension, vigilance, scanning, autonomic hyperactivity, and apprehension. Other conditions causing anxiety must be ruled out. Obsessive-compulsive disorder is characterized by repetitive behaviors that result from anxiety or preoccupation with particular irrational fears.

These disorders may interfere with function and compliance. Treatment of anxiety disorder is initiated with a psychiatric evaluation, reassurance, and behavioral modification. Cognitive behavioral therapy is an effective treatment for these syndromes, but requires patient commitment and compliance. Selective serotonin reuptake inhibitor (SSRI) antidepressants are the first-line medical therapies. Benzodiazepines are useful for an acute anxiety crisis, but should be avoided during pregnancy. They are highly addictive and there is some evidence that they are associated with fetal malformations.

Posttraumatic Stress Disorder

After an emotionally traumatic experience, some patients develop a constellation of symptoms typical of posttraumatic stress disorder (PTSD). These symptoms include a sense of recurrently experiencing the event (flashbacks, dreams), avoiding stimuli associated with the trauma (activities, people, places), and heightened arousal (anxiety, irritability, trouble concentrating). Treatments include cognitive behavioral therapy and medical therapy with SSRIs. The traumatic event may have been a traumatic medical experience, fetal loss, infertility, sexual assault, or the death of a close relative or friend that the patient associates with pregnancy or labor.

When counseling a woman with any of the above disorders, the clinician needs to address several questions: Is there a medical condition causing the disorder? Is there a basic psychiatric disorder, such as depression or schizophrenia, present? Does substance abuse complicate the clinical presentation? Is this patient abusing alcohol or other drugs? Consultation with a mental health professional is recommended. Some sexual assault survivors may strongly prefer a cesarean section to a vaginal

delivery.

Psychotropic Medications during Pregnancy and Lactation

No psychotropic medication has been approved by the Food and Drug Administration for use in pregnancy. Because of the unknown risk of medications to the fetus, medications have not traditionally been studied in pregnancy. As no definitive treatment regimen for the treatment of psychiatric disorders exists, each patient's treatment must be custom tailored. Consideration must be given to each patient with regard to her psychiatric history, past pregnancy history, the severity of her symptoms, her response to medication in the past, the likelihood that nonpharmacologic treatments will be effective, and her compliance. The risk of treatment must be less than the risk that psychiatric illness places on the patient and the baby. Given the mounting evidence that untreated psychiatric illness hinders pregnancy outcome and infant development, physicians have lowered the treatment threshold.

Ideally, these discussions regarding the use of psychiatric medications in pregnancy start before the patient is pregnant. Patients with psychiatric illness may benefit from a planned pregnancy, during a time when stressors are minimal and support is adequate. In general, medications should be avoided during the first trimester, given that the fetus is undergoing organogenesis. Certain medications, such as lithium, should be avoided. Anticonvulsants (teratogens) should be used only after careful consideration of the risks and benefits and in conjunction with folic acid supplementation.

Antidepressants are the most commonly used psychotropic medications in pregnancy and the postpartum period. Although they cross the placenta, they are not teratogens. In the few studies that have been performed, no clear morbidity outcomes were associated with the use of SSRIs (mainly fluoxetine) and tricyclic antidepressants (TCAs). Both SSRI and TCA use in the third trimester is associated with a perinatal syndrome in neonates. Symptoms include irritability, gastrointestinal problems, urinary retention, sweating, jerky movements, tachycardia and tachypnea. Antidepressants may be tapered in the third trimester to minimize these symptoms (when appropriate). SSRIs are the first-line medical treatment for depression, as they are less often associated with the perinatal syndrome and side effects than the TCAs. A pregnant patient may require higher doses than a nonpregnant woman, given her increased metabolism and liver function.

With regard to lactation, one may not assume that drug concentrations are lower in breast milk than in maternal circulation. Drugs are excreted in breast milk at differing rates, depending on the specific drug's pharmacokinetics and the patient. Infant serum drug concentrations do not correlate well with maternal drug concentration. For this reason, there are no clear guidelines regarding psychotropic medication use in lactating women. However, when using lithium to treat bipolar disorder, breastfeeding should be discontinued.

As a general rule, a patient and her physician should carefully discuss the risks and benefits on a case-by-case basis before prescribing psychotropic drugs during pregnancy or lactation. Psychiatric and pediatric consultation may be an important component of your evaluation, assessment, and planning. It is important to remember that psychiatric illness has deleterious effects on pregnancy and infant outcomes and that proper treatment is warranted.

Substance and Alcohol Abuse

Substance abuse can cause major problems in pregnancy and the puerperium. These problems may be mild or may be severe enough to lead to fetal abnormalities, morbidity, and death of infant and mother. Therefore, inquiry concerning drug use should be made during prenatal visits and documented in the record.

GRIEF & GRIEVING: PERI NATAL LOSS

Grief in pregnancy can accompany an elective or therapeutic abortion, still birth, neonatal loss, or neonatal illness. Relinquishment of a baby for adoption may have the same psychological effect as loss as a result of death. Death of a fetus or baby is often felt to be a loss of part of the mother's self. Grief is the process of adapting to such a loss by detaching little by little through anger, pain, and sadness. The mother and father may feel an emptiness. Thoughtless comments such as "you can always have another," "you didn't know the baby anyway," or "plan another pregnancy right away" may only serve to increase the couple's emotional pain.

Parents grieve for the lost fetus or infant in their own way and in their own time. One difficulty in grieving for a lost pregnancy is the lack of identification that is useful in detaching from a known person. Parents should be encouraged to make their own decisions concerning seeing or holding the baby, disposition of the remains (burial or cremation), religious observances, and naming the baby. They should not be discouraged from seeing a malformed infant; they often recall the positive aspects. Photos should be obtained if desired. Autopsies often give parents more information about the normal as well as the abnormal features. Mothers, perhaps more than fathers, suffer from guilt and helplessness. Participation in decision making can help them achieve more control in dealing with their loss.

Physicians may also feel helpless and sad. They must talk with patients, give them as much information as possible, and assure them (if possible) that nothing the mother did caused the fetal or infant demise. Often, the anger that is part of the grieving process is displaced to hospital staff, especially physicians. It is important to deal with each set of parents individually, to meet with them, and encourage them to grieve in their own way. If severe grief persists beyond several months, psychiatric consultation should be obtained.

PSEUDOCYESIS

Pseudocyesis is a syndrome in which a nonpregnant woman believes she is pregnant and develops signs and symptoms suggestive of pregnancy. Pseudocyesis is a conversion reaction in which a psychic conflict is expressed in physical terms. It is an example of how a false belief may affect physiologic processes. It has been known since ancient times, and many cases have been described in women ages 7–79 years. The most common symptoms include menstrual abnormalities (oligomenorrhea, amenorrhea), abdominal enlargement, and breast changes. There may be nausea and vomiting. On examination, the uterus is not enlarged; the abdomen is firm to palpation and often tympanic to percussion. "Fetal movement" has been reported; it is usually intestinal activity or contractions of abdominal muscles. A supposed fetal heart rate may be maternal tachycardia. Galactorrhea may be present because of increased prolactin levels from other causes (eg, pituitary adenomas), long-term breast stimulation, or use of drugs such as phenothiazines. There are usually neuroendocrine abnormalities (eg, hypothalamic amenorrhea). Duration varies from 9 months to several years. Diagnosis of true pregnancy can be obtained with pregnancy tests and ultrasonography. However, negative test results may not convince a woman with this syndrome that she is not pregnant.

The clinical variants of pseudocyesis include "true" pseudocyesis, which should be distinguished from psychosis in women in whom the false belief in pregnancy is a delusion; factitious illness in which the woman knows she is not pregnant but simulates pregnancy for some secondary gain (eg, to keep a straying partner); organic diseases such as a pelvic tumor; and iatrogenic pseudopregnancy caused by administration of human chorionic gonadotropin to produce positive pregnancy tests in infertile women.

Management consists of a careful history, physical examination, and laboratory tests to rule out pregnancy and organic disease. Psychological assessment and treatment are also indicated.

THE REFERRAL PROCESS

Referral to mental health professionals may be indicated for any psychological process the gynecologist believes to be beyond his or her ability, training, or willingness to treat. The gynecologist may prefer to work closely with a psychiatrist, psychologist, social worker, or psychiatric nurse. The attitude taken should be comfort in the belief that counseling would be helpful, not that the patient is bothersome and therefore should be labeled or stigmatized by such referrals. Consultation–liaison psychiatrists have expertise in the psychological aspects of medical and surgical problems, as well as in the use of psychopharmacologic drugs. Most hospital staffs include social workers and psychiatric nurses who specialize in psychosocial issues. Marriage counselors offer much to those with relationship problems. As with obstetrics, the biopsychosocial approach is extremely useful.

Current OB/GYN > Chapter 62. Domestic Violence & Sexual Assault >

DOMESTIC VIOLENCE & SEXUAL ASSAULT: INTRODUCTION

For many victims of domestic violence and sexual assault, the first contact with the health care system is with the obstetrician-gynecologist or primary care doctor. Consequently, it is critical that these physicians be knowledgeable in the identification, evaluation, and treatment of such patients.

DOMESTIC VIOLENCE

While the home is often thought of as a safe haven, it is the site of the most common manifestations of violence in our society today. Domestic or intimate partner violence typically refers to violence perpetrated against adolescent and adult females within the context of family or intimate relationships. Although victims of domestic violence may be male or female, 90–95% of the victims are women. It is a behavior pattern that is manifested in physical and sexual attacks, as well as psychological and economic coercion. The abuser uses the behavior in order to establish and maintain domination and control over the victim. Because abuse is usually accompanied by shame and guilt, the victim often does not report the abuse.

As a result of significant underreporting, it is difficult to compile exact data on the incidence of domestic violence. Every year, approximately 4–5 million women are believed to be battered by their intimate partners. Violence by an intimate partner accounts for approximately 21% of all the violent crime experienced by women. More than 40% of all female murder victims are murdered by their husbands, boyfriends, or ex-partners. It is estimated that at least one-fifth of all American women will be physically assaulted by a partner or ex-partner during their lifetime.

Violent acts may include threats, throwing objects, pushing, kicking, hitting, beating, sexual assault, and threatening with or using a weapon. Domestic violence frequently includes verbal abuse, intimidation, progressive social isolation, and deprivation of things such as food, money, transportation, or access to health care. The violence typically occurs in a predictable, progressive cycle. The tension-building phase is characterized by arguing and blaming as anger intensifies. This leads to the battering phase that may involve verbal threats, sexual abuse, physical battering, and use of weapons. The battering phase is followed by a honeymoon phase during which the abuser may deny the violence, make excuses for battering, apologize, buy gifts, and promise never to do it again, until the next cycle begins. Although unemployment, poverty, and alcohol and substance abuse increase the likelihood of abuse, domestic violence cuts across all racial, ethnic, religious, educational, and socioeconomic lines. Domestic violence often occurs within a framework of family violence that can include child abuse, elder abuse, or abuse of adults who are disabled. It is estimated that child abuse occurs in 33–77% of families where adults are abused.

Clinical Presentation

Survivors of domestic violence or sexual abuse may present to health care professionals in a variety of clinical settings. The prevalence of domestic violence among patients in ambulatory care settings is estimated to be between 20% and 30%.

Such patients commonly report chronic pelvic pain to their gynecologists. A history of sexual abuse is found in significantly more women with chronic pelvic pain as compared with other gynecologic conditions. Others may complain of sexual dysfunctions such as decreased interest or arousal, dyspareunia, or anorgasmia. Incest victims have a very high rate of sexual dysfunction and may avoid sex or seek it out compulsively. Still others may present with chronic or recurrent vaginitis. Some women may present for a routine gynecologic appointment but become anxious and tearful before or during the pelvic examination.

Some women present to their primary care physicians with persistent multiple bodily complaints, such as chronic headaches, palpitations, abdominal complaints, or sleep and appetite disturbances. Eating disorders may be more common among abuse victims. Others may have a somatoform disorder. This condition is characterized by physical symptoms suggesting a physical condition for which there are no demonstrable organic findings or physiologic mechanisms. In the face of a negative work-up, there may be evidence of or a presumption that the symptoms are linked to psychological factors or conflicts. Women who meet the criteria for somatoform disorder often have a history of abuse.

In a mental health setting, victims of domestic violence or sexual assault may note feeling depressed or suicidal. They may have anxiety or sleep disorders that they may self-medicate with alcohol or other substances. Most commonly, these women may have posttraumatic stress disorder (PTSD), which occurs in individuals who have experienced a psychologically distressing event that is outside the range of usual human experience. Symptoms of PTSD include re-experiencing the traumatic event through intrusive memories, dreams, flashbacks, or exposure to events symbolic of the trauma. Patients with PTSD also exhibit a "psychic numbing," ie, they are detached from other people and have difficulty feeling emotions, especially those associated with intimacy or sexuality. Other clinical syndromes include personality disorders characterized by maladaptive character traits. In very extreme cases, patients may have multiple personality disorder (MPD), characterized by having two or more distinct personalities existing within them. This disorder is marked by a disturbance in the normally integrated functions of identity, memory, and consciousness as the result of dissociation from traumatic experiences.

The problem of domestic violence in pregnancy merits special mention because it is a threat to both the mother and her developing fetus. Estimates of prevalence of domestic violence in pregnancy are in the range of 1–20%, with most studies identifying rates between 4% and 8%. These estimates suggest that violence is a more common problem for pregnant women than preeclampsia, gestational diabetes, and placenta previa, conditions for which pregnant women are routinely screened and evaluated. Some evidence suggests that violence may escalate during pregnancy, especially in the postpartum period. Abuse is associated with increased physical and psychological stress, inadequate prenatal care utilization, poor nutrition and weight gain, and increased maternal behavioral risks (cigarette, alcohol, and substance abuse). These may lead to problems with fetal growth and development. Physical trauma can cause abruptio placentae, preterm labor, preterm premature rupture of membranes, and maternal and fetal injuries and demise.

Diagnosis & Treatment

Although battered women seek medical care frequently, as few as 1 in 20 are correctly identified by the practitioner to whom they turn for help. Barriers to diagnosis include the practitioner's lack of knowledge or training, lack of recognition of the widespread prevalence of the problem, time constraints, fear of offending the patient, and a feeling of powerlessness in the area of treatment. Research suggests that the use of abuse assessment questions on standard medical records may increase screening and documentation. In addition, because many women will not voluntarily disclose abuse, asking each patient directly about prior or ongoing victimization increases the likelihood of disclosure.

The screening assessment should be prefaced with a statement to establish that screening is universal, such as, "I would like to ask you a few questions about physical, sexual, and emotional trauma because we know that these are common and affect women's health." Direct questioning using behaviorally specific phrasing should follow:

- Has anyone close to you ever threatened to hurt you?
- Has anyone ever hit, kicked, choked, or hurt you physically?
- Has anyone, including your partner, ever forced you to have sex?
- Are you ever afraid of your partner?

Disclosure rates will be higher when the questions are asked face to face by the health care provider rather than through a questionnaire, and when behaviorally specific descriptions rather than the terms "abuse," "domestic violence," or "rape" are used. Abuse victims are often accompanied to health care appointments by the perpetrator, who may appear overprotective or overbearing, and may answer questions directed toward the woman. It is important to ask the patient questions in private, apart from the male partner. It is also important to ask the patient questions apart from children, family, or friends, and to avoid using them as interpreters when asking questions about violence.

In the office setting, the most effective and efficient strategy for providing assistance to a woman who has disclosed abuse involves acknowledging and documenting the trauma, assessing immediate safety and establishing a safety plan, and providing patient education and referrals to community support services. An essential first step is to acknowledge the trauma. It is important to reinforce to the victim that she is not to blame as many victims have trouble believing that they are not responsible for the abuse.

Documenting domestic violence is no different from documenting other patient interactions, but such documentation may provide important supportive evidence in the courtroom to put an end to the violence. Direct quotations of the patient's explanation of her injuries should be recorded. Photographs may be taken after consent is granted. Every effort should be made to maintain confidentiality to avoid retaliation by the perpetrators when they suspect disclosure of abuse. The physician or health care professional may be required by state law to report actual or suspected domestic violence.

Once domestic violence is acknowledged and documented, the next step is to assess immediate safety and to establish a safety plan. Lethality of the violence should be assessed by asking questions such as:

- Has your partner ever threatened to kill you or your children?
- Are there weapons in the house?
- Does your partner abuse alcohol or use drugs?
- Is it safe for you to go home?
- Are the children (or other dependents) safe?

If the violence has escalated to the point where she is afraid for her safety or that of her children, she should be offered shelter.

An important step in addressing ongoing violence is to help the victim establish a safety plan. The American College of Obstetricians and Gynecologists (www.acog.org) distributes pocket cards with suggested steps for making an exit plan. These cards can be handed to the patient or left in patient restrooms where a woman can pick it up without concern of being seen by an accompanying partner.

Providing educational materials about domestic violence and its consequences can sometimes help victims take action toward ending the violence. These materials demonstrate to women that their physicians' offices are both a resource and a safe place should they decide to take action. A list of referral resources should be readily available in medical offices. The list should include telephone numbers for police departments, emergency departments, shelters for battered women, rape crisis centers, counseling services, self-help programs, and advocacy agencies that can provide legal, financial, and emotional support.

Given the high rate of psychiatric symptomatology in this population, referral for psychiatric screening and counseling can be useful. Patients who are experiencing posttraumatic stress disorder can benefit from psychotherapy and possibly medication as well. Those with depression, substance abuse, or anxiety, personality, or dissociative disorders will also require ongoing treatment. Psychiatrists or other mental health professionals can serve to coordinate a variety of treatment modalities for the victims: individual, couples, and family therapy, detoxification and substance abuse treatment, and advocacy groups.

Despite the best efforts of physicians and other health care professionals, some women may initially be unable to extirpate themselves from victimization. For such women, an encounter with a health care system that they experience as nonblaming, accessible, and supportive will help to maximize the chances of their making a positive life change at some future point.

SEXUAL ASSAULT

Sexual assault is any sexual act performed by one person on another without the person's consent. Sexual assault includes genital, oral, or anal penetration by a part of the accused's body or by an object. It may result from force, the threat of force either on the victim or another person, or the victim's inability to give appropriate consent. Many states have now adopted the gender-neutral legal term *sexual assault* in favor of *rape*, which traditionally referred to forced vaginal penetration of a woman by a male assailant.

An estimated 700,000 to 1,000,000 American women are sexually assaulted every year. These estimates are higher than official crime reports because the majority of cases go unreported. According to one estimate, only 30% of rapes are reported to the police, and 50% of rape victims tell no one. At least 20% of adult women, 15% of college-age women, and 12% of adolescent girls have experienced sexual abuse and assault during their lifetime. Sexual assault occurs in all age, racial-ethnic, and socioeconomic groups, but its incidence may be higher for African American women and for adolescent females. In several studies, about one-fourth to one-half of the victims of sexual assault were younger than the age of 18 years. The very young, the elderly, and the physically or developmentally disabled may be particularly vulnerable to sexual assault.

Several variants of sexual assault deserve special mention. Marital rape is defined as forced coitus or related sexual acts within a marital relationship without the consent of a partner. Acquaintance rape refers to those sexual assaults committed by someone known to the victim. More than 75% of adolescent rapes are committed by an acquaintance of the victim. When the acquaintance is a family member, including step-relatives and parental figures living in the home, the sexual assault is referred to as incest. When the forced or unwanted sexual activity occurs in the context of a dating relationship, it is referred to as date rape. In this situation, the woman may voluntarily participate in sexual play but coitus occurs, often forcibly, without her consent. Alcohol use is frequently associated with date rape. "Date rape drugs" such as flunitrazepam (Rohypnol) and gamma-hydroxybutyrate (GHB) have also been used to diminish a woman's ability to consent or to remember the assault.

Statutory rape refers to sexual intercourse with a female under an age specified by state law (ranging from 14–18 years of age); the consent of an adolescent younger than this age is legally irrelevant because she is defined as being incapable of consenting. Child sexual abuse is defined as contact or interaction between a child and an adult when the child is being used for the sexual stimulation of that adult or another person. All 50 states and the District of Columbia mandate reporting of child abuse, including child sexual abuse. Nearly half of the states also require physicians to report statutory rape. Physicians should be familiar with the laws in their states; failure to report sexual assault against children may subject the physicians to fines and incarceration for up to 1 year.

Our society has many misperceptions about sexual assault. The victims are often blamed for having encouraged the assault by their behavior or dress, for not sufficiently resisting the assault, for being promiscuous, or for having ulterior motives for pressing charges. This misplaced culpability is often internalized by the victims, which (in addition to fear of retribution) may explain their reluctance to report the violent crime to the authorities. Another common misperception is that rape is an impulsive or aggressive extension of normal sex drive on the part of the rapist. The motivation for most sexual assault, however, seems not to be sexual gratification but rather degradation, terrorization, and humiliation of the victim. The assault is often a demonstration of power (power rape), anger (anger rape), or sadism manifested in ritualized torture or mutilation of the victim (sadistic rape) on the part of the rapist.

Clinical Presentation

The majority of rape victims who come to emergency rooms do not openly admit to having been sexually assaulted. Instead, they may complain of having been mugged or may voice concerns about acquired immune deficiency syndrome (AIDS) or other sexually transmitted diseases. Others may present with psychiatric symptoms including depression, anxiety, or a suicide attempt. Unless the primary care physician, obstetrician-gynecologist, or psychiatrist obtains a sexual history, assault victims will remain unidentified as such, and will be inadequately treated.

A "rape-trauma" syndrome often occurs after a sexual assault. The initial response (acute phase) may last for hours or days and is characterized by a distortion or paralysis of the individual's coping mechanisms. The initial outward responses vary from complete loss of emotional control (crying, uncontrolled anger) to an unnatural calm and detachment (although some physical signs such as shaking or lowered skin temperature are usually present). The latter behavior represents the victim's need to reestablish control over herself and her environment while simultaneously abandoning the defense mechanism of denial and allowing the renewed invasion of privacy represented by the questioning and examination. The initial reactions of shock, numbness, withdrawal and denial typically abate after the first 2 weeks. However, studies suggest there is a period, occurring from 2 weeks to several months postassault, in which symptomatology returns and may intensify. It is at this time that the victim may begin to seek help for her symptoms, often without telling the health care provider of the sexual assault that precipitated these symptoms.

The next phase (delayed phase) may occur months or years after the sexual assault and is characterized by chronic anxiety, feelings of vulnerability, loss of control, and self-blame. Long-term reactions include anxiety, nightmares, flashbacks, catastrophic fantasies, feelings of alienation and isolation, sexual dysfunction, psychological distress, mistrust of others, phobias, depression, hostility, and somatic symptoms. More than half of rape victims experience substantial difficulty in reestablishing sexual and emotional relationships with spouses or boyfriends. Thirty-three percent to 50% of victims report suicidal ideation; suicide attempts have been reported in nearly 1 in 5 rape victims who do not seek treatment.

PTSD is a common long-term sequela of sexual assault, characterized by psychic numbing, intrusive re-

experiencing of the trauma, avoidance of stimuli associated with the trauma, and intense psychological distress. Women with prior victimization histories often have more severe sequela. Women assaulted sexually by family members or dates experience as severe levels of distress as women assaulted by acquaintances or strangers.

Up to 40% of victims who are sexually assaulted sustain injuries. Although most injuries are minor, approximately 1% of the injuries require hospitalization and major operative repair, and 0.1% are fatal. Somatic symptoms are common during the acute phase and include disturbed sleeping and eating patterns, gastrointestinal irritability (with nausea predominating), musculoskeletal soreness, fatigue, tension headaches, and intense startle reactions. Symptoms of vaginal irritation occur in more than 50% of victims, and rectal pain and bleeding are frequent in patients subjected to anal penetration. Ongoing health concerns include gynecologic trauma, risk of pregnancy, and the potential for contracting infections or sexually transmitted diseases, including human immunodeficiency virus (HIV). Victims may also seek to escape the pain of rape's effects through the use of alcohol and drugs.

Rape victims appear to be frequent users of medical services in the months and years following the assault. In one study, visits to physicians increased 18% in the year of the assault, 56% in the following year, and 31% in the year after, compared to previctimization levels. Reintegration of the self following sexual assault is a slow process that may take months to years as the victim works through the trauma and the loss of the event and replaces it with other life experiences. The prognosis for complete recovery is improved if health care professionals responsible for the victim's care have a supportive, nonjudgmental approach and a well-developed understanding and competent treatment of the emotional, as well as physical, consequences of sexual assault.

Diagnosis & Treatment

The physician evaluating the victim has both medical and legal responsibilities, and should be aware of state statutory requirements. Such requirements may involve the use of sexual assault assessment kits, which list the steps necessary and the items to be obtained for forensic purposes. If personnel trained in collecting samples and information are available, it is appropriate to request their assistance.

Informed consent must be obtained prior to examining a sexual assault victim. A careful history and physical examination should be performed in the presence of a chaperon or victim advocate. The patient should be asked to state in her own words what happened, and to identify or describe her attacker, if possible. The history should include inquiry about last menstrual period, contraceptive use, preexisting pregnancy and infection, and last consensual intercourse before the assault. The patient's activities in the interval between the assault and the examination—whether the patient has eaten, drunk, bathed, douched, voided, or defecated—might affect findings on physical examination; such activities must be recorded.

A careful physical examination of the entire body should be performed. The physician should search for bruises, abrasions, or lacerations about the neck, back, buttocks, and extremities. Bite marks should be noted, particularly about the genitalia and breasts. Injuries to the mouth and pharynx may result from oral penetration. Injuries should be documented with photographs or drawings in the medical record. *Rape* and *physical assault* are legal terms that should not be used in medical records. Instead, the physician should report findings as "consistent with the use of force."

A pelvic examination should be performed. Injuries to the vulva, hymen, vagina, urethra, and rectum should be noted. Occasionally, foreign objects may be found in the orifices. The speculum must be moistened only with saline. Two milliliters of normal saline are injected into the vaginal vault. Nonabsorbent cotton swabs should be used to sample fluid from this vaginal pool and should then be

placed in sterile glass tubes and refrigerated. Air-dried, nonfixed smears of this same fluid should be placed on glass slides. A Papanicolaou (Pap) test may also be obtained. Evidence of coitus will be present in the vagina for as long as 48 hours after the attack. Motile sperms may be noted in the vagina for up to 8 hours after intercourse, but may be present in the cervical mucous for as long as 2–3 days. Nonmotile sperm may be noted in the vagina for up to 24 hours and in the cervix for up to 17 days. Acid phosphatase is an enzyme found in high concentrations in the seminal fluid. Evidence of acid phosphatase should be sought by swabbing the vaginal secretions, even in the absence of sperm because the attacker may have had a vasectomy. DNA evaluation may also be performed from the vaginal swab. Nonmotile sperm may be found in the rectum for up to 24 hours after the assault, and acid phosphatase can also be detected in the rectum.

A wet mount or vaginal swab should be obtained to detect *Trichomonas vaginalis*. Testing for *Neisseria gonorrhoeae* and *Chlamydia trachomatis* should be performed from specimens from any sites of penetration or attempted penetration. A serum sample should be collected for subsequent serologic analysis if test results are positive. The risk of acquiring gonorrhea from sexual assault is estimated to be between 6% and 12%. Baseline serologic tests for hepatitis B virus, HIV, and syphilis should also be offered. The risk of acquiring syphilis from sexual assault is estimated to be 3%; the risk of acquiring HIV is undetermined.

An important part of the physician's legal responsibilities is to collect samples for forensic purposes. Pubic hair combings should be collected to look for pubic hair from the assailant. Fingernail scrapings should be obtained to look for skin or blood of the attacker. Skin washings and clothing should be investigated for the presence of blood or semen. A Wood light may be helpful because dried semen will fluoresce under its light. Saliva should be collected from the victim. Because seminal fluid is rapidly destroyed by salivary enzymes, identification of seminal fluid in the mouth after a few hours is difficult. Consequently, victims should be encouraged to come to a medical facility immediately following an assault, where they can be evaluated before they bathe, urinate, defecate, wash out their mouths, or clean their fingernails.

Proper processing and labeling of collected specimens is crucial. All collected specimens are placed in a larger sealed container and processed in a "chain of evidence" fashion. The person who collects the specimens verifies their completeness by signature on the sealed master container. The individual to whom they are transferred must verify by signature that all specimens were received in an untampered state. Thus, each individual who has "custody" of the specimens during processing must verify that they were transmitted without alteration until they are turned over to the responsible law enforcement agency. The name of the law enforcement agent who receives the specimens should be noted in the medical record.

Treatment of physical injuries sustained at the time of assault should be initiated immediately; prophylactic medical treatment may be indicated for prevention of sexually transmitted infections and pregnancy. For prophylaxis against sexually transmitted infections, empiric recommended antimicrobial therapy for chlamydial, gonococcal, and trichomonal infections may be given. One such regimen consists of

- Ceftriaxone 125 mg intramuscularly in a single dose, plus
- Metronidazole 2 g orally in a single dose, plus
- Doxycycline 100 mg orally 2 times a day for 7 days.

Alternative treatment may be given as recommended by the Centers for Disease Control and Prevention. In addition, it is recommended that hepatitis B immunoglobulin be administered intramuscularly as soon as possible, but certainly within 14 days of exposure. It should be followed by the standard three-dose

active immunization series with hepatitis B vaccine at 0, 1, and 6 months, beginning at the time of passive immunization. Prophylaxis against HIV is controversial.

Emergency contraception can be offered as prophylaxis against pregnancy. The risk of pregnancy after sexual assault has been estimated to be 2–4% in victims who were not using some form of contraception at the time of the assault. A serum pregnancy test should be obtained prior to administration of emergency contraception to evaluate for preexisting pregnancy. Emergency contraception should be given within 72 hours of the assault, although it can still be effective up to 120 hours later. There are several different methods of emergency contraception. For many years, the most common method (Yuzpe method) involved the use of high-dose combined oral contraceptives within 72 hours of unprotected coitus, repeated 12 hours following the first dose. More recently, use of a progestin-only method has become popular. This method involves the use of levonorgestrel 0.75 mg, in 2 doses 12 hours apart, within 72 hours of unprotected coitus. A randomized study showed that this is more effective and better tolerated than the Yuzpe method. Levonorgestrel prevented 85% of pregnancies that would have occurred without treatment.

As most patients suffer significant psychological trauma as a consequence of sexual assault, the physician must be prepared to provide access to counseling. It is preferable that follow-up psychological counseling be provided by individuals who have extensive experience in the management of crisis-response to rape. Even if the victim appears to be in control emotionally, she will probably experience aspects of rape-trauma syndrome at some time in the future. She should be made aware of the symptoms that she may experience, and advised to seek help if and when these symptoms occur. No patient should be released from the facility until specific follow-up plans are made and agreed upon by the patient, physician, and counselor.

A follow-up visit should be scheduled approximately 2 weeks after the assault for repeat physical examination and collection of additional specimens. Testing for *N. gonorrhoeae*, *C. trachomatis*, and *T. vaginalis* should be repeated unless prophylactic antimicrobials have been provided. Follow-up counseling should be discussed again at the second visit. Additional visits may be scheduled according to the victim's needs; an additional follow-up visit approximately 12 weeks following the sexual assault is advisable to collect sera for detection of antibodies against *T. pallidum*, hepatitis B virus (unless vaccine was given), and HIV (repeat test at 6 months). During each of these visits, assessment of the patient's psychological symptoms should be performed, and referrals for further counseling are made as indicated.

Much of this chapter addresses the role and responsibilities of the health care professional in caring for victims of domestic violence and sexual assault after they have occurred. One of the greatest challenges for health care and public health professionals working to improve women's health continues to be the epidemic of violence against women in our society and around the world. A great deal remains to be learned and done about the primary prevention of violence.

Current OB/GYN > Chapter 63. The Breast > Anatomy of the Female Breast >

ANATOMY OF THE FEMALE BREAST: INTRODUCTION

The breasts are secondary reproductive glands of ectodermal origin. They are frequently referred to as modified sweat glands. Each breast lies on the superior aspect of the chest wall. In women the breasts are the organs of lactation, whereas in men the breasts are normally functionless and undeveloped.

HISTOLOGY

The adult female breast contains glandular and ductal elements, stroma consisting of fibrous tissue that binds the individual lobes together and adipose tissue within and between the lobes.

Each breast consists of 12–20 conical lobes. The base of each lobe is in close proximity to the ribs. The apex, which contains the major excretory duct of the lobe, is deep to the areola and nipple. In turn, each lobe consists of a group of lobules. The lobules have several lactiferous ducts, which unite to form a major duct that drains the lobes as they course toward the nipple–areolar complex. Each of the major ducts widens to form an ampulla as they travel toward the areola and then narrow at its individual opening in the nipple. The lobules are held in place by a meshwork of loose, fatty areolar tissue. The fatty tissue increases toward the periphery of the lobule and gives the breast its bulk and hemispheric shape.

Approximately 80–85% of the normal breast is adipose tissue. The breast tissues are joined to the overlying skin and subcutaneous tissue by fibrous strands.

In the nonpregnant, nonlactating breast, the alveoli are small and tightly packed. During pregnancy, the alveoli hypertrophy and their lining cells proliferate in number. During lactation, the alveolar cells secrete proteins and lipids, which comprise breast milk.

The deep surface of the breast lies on the fascia that covers the chest muscles. The fascial stroma, derived from the superficial fascia of the chest wall, is condensed into multiple bands that run from the breast into the subcutaneous tissues and the corium of the skin overlying the breast. These fascial bands—Cooper's ligaments—support the breast in its upright position on the chest wall. These bands may be distorted by a tumor, resulting in pathologic skin dimpling.

HISTOLOGIC CHANGES IN THE FEMALE BREAST DURING THE LIFE SPAN

In response to multiglandular stimulation during puberty, the female breast starts to enlarge and eventually assumes its conical or spherical shape. Growth is the result of an increase in acinar tissue, ductal size and branching, and deposits of adipose, the main factor in breast enlargement. Also during puberty, the nipple and areola enlarge. Smooth muscle fibers surround the base of the nipple, and the nipple becomes more sensitive to touch.

Once menses is established, the breast undergoes a periodic premenstrual phase during which the acinar cells increase in number and size, the ductal lumens widen, and breast size and turgor increase slightly. Many women have breast tenderness during this phase of the menstrual cycle. Menstrual bleeding is followed by a postmenstrual phase, characterized by a decrease in size and turgor, reduction in the number and size of the breast acini, and a decrease in diameter of the lactiferous ducts. Cyclic hormonal influences to the breast are quite variable. This is true for changes in breast size and turgor, as well as the degree of hypertrophic and regressive histologic changes that may occur.

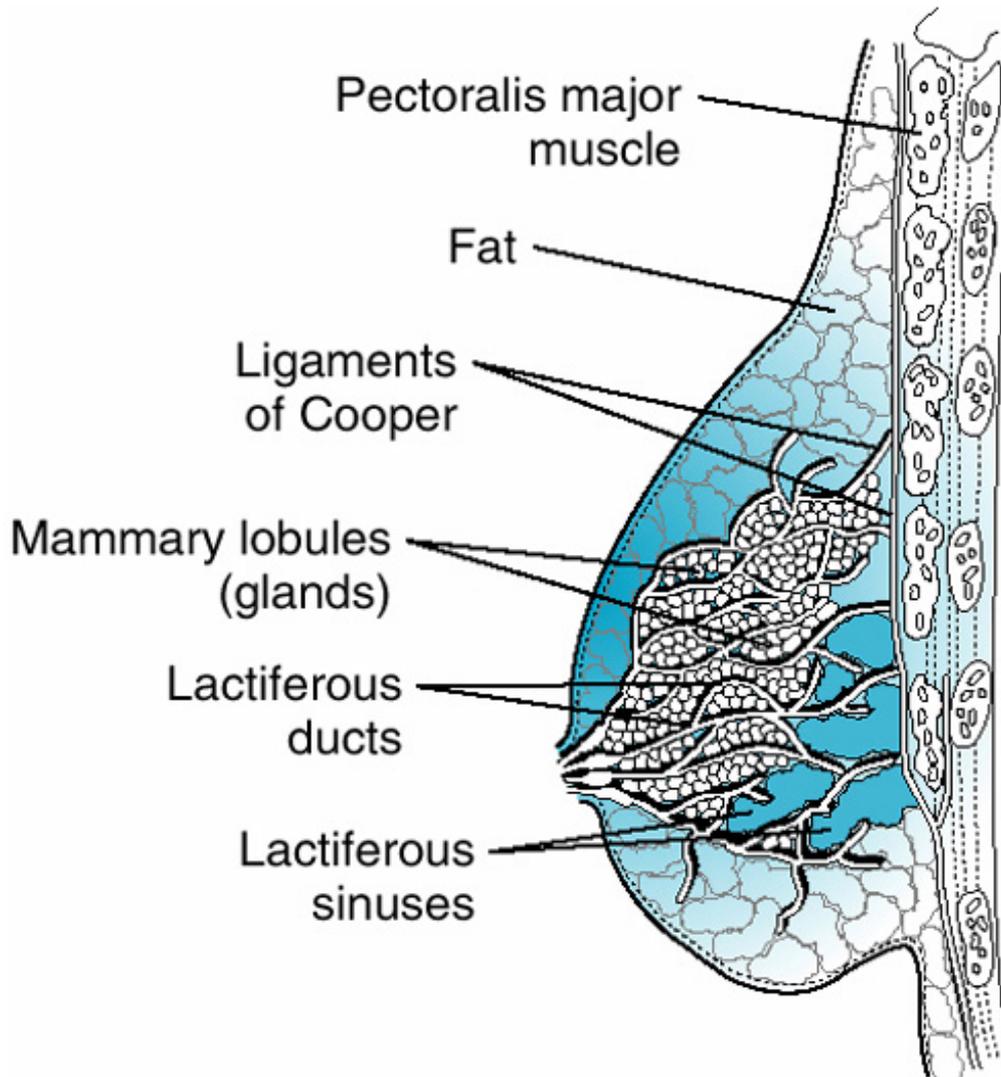

In response to progesterone during pregnancy, breast size and turgidity increase considerably. These changes are accompanied by deepening pigmentation of the nipple–areolar complex, nipple enlargement, areolar widening, and an increase in the number and size of the lubricating glands in the areola. The breast ductal system branches markedly, and the individual ducts widen. The acini increase in number and size. In late pregnancy, the fatty tissues of the breasts are almost completely replaced by cellular breast parenchyma. After delivery, the breasts, now fully mature, start to secrete milk. With cessation of nursing or administration of estrogens, which inhibit lactation, the breast rapidly returns to its prepregnancy state, with marked diminution of cellular elements and an increase in adipose deposits.

When menses ceases between the fifth and sixth decades of life, the breast undergoes a gradual process of atrophy and involution. There is a decrease in the number and size of acinar and ductal elements, so that the breast tissue regresses to an almost infantile state. Adipose tissue may or may not atrophy, with disappearance of the parenchymal elements.

GROSS ANATOMY

(Fig 63–1) The adult female breast mound characteristically forms a near hemispheric contour on each side of the chest wall, usually extending from just below the level of the second rib inferiorly to the sixth or seventh rib. The breast mound is usually situated between the lateral sternal border and the anterior axillary fold. The breast tissue extends over a larger anatomic area than the more obvious breast mound. The superior portion of the breast tissue emerges gradually from the chest wall inferior to the clavicle, whereas the lateral and inferior borders are better defined. The major portion of the breast tissue is located superficial to the pectoralis major muscle and projects laterally and ventrally toward the tail of Spence. Smaller portions of breast tissue extend laterally and inferiorly to lie superficial to the serratus anterior and external oblique muscles and as far caudad as the rectus abdominis. The tail of Spence is a triangular tongue-shaped portion of breast tissue that extends superiorly and laterally toward the axilla, perforating the deep axillary fascia, and enters the axilla, where it terminates in close proximity to the axillary lymph nodes and vessels as well as the axillary blood vessels and nerves.

Sagittal section of mammary gland.

The Nipple & Areola

The areola is a circular pigmented zone 2–6 cm in diameter at the tip of the breast. Its color varies from pale pink to deep brown depending on age, parity and skin pigmentation. The skin of the areola contains multiple small, elevated nodules beneath which are located the sebaceous glands of Montgomery. The glands are responsible for lubrication of the nipple and help prevent cracks and fissures in the nipple–areolar complex that occur during breastfeeding. During the third trimester of pregnancy, the sebaceous glands of Montgomery markedly hypertrophy.

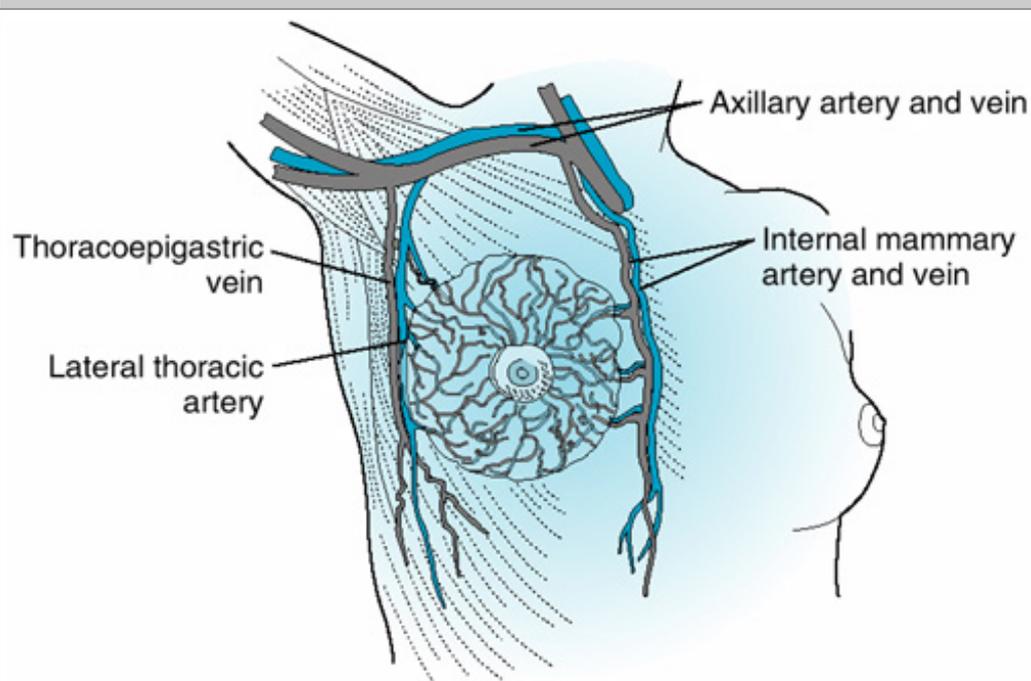

A circular smooth muscle band surrounds the base of the nipple. Longitudinal smooth muscle fibers branch out from this ring of circular smooth muscle to encircle the lactiferous ducts as they converge toward the nipple. The many small punctate openings at the superior aspect of the nipple represent the terminals of the major lactiferous ducts. As discussed earlier, the ampullae of the lactiferous ducts are deep to the nipple and the areola.

Blood Vessels, Lymphatics, & Nerves

ARTERIES

(Fig 63–2) The breast has a rich blood supply with multiple arteries and veins. Branches from the internal thoracic artery that penetrate the second, third and fourth intercostal interspaces supply blood to the medial half of the breast. These arteries perforate the intercostal muscles and the anterior intercostal membrane to supply both the breast and the pectoralis major and minor muscles. During pregnancy, and not infrequently in advanced breast disease, the intercostal perforators may enlarge from engorgement. Small branches from the anterior intercostal arteries also supply the medial aspect of the breast. Laterally, the pectoral branch of the thoracoacromial branch of the axillary artery and the external mammary branch of the lateral thoracic artery, which also is a branch of the second segment of the axillary artery, supply the breast. The external mammary artery passes along the lateral free edge of the pectoralis major muscle to reach the lateral half of the breast. The artery usually is located medial to the long thoracic nerve.

Figure 63–2.

Arteries and veins of the breast.

The medial and lateral arteries, as they reach the breast, tend to arborize mainly in the supra-areolar area; consequently, the arterial supply to the upper half of the breast is almost twice that of the lower half.

VEINS

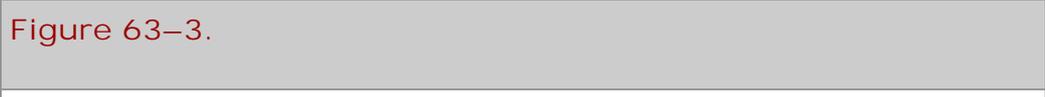

Venous return from the breast closely follows the routes of the arterial system. Blood returns to the superior vena cava via the axillary and internal thoracic veins. It also returns via the vertebral venous plexuses, which are fed by the intercostal and azygos veins. Through the azygos veins, there is also some minor flow into the portal system. A rich anastomotic plexus of superficial breast veins is located in the subareolar region. In thin-skinned, fair individuals, these veins are normally visible, and they are

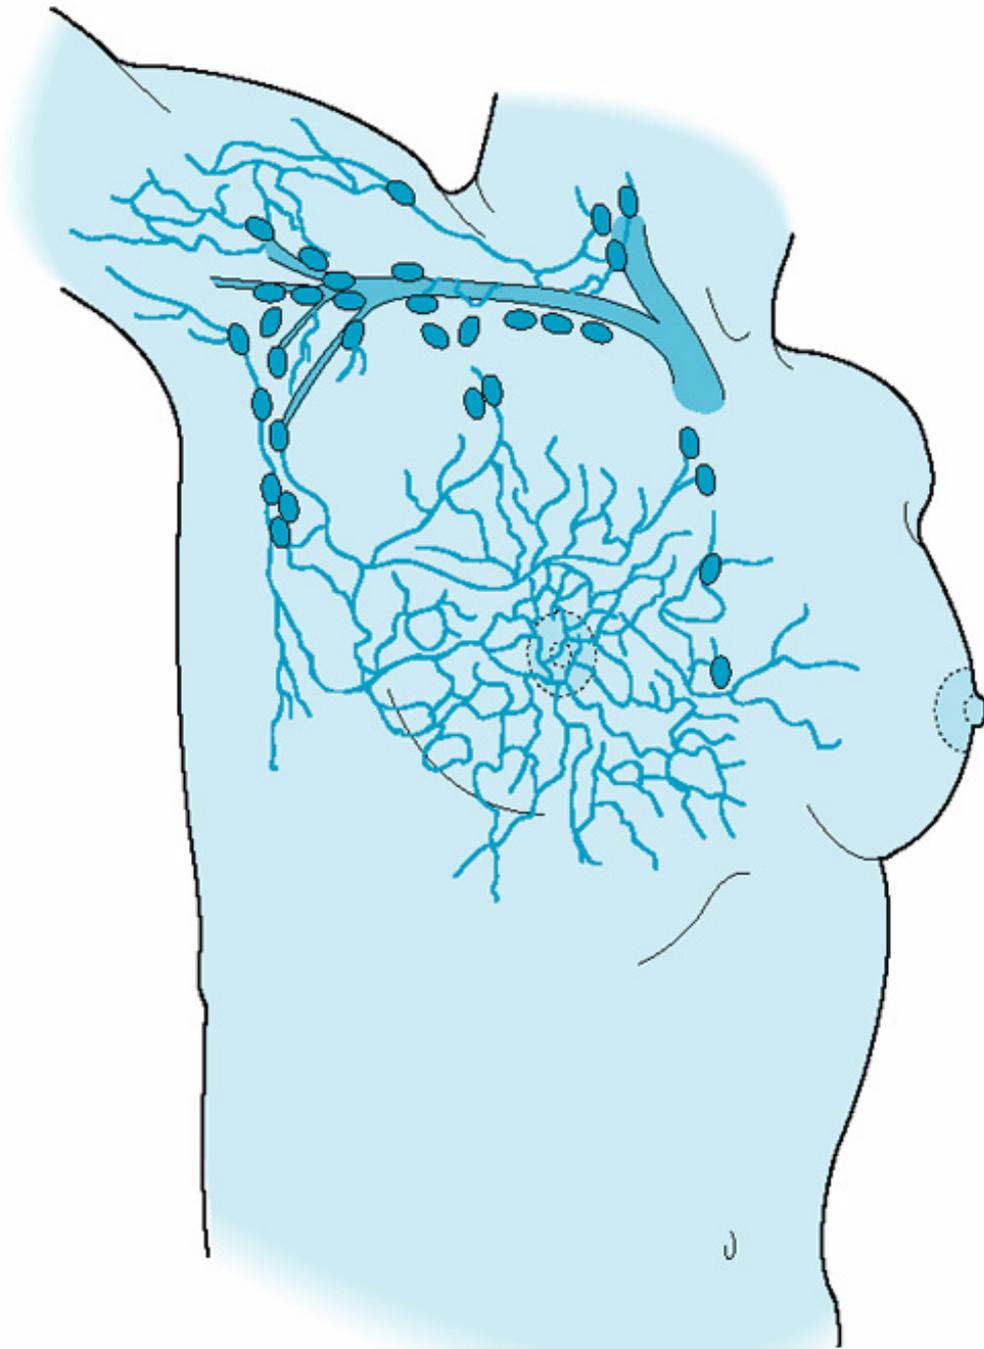

almost always visible during pregnancy. Their presence makes for marked vascularity of sub- and para-areolar incisions. Venous return flow is greater in the superior quadrants than in the inferior quadrants of the breast.

LYMPHATICS

(Fig 63–3) A thorough knowledge of the lymphatic drainage of the breast is of critical importance to the clinician. This is true because the lymphatic drainage has significant implications in several disease etiologies, including breast cancer. To a large extent, modern, less-invasive surgical management techniques such as sentinel lymph node biopsy are based on a solid understanding of the pattern of lymphatic drainage in the breast.

Figure 63–3.

Lymphatics of the breast and axilla.

Lymphatic drainage in the breast may be divided into 2 main categories: superficial (including cutaneous) drainage and deep parenchymatous drainage.

Superficial Drainage

A large lymphatic plexus exists in the subcutaneous tissues of the breast deep to the nipple–areolar complex. This plexus drains the areola and nipple regions, including the cutaneous and subcutaneous

tissues adjacent to the nipple–areolar complex. In addition, the superficial plexus drains the deep central parenchymatous region of the breast.

Deep Parenchymatous Drainage

The deep parenchymatous lymph vessels drain the remainder of the breast as well as some portion of the skin and subcutaneous tissues of the nipple–areolar complex not served by the superficial plexus. Small periductal and periacinal lymph vessels collect parenchymal lymph and deliver it to the larger interlobar lymphatics. Lymph from the cutaneous and nipple–areolar regions may drain either directly into the subareolar plexus or deeply into the parenchymatous lymph system. Once in the deep parenchymatous drainage, the lymph is delivered to the subareolar plexus for efferent transport.

The majority of lymphatic drainage from both the retroareolar and the deep interlobar lymphatics of the breast travel to the ipsilateral axillary lymph nodes. The route of drainage to the highest axillary node or nodes is not reproducible from patient to patient. For example, lymph flowing in either the superior or inferior mammary trunk may bypass the inferior or central group of axillary nodes and flow directly to the highest group of axillary nodes. In general, however, the drainage of the breast is to the anterior axillary or subpectoral nodes, which are located deep to the lateral border of the pectoralis major muscle, close to the lateral thoracic artery. From these nodes, lymph travels to nodes in close proximity to the lateral portion of the axillary vein. The lymph then passes superiorly, via the axillary chain of lymph vessels and nodes. Eventually, the drainage reaches the highest nodes of the axilla. Although this is the most regular pattern of lateral and superior breast lymphatic drainage, other paths are common, particularly when the lateral and superiorly directed channels are obstructed, for example, by tumor masses. When plugging occurs, the following pathways are available for lymphatic flow from the breast:

- a. From the breast directly to the highest axillary node, completely bypassing all other axillary nodal tissue. This may occur with superior quadrant breast tumors.
- b. From the breast directly to the subscapular group of axillary nodes, subsequently progressing ventrally and superiorly through channels lying close to the axillary vein.
- c. From the breast directly to the most inferior group of supraclavicular cervical nodes. Supraclavicular nodes, however, are more commonly involved via direct extension from the apical axillary nodes.
- d. From the breast across the sternal midline to the lymphatics of the contralateral breast.
- e. From the breast directly to the contralateral axilla.
- f. From the breast to the internal mammary group of nodes when the primary breast tumor is in a medial quadrant.
- g. Rarely, from the breast to lymphatics that drain to lymphatics closely related to the sheaths of the superior segments of the rectus abdominis and external oblique muscles and in turn drain inferiorly toward the upper abdominal wall, the diaphragm, and the intra-abdominal viscera (especially the liver).

NERVES ENCOUNTERED DURING AXILLARY DISSECTION

The lateral and anterior cutaneous branches of T4–6 supply the cutaneous tissues covering the breasts. Two major nerves and two smaller groups of nerves are in close proximity to the breast area and thus assume importance in breast surgery:

- (1) The thoracodorsal nerve, a branch of the posterior cord of the brachial plexus (C5–7), runs inferiorly along with the subscapular artery lying close to the posterior axillary wall and the ventral surface of the subscapular muscle. The nerve innervates the superior half of the latissimus dorsi muscle and is usually surrounded by a large venous plexus that drains into the subscapular veins.
- (2) The long thoracic nerve (nerve of Bell) arises from the anterior primary divisions of C5–7 at the level of the lower half of the anterior scalene muscle. In the neck, the nerve descends dorsal to the

trunks of the brachial plexus on the inferior segment of the middle scalene muscle. Further descent places it dorsal to the clavicle and the axillary vessels. On the lateral thoracic wall, it descends on the external surface of the serratus anterior muscle along the anterior axillary line. The long thoracic nerve supplies filaments to each of the digitations of the serratus anterior muscle. Injury to this nerve results in a "winged" scapula.

(3) The intercostal brachial nerves are three relatively minor cutaneous nerves that supply the skin of the medial surface of the upper arm. They transverse the lateral chest wall to the upper inner surface of the arm, passing across the base of the axilla.

(4) The medial and lateral pectoral nerves supply the two pectoral muscles and pass from the axilla to the lateral chest wall. At the lateral chest wall, they pierce the costocoracoid membrane. The medial pectoral nerve arises from the medial cord of the brachial plexus; the lateral pectoral nerve arises from the lateral cord of the plexus.

FIBROCYSTIC CHANGE

Essentials of Diagnosis

- Painful, often multiple, usually bilateral mobile masses in the breast.
- Rapid fluctuation in the size of the masses is common.
- Frequently, pain occurs or increases as does size during the premenstrual phase of the cycle.
- Most common age is 30–50 years; occurrence is rare in postmenopausal women.

General Considerations

Fibrocystic disease, or chronic cystic mastitis, formerly known as mammary dysplasia, is the most frequent benign condition of the breast. It is most common in women 30–50 years of age, but rare in postmenopausal women; this suggests that it is related to ovarian activity. The term mammary dysplasia, or fibrocystic disease, is imprecise and encompasses a wide spectrum of pathologic entities. The lesions are always associated with benign changes in the breast epithelium, some of which are found so frequently in normal breasts that they are probably variants of normal breast histology, but have, unfortunately, been termed a "disease."

The microscopic findings of fibrocystic change include cysts (gross and microscopic), papillomatosis, adenosis, fibrosis, and ductal epithelial hyperplasia.

Clinical Findings

Fibrocystic change may produce an asymptomatic lump or lumps in the breast that are discovered by palpation, but pain or tenderness is often the presenting symptom and calls attention to the mass. There may be discharge from the nipple. In many cases, discomfort occurs or is increased during the premenstrual phase of the cycle, at which time the cysts tend to enlarge. Some women seem to have more severe pain that is constant and not related to the menstrual cycle (mastodynia). Fluctuation in size and rapid appearance or disappearance of a breast mass are common in cystic changes. Multiple or bilateral masses are also common, and many patients give a history of a transient lump in the breast or cyclic breast pain. In many women, caffeine seems to potentiate these symptoms. However, the role of caffeine as a direct cause of these symptoms has never been proven. Pain, fluctuation in size, and multiplicity of lesions are the features most helpful in differentiation from carcinoma. However, if a dominant mass is present, it should be evaluated by biopsy.

Differential Diagnosis

Pain, fluctuation in size, and multiplicity of lesions help to differentiate these lesions from carcinoma and

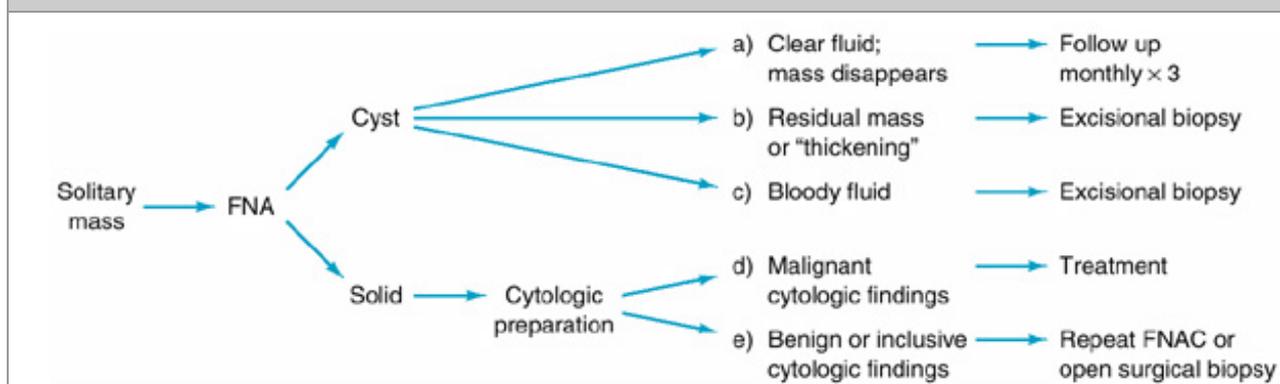

the benign entity of fibroadenoma. Final diagnosis often rests on biopsy and pathologic determination. Mammography may be helpful, but the breast tissue in these young women may be too radiodense to allow a meaningful evaluation. Aspiration and/or sonography may be useful in differentiating a cystic from a solid mass.

Treatment

Because the condition of fibrocystic change is frequently indistinguishable from carcinoma on the basis of clinical findings, it is often advisable to proceed with biopsy and histologic examination of suspicious lesions, which is usually done under local anesthesia. Surgery should be conservative, as the primary objective is to exclude a malignant process. Simple mastectomy or extensive removal of breast tissue is rarely, if ever, indicated for fibrocystic change.

When the diagnosis of fibrocystic change has been established by previous biopsy or is practically certain, because the history is classic, aspiration of a discrete mass suggestive of a cyst is another option. The patient is reexamined at intervals thereafter. If no fluid is obtained or if the fluid is bloody, if a mass persists after aspiration, or if anytime during follow-up a persistent lump is noted, biopsy should be performed (Fig 63–4).

Figure 63–4.

Algorithm for the use of fine-needle aspiration (FNA) and fine-needle aspiration cytology (FNAC) for office triage of breast lumps.

(Reproduced with permission from Hindle WH: *Breast Disease for Gynecologists*. Appleton & Lange, 1990.)

Breast pain associated with generalized fibrocystic change is best treated by avoiding trauma and by wearing a bra with adequate support.

The role of caffeine consumption in the development and treatment of fibrocystic change is controversial. Many patients report relief of symptoms after abstinence from coffee, tea, and chocolate.

Prognosis

Exacerbations of pain, tenderness, and cyst formation may occur at any time until menopause, when symptoms subside. The patient should be advised to examine her own breasts each month just after menstruation, conventionally 5 days after the last day of bleeding, and to inform her physician if a mass appears. Because the risk of breast cancer in women with fibrocystic change showing proliferative or atypical changes in the epithelium is higher than that of women in general, follow-up examinations at

regular intervals should be arranged.

FIBROADENOMA OF THE BREAST

This common, benign neoplasm occurs most frequently in young women, usually within 20 years after puberty. It is somewhat more frequent and tends to occur at an earlier age in black women than in white women. Multiple tumors in one or both breasts are found in 10–15% of patients.

The typical fibroadenoma is a round, firm, discrete, relatively movable, nontender mass 1–5 cm in diameter. The tumor is usually discovered accidentally. Clinical diagnosis in young patients is generally not difficult. In women older than age 30 years, cystic disease of the breast and carcinoma of the breast must be considered in the differential. Cysts can be identified by ultrasound examination and aspiration. Fibroadenoma does not normally occur after menopause, but postmenopausal women may occasionally develop fibroadenoma after administration of estrogenic hormone.

Treatment is either excision under local anesthesia or close, careful, clinical observation.

Cystosarcoma phyllodes is a type of fibroadenoma with cellular stroma that tends to grow rapidly. This tumor may reach a large size and if inadequately excised will recur locally. The lesion can be, but rarely is, malignant. Treatment is by local excision of the mass with a margin of surrounding normal breast tissue. The treatment of malignant cystosarcoma phyllodes is more controversial. In general, complete removal of the tumor and a rim of normal tissue should prevent recurrence. Because these tumors tend to be large, simple mastectomy is often necessary to achieve complete local control.

NIPPLE DISCHARGE

General Considerations

The most common causes of nipple discharge in the nonlactating breast are carcinoma, intraductal papilloma, and fibrocystic change with ectasia of the ducts. The important characteristics of the discharge and some other factors to be evaluated by history and physical examination are as follows:

- (1) Nature of discharge (serous, bloody, or other)
- (2) Association with or without a mass
- (3) Unilateral or bilateral
- (4) Single duct or multiple duct discharge
- (5) Discharge that is spontaneous, persistent or intermittent, or must be expressed
- (6) Discharge produced by pressure at a single site or by general pressure on the breast
- (7) Relation to menses
- (8) Premenopausal or postmenopausal
- (9) History of oral contraceptive use or estrogen replacement for postmenopausal symptoms

Differential Diagnosis

Unilateral, spontaneous serous or serosanguineous discharge from a single duct is usually caused by an intraductal papilloma or, more infrequently, by an intraductal malignancy. In either case, a palpable mass may not be present. The involved duct may be identified by pressure at different sites around the nipple at the margin of the areola. Bloody discharge is more suggestive of cancer but is usually caused by a benign papilloma in the duct. Cytologic examination of the discharge should be accomplished and may identify malignant cells, but negative findings do not rule out cancer, which is more likely in women older than age 50 years. In either situation, the involved duct, and a mass if present, should be excised.

In premenopausal women, spontaneous multiple duct discharge, unilateral or bilateral, most markedly just prior to menstruation, is often caused by fibrocystic change. Discharge may be green or brownish. Papillomatosis and ductal ectasia are also diagnostic possibilities. Biopsy may be necessary to establish the diagnosis of a diffuse nonmalignant process. If a mass is present, it should be surgically removed.

Milky discharge, galactorrhea, from multiple ducts in the nonlactating breast may occur in certain syndromes (Chiari-Frommel syndrome, Argonz-Del Castillo [Forbes-Albright] syndrome), usually as a result of increased secretion of pituitary prolactin. An endocrine work-up is generally indicated. Drugs of the chlorpromazine family and contraceptive pills may also cause milky discharge that ceases on discontinuance of the medication. Other medical illnesses may less frequently cause galactorrhea (Table 63–1).

Table 63–1. Causes of Galactorrhea.

Idiopathic

Drug induced

Phenothiazines, butyrophenones, reserpine, methyl dopa, imipramine, amphetamine, metoclopramide, sulpride, pimozide, oral contraceptive agents

Central nervous system (CNS) lesions

Pituitary adenoma, empty sella, hypothalamic tumor, head trauma

Medical conditions

Chronic renal failure, sarcoidosis, Schuller-Christian disease

Cushing's disease, hepatic cirrhosis, hypothyroidism

Chest wall lesions

Thoracotomy, herpes zoster

Reproduced, with permission, from Hindle WH: *Breast Disease for Gynecologists*. Appleton & Lange, 1990.

Oral contraceptive agents may cause clear, serous, or milky discharge from a single duct, but multiple duct discharge is more common. The discharge is most prevalent prior to menstruation and ceases with discontinuation of the medication. If it does not and the discharge is from a single duct, surgical exploration should be considered.

Purulent discharge can originate in a subareolar abscess and may require excision of the abscess and related lactiferous sinus.

When localization is not possible and no mass is palpable, the patient should be re-examined every week for 1 month. When unilateral discharge persists, even without definite localization or palpable mass, exploration must be considered. The alternative is careful follow-up at intervals of 1–3 months with accompanying mammography. Cytologic examination of nipple discharge for exfoliated cancer cells may be helpful in yielding a diagnosis.

Chronic unilateral nipple discharge, especially if bloody, is an indication for resection of the involved

ducts.

FAT NECROSIS

Fat necrosis is a rare condition of the breast but is of clinical importance because it produces a mass, often accompanied by skin or nipple retraction, that is clinically indistinguishable from carcinoma. Trauma is the presumed etiology, although only about half of patients recall a history of injury to the breast. Ecchymosis is occasionally observed in conjunction with the mass. Tenderness may or may not be present. If untreated, the mass associated with fat necrosis gradually disappears. Should the mass not resolve after several weeks, a biopsy should be considered. The entire mass should be excised, primarily to rule out malignant processes.

BREAST ABSCESS

During lactation and nursing, an area of redness, tenderness, and induration may develop in the breast. In its early stages, the infection can often be resolved while continuing nursing with the affected breast and administering an antibiotic. If the lesion progresses to form a palpable mass with local and systemic signs of infection, an abscess has developed and needs to be drained. At this point, nursing should be discontinued.

Less frequently, a subareolar abscess may develop in young or middle-age women who are not lactating. These infections tend to recur after simple incision and drainage unless the area is explored in a quiescent interval with excision of the involved lactiferous duct or ducts at the base of the nipple. Except for the subareolar type of abscess, infection in the breast is very rare unless the patient is lactating. Therefore, findings suggestive of abscess in the nonlactating breast require surgical evaluation with biopsy of indurated tissue.

MALFORMATION OF THE BREAST

Many women consult their physicians for abnormalities in either the size or the symmetry of their breasts. Difference in size between the two breasts is common. If extreme, however, these differences may be corrected by cosmetic surgery, although the breast tissue in these individuals is otherwise normal.

Similarly, woman may complain of overly large breasts (macromastia). Studies fail to show any endocrinologic or pathologic abnormalities, and these patients may also be considered candidates for cosmetic surgery such as breast-reduction mammoplasty.

Less-common malformations of the breast include amastia, complete absence of one or both breasts, or the presence of accessory nipples and breast tissue along the embryologic milk line, which occurs in 1–2% of whites.

PUERPERAL MASTITIS

See Chapter 31.

CARCINOMA OF THE FEMALE BREAST

Essentials of Diagnosis

- Early findings: Single, nontender, firm to hard mass with ill-defined margins; mammographic abnormalities and no palpable mass.
- Later findings: Skin or nipple retraction; axillary lymphadenopathy; breast enlargement, redness, edema, brawny induration, peau d'orange, pain, fixation of mass to skin or chest wall.
- Late findings: Ulceration; supraclavicular lymphadenopathy; edema of arm; bone, lung, liver,

brain, or other distant metastases.

General Considerations

Cancer of the breast is the most common cancer in women, excluding nonmelanoma skin cancers. After lung cancer, it is the second most common cause of cancer death for women. The American Cancer Society estimates 212,930 new cases of cancer of the breast and 40,870 deaths in 2005. These figures include male breast cancer, which accounts for less than 1% of annual breast cancer incidence. Despite a slight increase in yearly incidence, the cancer death rate for malignancies of the breast decreased an average of 2.3% per year from 1990 to 2001. The probability of developing the disease increases throughout life. The mean and the median age of women with breast cancer is 60–61 years.

At the present rate of incidence, a woman's risk of developing invasive breast cancer in her lifetime from *birth* to *death* is 1 in 8. This figure is from the Surveillance, Epidemiology, and End Results Program (SEER) of the National Cancer Institute (NCI) and is often cited but needs clarification. The data include all age groups in 5-year intervals with an open-ended interval at 85 years and above. When calculating risk, each age interval is weighted to account for the increasing risk of breast cancer with increasing age. A woman's risk of being diagnosed with breast cancer by age is as follows:

- By age 30: 1 in 2000
- By age 40: 1 in 233
- By age 50: 1 in 53
- By age 60: 1 in 22
- By age 70: 1 in 13
- By age 80: 1 in 9
- In a lifetime: 1 in 8

Although a woman's lifetime risk of developing breast cancer is 1 in 8, it must be emphasized that she still has a 7 in 8 chance of never developing breast cancer. Women whose mothers or sisters had breast cancer are more likely to develop the disease than controls. The presence of an inherited genetic mutation in the *BRCA1* and *BRCA2* genes, which accounts for approximately 5% of all breast cancers, also places women at increased risk of being diagnosed with breast cancer. Risk is increased when breast cancer has occurred before menopause, was bilateral, or was present in two or more first-degree relatives such as a mother and sister. However, there is no history of breast cancer among female relatives in more than 90% of patients with newly diagnosed breast cancer. Nulliparous women and women whose first full-term pregnancy was after age 30 years have a slightly higher incidence of breast cancer than multiparous women. Late menarche and artificial menopause are associated with a lower incidence of breast cancer, whereas early menarche (before age 12 years) and late natural menopause (after age 50 years) are associated with a slight increase in risk of developing breast cancer. Fibrocystic change of the breast, when accompanied by proliferative changes, papillomatosis, or atypical epithelial hyperplasia, is associated with an increased incidence of cancer. A personal history of breast cancer is the greatest risk factor for subsequent breast cancer events. A woman who has had cancer in one breast is at increased risk of recurrence and second primary in that ipsilateral breast, as well as developing cancer in the contralateral breast. Women with cancer of the uterine corpus have a breast cancer risk significantly higher than that of the general population, and women with breast cancer have a comparably increased risk of endometrial cancer. In the United States, breast cancer is more common in whites than in nonwhites. The incidence of the disease among nonwhites, mostly African Americans,

however, is increasing, especially in younger women. In general, rates reported from developing countries are low, whereas rates are high in developed countries, with the notable exception of Japan. Some of the variability may be a result of underreporting in the developing countries, but a real difference probably exists. Lifestyle factors such as diet, exercise, and increasing extent of antibiotic use are implicated as possible causes for this observed difference.

Women who are at greater-than-normal risk of developing breast cancer should be identified by their physicians and followed carefully. Screening programs involving periodic physical examination and mammography of asymptomatic high-risk women increase the detection rate of breast cancer and may improve the survival rate, although this has not yet been demonstrated. Unfortunately, more than 50% of women who develop breast cancer do not have significant identifiable risk factors.

Growth potential of tumor and resistance of host vary over a wide range from patient to patient and may be altered during the course of the disease. The doubling time of breast cancer cells ranges from several weeks in a rapidly growing lesion to nearly a year in a slowly growing one. If one assumes that the rate of doubling is constant and that the neoplasm originates in one cell, a carcinoma with a doubling time of 100 days may not reach clinically detectable size (1 cm) for about 8 years. On the other hand, rapidly growing cancers have a much shorter preclinical course and a greater tendency to metastasize to regional nodes or more distant sites before a breast mass is discovered.

The relatively long preclinical growth phase and the tendency of breast cancers to metastasize have led many clinicians to believe that breast cancer is a systemic disease at the time of diagnosis. Although it may be true that breast cancer cells are released from the tumor prior to diagnosis, variations in the host-tumor relationship may prohibit the growth of disseminated disease in many patients. For this reason, a pessimistic attitude concerning the management of localized breast cancer is not warranted, and many patients can be cured with proper treatment.

Staging

The physical examination of the breast and additional preoperative studies are used to determine the clinical stage of a breast cancer. Clinical staging is based on the TNM (tumor, node, metastasis) system of the International Union Against Cancer. This classification considers tumor size, clinical assessment of axillary nodes, and the presence or absence of distant metastases. The assessment of the clinical stage is important in planning therapy. Histologic (or pathologic) staging is determined following surgery and along with clinical staging helps determine prognosis (Table 63–2).

Table 63–2. Clinical Staging of Breast Carcinoma.

Tis carcinoma in situ	Stage 0		
	Tis	NO	MO
T1			
T1mic microinvasion \leq 0.1 cm	Stage I		
T1a > 0.1 but \leq 0.5 cm	T1	NO	MO

Clinical Findings

The patient with breast cancer usually presents with a lump in the breast or an abnormal screening mammogram. Clinical evaluation should include assessment of the local lesion, including a bilateral mammogram, if not previously performed, and a search for evidence of metastases in regional nodes or distant sites. After the diagnosis of breast cancer has been confirmed by tissue biopsy, additional studies are often needed to complete the evaluation for distant metastases or an occult primary lesion in the

other breast. Then, before any decision is made about treatment, all the available clinical data are used to determine the extent or "stage" of the patient's disease.

SYMPTOMS

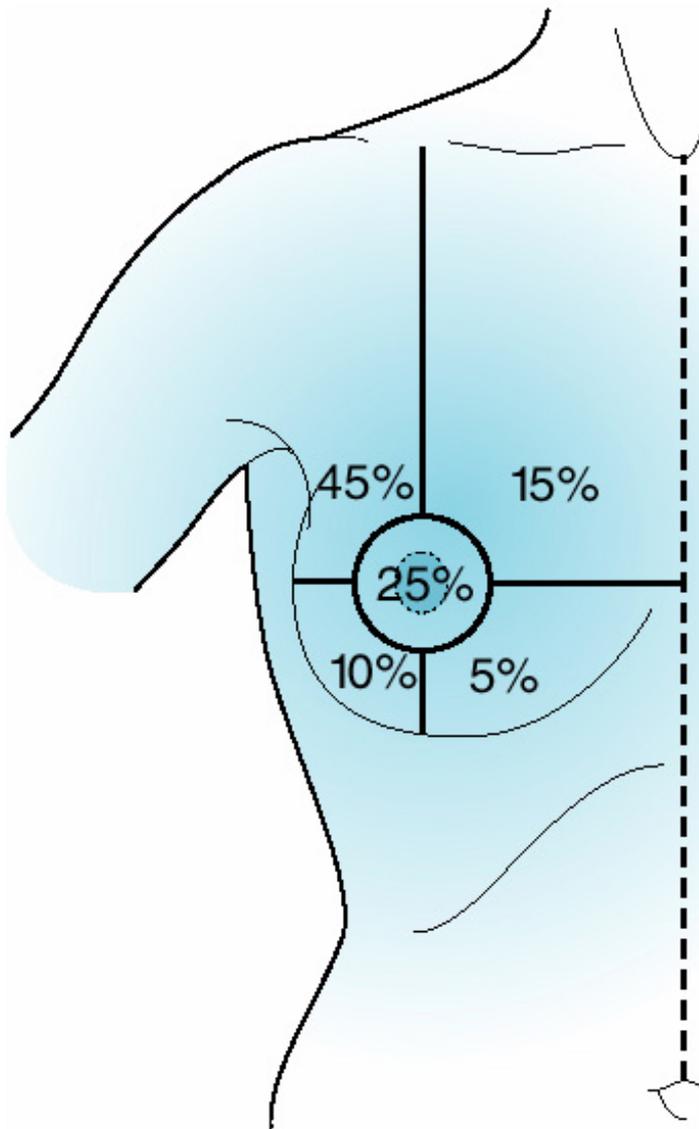

When the history is taken, special note should be made of the onset and duration of menarche, pregnancies, parity, artificial or natural menopause, date of last menstrual period, previous breast lesions and/or biopsies, hormonal supplementation, radiation exposure, and a family history of breast cancer. Back or other bone pain may be the result of osseous metastases. Systemic complaints or weight loss should raise the question of metastases, which may involve any organ but most frequently the bones, liver, and lungs. The more advanced the cancer in terms of aggressive histologic features, size of primary lesion, local invasion, and extent of regional node involvement, the higher is the incidence of metastatic spread to distant sites. Lymph node involvement is the single most significant prognostic feature and increases with increasing tumor size and aggressive histologic features such as pathological grade.

The presenting complaint in approximately 70% of patients with breast cancer is a lump (usually painless) in the breast. Approximately 90% of breast masses are discovered by the patient herself. Less-frequent symptoms are breast pain; nipple discharge; erosion, retraction, enlargement, or itching of the nipple; and redness, generalized hardness, enlargement, or shrinking of the breast. Rarely, an axillary mass, swelling of the arm, or bone pain (from metastases) may be the first symptoms. Approximately 35–50% of women involved in organized screening programs have cancers detected by mammography only.

SIGNS

Figure 63–5 shows the relative frequency of carcinoma in various anatomic sites in the breast.

Figure 63–5.

Frequency of breast carcinoma at various anatomic sites.

Inspection of the breast is the first step in physical examination and should be carried out with the patient sitting, arms at sides and then overhead. Abnormal variations in breast size and contour, minimal nipple retraction, and slight edema, redness, or retraction of the skin can be identified. Asymmetry of the breasts and retraction or dimpling of the skin can often be accentuated by having the patient raise her arms overhead or press her hands on her hips in order to contract the pectoralis muscles. Axillary and supraclavicular areas should be thoroughly palpated for enlarged nodes with the patient sitting (Fig 63–6). Palpation of the breast for masses or other changes should be performed with the patient both seated and supine with the arm abducted (Fig 63–7).

Palpation of breasts. Palpation is performed with the patient supine and the arm abducted.

Breast cancer usually consists of a nontender, firm or hard lump with poorly delineated margins generally caused by local infiltration. Slight skin or nipple retraction is an important sign as it may affect staging. Minimal asymmetry of the breast may be noted. Very small (1–2-mm) erosions of the nipple epithelium may be the only manifestation of Paget's carcinoma. Watery, serous, or bloody discharge from the nipple is an occasional early sign but is more often associated with benign disease as discussed earlier.

A lesion smaller than 1 cm in diameter may be difficult or impossible for a clinical examiner to feel and yet may be discovered by the patient's self-examination. She should always be asked to demonstrate the location of the mass; if the physician fails to confirm the patient's suspicions, radiographic evaluation should be attempted and the examination should be repeated in 1 month. During the premenstrual phase of the cycle, increased innocuous nodularity may suggest neoplasm or may obscure an underlying lesion. If there is any question regarding the nature of an abnormality under these circumstances, the patient should be asked to return after her period.

The following are characteristic of advanced carcinoma: edema, redness, nodularity, or ulceration of the skin; the presence of a large primary tumor (> 5 cm); fixation to the chest wall; enlargement, shrinkage, or retraction of the breast; marked axillary lymphadenopathy; edema of the ipsilateral arm; supraclavicular lymphadenopathy; and distant metastases.

Spread of disease is often, though not always, systematic. Most frequently, metastases initially tend to involve regional lymph nodes first, which may be clinically palpable, before spreading to distant sites. With regard to the axilla, 1 or 2 movable, nontender, not particularly firm lymph nodes 5 mm or less in diameter are frequently present and are generally of no clinical significance. Any firm or hard nodes larger than 5 mm in diameter are highly suspicious for nodal metastases. Axillary nodes that are matted

or fixed to skin or deep structures indicate locally advanced disease (at least stage III). Histologic studies show that microscopic metastases are present in approximately 40% of patients with clinically negative nodes. Conversely, if the examiner believes that the axillary nodes are involved, this is confirmed in approximately 85% of cases on pathologic examination. The incidence of positive axillary nodes increases with the size of the primary tumor, the degree of local invasiveness of the neoplasm and certain aggressive histologic features such as tumor grade.

Usually no nodes are palpable in the supraclavicular fossa. Firm or hard nodes of any size in this location or just beneath the clavicle (infraclavicular nodes) are indicative of locally advanced disease and suggest the strong possibility of distant metastatic sites of cancer. Biopsy or fine-needle aspiration to confirm nodal involvement in these areas is paramount. Ipsilateral supraclavicular nodes containing cancer indicate that the patient is in an advanced stage of the disease (stage IIIC). Edema of the ipsilateral arm, commonly caused by metastatic infiltration of regional lymphatics, is also a sign of advanced cancer.

SPECIAL CLINICAL FORMS OF BREAST CARCINOMA

Paget's Disease

This refers to eczematous changes about the nipple and is associated with cancer in 99% of cases. An underlying mass is palpable in 60% of patients with Paget's disease. Of these masses, 95% are found to be an invasive cancer, mostly infiltrating ductal. For patients with Paget's disease and no palpable mass, 75% of breast biopsies are found to harbor ductal carcinoma in situ, a noninvasive breast malignancy. The nipple epithelium is infiltrated, but gross nipple changes are often minimal, and a tumor mass may not be palpable. The first symptom is often itching or burning of the nipple, with a superficial erosion or ulceration. The diagnosis is established by biopsy of the erosion.

Paget's disease is not common (approximately 1% of all breast cancers), but it is important because it appears innocuous. It is frequently diagnosed and treated as dermatitis or bacterial infection, leading to an unfortunate delay in detection. If detected early, Paget's disease rarely involves the axillary lymph nodes. Treatment can be modified radical mastectomy or breast-conservation therapy, which includes postlumpectomy radiation, with an expected 8-year disease-free survival of 90% or greater.

Inflammatory Carcinoma

This is a clinical, pathologic entity defined as diffuse, brawny edema of the skin of the breast with an erysipeloid border, usually without an underlying palpable mass. Generally this is a clinical diagnosis with pathologic confirmation of tumor embolization in the dermal lymphatics by biopsy of the overlying skin. Inflammatory breast cancer is the most aggressive form of breast cancer. Luckily, it represents less than 5% of cases. At presentation, nearly 35% of patients with inflammatory breast cancer have evidence of metastases. The inflammatory component, often mistaken for an infectious process, is caused by the blockage of dermal lymphatics by tumor emboli, which results in edema and hyperemia. If a suspected skin infection does not rapidly respond (1–2 weeks) to a course of antibiotics, biopsy must be performed. Treatment usually consists of several cycles of neoadjuvant polychemotherapy followed by surgery or radiation depending on tumor response. Because of its severity and relatively small incidence, patients should be encouraged to enter into protocol therapy.

Occurrence during Pregnancy or Lactation

Cancer of the breast diagnosed in pregnancy has a ratio of occurrence from 1:3000 to 1:10,000. The association of pregnancy and breast cancer presents a therapeutic dilemma for the patient and the physician. Numerous studies differ regarding the prognosis; some show poorer outcome, while others demonstrate no difference. Termination of the pregnancy, formerly performed routinely in the first two trimesters, has not been demonstrated to improve outcome. In addition, the use of radiotherapy is contraindicated because of the potential for fetal damage. The use of most chemotherapy, for similar

reasons, is debatable but generally accepted as safe based on retrospective reviews and experience.

In most instances, modified radical mastectomy in pregnancy is the minimal treatment of choice, with the possible exception of the latter part of the third trimester, wherein lumpectomy and radiotherapy in the puerperium may be considered.

Bilateral Breast Cancer

Clinically evident simultaneous bilateral breast cancer occurs in less than 1% of cases, but there is a 5–8% incidence of later occurrence of cancer in the second breast. Bilaterality occurs more often in women younger than age 50 years and is more frequent when the tumor in the primary breast is lobular. The incidence of second breast cancers increases directly with the length of time the patient is alive after her first cancer and is approximately 1.0% per year.

In patients with breast cancer, mammography should be performed before primary treatment and at regular intervals thereafter to search for occult cancer in the opposite breast. Routine biopsy of the opposite breast is usually not warranted.

MAMMOGRAPHY

Mammography is the most reliable means of detecting breast cancer before a mass can be palpated in the breast. Some breast cancers can be identified by mammography as early as 2 years before reaching a size detectable by palpation.

Although false-positive and false-negative results are occasionally obtained with mammography, the experienced radiologist can interpret mammograms correctly in approximately 90% of cases. For women with a history of mammographically occult lesions or otherwise at high risk for harboring cancer that is not detectable by mammogram, magnetic imaging resonance (MRI) and ultrasound may be warranted but they are not recommended for screening the general population.

Other than for screening, indications for mammography are as follows: (a) to evaluate each breast when a diagnosis of potentially curable breast cancer has been made, and at yearly intervals thereafter; (b) to evaluate a questionable or ill-defined breast mass or other suspicious change in the breast; (c) to search for an occult breast cancer in a woman with metastatic disease in axillary nodes or elsewhere from an unknown primary; (d) to screen at regular intervals a selected group of women who are at high risk for developing breast cancer (see below); (e) to screen women prior to cosmetic operations or prior to biopsy; and (f) to follow women who have been treated with breast-conserving surgery and radiation.

Patients with a dominant or suspicious mass must undergo biopsy regardless of mammographic findings. The mammogram should be obtained prior to biopsy so that other suspicious areas can be noted and the contralateral breast can be checked. Mammography is never a substitute for biopsy because it may not reveal clinical cancer in a very dense breast, as may be seen in young women with fibrocystic change, and it often does not reveal medullary-type histology breast cancer.

CYTOLOGY

Cytologic examination of nipple discharge or cyst fluid may be helpful on rare occasions. As a rule, mammography and breast biopsy are required when nipple discharge or cyst fluid is bloody or cytologically equivocal.

BIOPSY

The diagnosis of breast cancer depends ultimately on examination of tissue removed by biopsy. Treatment should never be undertaken without an unequivocal histologic diagnosis of cancer. The safest course is biopsy examination of all suspicious masses found on physical examination and, in the absence of a mass, of suspicious lesions demonstrated by mammography. Approximately 30% of lesions thought

to be definitely cancer prove on biopsy to be benign, and approximately 15% of lesions believed to be benign are found to be malignant. These findings demonstrate the fallibility of clinical judgment and the necessity for biopsy.

The simplest method is needle biopsy, either by fine-needle aspiration (FNA) of tumor cells or by obtaining a small core of tissue with a stereotactic core-needle biopsy. A negative FNA should be followed by open biopsy because false-negative needle biopsies may occur in 10% of cancers.

The definitive diagnostic method is open biopsy under local anesthesia as a separate procedure prior to deciding on treatment. Palpable masses are readily evaluated by a general surgeon. With the aid of diagnostic radiology, a nonpalpable, radiographically detected mass may be biopsied with the use of needle localization. The patient need not be admitted to the hospital. Decisions on additional work-up for metastatic disease and on definitive therapy can be made and discussed with the patient after the histologic diagnosis of cancer is established. This approach has the advantage of avoiding unnecessary hospitalization and diagnostic procedures in many patients as cancer is found in the minority of patients who require biopsy for diagnosis of a breast lump.

In general, outpatient biopsy followed by definitive surgery at a later date gives patients time to adjust to the diagnosis of cancer, meet with members of the multidisciplinary team involved with managing breast cancer, and consider a second opinion, as well as alternative forms of treatment. Studies show no adverse effects from the short (1–2 weeks) delay of the two-step procedure, and this is the current recommendation of the NCI.

At the time of the initial biopsy of breast cancer, it is important for the physician to preserve a portion of the specimen for immunohistochemical staining for hormone and growth factor (eg, HER-2-Neu) receptors. Tumor analysis using reverse transcriptase polymerase chain reaction (RT-PCR) technology from pathologic specimens to assess the tumor recurrence risk is now available. Such tests can aid the patient and physician in the decision for further adjuvant therapy or not. At the time of pathologic confirmation of a breast cancer diagnosis, patients on hormone replacement therapy (HRT) should be instructed to stop hormone use until counseled by an oncologist.

LABORATORY FINDINGS

A complete blood cell count (CBC), chemistry panel including liver function tests (LFTs), and a β -human chorionic gonadotropin (β -hCG) in premenopausal patients to diagnose pregnancy should be obtained as part of the initial evaluation. An elevation in alkaline phosphatase or liver function may be an indication of distant metastatic disease and warrants further investigation. Hypercalcemia may be seen in advanced cases of metastatic cancer.

RADIOGRAPHIC FINDINGS

A baseline posteroanterior and lateral chest radiograph may reveal pulmonary disease involvement, which could include parenchymal metastases, plural thickening or studding, and effusions. A chest x-ray also provides for a radiographic evaluation of the cardiac silhouette prior to interventions, which could tax the cardiovascular system such as anthracycline chemotherapy, trastuzumab (Herceptin) and radiation therapy. Computed tomography (CT) scans of the brain and liver should be obtained sparingly and are generally reserved for locally advanced cases (stage IIA or IIB or greater), as well as early stage cases in which there is a strong clinical suspicion of metastatic disease. Magnetic resonance imaging (MRI) scans of the previously surgically altered breast in which there is a question of malignancy, or in the T0 N1 patient, may be helpful in better characterizing the soft tissue of the breast, but are otherwise not routinely used.

RADIONUCLIDE SCANNING

Bone scans using technetium 99m–labeled phosphonates are an important tool for the evaluation of metastatic breast cancer. There is no role for this imaging in screening or in the routine work-up of a patient. The incidence of a positive bone scan increases with advancing disease stage. Stages I and II patients have a 7% and 8% possibility, respectively, of having a positive bone scan, whereas a stage III patient has roughly a 25% risk. Therefore bone scans are reserved for the locally advanced patient (stage IIB [T3 N1 M0] or greater) with elevated alkaline phosphatase, or for the patient in whom there is clinical suspicion for metastatic disease.

Positron emission tomography (PET) is a promising tool in the staging and metastatic evaluation of breast cancer. Most often it is used for defining the extent of recurrent or metastatic disease and monitoring treatment response. PET is a diagnostic modality that is complementary to conventional studies such as bone scintigraphy and CT. Its role has not yet been firmly established or defined in the setting of breast cancer. Consequently, clinicians should resist the inclination to consider PET a substitute for the conventional staging studies and metastatic evaluation of patients with breast cancer.

Early Detection

SCREENING PROGRAMS

Mammography remains the single best screening procedure for the early detection of breast cancer. Both physical examination and mammography are necessary for maximum yield in detecting early breast cancer, as approximately 40% of early malignancies can be discovered only by mammography and another 40% can be detected by palpation. In general, depending on a woman's age and the density of her breasts, the sensitivity of mammography is 70–90% and its specificity is greater than 90%. Yearly mammogram screening among women continues to increase so that in 1997, roughly 85% of women had had a mammogram at least once previously. This was an increase of 15% from 1990 and of 47% from 1987. Women of color, however, have more advanced stages of disease at the time of diagnosis and are less likely to engage in screening practices than white women. It is postulated that socioeconomic status, education, and medical access may account for these differences.

Despite a consensus on the importance of mammographic screening, mammography has still not been demonstrated unequivocally to decrease breast cancer mortality across all age groups. In women between 50 and 69 years of age, there is reasonable evidence, based largely on 8 randomized controlled trials, that screening mammography is beneficial. In elderly patients, however, the optimal frequency of screening is still unknown. For younger women, the evidence is also not entirely clear. In the age group 40–49 years, there appears to be a small benefit, but this benefit emerges only after meta-analyses with varying levels of statistical significance and confidence intervals. Nevertheless, in the Health Insurance Plan of Greater New York screening study from the United States, which with 18 years has the longest follow-up of any randomized mammography screening study, there was a 30% reduction in mortality in women older than 50 years of age. Despite academic debate and challenges and controversy in the news media, the consensus that screening mammography saves lives has been upheld.

Current screening recommendations from the American College of Radiology, the American Cancer Society, and the American Medical Women's Association call for annual mammograms starting at age 40 years. The American College of Obstetricians and Gynecologists calls for screening mammography every 1–2 years for women age 40–49 and annually thereafter. There is no recommendation for a "baseline" examination prior to age 40 years, nor is there any evidence to support this practice in women younger than this age. Women with a first-degree relative who had breast cancer typically are requested to obtain a first mammogram 5 years prior to the age at which the relative was diagnosed with breast cancer. Mammographic patterns are an unreliable predictor of the risk of developing breast cancer.

Breast ultrasonography is very useful in distinguishing cystic from solid lesions but should be used only

as a supplement to physical examination and mammography in screening for breast cancer.

SELF-EXAMINATION

Once women have reached puberty and start to develop breasts, breast self-examination should be encouraged. Initially, this allows the woman to become acquainted with her body and foster good self-examination habits for the future. All women older than age 20 years should be advised to examine their breasts monthly. Premenopausal women should perform the examination 5–7 days after the completion of the menstrual cycle when breast tissue is less dense. High-risk patients may wish to perform another self-examination in midcycle. Postmenopausal women should pick a particular date each month, perhaps the anniversary of a special occasion, to perform breast self-examination.

Breast self-examination consists of two parts: inspection and palpation. Using a mirror, the breasts should be inspected while standing with arms at sides, with arms overhead and palms pressed together, and with hands on hips pressing firmly to contract the pectoralis muscles. Gross asymmetry of the breasts, masses, and skin dimpling and/or retraction may be more apparent through the use of these maneuvers. In the supine position, each breast should be palpated with the fingertips of the opposite hand. Numerous techniques are advocated but methodical palpation is the goal.

The American Cancer Society publishes instructive guides, which can be viewed online at www.cancer.org. Their recommendations, along with breast self-examination starting at age 20 years, are for a clinical breast examination to be performed by a health professional at least once every 3 years between the ages of 20 and 39 years. After age 40 years, a clinical breast examination should be performed annually. Physicians should instruct women in the technique of self-examination and advise them to report at once for medical evaluation if a mass or other abnormality is discovered. Many women report easier detection of breast abnormalities when the skin is moist while bathing or showering.

GENETIC TESTING

A positive family history of breast cancer is recognized as a risk factor for the subsequent development of breast cancer. With the discovery of two major breast cancer predisposition genes, *BRCA1* (17q21) and *BRCA2* (13q12-13), there has been increasing interest in genetic testing. Mutations in these two genes are associated with an elevated risk for breast cancer, as well as ovarian, colon, prostate, and pancreatic cancers. Of all women with breast cancer, approximately 5–10% may have mutations in *BRCA1* or *BRCA2*. The estimated risk of a patient developing cancer with a *BRCA1* or *BRCA2* mutation is believed to be between 40% and 85%. Particular mutations may be more common in specific ethnic groups like the Ashkenazi Jewish population. Genetic testing is available and may be considered for members of high-risk families. Currently, there are no established guidelines or recommendations for genetic testing. In general, women diagnosed with breast cancer before age 40 years, women with a first-degree relative diagnosed with breast cancer before age 50 years, and women with a family history that includes male breast or multiple, significant neoplasms such as ovarian, colon, and pancreatic cancer, are potential candidates for testing. Because of the complexities of genetic testing, genetic counseling before and after testing is necessary.

Differential Diagnosis

The lesions most often to be considered in the differential diagnosis of breast cancer include, in order of frequency, fibrocystic change, fibroadenoma, intraductal papilloma, and fat necrosis. The differential diagnosis of a breast lump should be established without delay by biopsy, either open or with localization guidance, or aspiration. Observation—even for a short, defined period—should be entertained with considerable caution.

Pathologic Types

Numerous pathologic subtypes of breast cancer can be identified histologically (Table 63–3). These pathologic types are distinguished by the histologic appearance and growth pattern of the tumor. In general, breast cancer arises either from the epithelial lining of the large or intermediate-sized ducts (ductal) or from the epithelium of the terminal ducts of the lobules (lobular). The cancer may be invasive or in situ. Most breast cancers arise from the intermediate ducts and are invasive (invasive ductal or infiltrating ductal), and most histologic types are merely subtypes of invasive ductal cancer with unusual growth patterns (colloid, medullary, scirrhus, etc). Ductal carcinoma that has not invaded the extraductal tissue is intraductal or ductal in situ. Lobular carcinoma may be either invasive or in situ.

Table 63–3. Histologic Types of Breast Cancer.

Type	Percent Occurrence
Invasive ductal (not otherwise specified)	80–85
Medullary	3–6
Colloid (mucinous)	3–6
Tubular	3–6
Papillary	3–6
Invasive lobular	4–10
Noninvasive	15–20
Intraductal	80
Lobular in situ	20

The histologic subtypes have only slight bearing on prognosis when outcomes are compared after accurate staging. Colloid (mucinous), medullary, papillary, adenoid cystic, and tubular histologies are generally believed to have a more favorable prognosis. Other histologic criteria have been studied in an attempt to substratify patients based on features such as tumor differentiation, lymph vascular space invasion, and tumor necrosis. Although these characteristics are important, stage is predominant and paramount in predicting outcome.

The noninvasive cancers by definition lack the ability to spread. However, in patients whose biopsies show noninvasive intraductal cancer, associated invasive ductal cancers are present in 1–3% of cases. Lobular carcinoma in situ is considered by some to be a premalignant lesion that by itself is not a true cancer. It lacks the ability to spread but is associated with the subsequent development of invasive ductal cancer in 25–30% of cases within 15 years.

Hormone Receptor Sites

The presence or absence of estrogen receptors in the cytoplasm of tumor cells is of critical importance in managing patients with initial, recurrent and metastatic disease. To further emphasis this point, up to 60% of patients with metastatic breast cancer will respond to hormonal manipulation if their tumors contain estrogen receptors. However, fewer than 10% of patients with metastatic, estrogen receptor–negative tumors can be successfully treated with hormonal manipulation.

Progesterone receptors may be an even more sensitive indicator than estrogen receptors of patients who may respond to hormonal manipulation. Up to 80% of patients with metastatic progesterone receptor-positive tumors seem to respond to hormonal manipulation. Receptors probably have no relationship to response to chemotherapy.

Estrogen receptors may be of prognostic significance, especially in the node-negative patient, but current evidence is still unclear. If there is a survival benefit, it is of a small magnitude, less than 10%. The defined role of establishing a tumor's hormone status is to help guide hormonal and systemic therapies. Two randomized trials (National Surgical Adjuvant Breast Project [NSABP] B-14 and B-20) have shown a disease-free survival and an overall survival advantage for women with node-negative, estrogen-positive tumors who received tamoxifen.

It is advisable to obtain an estrogen-receptor assay for every breast cancer at the time of initial diagnosis. Receptor status may change after hormonal therapy, radiotherapy or chemotherapy. The specimen requires special handling, and the laboratory should be prepared to process the specimen correctly.

Curative Treatment

All oncologic treatment may be classified as curative or palliative. Curative treatment intent is advised for early stage and locally advanced disease (clinical stages I to IIIC disease; see Table 63–2). Treatment intent is palliative for patients in stage IV disease and for previously treated patients who develop distant metastases or unresectable local recurrence.

THERAPEUTIC OPTIONS

Radical Mastectomy

Historically, Halsted is credited with performing the first modern radical mastectomy in 1882 in the United States. This surgical procedure was the en bloc removal of the breast, pectoral muscles, and axillary lymph nodes. It was the standard surgical procedure performed for breast cancer in the United States from the turn of the 20th century until the 1950s. During the 1950s, emerging information about lymph node drainage patterns prompted surgeons to undertake the extended radical mastectomy, which is a radical mastectomy and the removal of the internal mammary lymph nodes. It was postulated that a more extensive dissection of the draining lymphatics would improve control rates and translate into improved survival. A randomized trial, however, proved no benefit to the extended radical mastectomy versus the radical mastectomy, and the former was abandoned. Moreover, the failure of the extended radical mastectomy underscored the complications and morbidity of breast cancer surgery. This morbidity coupled with inadequate disease control led surgeons to explore less invasive and disfiguring techniques. Currently, radical mastectomy is rarely indicated or performed. Even in settings where radical resection may be entertained, such as invasion of the pectoralis muscles or large tumors, less-invasive surgery coupled with adjuvant or neoadjuvant treatments like radiation and chemotherapy are preferred.

Modified Radical Mastectomy

Replacing radical mastectomy, the modified radical mastectomy (MRM) is the removal of the breast, underlying pectoralis major fascia but not the muscle, and evaluation of selected axillary lymph nodes. Variations of this procedure include sacrificing the pectoralis minor muscle or not, and retracting, splitting, or transecting the pectoralis major to access the apex of the axilla for dissection. Because it is less invasive and less disfiguring, MRM provides a better cosmetic and functional result than radical mastectomy. Two prospective randomized trials, single-institution data, and several retrospective studies all demonstrate no difference in disease-free or overall survival rates between radical mastectomy and MRM for early stage breast cancer. Until the early 1980s and the emergence of breast-conservation therapy (BCT), MRM was the standard treatment available to women for early stage cancer. For locally advanced breast cancer and when the patient is not a candidate for BCT, or if the patient is not motivated for breast conservation, MRM remains a valid treatment option. A total mastectomy (simple mastectomy) is the removal of the whole breast, like a MRM, without the axillary dissection. Because an axillary evaluation is critical for staging purposes, total mastectomy is not performed for invasive cancers

and is generally reserved for in situ lesions with their low metastatic potential.

Breast Conservation Therapy

BCT involves a surgical procedure such as a lumpectomy—an excision of the tumor mass with a negative surgical margin—an axillary evaluation, and postoperative irradiation. Several other operations, more limited in the scope of surgical dissection than MRM, such as segmental mastectomy, partial mastectomy, and quadrantectomy, are also used in conjunction with radiation and are part of the surgical component of BCT. As a result of six prospective randomized trials that showed no significant difference in local relapse, distant metastases, or overall survival between conservative surgery with radiation and mastectomy, BCT has gained increasing acceptance as a treatment option for stages I and II breast cancers.

CHOICE OF LOCAL THERAPY

Breast cancer is a multidisciplinary disease in which surgeons, medical and radiation oncologists, radiologists, pathologists, nurses, and psychosocial support staff all play fundamental roles. Working with the patient, this team recommends the most appropriate treatment strategy. Clinical and pathologic stage (see Table 63–2), as well as biologic aggressiveness, are the principal determinants guiding local therapy, treatment strategy, and, ultimately, outcome. For early stage breast cancer, including node-positive cases, much of the decision for initial local therapy rests with the patient. MRM is always a valid choice for addressing the local treatment of breast cancer. A patient's decision to undergo MRM does not necessarily obviate the role of radiation in the further management of breast cancer, and postmastectomy irradiation may still be recommended in approximately 20–25% of cases. To be a candidate for BCT, the patient must not be pregnant and cannot have multicentric breast cancer (evidence of cancer in more than 1 quadrant of the breast), locally advanced disease, diffuse microcalcifications on mammogram, or a prior history of ipsilateral breast irradiation. Relative contraindications are collagen-vascular disorders that could lead to a poor cosmetic outcome with irradiation and breast implants or psychiatric issues that would make close follow-up and surveillance difficult. These restrictions are only a portion of the decision-making process that must be completed before embarking on BCT.

Perhaps most importantly, the patient must be motivated and desire to maintain her breast in the face of a cancer diagnosis. This may entail some degree of physical, emotional, and psychological distress. For example, a patient may have to endure multiple re-excisions to obtain a negative surgical margin on the lumpectomy specimen. A patient may also experience resistance to BCT in areas where it is not commonly offered and where a multidisciplinary approach to breast cancer is not practiced. It has been shown that the surgical management of breast cancer differs considerably based on geographic location in the United States, independent of patient and tumor characteristics. Nevertheless, both physicians and patients pursue BCT because it allows the patient to preserve her breast without any decrement to survival, and the vast majority of women are pleased with the cosmetic result.

Because the treatment options for locally advanced and inflammatory breast cancers are in some ways less flexible than those for early stage breast cancer, it is even more critical to engage the patient in the decision-making process for the choice of initial therapy. Many different strategies, which include mastectomy and less-invasive surgeries, with or without neoadjuvant chemotherapy and adjuvant chemotherapy, radiation, and further maintenance interventions, are commonly used. In many settings, protocol therapy may be the most desirable treatment option.

Mastectomy

For about three-quarters of a century, radical mastectomy was considered standard therapy for breast cancer. The procedure was designed to remove the primary lesion, the breast in which it arose, the

underlying muscle, and, by dissection in continuity, the axillary lymph nodes that are most often are the first site of regional spread beyond the breast. When radical mastectomy was introduced by Halsted, the average patient presented for treatment with locally advanced disease, and a relatively extensive procedure was often necessary just to remove all gross cancer. This is no longer the case. Patients now present with much smaller, less locally advanced lesions. Most of the patients in Halsted's original series would now be considered incurable by surgery alone, because they had extensive involvement of the chest wall, skin, and supraclavicular regions.

Although radical mastectomy is rarely performed today, MRM is a common initial local treatment for breast cancer. Radical mastectomy is seldom, if ever, indicated given advances in surgical technique and other more modern treatment modalities. Radical mastectomy has the disadvantage of being one of the most deforming of any of the available treatments for the management of primary breast cancer. Since the 1960s, MRM has supplanted the radical mastectomy because of its comparable disease control and a substantial decrease in morbidity and disfiguration.

In many cases, adjuvant therapy following MRM, eg, radiation, can even further reduce the incidence of local recurrence in certain patients with unfavorable tumor characteristics. In addition, three recent randomized trials of postmastectomy radiation, which confirmed a local-control advantage, demonstrated an overall survival benefit in certain subsets of both pre- and postmenopausal women. For patients with ≥ 4 positive lymph nodes or an advanced primary tumor, postmastectomy radiation is strongly recommended. The role of postmastectomy radiation in patients with 1–3 positive nodes is more nebulous. However, with increasing duration of follow-up of the three aforementioned randomized studies, the weight of evidence in favor of postmastectomy radiation for 1–3 nodes seems to be gathering strength. In addition, a prospective randomized intergroup trial enrolling patients with 1–3 nodes recently closed to accrual. Although it will take years to mature, definitive data surrounding the extent of benefit of postmastectomy chest wall radiation is forthcoming. When deciding on initial local therapy, therefore, a patient must keep in mind that choosing MRM does not necessarily exclude a recommendation for adjuvant radiation.

Breast-Conservation Therapy

As studies comparing radical mastectomy and MRM demonstrated no decrement in local control or survival, radical mastectomy has given way to MRM. With less-invasive surgery, there are fewer side effects, less morbidity, and, ultimately, an improvement in quality of life. Simple mastectomy performed alone, however, has an unacceptably high failure rate. (In part, this is because the lymph nodes are not removed. As many as 40% of patients with clinically negative nodes will have evidence of metastatic spread within these nodes at dissection, and roughly half of these patients subsequently develop regional recurrences.)

In the 1980s, six prospective randomized trials were conducted worldwide that showed no significant difference in local–regional relapse or overall survival between breast-conserving surgery and radiation versus MRM for early stage invasive breast cancer. Two of these studies included patients with node-positive breast cancer. With the addition of radiation to breast-conserving surgery techniques such as lumpectomy with an axillary evaluation, local failure is reduced to rates comparable to MRM with no compromise to overall survival.

The next step has been to perform breast-conserving surgery without the addition of adjuvant radiation. Two recent randomized trials confirmed the existence of a continuum of local control benefit to subsets of postmenopausal women treated with adjuvant tamoxifen and radiation versus tamoxifen without radiation. Similarly, in the setting of in situ breast cancer, radiation confers a local control benefit although the magnitude may vary from patient to patient. Several trials including a seminal study by the

NSABP established the efficacy of BCT for noninvasive breast cancer. For in situ disease, a group from Van Nuys, California, has proposed a prognostic index to determine which patients might not benefit from or need radiation after excision. With the exception of a small number of highly selected cases, the work of this group has not yet produced reproducible results sufficient to justify omitting radiation as standard practice.

Axillary Evaluation

It is important to recognize that axillary evaluation is valuable both in planning therapy and in staging of the cancer. Surgery is extremely effective in preventing axillary recurrences. Although the removal of even occult cancer in axillary lymph nodes generally does not translate into an improvement in overall survival rates, regional failures will be lower. In addition, lymph nodes removed during the procedure can be pathologically assessed. This assessment is essential for the planning of adjuvant therapy, which is often recommended for patients with gross or occult involvement of axillary nodes.

A standard alternative to formal axillary dissection for the pathologic assessment of the clinically negative axilla is sentinel lymph node biopsy (SLNB). This procedure uses a tracer material that is injected into the tumor bed to map the tumor drainage to the primary or "sentinel" axillary lymph node(s). The sentinel lymph node is excised and pathologically examined. If the sentinel lymph node is found to harbor metastatic disease, a subsequent formal dissection is done. Conversely, if the sentinel lymph node is negative, no further surgical evaluation need be performed. Although this procedure relies heavily on the surgeon's expertise with a new technique and has some inherent limitations, SLNB is another step toward less-invasive breast-cancer management. Potential side effects and complications are minimized, and recovery is quick without sacrificing diagnostic or therapeutic results. A practical example of the benefits of SLNB is that, when used in conjunction with BCT, reported rates of lymphedema are lower than with axillary dissection.

Current Recommendations

I believe that BCT, which includes radiation, with an axillary evaluation or MRM is the best initial local treatment for most patients with potentially curable carcinoma of the breast. It cannot be overemphasized, however, that a diagnosis of breast cancer should be managed with a multidisciplinary approach and treatment should be individualized. Treatment of the axillary nodes is not indicated, although evaluation may be given size and grade of the primary lesion, for noninvasive cancers, because by definition in situ lesions do not have metastatic potential. Nevertheless, axillary nodal metastases are detected in a small minority of cases, most of which are subsequently found to harbor microinvasive disease.

Preoperatively, full discussion with the patient regarding the rationale for BCT and mastectomy, as well as the manner of coping with the cosmetic and psychological effects of the operation, is essential. Patients often have numerous questions about BCT and MRM and wish detailed explanations of the risks and benefits of the various procedures. If a patient decides on MRM, breast reconstruction should be discussed. Time spent preoperatively in educating the patient and her family is time well spent.

Adjuvant Systemic Therapy

CHEMOTHERAPY

Cytotoxic chemotherapy is commonly offered to women as adjuvant treatment for early stage, as well as locally advanced, breast cancer. The goal of adjuvant chemotherapy is to eliminate occult microscopic metastases that are often responsible for late recurrences. It is systemic treatment and should not be confused with efforts to address known local disease. In the past, only premenopausal women with lymph node-positive cancers were routinely candidates for cytotoxic chemotherapy. For a host of

reasons, recent guidelines recommend the use of chemotherapy on a more individualized basis and thus broaden the scope of who may be a candidate for therapy. Node-negative patients are now stratified into risk categories to help guide the decisions for adjuvant systemic therapy (Table 63–4).

Table 63–4. NIH Consensus Conference on Adjuvant Treatment for Women with Breast Cancer Risk Categories for Node-Negative Patients.

	Low Risk (All listed factors)	Intermediate Risk	High Risk (≥ 1 factor)
Tumor size	< 1.0 cm	1–2 cm	> 2 cm
ER or PR	+	+	–
Tumor grade	Grade I	Grade I–II	Grade II–III

Abbreviations: ER, estrogen receptor; NIH, National Institutes of Health; PR, progesterone receptor.

The National Institutes of Health (NIH) Consensus Statement on Adjuvant Therapy for Breast Cancer recommends that chemotherapy be offered to most women with localized breast cancer > 1 cm regardless of nodal, menopausal or hormone receptor status. Polychemotherapy (≥ 2 agents) is superior to single-agent chemotherapy. Duration for 3–6 months or 4–6 cycles appears to offer optimal benefit without subjecting the patient to undue toxicity associated with more prolonged treatment, which adds little benefit in terms of overall outcome. Cytotoxic chemotherapy with an anthracycline-based (doxorubicin [A] or epirubicin [E]) regimen is favored, as a small but statistically significant improvement in survival has been demonstrated compared with nonanthracycline-containing regimens. The cardiac toxicity caused by anthracyclines is not considered detrimental in women without significant cardiac disease but does occur in 1% of cases or less. Nevertheless, traditional regimens using 6 cycles of cyclophosphamide, methotrexate, and 5-fluorouracil (CMF), which do not cause alopecia, are not necessarily inferior to regimens now commonly used, such as 4 cycles of doxorubicin and cyclophosphamide (AC). Alterations in dose schedule (eg, "dose-dense" regimens) also offer advantages over other combinations and administrations of chemotherapy for well-defined patient populations. The choice of adjuvant chemotherapy is complex. The medical oncologist must consider multiple tumor and patient features and individualize treatment for breast cancer patients.

Several areas concerning chemotherapy have generated considerable interest but lack conclusive evidence. For instance, the current data support the administration of taxanes (paclitaxel or docetaxel) in node-positive patients with estrogen receptor-negative tumors. By extrapolation and some inference, however, most node-positive patients are offered a taxane in addition to other standard chemotherapy agents. For node-negative patients, there is no direct evidence to justify their routine use but consideration is often given to individual cases. High-dose chemotherapy with bone marrow or stem cell rescue is also not recommended. There is no evidence that high-dose regimens are superior to standard-dose polychemotherapy. Stem cell support or bone marrow transplant should be offered only on protocol.

Further investigations need to be performed to clarify the role of high-dose regimens and new chemotherapy as well as biologic agents and dosing schedules. Trials need to enroll more patients older than age 70 years to assess the benefits and toxicities of adjuvant chemotherapy in this population. Finally, studies designed to measure quality of life need to be done to place the benefits versus toxicity question of adjuvant therapies into context.

HORMONAL THERAPY

Adjuvant hormonal therapy or manipulation is recommended for all women whose breast cancer expresses hormone receptors. Even if the tumor does not express estrogen hormone receptor protein but

only progesterone, hormonal therapy may be beneficial. This recommendation is made regardless of age, menopausal status, involvement or number of positive lymph nodes, or tumor size. The benefit of adjuvant hormonal therapy is seen across all subgroups of breast cancer patients, with both invasive and in situ lesions. Although the absolute decrease in recurrence, second primary breast cancer, and death may vary from group to group, there is a firmly established role for adjuvant hormonal intervention. Two possible exceptions, according to the NIH Consensus Conference, are the premenopausal patient with a tumor < 1 cm who wants to avoid estrogen loss and the elderly patient with a similar-size tumor and a history of thromboembolic events. Because of the overwhelming benefit of hormonal therapy, however, this determination should be made by an experienced medical oncologist (Tables 63–5 and 63–6).

Table 63–5. Summary of NIH Conference on Adjuvant Treatment for Women with Axillary Node–Negative Breast Cancer.

Patient Group	Low Risk	Intermediate Risk	High Risk
Premenopausal ER/PR–	None or TAM	TAM + CT TAM Ablation GnRH	CT + TAM CT + Ablation/GnRH CT + TAM + Ablation/GNRH
Premenopausal ET/PR–	N/A	N/A	CT
Postmenopausal ER/PR +	None or TAM	TAM + CT TAM	TAM + CT TAM
Postmenopausal ER/PR–	N/A	N/A	CT
> 70 years	None or TAM	TAM TAM ± CT	TAM ± CT if receptor–

Abbreviations: Ablation, ovarian ablation; CT, chemotherapy; ER, estrogen receptor; GnRH, gonadotropin-releasing hormone analogue; PR, progesterone receptor; TAM, tamoxifen.

Table 63–6. Summary of NIH Consensus Conference on Adjuvant Treatment for Women with Axillary Node–Positive Breast Cancer.

Patient Group	Treatment
Premenopausal ER/PR +	CT + TAM
	CT + Ablation/GnRH
	CT + TAM + Ablation/GnRH
Premenopausal	CT
Postmenopausal ER/PR +	TAM + CT
Postmenopausal ER/PR–	CT
> 70 years	TAM + CT if ER/PR–

Abbreviations: See Table 63–5.

Five years of tamoxifen is currently the most common regimen of hormonal therapy, although other forms of manipulation, such as ovarian ablation, exist. Randomized trials support the 5-year duration, which is superior to shorter courses and does not expose the patient to the increased risk of adverse effects associated with longer use. Furthermore, use longer than 5 years doesn't appear to enhance the long-term benefit seen with just 5 years of use. Although tamoxifen carries a slight increased risk of endometrial cancer and venous thromboembolism (5–6 events per 1000 patient-years of treatment), the benefits outweigh the risks for the vast number of patients. Surveillance screening procedures such as transvaginal ultrasound and endometrial biopsy are not necessary in asymptomatic patients on tamoxifen.

More recently, aromatase inhibitors (AI) such as anastrozole have been shown to be superior to tamoxifen in postmenopausal women with early stage, invasive breast cancer. In fact, anastrozole is superior to tamoxifen and was found to be superior to the combination of anastrozole and tamoxifen, in terms of disease-free survival, time to recurrence, and the incidence of contralateral breast cancer. The toxicity profile of AIs is also favorable. Compared to tamoxifen, the use of AIs confers a smaller risk of endometrial cancer, venous thromboembolic events, and hot flashes for patients. However, AIs have a higher risk of musculoskeletal disorders and fractures when compared to tamoxifen. Ongoing studies seek to answer questions about the role of AIs in noninvasive, in situ cancers and in premenopausal patients.

Follow-Up Care

After primary treatment, breast cancer patients should be followed for life because of the long, insidious natural history of breast cancer. The goals of close breast cancer follow-up are to detect recurrences and second primaries after treatment in the ipsilateral breast and to detect new cancers in the contralateral breast. The risk of a second primary in the contralateral breast of a patient with a history of breast cancer is believed to be roughly 0.5–1% per year. Although there are no universally accepted guidelines, several consensus conferences have met to establish recommendations. After the completion of treatment, it is recommended that the patient undergo a physical examination every 4 months for the first 2 years, then every 6 months until year 5, and annually thereafter. A mammogram should be obtained annually for all patients. For patients who received irradiation, a chest radiograph is also obtained yearly. Routine laboratory tests including CBC, chemistry profile, and liver function tests can be ordered yearly, especially if the patient received chemotherapy, or else as needed. There is no role for routine bone scans or additional imaging unless the patient is symptomatic or there is clinical suspicion of an abnormality. Patients taking tamoxifen should have annual pelvic examinations and be counseled to report any irregular vaginal bleeding. Patients on AIs need periodic, usually annual, bone density studies to monitor their risk of developing osteopenia.

LOCAL RECURRENCE

The development of local recurrence correlates with stage and thus tumor size as well as the presence and number of positive axillary lymph nodes, margin status, nuclear grade, and histologic type. The median time to recurrence is roughly 4 years, with a 1–2% risk per year for the first 5 years and a 1% risk per year thereafter. Late failures occurring 15–20 years or more after treatment, however, do occur. The risk of local recurrence following BCT or MRM is generally < 15% 20 years after treatment. Positive axillary lymph nodes are prognostic for local failure at the chest wall following MRM, but they are not prognostic for a local failure following BCT.

The treatment of local recurrences depends on the initial local therapy. In the breast, failures after BCT can be treated with salvage mastectomy with salvage rates of approximately 50%. In general, there is no difference in overall survival for an isolated breast recurrence successfully treated with salvage

mastectomy. Node failures are more ominous. Axillary failures have roughly a 50% 3–5-year disease-free survival and supraclavicular failures 0–20% 3-year disease-free survival. All chest wall abnormalities should be biopsied to rule out recurrence and resected with a wide local excision if possible. Adjuvant salvage therapies such as radiation, cytotoxic chemotherapy, and hormonal therapy may also be instituted.

Local recurrence may signal the presence of widespread disease and is an indication for bone and liver scans, posteroanterior and lateral chest x-rays, and other examinations as needed to search for evidence of distant metastases. When there is no evidence of metastases beyond the chest wall and regional nodes, radical irradiation for cure and complete local excision should be attempted. Most patients with locally recurrent tumors will develop distant metastases within 2 years. For this reason, many physicians use systemic therapy for treatment of patients with local recurrence. Although this seems reasonable, it should be pointed out that patients with local recurrence may be cured with local resection and/or radiation. Systemic chemotherapy or hormonal treatment should be used for patients who develop disseminated disease or for patients in whom local recurrence occurs following adequate local therapy.

EDEMA OF THE ARM

Lymphedema of the arm is a significant and often dreaded complication of breast cancer treatment. Lymphedema occurs as a result of lymphatic disruption and insult caused primarily by local treatment modalities like surgery and radiation. Although each of these modalities carries its own a risk with respect to arm edema, a combined modality approach further increases this risk. With a typical level I/II axillary lymph node dissection and radiation, the risk of lymph edema is roughly < 10%. This risk approached 30% when a more aggressive level III dissection was more commonly performed in the past. The rates of clinically significant lymphedema—that is edema, that affects function and is not merely detectable with sophisticated measurement tools—are generally considered to be much lower. With the advent of SLNB, lymphedema rates are expected to continue to improve.

Late or secondary edema of the arm may develop years after MRM, as a result of axillary recurrence or of infection in the hand or arm, with obliteration of lymphatic channels. Interestingly, there is usually no obvious initiating event causing late arm swelling in a patient with a history of breast cancer treatment.

BREAST RECONSTRUCTION

Breast reconstruction, with the implantation of a prosthesis or transverse rectus abdominis myocutaneous flap (TRAM), is usually feasible after MRM. Reconstruction should be discussed with patients prior to mastectomy because it offers an important psychological focal point for recovery. Reconstruction is not an obstacle to the diagnosis of recurrent cancer.

Prognosis

The stage of breast cancer is the single most reliable indicator of prognosis. Patients with disease localized to the breast and no evidence of regional spread after microscopic examination of the lymph nodes have by far the most favorable prognosis. Estrogen and progesterone receptors appear to be an important prognostic variable because patients with hormone receptor-negative tumors and no evidence of metastases to the axillary lymph nodes have a much higher recurrence rate than do patients with hormone receptor-positive tumors and no regional metastases. The histologic subtype of breast cancer (eg, medullary, lobular, comedo) seems to have little significance in prognosis once these tumors are truly invasive.

As mentioned above, several different treatment regimens achieve approximately the same results when given to the appropriately selected patient. Localized disease can be controlled with local therapy—either MRM or BCT, which includes radiation. However, the criteria for selection of patients to be treated with

conservative resection and radiation therapy require further clarification.

Many patients who develop breast cancer will ultimately die of breast cancer. The mortality rate of breast cancer patients exceeds that of age-matched normal controls for nearly 20 years. Thereafter, the mortality rates are equal, although deaths that occur among the breast cancer patients are often directly the result of tumor. Five-year statistics do not accurately reflect the final outcome of therapy.

When cancer is localized to the breast, with no evidence of regional spread after pathologic examination, the clinical cure rate with most accepted methods of therapy is 75–80%. Exceptions to this may be related to the hormonal receptor content of the tumor, tumor size, host resistance, or associated illness. Patients with small estrogen and progesterone receptor-positive tumors and no evidence of axillary spread probably have a 5-year survival rate of nearly 90%. When the axillary lymph nodes are involved with the tumor, the survival rate drops to 50–60% at 5 years, and probably to less than 25% at 10 years. In general, breast cancer appears to be somewhat more aggressive in younger than in older women, which may be related to the fact that relatively fewer younger women have estrogen receptor-positive tumors.

PALLIATIVE TREATMENT OF RECURRENT AND METASTATIC BREAST CANCER

This section discusses palliative therapy of disseminated disease incurable by surgery (stage IV).

Radiotherapy

Palliative radiotherapy may be advised for locally advanced cancers with distant metastases in order to control ulceration, pain and other manifestations in the breast and regional nodes. As part of multimodality treatment, radical irradiation of the chest wall and the axillary, internal mammary, and supraclavicular nodes should be undertaken in an attempt to cure locally advanced and inoperable lesions when there is no evidence of distant metastases. A small number of patients in this group are cured in spite of extensive breast and regional node involvement. Adjuvant chemotherapy also plays a valuable role in the treatment of such patients.

Palliative irradiation is also of value in the treatment of certain bone or soft tissue metastases to control pain or avoid pathological fracture. Radiotherapy is especially useful in the treatment of the isolated bony metastasis and chest wall recurrences.

Hormonal Therapy

Disseminated disease may respond to prolonged endocrine therapy such as ovarian ablation or administration of drugs that block hormone receptor sites or that block hormone synthesis or production. Hormonal manipulation is usually more successful in postmenopausal women. If treatment is based on the presence of estrogen receptor protein in the primary tumor or metastases, however, the rate of response is nearly equal in premenopausal and postmenopausal women. A favorable response to hormonal manipulation occurs in about one-third of patients with metastatic breast cancer. Of those whose tumors contain estrogen receptors, the response is approximately 60%, and perhaps as high as 80%, for patients whose tumors contain progesterone receptors as well. Tumors negative for both estrogen and progesterone receptors have response rates to hormonal therapy that are 10% or less.

Because the quality of life during a remission induced by endocrine manipulation is usually superior to a remission following cytotoxic chemotherapy, it may be best to try endocrine manipulation as a first-line systemic treatment for tumor recurrence or palliation.

As a general rule, only one type of systemic therapy should be given at a time. The systemic modality may be given in combination with a local or regional treatment if symptomatic lesions develop. For

instance, it may be necessary to irradiate a destructive lesion of weight-bearing bone while the patient is taking a hormonal agent or chemotherapy. The palliative systemic regimen should be changed only if the disease is clearly progressing but not if disease appears stable. This is especially important for patients with destructive bone metastases, because minor changes in the status of these lesions are difficult to determine radiographically. A plan of therapy that would simultaneously minimize toxicity and maximize benefits is often best achieved by hormonal manipulation.

The choice of endocrine therapy depends on the menopausal status of the patient. Women within 1 year of their last menstrual period are considered to be premenopausal, whereas women whose menstruation ceased more than 1 year ago are usually classified as postmenopausal. The initial choice of therapy is referred to as primary hormonal manipulation; subsequent endocrine treatment is called secondary or tertiary hormonal manipulation.

PRIMARY HORMONAL THERAPY

In the past, ovarian ablation usually by bilateral surgical oophorectomy, chemical means or radiation was the standard method of hormone manipulation employed in premenopausal women with advanced breast cancer. However, it has subsequently become clear that tamoxifen is equally effective and has none of the attendant risks of surgical ablation of the ovaries. Tamoxifen is recommended as the treatment of choice for hormonal therapy in the premenopausal woman with advanced breast cancer. For postmenopausal patients, AIs and tamoxifen are the initial therapy of choice for metastatic breast cancer amenable to endocrine manipulation.

SECONDARY OR TERTIARY HORMONAL THERAPY

A favorable response to initial hormonal therapy with tamoxifen is predictive of future responses to hormonal maneuvers.

Other hormonal agents have been found effective in premenopausal patients. Gonadotropin-releasing hormone (GnRH) agonists that act on the pituitary to eventually suppress follicle-stimulating hormone (FSH) and leuteinizing hormone (LH) and the pituitary–ovarian axis, thereby decreasing estrogen production, have been used since the 1980s. They are an alternative to oophorectomy if used alone or can be combined with tamoxifen to provide a slight improvement in progression-free survival and overall survival.

The use of AIs, which work by blocking the conversion of testosterone to estradiol and androstenedione to estrogen both in the adrenal cortex and in peripheral tissue, including breast cancers themselves, are effective in postmenopausal patients.

Progestins, megestrol acetate, and medroxyprogesterone acetate are alternative agents reserved mainly for cases resistant to tamoxifen.

Chemotherapy

Cytotoxic drugs should be considered for the treatment of metastatic breast cancer in the following instances: (a) if visceral metastases are present (especially brain or lymphangitic pulmonary spread), (b) if hormonal treatment is unsuccessful or the disease has progressed after an initial response to hormonal manipulation, or (c) if the tumor is estrogen and progesterone receptor-negative. With response rates of 35–55% in many series, the taxanes are quickly eclipsing the anthracyclines in the single-agent treatment of hormone-refractory metastatic breast cancer. Where once doxorubicin could achieve response rates of 40–50%, in some trials the taxanes seem to offer a small overall survival advantage. In addition, they are generally well tolerated with an acceptable side-effect profile. Questions about dosing, schedule of administration, and use with other agents, however, still have to be thoroughly answered.

Combination chemotherapy using multiple agents is appealing because, theoretically, the risk of drug resistance and cumulative toxicity is decreased. When compared to single-agent doxorubicin therapy, combination chemotherapy provides higher response rates and longer intervals until first progression. Nevertheless, the use of combination chemotherapy has never been shown to decrease drug resistance or toxicity in breast cancer. When combination chemotherapy has been compared to single-agent taxane therapy, although response rates were slightly lower, quality-of-life measurements were higher for the single agent. Thus, either a single-agent taxane or an anthracycline-containing combination regimen is frequently used as a first-line treatment. The use of cytotoxic chemotherapy or any other treatment modality should always be highly individualized, especially in the palliative setting.

Bisphosphonate Therapy

Subsequent to a definitive treatment of primary breast cancer, bone is the most common site of disseminated breast cancer recurrence. It is also the most common site of metastatic disease at initial presentation. Bone metastases are often detected with a bone scan obtained in the staging of locally advanced cases or obtained because of clinical suspicion in the previously treated patient. Confirmation with plain radiographs, MRI, and/or CT is frequently needed as nearly 10% of lytic lesions may not be detected with a nuclear medicine scan. These other radiographic studies also help to delineate the extent of the metastatic disease. After bone metastases are confirmed, bisphosphonate therapy should be started. Although no survival advantage has been demonstrated, bisphosphonates have been shown to reduce bony as well as visceral metastases. Bisphosphonate therapy should be administered with other palliative systemic treatments such as hormonal manipulation or chemotherapy. It is typically given intravenously every 3–4 weeks for 2 years or for the duration of other systemic treatment.
