

Preface

As in the previous editions, this text is a single-source reference for practitioners in both the inpatient and outpatient setting focusing on the practical aspects of clinical diagnosis and patient management.

Contained within the text is a thorough review of all of obstetrics and gynecology, including medical advances up to the time of publication. More than 1000 diseases and disorders are included.

A continued emphasis on disease prevention and evidence-based medicine remains paramount. In addition to diagnosis and treatment of disease, pathophysiology is a major area of focus. The concise format facilitates quick access.

A new and improved layout will certainly be appreciated, with more than 500 anatomic drawings, imaging studies, and diagrams as part of the basic text.

Medical students will find *CDTOG* to be an authoritative introduction to the specialty and an excellent source for reference and review. House officers will welcome the concise practical information for commonly encountered health problems. Practicing obstetricians and gynecologists, family physicians, internists, nurse practitioners, nurse midwives, physician assistants, and other healthcare providers whose practice includes women's health can use the book to answer questions that arise in the daily practice of obstetrics and gynecology.

Medicine, including OB/GYN, is undergoing rapid change and every attempt has been made to keep the Lange Series current. A great deal of effort has gone into checking the sources to make sure that this book presents standards of care and acceptable modes of treatment and diagnosis.

Just as the preface has been updated, modified, and modernized from the ninth edition, so has what lies between the covers of the tenth edition of *Current Diagnosis & Treatment Obstetrics & Gynecology*.

Notice

Medicine is an ever-changing science. As new research and clinical experience broaden our knowledge, changes in treatment and drug therapy are required. The authors and the publisher of this work have checked with sources believed to be reliable in their efforts to provide information that is complete and generally in accord with the standards accepted at the time of publication. However, in view of the possibility of human error or changes in medical sciences, neither the authors nor the publisher nor any other party who has been involved in the preparation or publication of this work warrants that the information contained herein is in every respect accurate or complete, and they disclaim all responsibility for any errors or omissions or for the results obtained from use of the information contained in this work. Readers are encouraged to confirm the information contained herein with other sources. For example and in particular, readers are advised to check the product information sheet included in the package of each drug they plan to administer to be certain that the information contained in this work is accurate and that changes have not been made in the recommended dose or in the contraindications for administration. This recommendation is of particular importance in connection with new or infrequently used drugs.

Current OB/GYN > Chapter 1. Approach to the Patient >

APPROACH TO THE PATIENT: INTRODUCTION

An effective relationship between health care provider and patient is based on the knowledge and skill that qualify the provider for adequate communication between the individuals and for an appreciation of the ethical standards that govern the conduct of the participants in the relationship.

THE KNOWLEDGE BASE

The health care of women encompasses all aspects of medical science and therapeutics. Physicians in the practice of obstetrics and gynecology are called upon as consultants. In addition, they frequently act as primary care providers for their patients. The special medical needs and concerns of women vary with the patient's age, reproductive status, and desire to reproduce. Certainly the diagnostic possibilities and the choice of diagnostic or therapeutic intervention will be influenced by the possibility of, or desire for, pregnancy or, in some cases, by the patient's hormonal profile. In addition, the gynecologic or obstetric assessment must include an evaluation of the patient's general health status and should be placed in the context of the psychologic, social, cultural, and emotional status of the patient. In this day of e-medicine and evidence-based medicine, the patient's and physician's knowledge base will be dependent on information that is retrieved online. It will become the job of the physician to use the most up-to-date evidence for medical decision making and to assist the patient in deciphering what Internet information is true or false.

History

To offer each woman optimal care, the information obtained at each visit should be as complete as possible. Whether the contact is a routine visit or is occasioned by a particular problem or complaint, the woman should be encouraged to view the visit as an opportunity to participate in improving her health. The clinical database should include general information about the patient and her goals in seeking care. The history of the present problem, past medical history, family history, medications used, allergies, social history, and review of systems should be concise but thorough. Portions of the history provided by questionnaires or by other members of the health care team should be reviewed with the patient, in part to verify the information but also to begin assessing the patient's personality and to determine her attitude toward the health care system. The developmental history, menstrual history, sexual history, and obstetric history obviously assume central importance for the gynecologic or obstetric visit. In addition, the habit of systematically categorizing the nature of complaints such as pain, abnormal bleeding, or vaginal discharge will usually narrow the differential diagnoses. For example, the categorization of a complaint of pain should include its character, location, onset, radiation, intensity, events associated, and palliative and provocative factors. Such thoroughness will permit assessment of change as well as determination of the appropriate mode of investigation or therapy.

The initial contact with the patient, made while she is fully clothed and comfortable, may help in decreasing her anxiety about the physical examination. Concerns about the examination may be elicited, and a history of previous unfortunate experiences may alert the examiner to the need for extra attention, time, and gentleness.

Physical Examination

The second component of the patient assessment, the physical examination, should also be directed toward evaluation of the total patient. The patient again should be encouraged to view the examination as a positive opportunity to gain information about her body, and she should be offered feedback regarding the general physical examination and any significant findings. The examination should always include a discussion of any concerns expressed by the patient. The breast examination provides a good opportunity to reinforce the practice of breast self-examination. The pelvic examination is usually an occasion of heightened anxiety for the patient, and every effort should be made to make the experience a positive one. Starting from the beginning, with the correct positioning of the patient, the physician should give the patient as much control over the process as possible, by asking if she is ready, asking for feedback on whether the examination is painful, and seeking her cooperation in relaxation and muscle control. Information about each step of the examination can be provided so that the patient is involved and appropriately aware of the value of each maneuver.

Inspection of the external genitalia is followed by the gentle insertion of an appropriately sized, warmed metal speculum or a plastic vaginal speculum with a small amount of water-soluble gel lubricant on the outer inferior blade, to permit examination of the vagina and the cervix. For patients with pain or increased anxiety, their cooperation must be continually reinforced by slow, gentle placement of the instrument, maintaining downward pressure against the relaxed perineal body and away from the urethral and anterior vaginal areas. Some women may wish to watch, using a mirror, as the genitalia are inspected and may gain confidence from visualizing the cervix and vagina. The Papanicolaou (Pap) smear may be uncomfortable for some women, so patients should be alerted when the test is being done. The bimanual examination should also be explained to the patient. When the uterus is anteflexed, the woman may want to appreciate the size and location of her uterus by feeling it with the guidance of the examiner. The rectovaginal and rectal examinations, if performed while the patient relaxes her anal sphincter, provide additional information and can be another source of reassurance for the normal patient or a means of diagnosis for the patient with disease. If an ultrasound is indicated as part of the gynecologic or obstetric examination, additional patient participation in the evaluation can be obtained by providing explanations of the visualized anatomy.

Implications of Technology

The scientific knowledge base for obstetric and gynecologic care has grown in parallel with general medical advances. In some cases this proliferation of information and technology has profoundly altered the relationship between health care providers and their patients. For example, the change from an intuitive management of labor and delivery to active monitoring and subsequent interpretation of data has provided a more rational basis for decision making. This change of management style has also created a potential for conflict or confusion in the relationship between patient and physician. In seeking to obtain additional information, the physician can be perceived to be intervening unnecessarily. More than ever before, issues of consumerism and participation in decision making require an understanding of the expectations of each individual woman. Whether a woman perceives herself as a "client" or as a "patient," and the degree to which this perception coincides with the views of her physician, may alter her acceptance of recommendations for care. Women are turning to the Internet for health information, and the quality of this information is an important factor in determining whether it will have a negative or positive impact on their health care experience. The fact that several options are available in the management of many obstetric or gynecologic situations may further complicate the relationship. However, this situation provides an opportunity to allow the patient to participate actively in choosing the best therapy for her particular circumstance.

COMMUNICATION

If the first foundation of a strong therapeutic relationship is knowledge, the second is communication. The ability to establish trust, to obtain and deliver complete and accurate information, and to ensure compliance with recommendations depends in large measure on the health care provider's communication skills. In some individuals these skills are innate, but for most the ability to become an effective communicator in a variety of settings requires an active process of learning and a willingness to be evaluated by peers. The information communicated in each encounter, whether by written material, face-to-face discussion, telephone contact, or e-mail, extends beyond the factual content provided to include a demonstration of the provider's willingness to be available to answer questions and to encourage patient involvement in decision making.

One common barrier from the patient's perspective is that medical information is communicated via medical jargon to the layperson. This medical jargon is often spoken in a hurried fashion, and the listener is not given the opportunity to ask questions for clarification. The patient may also find it difficult to voice her concerns within the traditional doctor-patient relationship. She may be embarrassed to reveal intimate details about her personal life to a provider who does not take the time to show interest in her story. By not allowing the patient to express her fears, concerns, or questions, the provider can miss valuable clues to diagnosis and formulation of a treatment plan. Also, with the rapidly growing proportion of minority groups within the United States (U.S.) population, the physician is faced with barriers such as foreign languages and the use of translators.

Solutions to these communication barriers can be found by educating patients and providers. The physician should provide a comfortable environment, encourage the patient to ask questions, listen carefully to both her story and the way she tells it, explore with her the goals and expectations she has about the treatment, and have interpreter services available for patients in need. Videotaped interviews as well as more structured teaching programs in medical schools are very effective means of educating providers about these skills. The patient should be asked to repeat instructions, and written material should be provided whenever possible. For her part the patient can be asked to take notes and keep a diary for review at subsequent visits.

To enhance women's health and to decrease the discontinuation of hormones taken to prevent unintended pregnancy, clinicians need to focus on communication and counseling issues. In doing so, physicians can provide patients with the knowledge of benefits of hormone therapy, dispel fears about contraceptives, and promote the health benefits in an effort to increase adherence and continuance of hormonal contraceptives. For the health care practitioner, the counterbalance of a litigious society that may hold the physician responsible for treatment outcome places a high premium on documentation and scientific justification for each intervention or nonintervention and can place the physician in an adversarial position with respect to the patient's desires. The obligation to inform the patient, to obtain surgical informed consent, or to advise about choices regarding pregnancy outcome is becoming in some instances a matter of law rather than established medical practice. These legislative initiatives, while offensive to many, are signals that the public feels it requires protection from manipulation at the hands of those who have the power of knowledge and training not available to the layperson. Regardless of the validity of this perception, it can only be countered by efforts to establish and maintain the trust of each individual with whom the physician has a medical relationship. This trust is rooted in the physician's medical knowledge and is maintained by conscientious structured lifetime learning, the frank assessment and acknowledgment of areas of ignorance, and the willingness to discuss with the patient what is known and what is uncertain.

ETHICS

If the bricks of the foundation of the relationship between physician and patient are knowledge and communication, then the mortar that forms the basis for trust is the integrity and ethical behavior of all participants in the relationship. Ethical dilemmas in obstetrics and gynecology are receiving increasing recognition, particularly as they deal with the provocative issues surrounding the beginnings of life and the control of individual patients over their own treatment plans, including their route of delivery (vaginal versus elective cesarean section). Ethical dilemmas only arise when there are conflicting obligations, rights, or claims. Because the delivery of health care involves multiple participants, a consensus of values often must be sought when the patient is cared for by a team, even when significant pluralism of views might be represented. To minimize potential ethical conflicts, to anticipate potential areas of difficulty, and to achieve consistency in behavior, individuals may avail themselves of a number of resources for ethical decision making. In addition to the growing literature in the field, many hospitals and practice settings have formal consultation services for resolution of ethical dilemmas. Before seeking an external framework, however, the practitioner should be aware of his or her own values and understand the basis of these values. The values of the medical profession and of the institutions in which the physician practices, as formulated by codes and standards but also as expressed indirectly through past actions, usually are helpful in providing a decision-making framework. Finally, a familiarity with ethical theories may permit decision making that achieves an acceptable consensus in the face of conflicting values. Discussions based on consideration of the ethical principles of patient autonomy (respect for persons), beneficence (doing good), nonmaleficence (refraining from doing harm), and justice (consideration of resources and fairness of opportunity) will prevent capricious and arbitrary decisions.

The principle of autonomy, or respect for each individual person, may form the underlying basis for resolving many ethical questions and will determine appropriate attitudes toward confidentiality, privacy, right to information, and the ultimate primacy of the patient in making treatment decisions. Because caring for women necessarily involves information regarding sensitive and intimate relationships and activities, as well as access to a woman's thoughts, feelings, and emotions, full disclosure of such information by the patient places a burden of trust on the health care provider to protect the rights and privacy of each patient. The relationship established at an initial gynecologic visit between a young adolescent and the physician may potentially extend throughout the patient's adult life and include major life events such as education about reproductive health, assistance in family planning and childbearing, and preservation of physical fitness and well-being through the postmenopausal years. To successfully establish such an enduring clinical relationship requires a sensitivity to the changing goals and needs of the individual patient. Offering care to some patients or providing some types of services may not be comfortable for all practitioners. For example, establishing a rapport with an adolescent seeking birth control or providing health care to a lesbian may require a nonjudgmental approach when interviewing the patient and a balanced consideration of lifestyle options. Recognition of these special needs has led to a compartmentalization of health care in some regions such that specialty practices or clinics directed toward adolescent health care, family planning, fertility, oncology, and menopausal care are frequently available. These resources can best be utilized by referral, with guidance from the primary care provider, so that appropriate use of such resources can be an integral part of the general health care of each woman. In addition, we can integrate these multiple disciplines in a deliberate effort to expand the concept of women's health beyond its traditional focus on reproductive health to more fully evaluate and care for the female patient.

Current OB/GYN >Chapter 2. Anatomy of the Female Reproductive System >

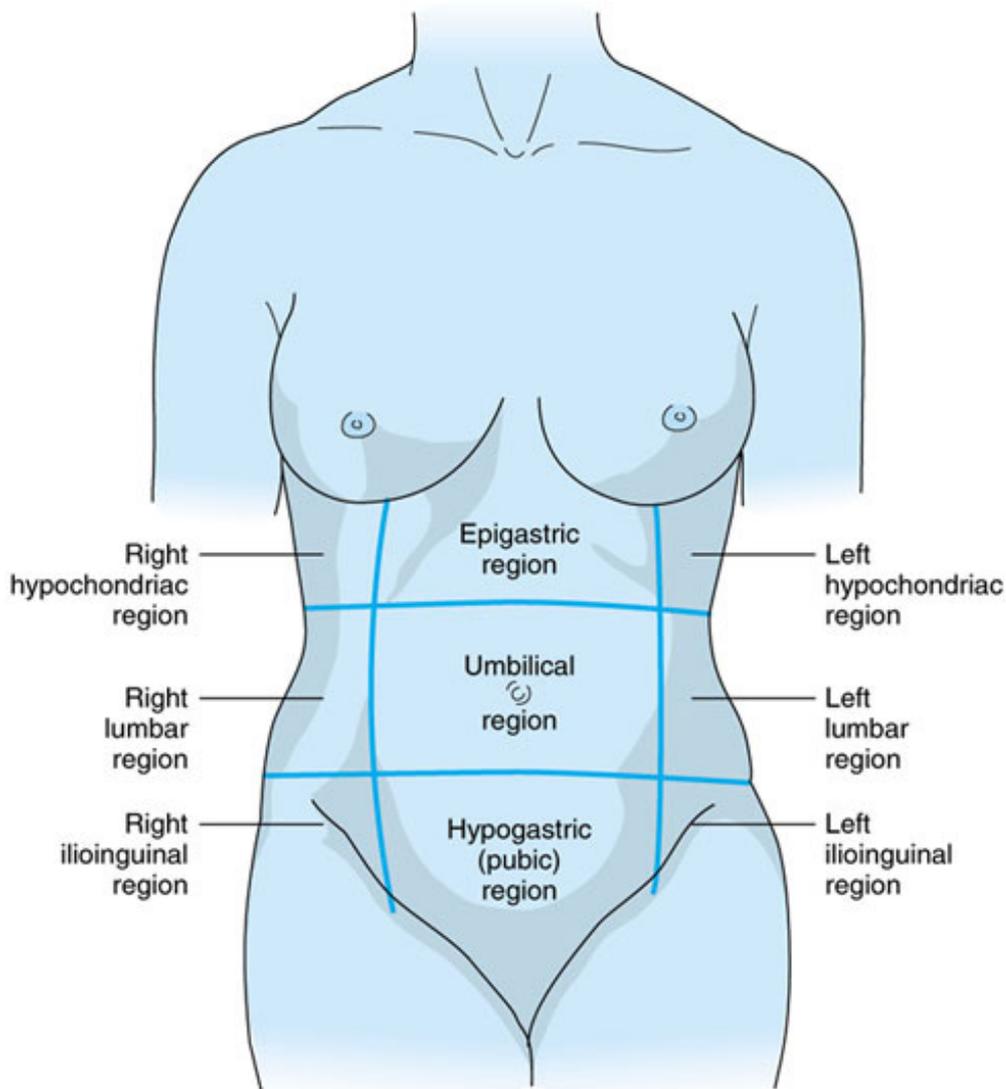

ABDOMINAL WALL

Topographic Anatomy

The anterior abdominal wall is divided into sections for descriptive purposes and to allow the physician to outline the viscera in the abdominal cavity. The centerpoint of reference is the sternoxiphoid process, which is in the tenth thoracic vertebra. The upper 2 sections are formed by the subcostal angle; the lower extends from the low of the ilium and forward to the anterior superior iliac spines. The base is formed by the inguinal ligaments and the pubica.

The viscera are located by dividing the anterolateral abdominal wall into regions. One line is placed from the level of the costal cartilage to the iliac crests. Two other lines are drawn from the middle of the inguinal ligaments to the carinae. The 9 regions formed (Fig 2–1) are the epigastric, umbilical, hypogastric, and right and left hypochondriac, and ilioinguinal.

All rights reserved.

Regions of the abdomen.

Within the right hypochondriac zone are the right lobe of the liver, the gallbladder at the anterior inferior angle, kidney deep within the region, and, occasionally, the right colic flexure.

The epigastric zone contains the left lobe of the liver and part of the right lobe, the stomach, the proximal duode pancreas, the suprarenal glands, and the upper poles of both kidneys (Fig 2-2).

Figure 2-2.

All rights reserved.

Abdominal viscera in situ. Inset shows projection of fetus in situ.

The left hypochondriac region marks the situation of the spleen, the fundus of the stomach, the apex of the liver flexure.

Within the right lumbar region are the ascending colon, coils of intestine, and, frequently, the inferior border of the right kidney.

The central umbilical region contains the transverse colon, the stomach, the greater omentum, the small intestine third portions of the duodenum, the head of the pancreas, and parts of the medial aspects of the kidneys.

Located in the left lumbar region are the descending colon, the left kidney, and small intestine. Within the limits ilioinguinal region are the cecum and appendix, part of the ascending colon, small intestine, and, occasionally, the greater omentum.

The hypogastric region includes the greater omentum, loops of small intestine, the pelvic colon, and often part of the colon.

The left ilioinguinal region encloses the sigmoid colon, part of the descending colon, loops of small intestine, and

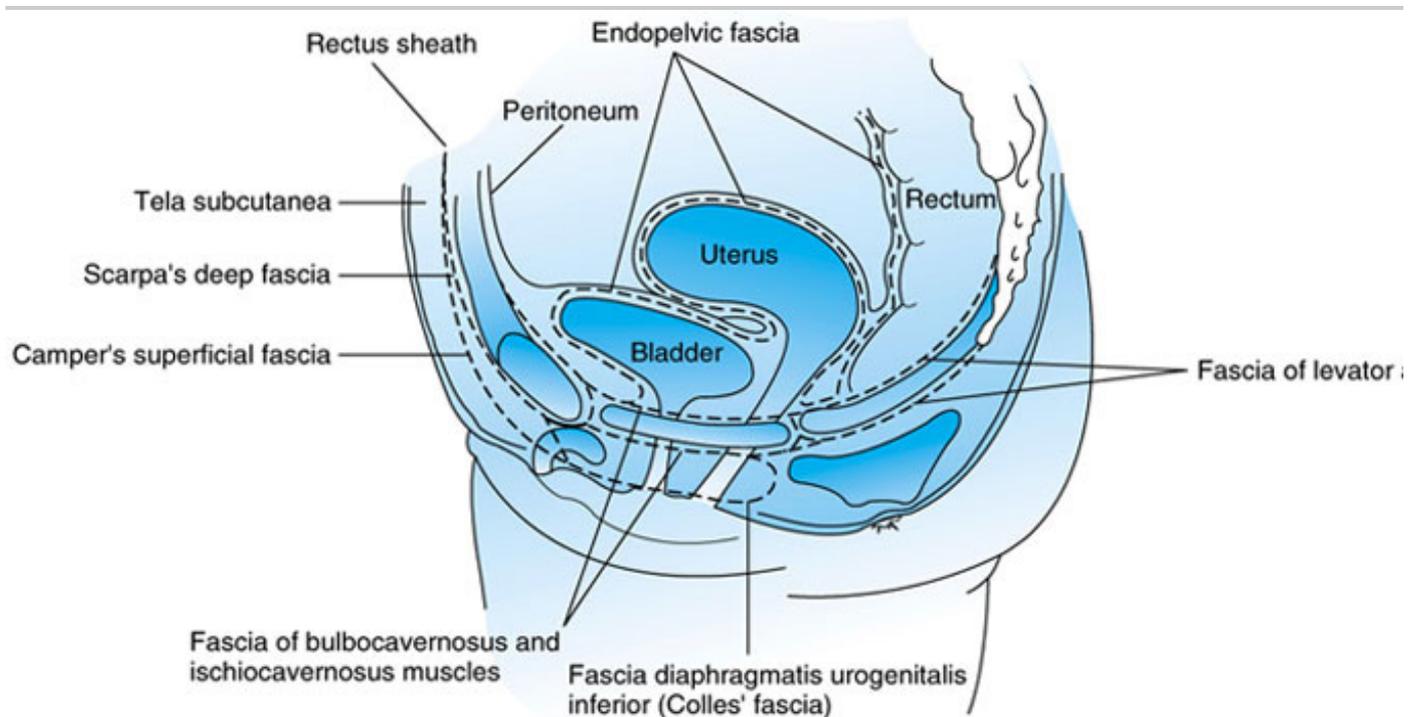

greater omentum.

There is considerable variation in the position and size of individual organs due to differences in body size and condition. Throughout life, variations in the positions of organs are dependent not only on gravity but also on the movements of the viscera, which induce further changes in shape when filling and emptying. The need to recognize the relationship between the abdominal regions becomes most apparent when taking into account the distortion that occurs during pregnancy; the appendix lies in the right ilioinguinal region (right lower quadrant) until the 12th week of gestation. At 16 weeks, it is at the level of the right iliac crest. At 20 weeks, it is at the level of the umbilicus, where it will remain until after delivery. Displacement of the symptoms of appendicitis will be different during the 3 trimesters. Similarly, displacement of problems involving the bowel.

Skin, Subcutaneous Tissue, & Fascia

The abdominal skin is smooth, fine, and very elastic. It is loosely attached to underlying structures except at the umbilicus where it is firmly adherent. Beneath the skin is the superficial fascia (tela subcutanea) (Fig 2–3). This fatty protective layer covers the entire abdomen. Below the navel, it consists principally of 2 layers: Camper's fascia, the more superficial layer composed of fat; and Scarpa's fascia (deep fascia), the fibroelastic membrane firmly attached to midline aponeuroses and

Fascial planes of the pelvis.

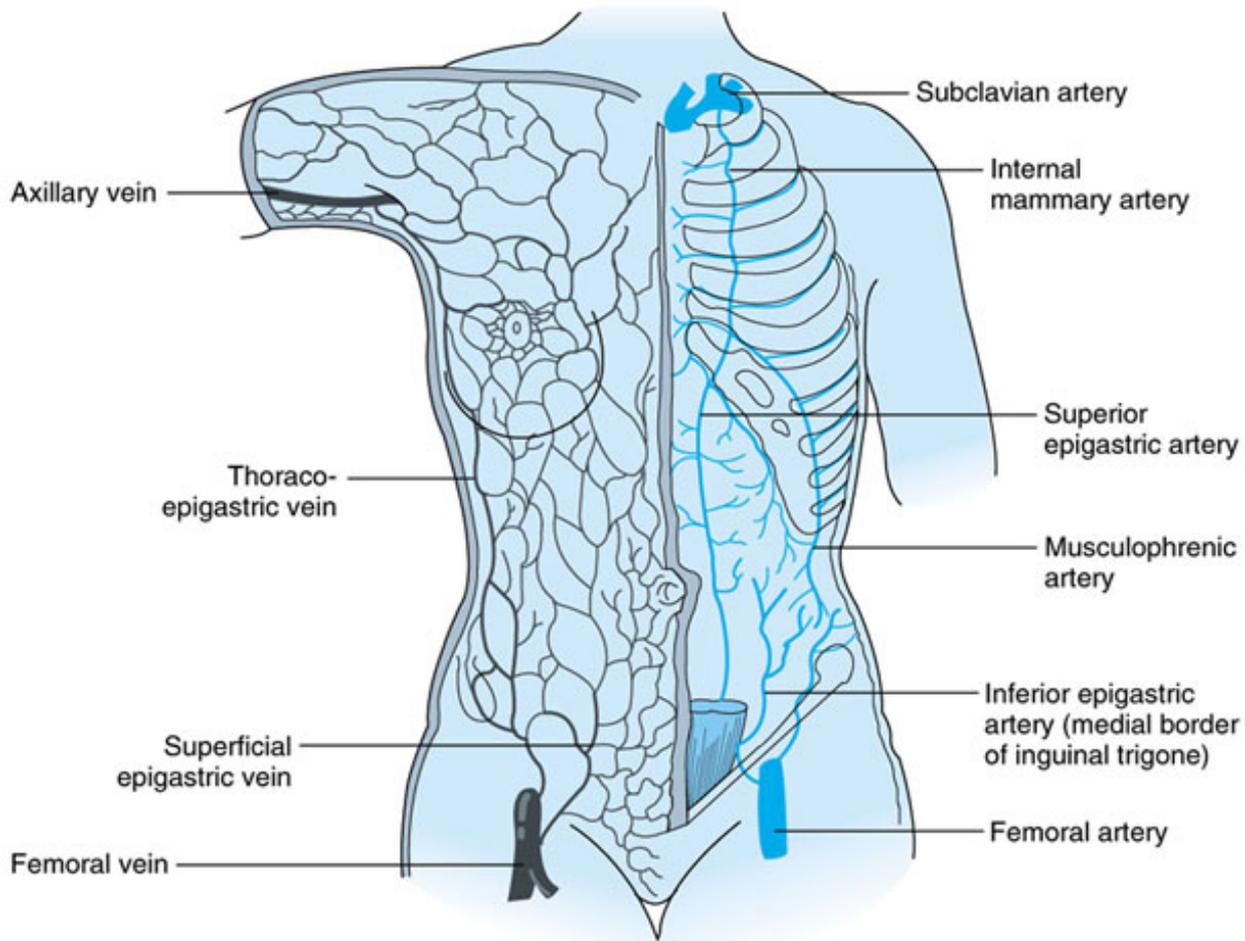

(Modified after Netter. Reproduced, with permission, from Benson RC: *Handbook of Obstetrics & Gynecology*, 8th ed, 1983.)

Arteries

The anterior cutaneous branches of the superficial arteries are grouped with the anterior cutaneous nerves (Fig 2–4). The anterior cutaneous branches stem from the lower aortic intercostal arteries and the subcostal arteries. The femoral artery, superficial epigastric and the superficial circumflex iliac arteries. From its origin beneath the fascia lata at approximately the inguinal ligament, the superficial epigastric artery passes immediately through the fascia lata or thro

ovalis. From there, it courses upward, primarily within Camper's fascia, in a slightly medial direction anterior to the rectus abdominis muscle almost as far as the umbilicus, giving off small branches to the inguinal lymph nodes and to the skin and subcutaneous tissue. It ends in numerous small twigs that anastomose with the cutaneous branches from the inferior epigastric and the superficial circumflex iliac arteries. Arising either in common with the superficial epigastric artery or as a separate branch from the femoral superficial circumflex iliac artery passes laterally over the iliacus. Perforating the fascia lata slightly to the lateral ovalis, it then runs parallel to the inguinal ligament almost to the crest of the ilium, where it terminates in branches that anastomose with the deep circumflex iliac artery. In its course, branches supply the iliacus and sartorius muscles, the inguinal lymph nodes, and the superficial fascia and skin.

Superficial veins and arteries of abdomen.

Veins

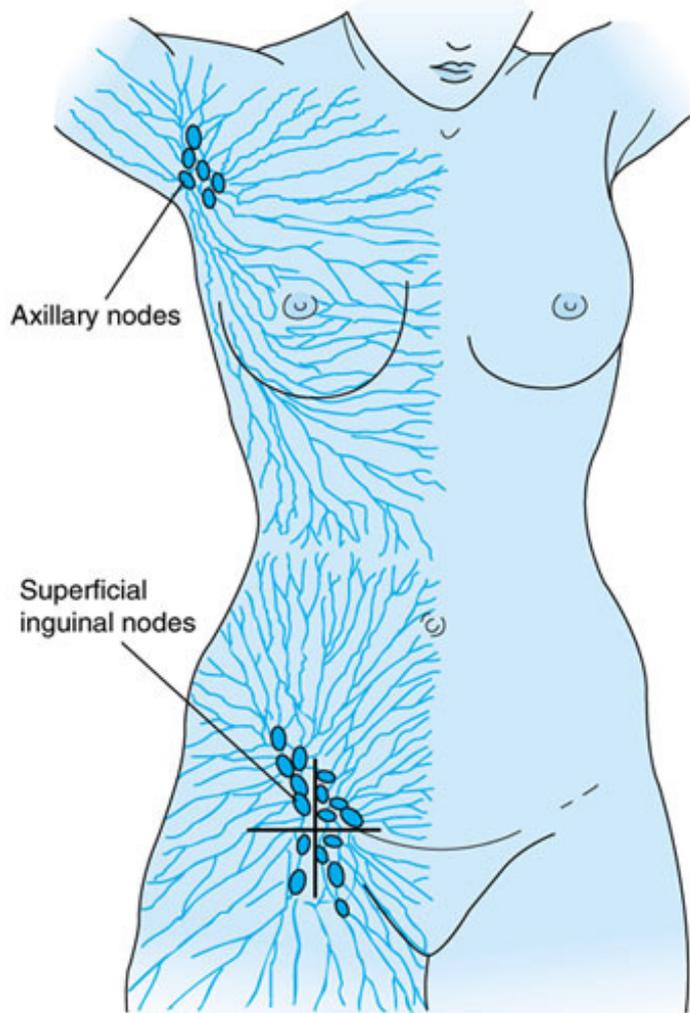

The superficial veins are more numerous than the arteries and form more extensive networks. Above the umbilicus, the superficial veins are the superficial epigastric veins, the superficial circumflex iliac veins, and the paired thoracoepigastric veins. A cruciate anastomosis exists, therefore, between the femoral and the superficial epigastric veins.

Lymphatics

The lymphatic drainage of the lower abdominal wall (Fig 2–5) is primarily to the superficial inguinal nodes, which are located in the area of the inguinal ligament. These nodes may be identified by dividing the area into quadrants by int

and vertical lines that meet at the saphenofemoral junction. The lateral abdominal wall drainage follows the superficial iliac vein and drains to the lymph nodes in the upper lateral quadrant of the superficial inguinal nodes. The drain aspect follows the superficial epigastric vein primarily to the lymph nodes in the upper medial quadrant of the superficial inguinal nodes. Of major clinical importance are the frequent anastomoses between the lymph vessels of the right and left abdomen.

Abdominal Muscles & Fascia

The muscular wall that supports the abdominal viscera (Fig 2–6) is composed of 4 pairs of muscles and their aponeuroses. The paired lateral muscles are the external oblique, the internal oblique, and the transversus. Their aponeuroses interdigitate at the midline to connect opposing lateral muscles, forming a thickened band at this juncture, the linea alba, which extends from the xiphoid process to the pubic symphysis. Anteriorly, a pair of muscles—the rectus abdominis, with the paired pyramidal muscles—constitute the abdominal wall.

Figure 2–6.

Musculature of abdominal wall.

EXTERNAL OBLIQUE MUSCLE

The external oblique muscle consists of 8 pointed digitations attached to the lower 8 ribs. The lowest fibers insert half of the iliac crest and the inguinal ligament. At the linea alba, the muscle aponeurosis interdigitates with that side and fuses with the underlying internal oblique.

INTERNAL OBLIQUE MUSCLE

The internal oblique muscle arises from thoracolumbar fascia, the crest of the ilium, and the inguinal ligament. In the opposite oblique direction, the muscle inserts into the lower 3 costal cartilages and into the linea alba on either side of the abdominis. The aponeurosis helps to form the rectus sheath both anteriorly and posteriorly. The posterior layer of the rectus muscle rib insertions to below the umbilicus.

TRANSVERSUS MUSCLE

The transversus muscle, the fibers of which run transversely and arise from the inner surfaces of the lower 6 costal cartilages, the thoracolumbar fascia, the iliac crest, and the inguinal ligament, lies beneath the internal oblique. By inserting into the aponeurosis of the transversus fuses to form the posterior layer of the posterior rectus sheath. The termination is called the arcuate line, and below it lie transversalis fascia, properitoneal fat, and peritoneum. Inferiorly, the thin layer of the transversus abdominis becomes part of the anterior rectus sheath.

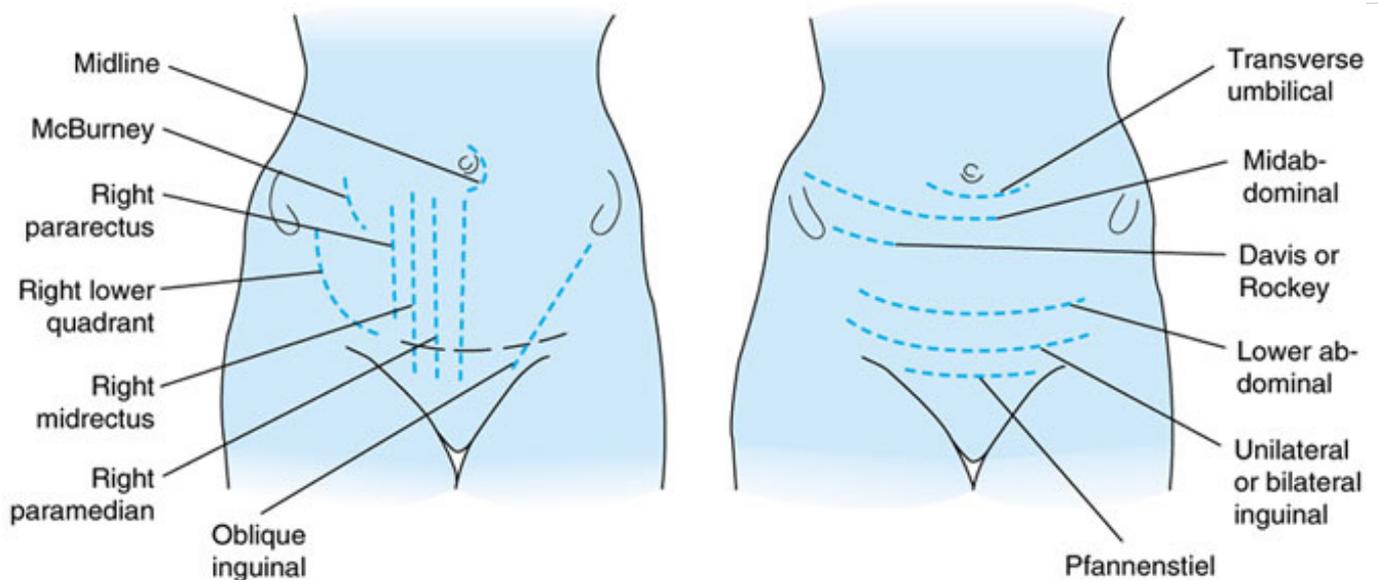

RECTUS MUSCLES

The rectus muscles are straplike and extend from the thorax to the pubis. They are divided by the linea alba and by the linea semilunaris. Three tendinous intersections cross the upper part of each rectus muscle, and a fourth is present below the umbilicus. The pyramidalis muscle, a vestigial muscle, is situated anterior to the lowermost part of the rectus muscle. It arises from and inserts into the pubic periosteum.

Beneath the superficial fascia and overlying the muscles is the thin, semitransparent deep fascia. Its extensions divide the lateral muscles into coarse bundles.

Abdominal incisions are shown in Fig 2–7. The position of the muscles influences the type of incision to be made to adequately expose the operative field, avoiding damage to parietal structures, blood vessels, and nerves. The incision is placed so as to create minimal tension on the lines of closure.

Figure 2–7.

Abdominal incisions. Transverse incisions are those in which rectus muscles are cut. A Cherney incision is one in taken off the pubic bone and then sewed back; the pyramidalis muscle is left on pubic tubercles.

Abdominal Nerves

The lower 6 thoracic nerves align with the ribs and give off lateral cutaneous branches (Fig 2–8). The intercostal to the upturned rib cartilages and enter the abdominal wall. The main trunks of these nerves run forward between oblique and the transversus. The nerves then enter the rectus sheaths and the rectus muscles, and the terminat emerge as anterior cutaneous nerves. The iliohypogastric nerve springs from the first lumbar nerve after the lati by the communicating branch from the last (12th) thoracic nerve. It pierces the lateral border of the psoas and the quadratus lumborum muscle but posterior to the kidney and colon. At the lateral border of the quadratus lur the aponeurosis of origin of the transversus abdominis and enters the areolar tissue between the transversus an oblique muscle. Here, it frequently communicates with the last thoracic and with the ilioinguinal nerve, which als the first lumbar and last thoracic nerves. The iliohypogastric divides into 2 branches. The iliac branch pierces the external oblique muscles, emerging through the latter above the iliac crest and supplying the integument of the part of the thigh. The hypogastric branch, as it passes forward and downward, gives branches to both the transv and internal oblique. It communicates with the ilioinguinal nerve and pierces the internal oblique muscle near th spine. The hypogastric branch proceeds medially beneath the external oblique aponeurosis and pierces it just ab subcutaneous inguinal ring to supply the skin and symphysis pubica.

Cutaneous innervation of the abdominal wall.

Abdominal Arteries

ARTERIES OF THE UPPER ABDOMEN

The lower 5 intercostal arteries and the subcostal artery accompany the thoracic nerves. Their finer, terminal branches pierce the rectus sheath to anastomose with the superior and inferior epigastric arteries. The superior epigastric artery is the terminal prolongation of the internal mammary artery. This artery descends between the posterior surface of the rectus abdominis muscle and its sheath to form an anastomosis with the inferior epigastric artery upon the muscle. The inferior epigastric artery, a branch of the external iliac artery, usually arises just above the inguinal ligament and passes on the medial side of the round ligament of the uterus through the abdominal inguinal ring. From there, it ascends in a slightly medial direction, passing above and lateral to the superior epigastric artery, which lies between the fascia transversalis and the peritoneum. Piercing the fascia transversalis, it pierces the linea semicircularis, turns upward between the rectus abdominis muscle and its sheath, enters the substance of the rectus abdominis muscle, and anastomoses with the superior epigastric artery. The superior epigastric supplies the upper central abdominal wall, the inferior supplies part of the anterior abdominal wall, and the deep circumflex supplies the lower lateral part of the abdominal wall.

ARTERIES OF THE LOWER ABDOMEN

The deep circumflex iliac artery is also a branch of the external iliac artery, arising from its side either opposite to or slightly below the origin of that vessel. It courses laterally behind the inguinal ligament lying between the fascia lata and the peritoneum. The deep circumflex artery perforates the transversus abdominis near the anterior superior spine of the ilium, and continues between the transversus abdominis and internal oblique along and slightly above the crest of the ilium, finally running to anastomose with the iliolumbar artery. A branch of the deep circumflex iliac artery is important to the surgeon because it anastomoses with branches of the inferior epigastric. The deep veins correspond in name with the arteries they accompany. Below the umbilicus, these veins run caudad and medially to the external iliac vein; above that level, they run cephalad and laterally to the intercostal veins. Lymphatic drainage in the deeper regions of the abdominal wall follows the deep veins directly.

superficial inguinal nodes.

The various incisions on the abdomen encounter some muscle planes and vasculature of clinical significance. The paramedian incision requires separation of the external and internal oblique muscles and splitting of the transversus abdominis. The deep circumflex iliac artery is frequently encountered. The paramedian incision is made in the right or left rectus abdominis. Above the arcuate line, the external and internal oblique, as well as the transversus abdominis muscles when present, go over the rectus abdominis; below the line, the transversus abdominis and part of the internal oblique go under the rectus. The vasculature is primarily perforator vessels. The thoracoabdominal vein. Inferiorly, the superficial epigastric artery and vein may be encountered. In the Pfannenstiel incision the external and internal oblique go over the rectus muscle as well as the transversus abdominis muscle when present. After the rectus abdominis is incised, the muscles can be separated. The superficial epigastric artery and vein are encountered in the paramedian incision. Laterally, the superficial and deep circumflex iliac arteries may be at the margin of the incision. Lying under the transversus abdominis and entering the rectus abdominis approximately halfway to the umbilicus is the inferior epigastric artery.

In the transverse incision, the arcuate line may be encountered. As the rectus abdominis muscle is incised, the inferior epigastric artery and its anastomosis with the thoracoabdominal artery must be recognized.

In the Cherney incision, care should be taken to avoid the inferior epigastric artery, which is the primary blood supply to the rectus abdominis.

Special Structures

There are several special anatomic structures in the abdominal wall, including the umbilicus, linea alba, linea semilunaris, and rectus sheath.

UMBILICUS

The umbilicus is situated opposite the disk between the third and fourth lumbar vertebrae, approximately 2 cm lateral to a line drawn from the sternoxiphoid process to the top of the pubic symphysis. The umbilicus is a dense, wrinkled fibrous tissue enclosed by and fused with a ring of circular aponeurotic fibers in the linea alba. Normally, it is the central point of the abdominal wall.

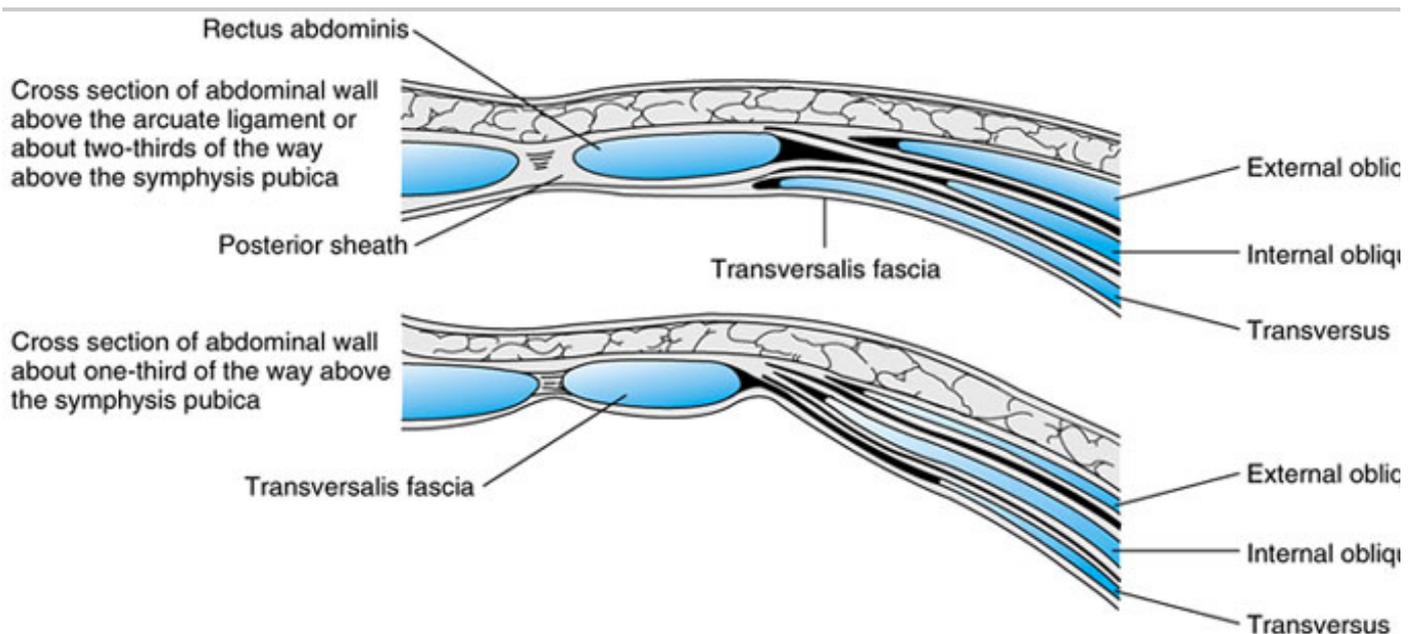

LINEA ALBA

The linea alba, a fibrous band formed by the fusion of the aponeuroses of the muscles of the anterior abdominal wall, runs along the medial side of the rectus abdominis; the linea semilunaris forms the lateral border, which courses from the tip of the xiphoid cartilage to the pubic tubercle. The linea alba extends from the xiphoid process to the pubic symphysis, representing the umbilicus as a shallow median groove on the surface.

RECTUS SHEATH AND APONEUROSIS OF THE EXTERNAL OBLIQUE

The rectus sheath serves to support and control the rectus abdominis muscles. It contains the rectus abdominis and pyramidalis muscles, branches of the lower 6 thoracic nerves and vessels, and the inferior and superior epigastric vessels. Cranially, the widest, its anterior wall extends upward onto the thorax to the level of the fifth costal cartilage and is attached to the deeper wall is attached to the xiphoid process and the lower borders of the seventh to ninth costal cartilages and extends upward onto the anterior thorax. Caudally, where the sheath narrows considerably, the anterior wall is attached to the symphysis pubica. Above the costal margin on the anterior chest wall, there is no complete rectus sheath (the rectus abdominis muscle is covered only by the aponeurosis of the external oblique. In the region of the abdomen, the aponeurosis of the internal oblique splits at the lateral border of the rectus abdominis muscle into anterior and posterior lamellae. The anterior lamella passes in front of the external oblique and blends with the external oblique aponeurosis. The posterior lamella is formed by the posterior lamella and the aponeurosis of the transversus abdominis muscle. The anterior and posterior lamellae meet at the midline. The lower third of the internal oblique aponeurosis is undivided. Together with the aponeuroses of the external and transversus abdominis muscles, it forms the anterior wall of the sheath. The posterior wall is occupied by transversalis fascia over the interior surfaces of both the rectus abdominis and the transversus abdominis muscles, separating them from peritoneum and inguinal and lacunar ligaments. The transition from aponeurosis to fascia usually is fairly sharp, marked by a curved arcuate line.

Figure 2–9.

Formation of rectus sheath.

FUNCTION OF ABDOMINAL MUSCLES

In general, the functions of the abdominal muscles are 3-fold: (1) support and compression of the abdominal viscera by the external oblique, internal oblique, and transversus muscles; (2) depression of the thorax in conjunction with the rectus abdominis, external oblique, internal oblique, and transversus muscles, as evident in respiration, coughing, defecation, and parturition; and (3) assistance in bending movements of the trunk through flexion of the vertebral column by the rectus abdominis, external oblique, and internal oblique muscles. There is partial assistance in rotation of the trunk to the same side when the pelvis is fixed by the internal oblique and by the external oblique to the opposite side. In addition, the upper external oblique serves as a fixation muscle in abduction of the upper limb of the same side and adduction of the upper limb of the opposite side. The pyramidalis muscle secures the linea alba in the median line.

Variations of Abdominal Muscles

Variations have been noted in all of the abdominal muscles.

RECTUS MUSCLE

The rectus abdominis muscle may differ in the number of its tendinous inscriptions and the extent of its thoracic aponeurotic slips or slips of muscle on the upper part of the thorax are remnants of a more primitive state in which the muscle was extended to the neck. Absence of part or all of the muscle has been noted. The pyramidalis muscle may be missing, underdeveloped, double, or may extend upward to the umbilicus.

EXTERNAL OBLIQUE MUSCLE

The external oblique muscle varies in the extent of its origin from the ribs. Broad fascicles may be separated by the main belly of the muscle, either on its deep or on its superficial surface. The supracostalis anterior is a rare muscle found on the upper portion of the thoracic wall. Transverse tendinous inscriptions may also be found.

INTERNAL OBLIQUE MUSCLE

The internal oblique deviates at times, both in its attachments and in the extent of development of the fleshy part. Occasionally, tendinous inscriptions are present, or the posterior division forms an extra muscle 7–7.5 cm wide and

the internal oblique by a branch of the iliohypogastric nerve and a branch of the deep circumflex iliac artery.

TRANSVERSUS MUSCLE

The transversus muscle fluctuates widely in the extent of its development but is rarely absent. Rarely, it extends to the ligamentum teres uteri (round ligament), and infrequently it is situated superior to the anterior superior spinous process. It generally occupies an intermediate position.

OTHER VARIATIONS

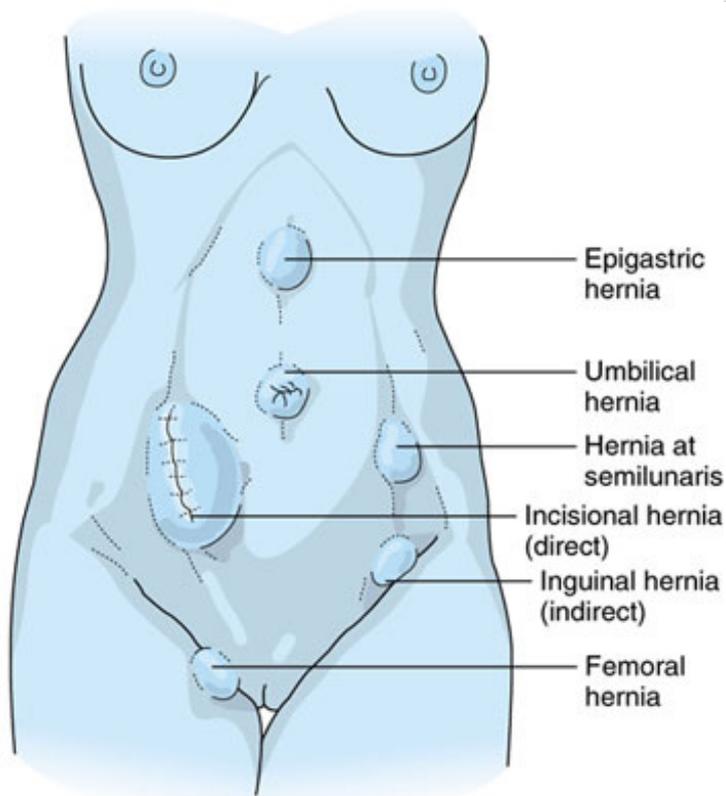

Several small muscles may be present.

1. The pubotransversalis muscle may extend from the superior ramus of the pubis to the transversalis fascia near the umbilicus.
2. The puboperitonealis muscle may pass from the pubic crest to the transversus near the umbilicus.
3. The posterior rectus abdominis (tensor laminae posterioris vaginae musculi recti abdominis) may spread from the posterior rectus abdominis to the rectus sheath on the deep surface of the rectus muscle near the umbilicus.
4. The tensor transversalis (tensor laminae posterioris vaginae musculi recti et fasciae transversalis abdominis) may pass from the tensor transversalis to the transversalis fascia near the abdominal inguinal ring to the linea semicircularis.

Hernias

A hernia (Fig 2–10) is a protrusion of any viscus from its normal enclosure, which may occur with any of the abdominal organs, especially the jejunum, ileum, and greater omentum. A hernia may be due to increased pressure, such as that resulting from strenuous exercise, lifting heavy weights, tenesmus, or increased expiratory efforts, or it may result from decreased resistance of the abdominal wall (congenital or acquired), such as occurs with debilitating illness or old age, prolonged distention, tumors, pregnancy, corpulence, emaciation, injuries (including surgical incisions), congenital absence, or poor development. Hernias are likely to occur where the abdominal wall is structurally weakened by the passage of large vessels or developmental peculiarities. Ventral hernias occur through the linea semilunaris or the linea alba. Umbilical hernias occur frequently and can be 1 of 3 types.

Figure 2–10.

Copyright ©2006 by The McGraw-Hill Companies, Inc.
All rights reserved.

Hernia sites.

During early fetal development, portions of the mesentery and a loop of the intestine pass through the opening in the body cavity (the umbilical coelom) situated in the umbilical cord. Normally, the mesentery and intestine later return to the abdominal cavity. If they fail to do so, a congenital umbilical hernia results. Infantile umbilical hernias occur if they fail to fuse completely in early postnatal stages. The unyielding nature of the fibrous tissue forming the margin of the hernia predisposes to strangulation. Adult umbilical hernias occur frequently in females. When the hernia comes through the umbilical ring, it is always at the upper part.

INGUINAL REGION

The inguinal region of the abdominal wall is bounded by the rectus abdominis muscle medially, the line connecting the superior iliac spines superiorly, and the inguinal ligament inferiorly. The region contains 8 layers of abdominal wall; from the most superficial inward, are (1) the skin, (2) the tela subcutanea, (3) the aponeurosis of the external oblique muscle, (4) the internal oblique muscle, (5) the transversus abdominis muscle (below the free border, the layer is incomplete), (6) the transversalis fascia, (7) the subperitoneal fat and connective tissue, and (8) the peritoneum. The tela subcutanea is the superficial fatty Camper's fascia, which is continuous with the tela subcutanea of the whole body, and the deeper Scarpa's fascia, which covers the lower third of the abdominal wall and the medial side of the groin, both joining the inguinal ligament to form the fascia lata of the thigh.

Subcutaneous Inguinal Ring

A triangular evagination of the external oblique aponeurosis, the subcutaneous inguinal ring (external abdominal ring) is bounded by an aponeurosis at its edges and by the inguinal ligament inferiorly. The superior or medial crus is smaller and attached to the pubic symphysis pubica. The inferior or lateral crus is stronger and blends with the inguinal ligament as it passes to the thigh. The sharp margins of the ring are attributed to a sudden thinning of the aponeurosis. In the female, the ligament of the round ligament passes through this ring. The subcutaneous inguinal ring is much smaller in the female than in the male.

abdominal wall is relatively stronger in this region.

Ligaments, Aponeuroses, & Fossae

The inguinal ligament itself forms the inferior thickened border of the external oblique aponeurosis, extending from the superior iliac spine to the pubic tubercle. Along its inferior border, it becomes continuous with the fascia lata of the medial portion of the inguinal ligament, a triangular band of fibers attaches separately to the pecten ossis pubis, known as the lacunar (Gimbernat's) ligament. The reflex inguinal ligament (ligament of Colles or triangular fascia) is formed by a small band of fibers, often poorly developed, and derived from the superior crus of the subcutaneous inguinal ligament, lower part of the linea alba. These fibers cross to the opposite side to attach to the pecten ossis pubis. The falx inguinalis (conjoined tendon) is formed by the aponeurosis of the transversus abdominis and internal oblique muscles. These muscles arch over the inguinal ligament and arch downward and forward to insert on the pubic crest and pecten ossis pubis, behind the lacunar ligaments. The interfoveolar ligament is composed partly of fibrous bands from the aponeurosis of the transversus abdominis of the same and opposite sides. Curving medial to and below the internal abdominal ring, they attach to the lacunar ligament and pectineal fascia.

Abdominal Inguinal Ring

The abdominal inguinal ring (internal abdominal ring) is the rounded mouth of a funnel-shaped expansion of the peritoneum that lies approximately 2 cm above the inguinal ligament and midway between the anterior superior iliac spine and the pubic tubercle. Medially, it is bounded by the inferior epigastric vessels; the external iliac artery is situated below. The area of the ring represents the area where the round ligament emerges from the abdomen. The triangular area medial to the external iliac artery, bounded by the inguinal ligament below and the lateral border of the rectus abdominis sheath, is known as the trigonum inguinale (Hesselbach's triangle), the site of congenital direct hernias.

Inguinal Canal

The inguinal canal in the female is not well demarcated, but it normally gives passage to the round ligament of the uterus, an artery from the uterus that forms a cruciate anastomosis with the labial arteries, and extraperitoneal fat. The testis, an abdominal organ, possesses a gubernaculum that extends from its lower pole downward and forward to the abdominal inguinal ring, through which it continues into the labia majora. The processus vaginalis is a diverticulum of peritoneum at the level of the abdominal inguinal ring occurring during the third fetal month. In the male, the processus vaginalis descends with the testis. The processus vaginalis of the female is rudimentary, but occasionally a diverticulum of peritoneum is found passing partway through the inguinal region; this diverticulum is termed the processus vaginalis peritonei (canal of Nuck). Instead of descending, as does the testis, the ovary moves medially, where it is attached to the uterus. The intra-abdominal portion of the gubernaculum ovarii becomes attached to the lateral border of the uterus, evolving as the ligament of the ovary and the round ligament of the uterus. The extra-abdominal portion of the gubernaculum of the uterus becomes attenuated in the adult and may appear as a small fibrous band. The inguinal canal is an intermuscular passageway that extends from the abdominal ring downward, medially, and somewhat forward to the inguinal ring (about 3–4 cm). The canal is roughly triangular in shape, and its boundaries are largely artificial. The lateral boundaries are the inguinal ligaments. The base of the canal is formed by the external oblique muscle. The anterior or superficial wall is formed by the external oblique muscle and the lowermost fibers of the internal oblique muscle add additional strength in its lateral part. The posterior or deep wall is formed by transversalis fascia throughout and is strengthened medially by the falx inguinalis.

Abdominal Fossae

The abdominal fossae in the inguinal region consist of the foveae inguinalis lateralis and medialis. The fovea inguinalis lateralis is a slight fold, the plica epigastrica, formed by the inferior epigastric vessels, and just medial to the abdominal inguinal ring, which slants medially and upward toward the rectus abdominis muscle. From the lateral margin of the tendinous insertion of the external oblique muscle, upward toward the umbilicus, and over the obliterated artery extends a more accentuated fold, the plica inguinalis lateralis. The fovea inguinalis medialis lies between the plica epigastrica and the plica inguinalis lateralis, the base of the canal facing the trigonum inguinale (Hesselbach's triangle). This region is strengthened by the interfoveolar ligament and the interfoveolar fascia.

of the abdominal inguinal ring and the conjoined tendon lateral to the rectus muscle; however, these bands vary are supportive.

Ligaments & Spaces

The inguinal ligament forms the roof of a large osseoligamentous space leading from the iliac fossa to the thigh. space is formed by the superior ramus of the pubis medially and by the body of the ilium laterally. The iliopectin extends from the inguinal ligament to the iliopectineal eminence, dividing this area into 2 parts. The lateral, large muscular lacuna and is almost completely filled by the iliopsoas muscle, along with the femoral nerve medial femoral cutaneous nerves laterally. The medial, smaller division is known as the vascular lacuna and is traversed by the iliac (femoral) artery, vein, and lymphatic vessels, which do not completely fill the space. The anterior border of is formed by the inguinal ligament and the transversalis fascia. The posterior boundary is formed by the ligamentum superius (Cooper's ligament), a thickening of fascia along the pubic pecten where the pectineal fascia and iliopectin meet. The transversalis fascia and iliac fascia are extended with the vessels, forming a funnel-shaped fibrous inguinal femoral sheath. The sheath is divided into 3 compartments: (1) the lateral compartment, containing the femoral artery; (2) the intermediate compartment, containing the femoral vein; and (3) the medial compartment or canal, containing the lymphatic vessels [node of Rosenmüller or Cloquet] and the lymphatic vessels that drain most of the perineum. The femoral canal also contains areolar tissue, which frequently condenses to form the "femoral septum". In the greater spread of the pelvis in the female, the muscular and vascular lacunae are relatively large spaces. The abdominal opening of the femoral canal is known as the femoral ring and is covered by the parietal peritoneum.

Arteries

In front of the femoral ring, the arterial branches of the external iliac artery are the inferior epigastric and the deep circumflex iliac. The inferior epigastric artery arises from the anterior surface of the external iliac, passing forward and upward on the abdominal wall between peritoneum and transversalis fascia. It pierces the fascia just below the arcuate line, enters the abdominal cavity and courses along its inferior surface to anastomose with the superior epigastric from the inferior vena cava. The inferior epigastric artery forms the lateral boundary of the trigonum inguinale (Hesselbach's triangle). At its origin it gives off a branch to the inguinal canal, as well as a branch to the pubis (pubic artery), which anastomoses with the obturator artery. The pubic branch of the inferior epigastric often becomes the obturator artery. The deep circumflex iliac artery arises laterally and traverses the iliopsoas to the anterior superior iliac spine, where it pierces the transversus abdominis between the transversus and the internal oblique, sending perforators to the surface. It often has anastomoses with the branches of the inferior epigastric via its perforators through the rectus abdominis. The veins follow a similar course.

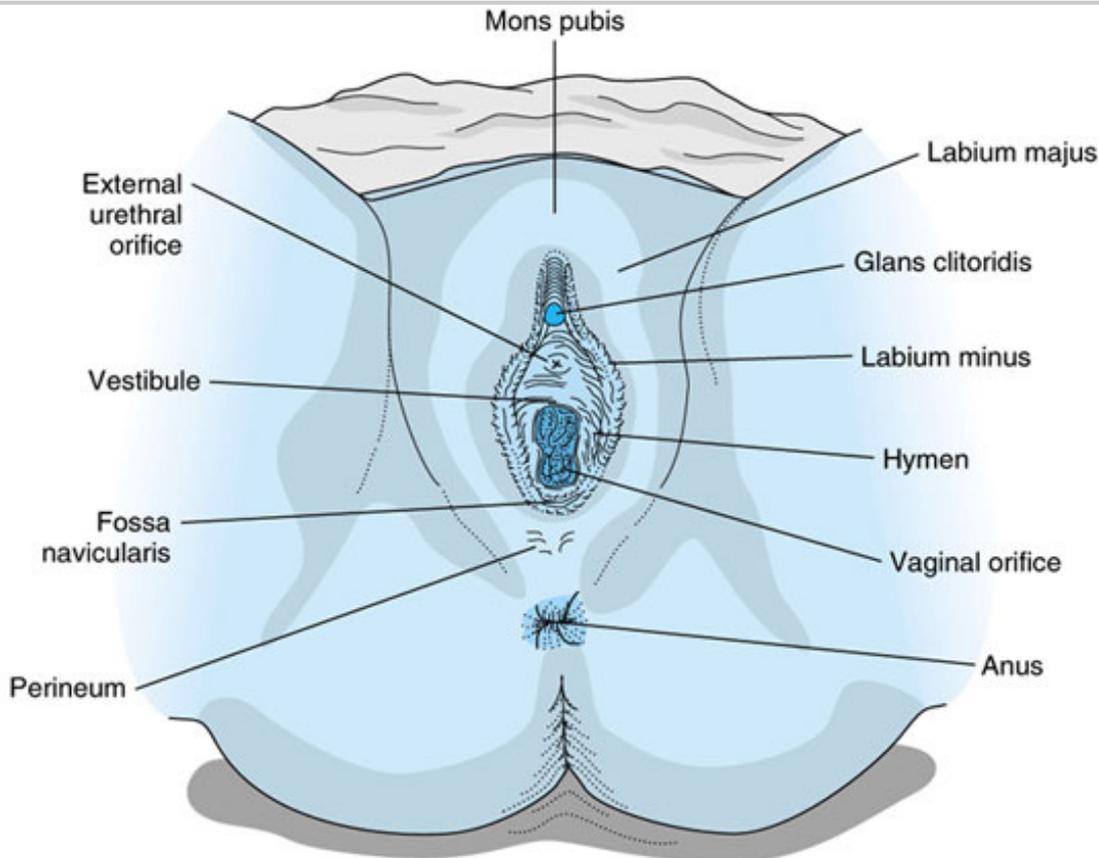

As the external iliac artery passes through the femoral canal, which underlies the inguinal ligament, it courses near the femoral vein and nerve, resting in what is termed the femoral triangle (Scarpa's triangle). The femoral sheath is a continuation of the inguinal ligament anterior to the femoral vessel and nerve.

The branches of the femoral artery supplying the groin are (1) the superficial epigastric, (2) the superficial circumflex iliac, (3) the superficial external pudendal, and (4) the deep external pudendal. The superficial epigastric artery passes upward in the femoral sheath over the inguinal ligament, to rest in Camper's fascia on the lower abdomen. The superficial circumflex iliac artery arises adjacent to the superior epigastric, piercing the fascia lata and running parallel to the inguinal ligament as its crest. It then divides into branches that supply the integument of the groin, the superficial fascia, and the lymphatics, anastomosing with the deep circumflex iliac, the superior gluteal, and the lateral femoral circumflex arteries. The superficial external pudendal artery arises from the medial side of the femoral artery, close to the preceding vessels. It pierces the femoral sheath and fascia cribrosa, coursing medially across the round ligament to the integument on the lower part of the labium majus, anastomosing with the internal pudendal. The deep external pudendal artery passes medially between the pectineus and adductor longus muscles, supplying the integument of the labium majus and forming, together with the superficial external pudendal artery, a rete with the labial arteries.

PUDENDUM

The vulva consists of the mons pubis, the labia majora, the labia minora, the clitoris, and the glandular structure the vestibulum vaginae (Fig 2–11). The size, shape, and coloration of the various structures, as well as the hair among individuals and racial groups. Normal pubic hair in the female is distributed in an inverted triangle, with t over the mons pubis. Nevertheless, in approximately 25% of normal women, hair may extend upward along the type of hair is dependent, in part, on the pigmentation of the individual. It varies from heavy, coarse, crinkly hai to sparse, fairly fine, lanugo-type hair in Asian women. The length and size of the various structures of the vulva; the pelvic architecture, as is the position of the external genitalia in the perineal area. The external genitalia of t their exact counterparts in the male.

External genitalia of adult female (parous).

Labia Majora

SUPERFICIAL ANATOMY

The labia majora are comprised of 2 rounded mounds of tissue, originating in the mons pubis and terminating in They form the lateral boundaries of the vulva and are approximately 7–9 cm long and 2–4 cm wide, varying in s weight, race, age, parity, and pelvic architecture. Ontogenetically, these permanent folds of skin are homologou the male. Hair is distributed over their surfaces, extending superiorly in the area of the mons pubis from one sid lateral surfaces are adjacent to the medial surface of the thigh, forming a deep groove when the legs are togeth surfaces of the labia majora may oppose each other directly or may be separated by protrusion of the labia minc is formed by this opposition anteriorly is termed the anterior commissure. Posteriorly, the cleft is less clearly def the posterior commissure. The middle portion of the cleft between the 2 labia is the rima pudendi.

DEEP STRUCTURES

Underlying the skin is a thin, poorly developed muscle layer called the tunica dartos labialis, the fibers of which are in most part, at right angles to the wrinkles of the surface, forming a crisscross pattern. Deep to the dartos layer is fascia, most readily recognizable in the old or the young because of the large amount of adipose and areolar tissue. Sweat glands are found in the labia majora, with the greater number on the medial aspect. In the deeper substance of the labia majora are longitudinal bands of muscle that are continuous with the ligamentum teres uteri (round ligament) at the inguinal canal. Occasionally, a persistent processus vaginalis peritonei (canal of Nuck) may be seen in the upper part of the labia. In most women, it has been impossible to differentiate the presence of the cremaster muscle beyond its attachment to the inguinal canal.

ARTERIES

The arterial supply into the labia majora comes from the internal and external pudendals, with extensive anastomoses. The arterial supply to the labia majora is a circular arterial pattern originating inferiorly from a branch of the perineal artery, from the external pudendal artery in the anterior lateral aspect, and from a small artery of the ligamentum teres uteri superiorly. The inferior perineal artery, which originates from the internal pudendal as it emerges from the canalis pudendalis (Alcock's space) at the base of the rete with the external pudendal arteries. These arise from the medial side of the femoral artery, occasionally from deep arteries just beneath the femoral ring, coursing medially over the pectineus and adductor muscles, to which they give off branches. They terminate in a circular rete within the labium majus, penetrating the fascia lata adjacent to the femoral ring, passing over the round ligament to send a branch to the clitoris.

VEINS

The venous drainage is extensive and forms a plexus with numerous anastomoses. In addition, the veins communicate with the dorsal vein of the clitoris, the veins of the labia minora, and the perineal veins, as well as with the inferior hemorrhoidal veins on each side, the posterior labial veins connect with the external pudendal vein, terminating in the great saphenous vein (just prior to its entrance (saphenous opening) in the fossa ovalis). This large plexus is frequently manifested by the presence of large varicosities during pregnancy.

LYMPHATICS

The lymphatics of the labia majora are extensive and utilize 2 systems, one lying superficially (under the skin) and the other deeper, within the subcutaneous tissues. From the upper two-thirds of the left and right labia majora, superficial lymphatics course toward the symphysis and turn laterally to join the medial superficial inguinal nodes. These nodes drain into the nodes overlying the saphenous fossa. The drainage flows into and through the femoral ring (fossa ovalis) to the inguinales profundi (nodes of Rosenmüller or Cloquet; deep subinguinal nodes), connecting with the external iliac lymphatics. The superficial subinguinal nodes, situated over the femoral trigone, also accept superficial drainage from the lower part of the gluteal region. This drainage may include afferent lymphatics from the perineum. In the region of the symphysis, the lymphatics anastomose in a plexus between the right and left nodes. Therefore, any lesion involving the labia majora may involve involvement of the lymphatic structures of the contralateral inguinal area. The lower part of the labium majus has a deep drainage that is shared with the perineal area. The drainage passes, in part, through afferent lymphatics to the subinguinal nodes; from the posterior medial aspects of the labia majora, it frequently enters the lymphatic plexus of the rectum.

NERVES

The innervation of the external genitalia has been studied by many investigators. The iliohypogastric nerve originates from L1 and traverses laterally to the iliac crest between the transversus and internal oblique muscles, at which point it gives off branches: (1) the anterior hypogastric nerve, which descends anteriorly through the skin over the symphysis, supplying the superior portion of the labia majora and the mons pubis; and (2) the posterior iliac, which passes to the gluteal region.

The ilioinguinal nerve originates from L1 and follows a course slightly inferior to the iliohypogastric nerve, with which it frequently anastomoses, branching into many small fibers that terminate in the upper medial aspect of the labium majus.

The genitofemoral nerve (L1–L2) emerges from the anterior surface of the psoas muscle to run obliquely down the femoral surface, branching in the deeper substance of the labium majus to supply the dartos muscle and that vestige of the cremaster muscle.

present within the labium majus. Its lumboinguinal branch continues downward onto the upper part of the thigh. From the sacral plexus, the posterior femoral cutaneous nerve, originating from the posterior divisions of S1 and anterior divisions of S2 and S3, divides into several rami that, in part, are called the perineal branches. They supply the medial aspect of the thigh and the labia majora. These branches of the posterior femoral cutaneous nerve are derived from the sacral plexus. The pudendal nerve, composed primarily of S2, S3, and S4, often with a fascicle of S1, sends a small branch to the medial aspect of the labia majora. The pattern of nerve endings is illustrated in Table 2–1.

Labia Minora

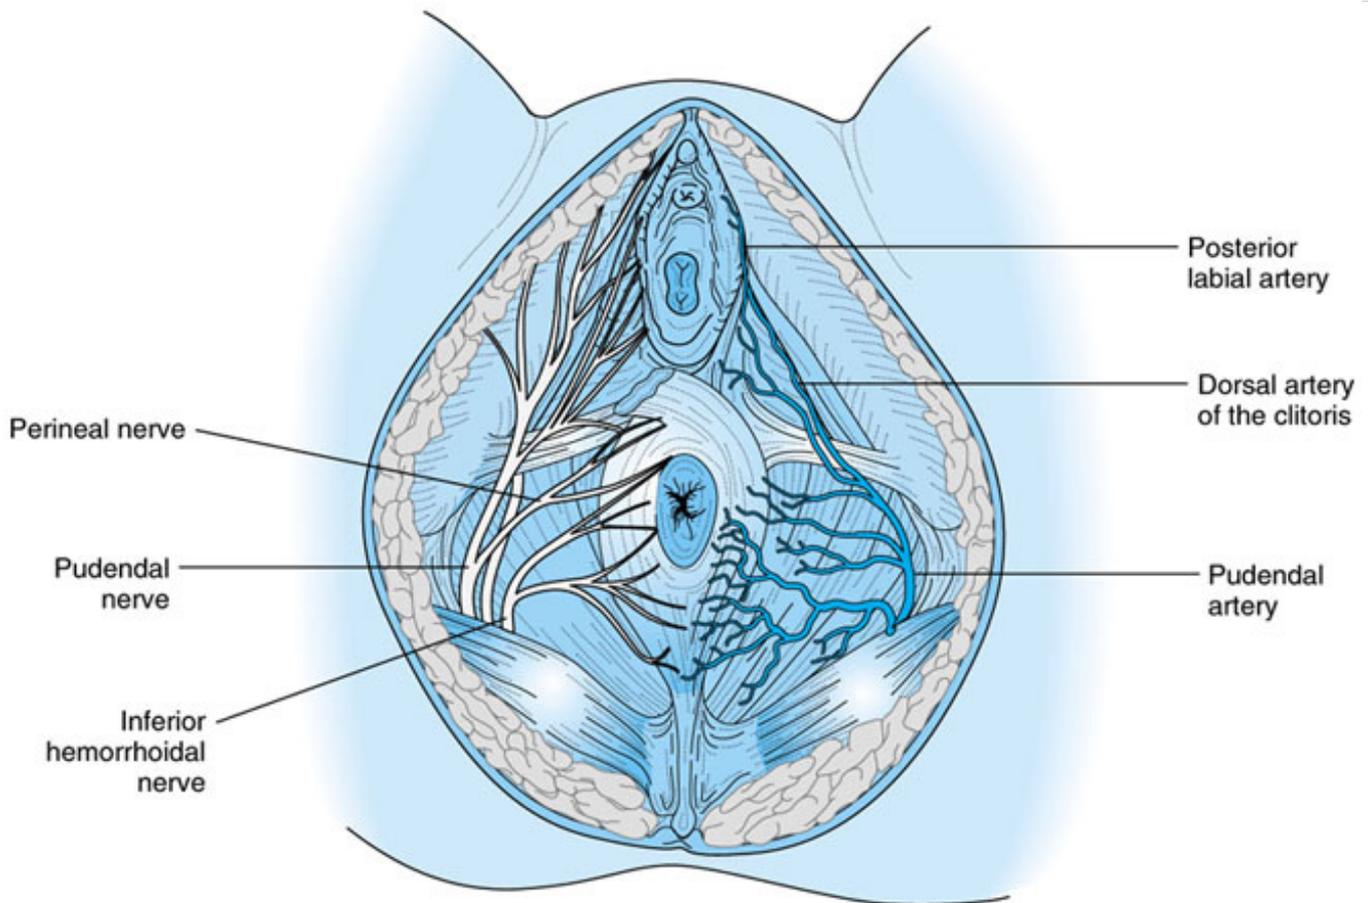

SUPERFICIAL ANATOMY

The labia minora are 2 folds of skin that lie within the rima pudendi and measure approximately 5 cm in length and thickness. The width varies according to age and parity, measuring 2–3 cm at its narrowest diameter to 5–6 cm at its widest diameter. The surface is covered with multiple corrugations over the surface. The labia minora begin at the base of the clitoris, where fusion of the labia minora with the prepuce, extending posteriorly and medially to the labia majora at the posterior commissure. On their superior surface, they unite to form the frenulum adjacent to the urethra and vagina, terminating at the clitoris. On the right and left sides of the fossa navicularis and ending posteriorly in the frenulum of the labia pudendi, just anterior to the posterior commissure. A deep cleft is formed on the lateral surface between the labium majus and the labium minus. The surface of the labia minora is smooth and pigmented. The color and distention vary, depending on the level of sexual excitement. The glands of the labia are homologous to the glandulae preputiales (glands of the foreskin) of the male urethra.

ARTERIES

The main source of arterial supply (Fig 2–12) occurs through anastomoses from the superficial perineal artery, the dorsal artery of the clitoris, and from the medial aspect of the rete of the labia majora. Similarly, the venous plexus is extensive.

Figure 2–12.

Arteries and nerves of perineum.

VEINS

The venous drainage is to the medial vessels of the perineal and vaginal veins, directly to the veins of the labia inferior hemorrhoidals posteriorly, and to the clitoral veins superiorly.

LYMPHATICS

The lymphatics medially may join those of the lower third of the vagina superiorly and the labia majora laterally, superficial subinguinal nodes and to the deep subinguinal nodes. In the midline, the lymphatic drainage coincide clitoris, communicating with that of the labia majora to drain to the opposite side.

NERVES

The innervation of the labia minora originates, in part, from fibers that supply the labia majora and from branch nerve as it emerges from the canalis pudendalis (Alcock's canal) (Fig 2-12). These branches originate from the labia minora and the vestibule area are homologous to the skin of the male urethra and penis. The short membr approximately 0.5 cm of the male urethra, is homologous to the midportion of the vestibule of the female.

Clitoris

SUPERFICIAL ANATOMY

The clitoris is the homologue of the dorsal part of the penis and consists of 2 small erectile cavernous bodies, rudimentary glans clitoridis. The erectile body, the corpus clitoridis, consists of the 2 crura clitoridis and the glan overlying skin and prepuce, a miniature homologue of the glans penis. The crura extend outward bilaterally to the anterior portion of the vulva. The cavernous tissue, homologous to the corpus spongiosum penis of the male, ap

vascular pattern of the labia minora in the female. At the lower border of the pubic arch, a small triangular fibrous band extends from the pubic symphysis onto the clitoris (suspensory ligament) to separate the 2 crura, which turn inward, downward, and laterally at the inferior rami of the pubic symphysis. The crura lie inferior to the ischiocavernosus muscles and bodies. The clitoris is attached superiorly at the fused termination of the crura. It is composed of erectile tissue and contains an integument, hence termed the prepuce. On its ventral surface, there is a frenulum clitoridis, the fused junction of the labia minora.

ARTERIES

The blood supply to the clitoris is from its dorsal artery, a terminal branch of the internal pudendal artery, which is a division of the posterior portion of the internal iliac (hypogastric) artery. As it enters the clitoris, it divides into 2 dorsal and ventral arteries. Just before entering the clitoris itself, a small branch passes posteriorly to supply the area of the urethral meatus.

VEINS

The venous drainage of the clitoris begins in a rich plexus around the corona of the glans, running along the anterior surface of the deep vein and continuing downward to join the pudendal plexus from the labia minora, labia majora, and perineum. The deep vein joins the pudendal vein.

LYMPHATICS

The lymphatic drainage of the clitoris coincides primarily with that of the labia minora, the right and left sides having their own contralateral nodes in the superficial inguinal chain. In addition, its extensive network provides further access deep to the superficial nodes posteriorly to the external urethral meatus toward the anterior portion of the vestibule.

NERVES

The innervation of the clitoris is through the terminal branch of the pudendal nerve, which originates from the sacral plexus of the sacral spinal nerves, as previously discussed. It lies on the lateral side of the dorsal artery and terminates in branches within the glans, prepuce, and frenulum. The nerve endings in the clitoris vary from a total absence within the glans to a rich supply primarily to the prepuce (Table 2–1). A total absence of endings within the clitoris itself takes on clinical significance when one places emphasis on the clitoris in discussing problems of sexual gratification in women.

Vestibule

SUPERFICIAL ANATOMY

The area of the vestibule is bordered by the labia minora laterally, by the frenulum labiorum pudendi (or posterior commissure) posteriorly, and by the urethra and clitoris anteriorly. Inferiorly, it is bordered by the hymenal ring. The opening of the vagina into the vestibule is limited by a membrane stretching from the posterior and lateral sides to the anterior surface of the external urethral orifice. This membrane is termed the hymen. Its shape and openings vary and depend on parity, and sexual experience. The form of the opening may be infantile, annular, semilunar, cribriform, septate, or imperforate. In parous women and in the postcoital state, the tags of the hymenal integument are termed carunculae myrtiliformes. The external urethral orifice, which is approximately 2–3 cm posterior to the clitoris, has an irregular surface with depressed areas on the sides, may appear to be stellate or crescentic in shape. It is closed by many small mucosal folds around its opening. Bilaterally and on the surface are the orifices of the paraurethral glands (ductus paraurethrales [ducts of Skene and Astruc]). At approximately the 5 and 7 o'clock positions, just anterior to the hymenal rings, are 2 small papular elevations that represent the orifices of the ducts of the glandulae vestibulares maiores (Bartholin) of the female (bulbourethral gland of the male). The fossa navicularis lies between the clitoris, labiorum pudendi and the hymenal ring. The skin surrounding the vestibule is stratified squamous in type, with numerous sebaceous glands, hair pegs and papillae.

ARTERIES

The blood supply to the vestibule is an extensive capillary plexus that has anastomoses with the superficial transverse perineal artery. A branch comes directly from the pudendal artery and anastomoses with the inferior hemorrhoidal artery in the region of the fossa navicularis. The blood supply of the urethra anteriorly, a branch of the dorsal artery of the clitoris and the azygos vein of the anterior vaginal wall, also contributes.

VEINS

Venous drainage is extensive, involving the same areas described for the arterial network.

LYMPHATICS

The lymphatic drainage has a distinct pattern. The anterior portion, including that of the external urethral meatus and outward with that of the labia minora and the clitoris. The portion next to the urethral meatus may join that urethra, which empties into the vestibular plexus to terminate in the superficial inguinal nodes, the superficial and the deep subinguinal nodes, and the external iliac chain. The lymphatics of the fossa navicularis and the hymen and the posterior vaginal wall, intertwining with the intercalated lymph nodes along the rectum, which follow the inferior arteries. This pattern becomes significant with cancer. Drainage occurs through the pudendal and the hemorrhoidal through the vestibular plexus onto the inguinal region.

NERVES

The innervation of the vestibular area is primarily from the sacral plexus through the perineal nerve. The absence of modalities of touch is noteworthy. The vestibular portion of the hymenal ring contains an abundance of free nerve endings.

Vestibular Glands

The glandulae vestibulares majores (larger vestibular glands or Bartholin glands) have a duct measuring approximately 1 cm in diameter. The gland itself lies just inferior and lateral to the bulbocavernosus muscle. The gland is tubular and has a characteristic character, with a thin capsule and connective tissue septa dividing it into lobules in which occasional smooth muscle is found. The epithelium is cuboid to columnar and pale in color, with the cytoplasm containing mucigen droplets and with acidophilic inclusions. The epithelium of the duct is simple in type, and its orifice is stratified squamous like. Secretion is a clear, viscid, and stringy mucoid substance with an alkaline pH. Secretion is active during sexual arousal. Nonetheless, after about age 30, the glands undergo involution and become atrophic and shrunken.

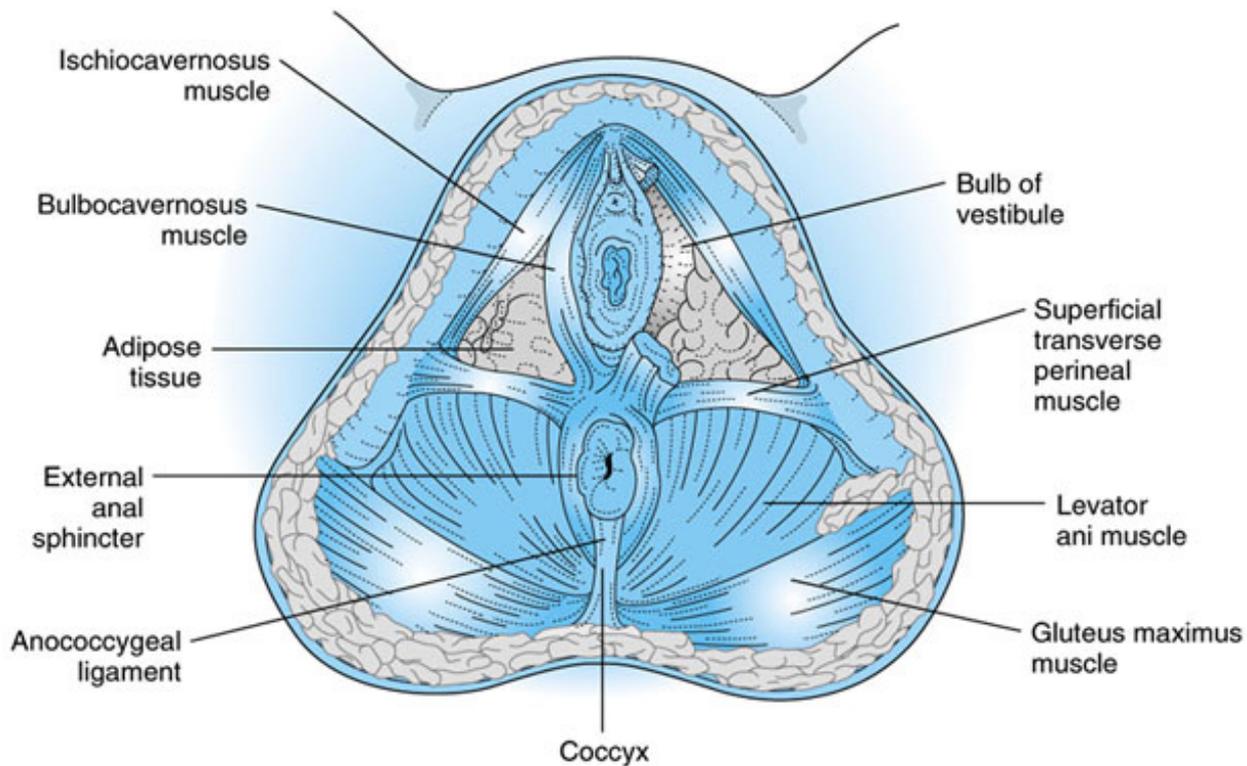

The arterial supply to the greater vestibular gland comes from a small branch of the artery on the bulbocavernosus penetrating deep into its substance. Venous drainage coincides with the drainage of the bulbocavernosus body. They drain directly into the lymphatics of the vestibular plexus, having access to the posterior vaginal wall along the internal hemorrhoidal channels. They also drain via the perineum into the inguinal area. Most of this minor drainage is in the superficial vessels in the canalis pudendalis and explains, in part, the difficulty in dealing with cancer involving the gland.

The greater vestibular gland is homologous to the bulbourethral gland (also known as Cowper's glands, Duverney's glands, Tiedemann's glands, or the Bartholin glands of the male). The innervation of the greater vestibular gland is from the perineal nerve, which penetrates directly into its substance.

Muscles of External Genitalia

The muscles (Fig 2–13) of the external genitalia and cavernous bodies in the female are homologous to those of the male; they are less well developed.

Figure 2–13.

Pelvic musculature (inferior view).

BULBOCAVERNOSUS MUSCLE

The bulbocavernosus muscle and deeper bulbus vestibuli or cavernous tissue arise in the midline from the postcentral tendon of the perineum, where each opposes the fibers from the opposite side. Each ascends around the enveloping the bulbus vestibuli (the corpus cavernosum bodies of the male) to terminate in 3 heads: (1) the fiber to the clitoris, (2) the tunica fibrosa of the corpus cavernosa overlying the crura of the clitoris, and (3) decussating those of the ischiocavernosus to form the striated sphincter of the urethra at the junction of its middle and lower supply is derived from the perineal branch of the internal pudendal artery as it arises in the anterior part of the deep to the fascia diaphragmatis urogenitalis inferior (Colles' fascia) and crossing between the ischiocavernosus and bulbocavernosus muscles, the pudendal artery sends 1–2 branches directly into the bulbocavernosus muscle and continuing anteriorly to terminate in the dorsal artery of the clitoris. The venous drainage accompanies the pudendal artery, it passes posteriorly with the inferior hemorrhoidal veins and laterally with the perineal vein, a branch of the pudendal vein. The lymphatics run primarily with those of the vestibular plexus, with drainage inferiorly toward the lymph nodes of the rectum and anteriorly and laterally with the labia minora and majora to the superficial inguinal lymph nodes. Drainage in the upper portion of the muscle and body is evident.

ISCHIOCAVERNOSUS MUSCLE

The ischiocavernosus muscle and its attendant cavernous tissue arise from the ischial tuberosity and inferior ramus of the ischial spine. It envelops the crus of its cavernous tissue in a thin layer of muscle ascending toward and over the medial and lateral surfaces of the symphysis pubica to terminate in the anterior surface of the symphysis at the base of the clitoris. It then sends fibers to the region of the upper and middle thirds of the urethra, forming the greater part of the organ's voluntary sphincter. Its blood supply is through perforating branches from the perineal artery as it ascends between the bulbocavernosus and ischiocavernosus muscles to terminate as the dorsal artery of the clitoris. The innervation stems from an ischiocavernosus branch of the perineal division of the pudendal nerve.

TRANSVERSUS MUSCLE

The transversus perinei superficialis muscle arises from the inferior ramus of the ischium and from the ischial tuberosity. The fibers of the muscle extend across the perineum and are inserted into its central tendon, meeting those from the opposite side. Frequently, the muscle fibers from the bulbocavernosus, the puborectalis, the superficial transverse perinei, and the external anal sphincter will interdigitate. The blood supply is from a perforating branch of the perineal division of the pudendal artery, and the nerve supply is from the perineal division of the pudendal nerve.

SENSORY CORPUSCLES

In the cavernous substances of both the bulbocavernosus and ischiocavernosus muscles, Vater-Pacini corpuscles (lamellosa) and Dogiel and Krause corpuscles (corpuscula bulboidea) are present.

INFERIOR LAYER OF UROGENITAL DIAPHRAGM

The inferior layer of urogenital diaphragm is a potential space depending upon the size and development of the female, and the pelvic architecture. It contains loose areolar connective tissue interspersed with fat and the bulbocavernosus muscles, with the support of the superficial transverse perinei muscles and the puborectalis muscle. The point of fixation on each side for support of the vulva, the external genitalia, and the vagina.

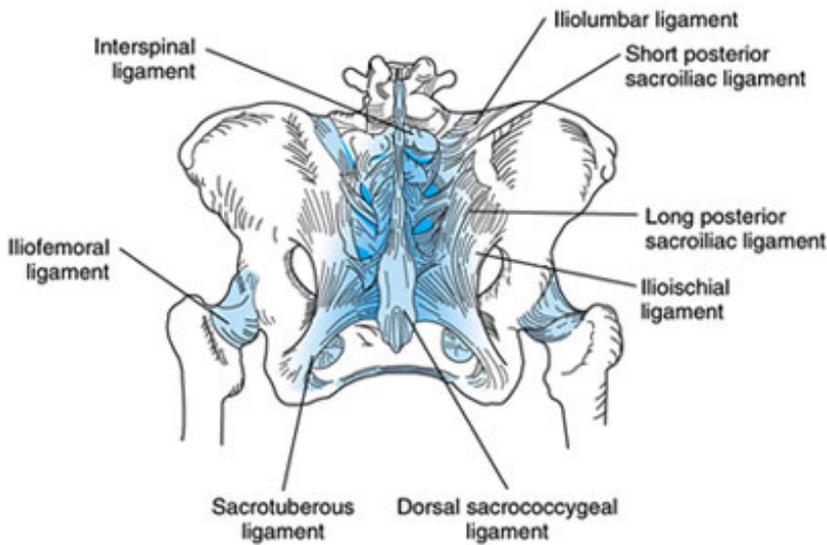

SURGICAL CONSIDERATIONS

A midline perineotomy is most effective to minimize trauma to vital supports of the vulva, bulbocavernosus, and superficial transverse perinei muscles. Overdistention of the vagina caused by the presenting part and body of the infant may lead to vaginal sacculation. If distention occurs too rapidly or if dilatation is beyond the resilient capacity of the vagina, rupture of the musculature may occur, often demonstrated by a cuneiform groove on the anterior wall and a tongue-like protrusion on the posterior wall of the vagina. Therefore, return of the vagina and vulva to the nonpregnant state is dependent upon the tone of the muscle and the degree of distention of the vagina during parturition.

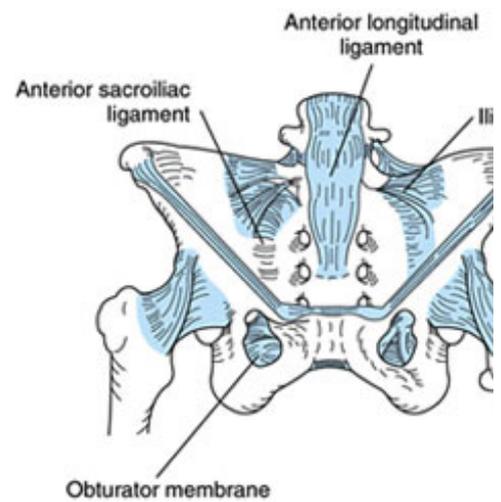

BONY PELVIS

The pelvis (Fig 2–14) is a basin-shaped ring of bones that marks the distal margin of the trunk. The pelvis rests on the lower extremities and supports the spinal column. It is composed of 2 innominate bones, one on each side, joined anteriorly and posteriorly. The innominate bones are articulated with the sacrum posteriorly. The 2 major pelvic divisions are the pelvis major (upper or false pelvis) and the pelvis minor (lower or true pelvis). The pelvis major consists primarily of the space superior to the iliopectineal line, including the iliac fossae and the region between them. The pelvis minor, located below the iliopectineal line, is bounded anteriorly by the pubis, posteriorly by the sacrum and coccyx, and laterally by the ischium and a small segment of the ilium.

The bony pelvis.

(Reproduced, with permission, from Benson RC: *Handbook of Obstetrics & Gynecology*, 8th ed. Lange, 1983.)

Innominate Bone

The innominate bone is composed of 3 parts: ilium, ischium, and pubis.

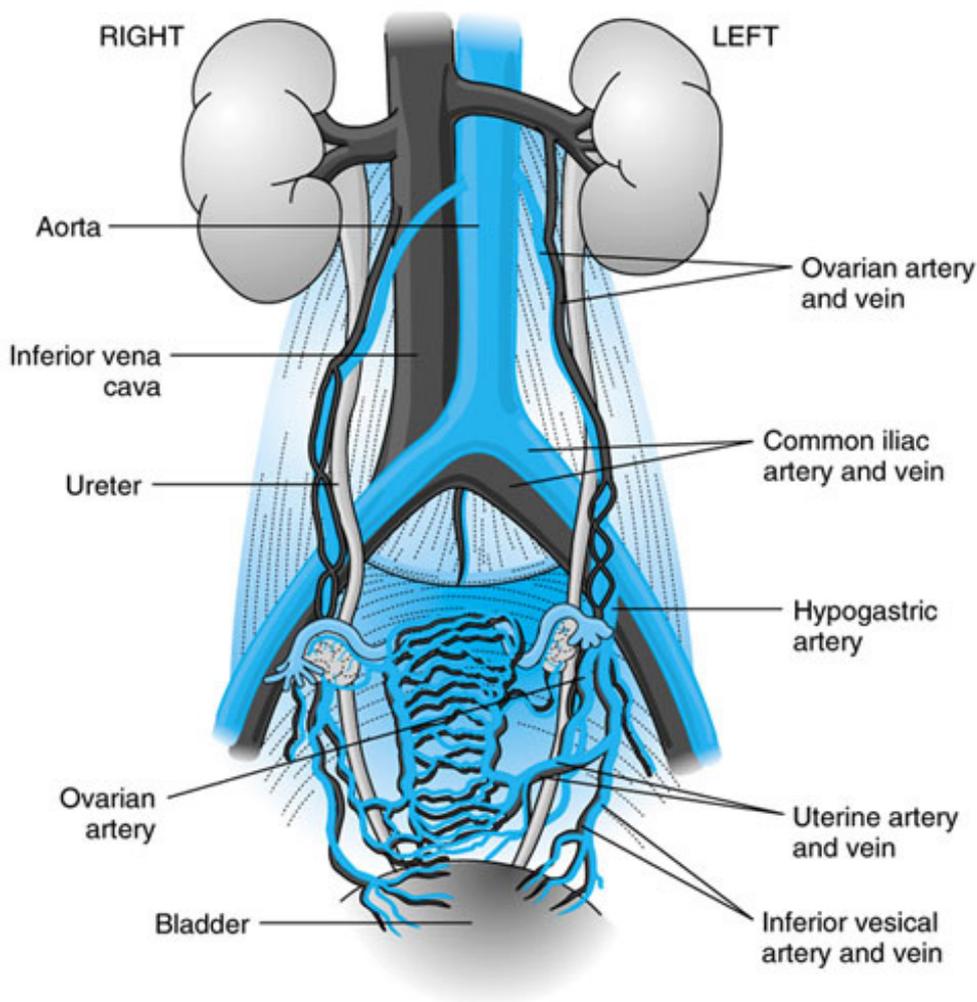

ILIUM

The ilium consists of a blade-like upper part or ala (wing) and a thicker, lower part called the body. The body forms a portion of the acetabulum and unites with the bodies of the ischium and pubis. The medial surface of the ilium presents a concave area: the anterior portion is the iliac fossa; the smaller posterior portion is composed of a rough upper tuberosity; and the lower part contains a large surface for articulation with the sacrum. At the inferior medial margin, a rounded ridge, the arcuate line, ends anteriorly in the iliopectineal eminence. Posteriorly, the arcuate line unites with the anterior margin of the ala of the sacrum across the anterior aspect of the sacroiliac joint. Anteriorly, it is

the ridge or pecten on the superior ramus of the pubis. The lateral surface or dorsum of the ilium is traversed by posterior, anterior, and inferior gluteal lines. The superior border is called the crest, and at its 2 extremities are posterior superior iliac spines. The principal feature of the anterior border of the ilium is the heavy anterior inferior iliac spine. Important aspects of the posterior border are the posterior superior and the inferior iliac spines and, below the lesser sciatic notch, the inferior part of which is bounded by the ischium. The inferior border of the ilium participates in the acetabulum.

The main vasculature (Fig 2–15) of the innominate bone appears where the bone is thickest. Blood is supplied to the ilium through twigs of the iliolumbar, deep circumflex iliac, and obturator arteries by foramina on the crest and below the terminal line near the greater sciatic notch. The outer surface of the ilium is supplied mainly below gluteal line through nutrient vessels derived from the gluteal arteries. The inferior branch of the deep part of the artery forms the external nutrient artery of the ilium and continues in its course to anastomose with the lateral circumflex artery. Upon leaving the pelvis below the piriform muscle, it divides into a number of branches, a group of which passes

Figure 2–15.

Blood supply to pelvis.

ISCHIUM

The ischium is composed of a body, superior and inferior rami, and a tuberosity. The body is the heaviest part of

joined with the bodies of the ilium and pubis to form the acetabulum. It presents 3 surfaces. (1) The smooth internal surface is continuous above with the body of the ilium and below with the inner surface of the superior ramus of the ischium. These parts form the posterior portion of the lateral wall of the pelvis minor. (2) The external surface of the ischium enters into the formation of the acetabulum. (3) The posterior surface is the area between the acetabular rim and the greater sciatic foramen. It is convex and is separated from the ischial tuberosity by a wide groove. The posterior border, with the bony margin of the greater sciatic notch. The superior ramus of the ischium descends from the body of the bone at an angle of approximately 90 degrees. The large ischial tuberosity and its inferior portion are situated at this angle. The inferior portion of the tuberosity forms the point of support in the sitting position. The posterior surface is divided into 2 areas by an oblique line. The lesser sciatic notch occupies the posterior border of the superior ramus between the tuberosity. The inferior ramus, as it is traced forward, joins the inferior ramus of the pubis to form the arcus pubis (ischio-pubic arch).

The ischium is supplied with blood from the obturator medial and lateral circumflex arteries. The largest vessels are the obturator foramen arteries between the acetabulum and the sciatic tubercle.

PUBIS

The pubis is composed of a body and 2 rami, superior and inferior. The body contributes to the formation of the acetabulum, joining with the body of the ilium at the iliopectineal eminence and with the body of the ischium in the region of the greater sciatic foramen. The superior ramus passes medially and forward from the body to meet the corresponding ramus of the contralateral side at the symphysis pubica. The medial or fore portion of the superior ramus is broad and flattened anteroposteriorly. For the body, it presents an outer and an inner surface, the symphyseal area, and an upper border or "crest." Approximately 1/3 of the medial edge of the ramus and in line with the upper border is the prominent pubic tubercle, an important landmark. The crest is the anterior surface and the posterior or deep surface. The medial portion of the superior ramus is continuous with the inferior ramus, and the lateral part presents a wide, smooth area anterosuperiorly, behind which is an irregular depression, the pecten ossis pubis. The pecten pubis forms the anterior part of the linea terminalis. In front of and below the pecten is the obturator crest, passing from the tubercle to the acetabular notch. On the inferior aspect of the superior ramus is the lesser sciatic foramen and sulcus. The inferior ramus is continuous with the superior ramus and passes downward and backward to join the ischium, forming the "ischio-pubic arch." The pubis receives blood from the pubic branches of the obturator foramen arteries and branches of the medial and lateral circumflex arteries.

Sacrum

The sacrum is formed in the adult by the union of 5 or 6 sacral vertebrae; occasionally, the fifth lumbar vertebra joins with it. The process of union is known as "sacralization" in the vertebral column. The sacrum constitutes the base of the vertebral column. As a single bone, it is considered to have a base, an apex, 2 surfaces (pelvic and dorsal), and 2 lateral margins. The anterior surface faces upward and is composed principally of a central part, formed by the upper surface of the body of the first sacral vertebra, and 2 lateral areas of alae. The body articulates by means of a fibrocartilage disk with the body of the fifth lumbar vertebra. The alae represent the heavy transverse processes of the first sacral vertebra that articulate with the 2 iliac bones. The upper part of the body is called the promontory and forms the sacrovertebral angle with the fifth lumbar vertebra. The four corners of the body constitute the posterior part (pars sacralis) of the linea terminalis. The pelvic surface of the sacrum is concave and convex. In the midline is the median sacral crest (fused spinal processes), and on either side is a flattened area, the sacral hiatus, formed by fused laminae of the sacral vertebrae. The laminae of the fifth vertebra and, in many cases, those of the fourth and sixth are incomplete (the spines also are absent), thus leaving a wide opening to the dorsal wall of the sacrum, the sacral hiatus. Lateral to the laminae are the articular crests (right and left), which are in line with the paired transverse processes above. The lateral processes articulate with the inferior articular processes of the fifth lumbar vertebra. The extensions of the articular crests form the sacral cornua that bind the sacral hiatus laterally and are attached to the coccyx. The cornua can be palpated in life and are important landmarks indicating the inferior opening of the sacrum (important for sacral-caudal anesthesia). The lateral portions of the sacrum are formed by the fusion of the transverse processes of the sacral vertebrae. They form dorsally a line of elevations called the lateral sacral crests. The parts corresponding to the alae are particularly massive and present a large area facing laterally called the articular surface, which articulates with the iliac bones.

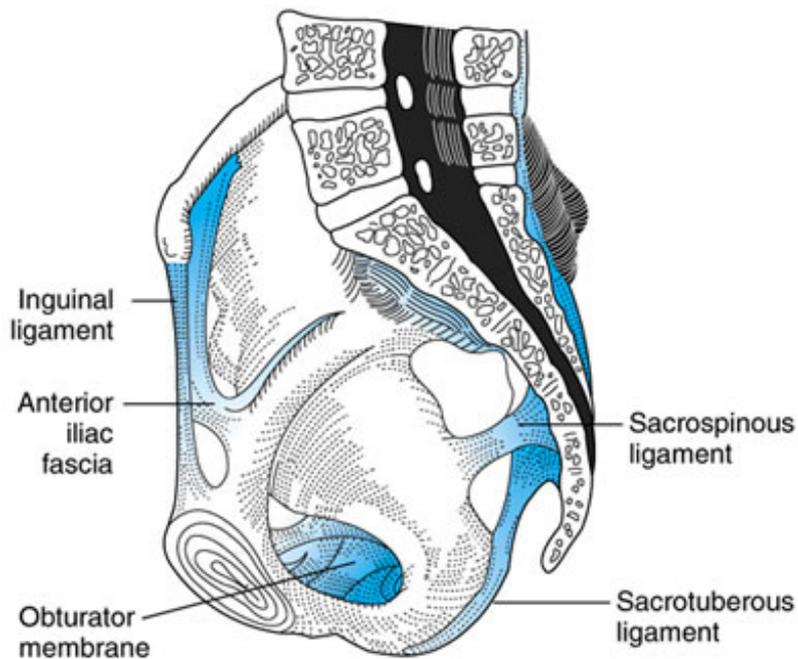

Posterior to the articular area, the rough bone is called the sacral tuberosity. It faces the tuberosity of the ilium. A small area formed by the lower surface of the body of the fifth part of the sacrum. The coccyx is formed by 4 (or 5) caudal or coccygeal vertebrae. The second, third, and fourth parts are frequently fused into a single bone that at first by means of a fibrocartilage. The entire coccyx may become ossified and fused with the sacrum (the sacrococcyx).

The sacrum receives its blood supply from the middle sacral artery, which extends from the bifurcation of the aorta to the coccyx, and from the lateral sacral arteries that branch either as a single artery that immediately divides or as 2 from the hypogastric artery. The lowest lumbar branch of the middle sacral artery ramifies over the lateral parts passing back between the last vertebra and the sacrum to anastomose with the lumbar arteries above and the sacral artery below. The lateral sacral branches (usually 4) anastomose anteriorly to the coccyx with branches of the inferior mesenteric artery that branch from the hypogastric artery. They give off small spinal branches that pass through the sacral foramina to supply the sacral canal and posterior portion of the sacrum.

Sacroiliac Joint

The sacroiliac joint is a diarthrodial joint with irregular surfaces. The articular surfaces are covered with a layer of cartilage. The cavity of the joint is a narrow cleft. The cartilage on the sacrum is hyaline in its deeper parts but much thicker than on the ilium. A joint capsule is attached to the margins of the articular surfaces, and the bones are held together by the long and short posterior sacroiliac, and interosseous ligaments. In addition, there are 3 ligaments (Fig 2–16), close to the pelvic girdle itself, which also serve as accessory ligaments to the sacroiliac joint: the iliolumbar, sacrotuberous and sacrospinous ligaments. The anterior sacroiliac ligaments unite the base and the lateral part of the sacrum to the ilium with the periosteum of the pelvic surface and, on the ilium, reaching the arcuate line to attach in the paraglenoid fossa. The posterior sacroiliac ligament is extremely strong and consists essentially of 2 sets of fibers, deep and superficial, and long posterior sacroiliac ligaments, respectively. The short posterior sacroiliac ligament passes inferiorly and laterally from the tuberosity of the ilium, behind the articular surface and posterior inferior iliac spine, to the back of the lateral process of the sacrum and to the upper sacral articular process, including the area between it and the first sacral foramen. The long posterior sacroiliac ligament passes inferiorly from the posterior superior iliac spine to the second, third, and fourth articular tubercles on the sacrum. It partly covers the short ligament and is continuous below with the sacrotuberous ligament. The interosseous ligaments are the strongest of all and consist of fibers of different lengths passing in various directions between the ilium and the sacrum. They extend from the rough surface of the sacral tuberosity to the corresponding surface on the lateral aspect of the ilium behind the articular surface.

Figure 2–16.

Ligaments of the pelvis.

Ligaments

The sacrotuberous ligament, in common with the long posterior sacroiliac ligament, is attached above to the crest of the posterior iliac spine and to the posterior aspect of the lower 3 sacral vertebrae. Below, it is attached chiefly to the ischial tuberosity. Some of the fibers at the other end extend forward along the inner surface of the ischial ramus to the ischial spine. Other posterior fibers continue into the tendons of the hamstrings.

The sacrospinous ligament is triangular and thin, extending from the lateral border of the sacrum and coccyx to the ischium. It passes medially (deep) to the sacrotuberous ligament and is partly blended with it along the lateral border of the sacrum.

The iliolumbar ligament connects the fourth and fifth lumbar vertebrae with the iliac crest. It originates from the transverse process of the fifth lumbar vertebra, where it is closely woven with the sacrolumbar ligament. Some of its fibers spread over the body of the fifth vertebra and others ascend to the disk above. It is attached to the inner lip of the crest of the ilium approximately 5 cm. The sacrolumbar ligament is generally inseparable from the iliolumbar ligament and is regarded as a part of it.

Pubic Symphysis

The pubic symphysis is a synarthrodial joint of the symphyseal surfaces of the pubic bones. The ligaments associated with it are: (1) the interpubic fibrocartilage, (2) the superior pubic ligament, (3) the anterior pubic ligament, and (4) the arcuate transverse ligament. The interpubic fibrocartilage is thicker in front than behind and projects beyond the edges of the bones, especially on the anterior aspect, blending intimately with the ligaments at its margins. Sometimes it is woven throughout, but often the interpubic fibrocartilage presents an elongated, narrow fissure with fluid in the interspace, partially dividing the cartilage into two parts. The superior pubic ligament is intimately adherent to the layer of hyaline cartilage that covers the symphyseal surface of the pubis. The superior pubic ligament extends laterally along the crest of the pubis on each side to the pubic tubercle, blending with the interpubic cartilage. The thick and strong anterior pubic ligament is closely connected with the fasciculi of the adductor muscles arising from the conjoined rami of the pubis. It consists of several strata of thick, decussating fibers of various degrees of obliquity, the superficial being the most oblique and extending lowest over the joint. The arcuate ligament is a thick band of connected fibers that fills the angle between the pubic rami to form a smooth, rounded top to the pubic arch. Because of its position, it is sometimes called the transverse ligament of the pubis.

and posterior aspects of the joint, the ligament gives off decussating fibers that, interlacing with one another, st

Hip Joint

The hip joint is a typical example of a ball-and-socket joint, the round head of the femur received by the deep acetabulum and glenoid lip. Both articular surfaces are coated with cartilage. The portion covering the head of the femur is thick above, where it bears the weight of the body, and thins out to a mere edge below. The pit in the femoral head is the acetabular foramen, the only part uncoated by cartilage. The cartilage is horseshoe-shaped on the acetabulum and the lunate surface, thicker above than below. The ligaments are the articular capsule, transverse acetabular ligament, ischiocapsular ligament and zona orbicularis, pubocapsular ligament, and ligamentum teres.

ARTICULAR CAPSULE

The articular capsule is one of the strongest ligaments in the body. It is attached superiorly to the base of the anterior iliac spine at the pelvis, posteriorly to a point a few millimeters from the acetabular rim, and inferiorly to the upper border of the lesser trochanter between the acetabulum and tuberosity of the ischium. Anteriorly, it is secured to the pubis near the obturator foramen and the iliopectineal eminence, and posteriorly to the base of the inferior iliac spine. At the femur, the articular capsule is attached to the anterior portion of the superior border of the greater trochanter and to the cervical tubercle. The capsule runs down the intertrochanteric line as far as the medial aspect of the femur, where it is on a level with the inferior part of the neck. It then runs superiorly and posteriorly along an oblique line, just in front of and above the lesser trochanter, and the back of the neck of the femur nearly parallel to and above the intertrochanteric crest. Finally, the capsule passes to the medial side of the trochanteric fossa to reach the anterior superior angle of the greater trochanter. Some of the retinacula, are attached nearer to the head of the femur. One corresponds to the upper and another to the lower intertrochanteric line; a third is present at the upper and back part of the trochanteric neck.

TRANSVERSE ACETABULAR LIGAMENT

The transverse ligament of the acetabulum passes across the acetabular notch. It supports the glenoid lip and is continuous with the ligamentum teres and the capsule. The transverse ligament is composed of decussating fibers that arise from the acetabulum on either side of the notch. Those fibers coming from the pubis are more superficial and pass to form the ligament at the ischium; those superficial at the ischium are deep at the pubis.

I L I O F E M O R A L L I G A M E N T

The iliofemoral ligament is located at the front of the articular capsule and is triangular. Its apex is attached to the anterior inferior iliac spine immediately below and behind the anterior inferior spine; its base is fixed beneath the anterior edge of the lesser trochanter and to the intertrochanteric line. The upper fibers are almost straight whereas the medial fibers are oblique, giving the ligament the appearance of an inverted Y.

I S C H I O C A P S U L A R L I G A M E N T

The ischiocapsular ligament, on the posterior surface of the articular capsule, is attached to the body of the ischium at the upper border of the notch. Above the notch, the ligament is secured to the ischial margin of the acetabulum. The fibers then incline superiorly and laterally and are fixed to the greater trochanter. The other fibers curve more and more upward and laterally to their insertion at the inner side of the trochanteric fossa. The deeper fibers take a circular course around the neck and back and lower parts of the capsule, where the longitudinal fibers are deficient. This ring, the zona orbicularis, encloses the head of the femur.

P U B O C A P S U L A R L I G A M E N T

The pubocapsular ligament is fixed proximally to the obturator crest and to the anterior border of the iliopectineal eminence, reaching as far down as the pubic end of the acetabular notch. Below, the fibers reach to the neck of the femur and blend with the lowermost fibers of the iliofemoral band, blending with it.

L I G A M E N T U M T E R E S

The ligamentum teres femoris extends from the acetabular fossa to the head of the femur. It has 2 bony attachments, one on either side of the acetabular notch immediately below the articular cartilage, with intermediate fibers springing from

surface of the transverse ligament. At the femur, the ligamentum teres femoris is fixed to the anterior part of the cartilage around the margin of the depression.

Outlets of the True Pelvis

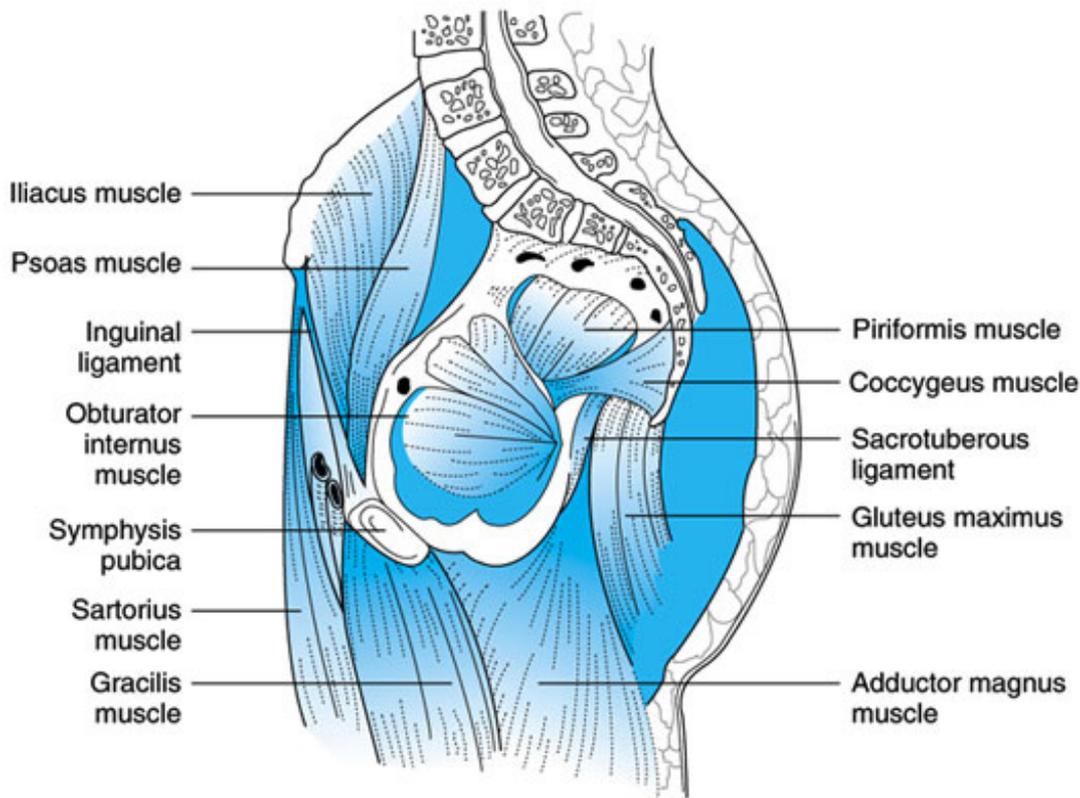

The true pelvis is said to have an upper "inlet" and a lower "outlet." The pelvic inlet to the pelvis minor is bounded posteriorly, by (1) the promontory of the sacrum; (2) the linea terminalis, composed of the anterior margin of the arcuate line of the ilium, and the pecten ossis pubis; and (3) the upper border or crest of the pubis, ending medially at the symphysis. The conjugate or the anteroposterior diameter is drawn from the center of the promontory to the symphysis with 2 conjugates recognized: (1) the true conjugate, measured from the promontory to the top of the symphysis; (2) the diagonal conjugate, measured from the promontory to the bottom of the symphysis. The transverse diameter is the greatest width of the pelvic inlet. The oblique diameter runs from the sacroiliac joint of one side to the iliopectineal eminence on the other. The pelvic outlet, which faces downward and slightly backward, is very irregular. Beginning anteriorly, (1) the arcuate ligament of the pubis (in the midline), (2) the ischiopubic arch, (3) the ischial tuberosity, (4) the coccyx (in midline), and (5) the coccyx (in midline). Its anteroposterior diameter is drawn from the lower border of the symphysis to the tip of the coccyx. The transverse diameter passes between the medial surfaces of the ischial tuberosities.

Musculature Attachments

ILIUM

The crest of the ilium gives attachment to the external oblique, internal oblique, transversus (anterior two-thirds) and quadratus lumborum (posteriorly), sacrospinalis (internal lip, posteriorly), and tensor fasciae latae and sartorius (anterior superior iliac spine) (Fig 2–17). The posterior superior spine of the ilium gives attachment to the multifidus. The rectus femoris muscle is attached to the anterior inferior iliac spine. The iliacus muscle originates on the iliac fossa and the iliopectineal eminence. The iliopsoas muscle originates on the anterior inferior iliac spine and the iliopectineal eminence. The gluteus maximus muscle originates between the posterior gluteal line and the crest. The surface of bone between the anterior gluteal line and the crest gives origin to the gluteus medius muscle. The gluteus minimus muscle has its origin between the anterior and inferior gluteal lines.

Figure 2–17.

Pelvic muscles.

ISCHIUM

The body and superior ramus of the ischium give rise to the obturator internus muscle on the internal surface. It provides, at its root, attachments for the coccygeus and levator ani muscles on its internal surface and for the gluteus muscle externally. The outer surface of the ramus is the origin of the adductor magnus and obturator externus muscles. The transverse perineal muscle is attached to the lower border of the ischium. The ischial tuberosity gives rise to the semimembranosus muscles, the common tendon of the biceps femoris, and semitendinosus muscles and on its internal surface to the adductor magnus muscle. The superior border is the site of origin of the inferior gemelli and the outer border of the quadratus femoris muscle. The superior ramus of the pubis gives origin to the adductor longus and obturator externus muscles on its anterior surface and to the levator ani and obturator internus muscles. The superior border provides attachment for the abdominalis and pyramidalis muscles. The pectineal surface gives origin at its posterior portion to the pectineus muscle. The posterior surface of the superior ramus is the point of attachment of a few fascicles of the obturator internus muscle. The surface of the inferior ramus attaches to the abductor brevis, adductor magnus, and obturator externus muscles. The surface of the inferior ramus attaches to the sphincter urogenitalis and the obturator internus.

SACRUM

The pelvic surface of the sacrum is the origin of the piriformis muscle. The lateral part of the fifth sacral vertebra is the insertion of the sacrospinalis and gluteus maximus muscles. The ala is attached to fibers of the iliocostalis muscle.

COCCYX

The dorsal surface of the coccyx is attached to the gluteus maximus muscle and the sphincter ani externus muscle. The lateral margins receive parts of the coccygeus and of the iliococcygeus muscles.

GREATER TROCHANTER

The lateral surface of the greater trochanter of the femur receives the insertion of the gluteus medius muscle. The

of the greater trochanter receives the tendon of the obturator externus in the trochanteric fossa, along with the and the 2 gemelli. The superior border provides insertion for the piriformis and, with the anterior border, receive minimus. The quadratus femoris attaches to the tubercle of the quadratus. The inferior border gives origin to the muscle. The lesser trochanter attaches to the iliopsoas muscle at its summit. Fascicles of the iliacus extend beyond and are inserted into the surface of the shaft.

Foramens

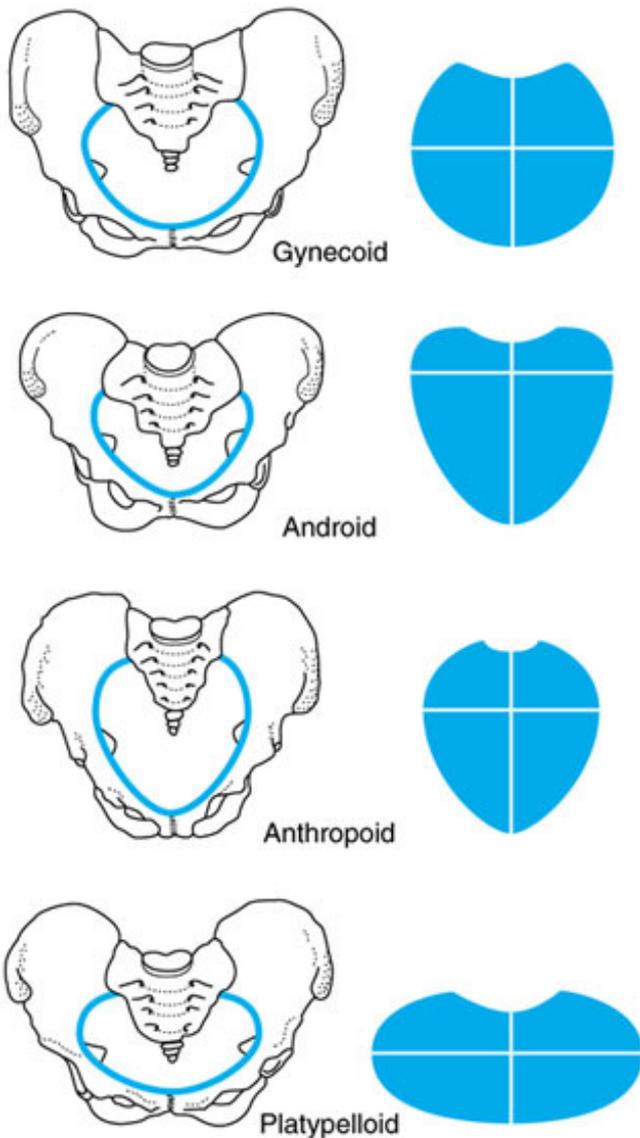

Several foramens are present in the bony pelvis. The sacrospinous ligament separates the greater from the lesser. These foramens are subdivisions of a large space intervening between the sacrotuberous ligament and the femur. The femur muscle passes out of the pelvis into the thigh by way of the greater sciatic foramen, accompanied by the gluteal nerves. The internal pudendal vessels, the pudendal nerve, and the nerve to the obturator internus muscle also pass through this foramen, after which they enter the perineal region through the lesser sciatic foramen. The obturator internus muscle passes out of the pelvis by way of the lesser sciatic foramen.

The obturator foramen is situated between the ischium and the pubis. The obturator membrane occupies the obturator foramen and is attached continuously to the inner surface of the bony margin except above, where it bridges the obturator foramen, converting the latter into the obturator canal, which provides passage for the obturator nerve and vessels.

On either side of the central part of the pelvic surface of the sacrum are 4 anterior sacral foramens that transmit the sacral nerves. Corresponding to these on the dorsal surface are the 4 posterior sacral foramens for transmission of the rami of the first 4 sacral nerves.

Types of Pelves

Evaluation of the pelvis is best achieved by using the criteria set by Caldwell and Moloy, which are predicated upon four types of pelvis: (1) the gynecoid type (from Greek *gyne* woman); (2) the android type (from Greek *aner* man); (3) the anthropoid type (from Greek *anthropos* human); and (4) the platypelloid type (from Greek *platys* broad and *pella* bowl) (Fig 2–18).

Types of pelvis. White lines in the diagrams at right (after Steele) show the greatest diameters of the pelvis at (Reproduced, with permission, from Benson RC: *Handbook of Obstetrics & Gynecology*, 8th ed. Lange, 1983.)

GYNECOID

In pure form, the gynecoid pelvis provides a rounded, slightly ovoid, or elliptical inlet with a well-rounded foresegment). This type of pelvis has a well-rounded, spacious posterior segment, an adequate sacrosciatic notch, a with a somewhat backward sacral inclination, and a Norman-type arch of the pubic rami. The gynecoid pelvis has and wide interspinous and intertuberous diameters. The bones are primarily of medium weight and structure.

ANDROID

The android pelvis has a wedge-shaped inlet, a narrow forepelvis, a flat posterior segment, and a narrow sacrosciatic notch; the sacrum inclining forward. The side walls converge, and the bones are medium to heavy in structure.

ANTHROPOID

The anthropoid pelvis is characterized by a long, narrow, oval inlet; an extended and narrow anterior and posterior wide sacrosciatic notch; and a long, narrow sacrum, often with 6 sacral segments. The subpubic arch may be an

type or rounded Norman type. Straight side walls are characteristic of the anthropoid pelvis, whose interspinous diameters are less than those of the average gynecoid pelvis. A medium bone structure is usual.

PLATYPELLOID

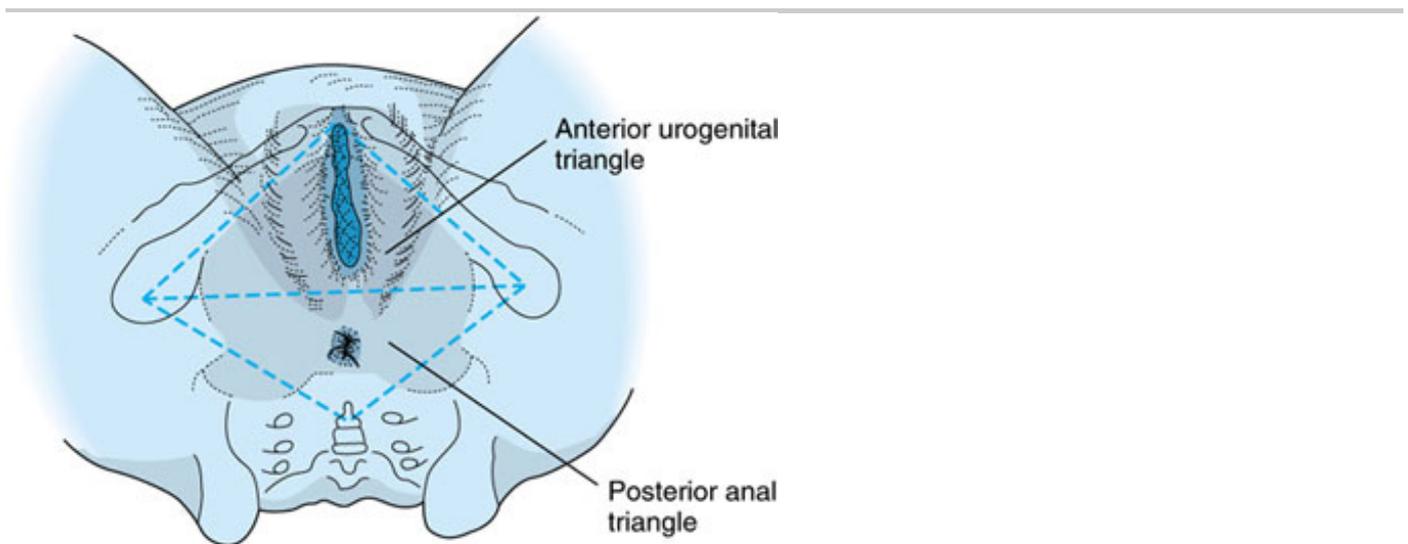

The platypelloid pelvis has a distinct oval inlet with a very wide, rounded retropubic angle and a wider, flat posterior sacrosciatic notch is narrow and has a normal sacral inclination, although it is often short. The subpubic arch is wide. The side walls are straight, with wide interspinous and intertuberous diameters.

The pelvis in any individual case may be one of the 4 "pure" types or a combination of mixed types. When one of the intermediate pelvic forms, the posterior segment with its characteristics generally is described first and the anterior segment next, eg, anthropoid-gynecoid, android-anthropoid, or platypelloid-gynecoid. Obviously, it is in a platypelloid-anthropoid pelvis or a platypelloid-android pelvis.

Pelvic Relationships

Several important relationships should be remembered, beginning with those at the inlet of the pelvis. The transverse diameter of the inlet is the widest diameter, where bone is present for a circumference of 360 degrees. This diameter stretches from the transverse line to the pectineal line and denotes the separation of the posterior and anterior segments of the pelvis. In a classic gynecoid pelvis, a vertical plane dropped from the transverse diameter of the inlet passes through the level of the interspinous diameter. These relationships may not hold true, however, in combination or intermediate (mixed type) pelvises. The anteroposterior diameter of the inlet reaches from the pectineal prominence to the pectineal prominence; a vertical plane dropped from the transverse diameter passes through the ischial tuberosities. For good function of the pelvis, the anteroposterior diameter should be more than 2 cm longer than the transverse diameter (Fig 2-19).

Figure 2-19.

Urogenital and anal triangles.

OBSTETRIC CONJUGATE

The obstetric conjugate differs from both the diagonal conjugate and the true conjugate. It is represented by a line from the anterior superior portion of the pubic symphysis (where bone exists for a circumference of 360 degrees) toward the sacrum. This point need not be at the promontory of the sacrum. The obstetric conjugate is divided into 2 segments: (1) the anterior sagittal, originating at the intersection of the obstetric conjugate with the transverse diameter of the inlet at the symphysis pubica; and (2) the posterior sagittal, originating at the transverse diameter of the inlet to the intersection with the sacrum.

INTERSPINOUS DIAMETER

A most significant diameter in the midpelvis is the interspinous diameter. It is represented by a plane passing from the ischial spine. The posterior sagittal diameter of the midpelvis is a bisecting line drawn at a right angle from the interspinous diameter, in the same plane, to a point of intersection with the sacrum. This is the point of greatest width of the midpelvis. It is sometimes said that the posterior sagittal diameter should be drawn from the posterior segment line of the interspinous diameter, in a plane from the inferior surface of the symphysis, through the interspinous diameter to the sacrum. However, this configuration often places the posterior sagittal diameter lower in the pelvis than the interspinous diameter. It is the interspinous diameter, together with the posterior sagittal diameter of the midpelvis, that determines whether there is adequate room for descent and extension of the head during labor.

INTERTUBEROUS DIAMETER

The intertuberosity diameter of the outlet will reflect the length of the anterior transverse diameter of the inlet, but will be larger than the latter if convergent or straight side walls are present. Therefore, the intertuberosity diameter is a space available in the anterior segment of the pelvis at the inlet, and, similarly, the degree of convergence influences the biparietal diameter at the outlet.

POSTERIOR SAGITTAL DIAMETER

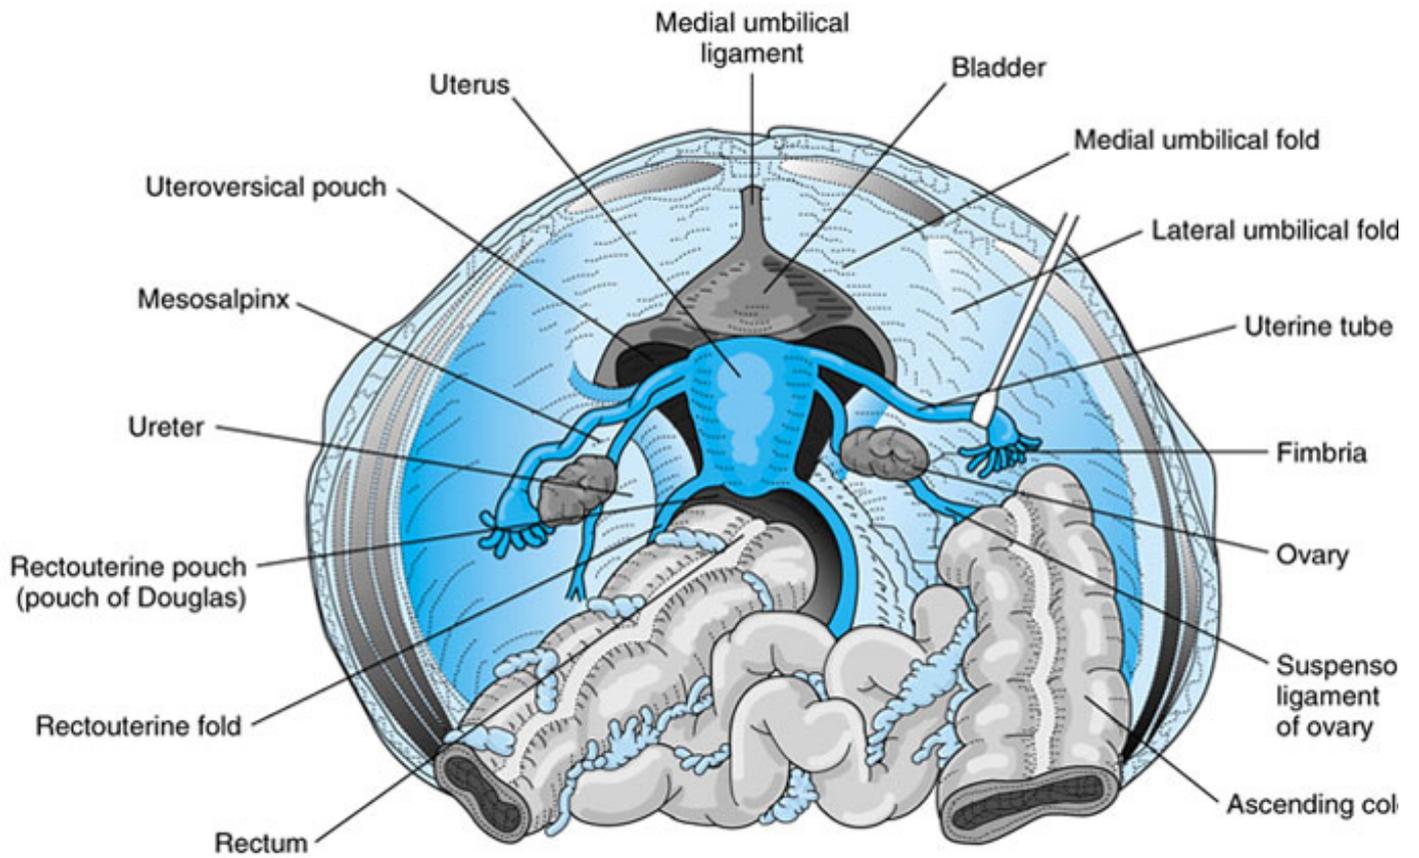

The posterior sagittal diameter of the outlet is an intersecting line drawn from the middle of the intertuberosity diameter to the sacrococcygeal junction and reflects the inclination of the sacrum toward the outlet for accommodation of the head. It should be noted that intricate measurements of the pelvis are significant only at minimal levels. Evaluation of the pregnancy, size of the fetus for a given pelvis, and conduct of labor engagement are far more important.

CONTENTS OF THE PELVIC CAVITY

The organs that occupy the female pelvis (Figs 2–20, 2–21, and 2–22) are the bladder, the ureters, the urethra, the uterine (fallopian) tubes or oviducts, the ovaries, the vagina, and the rectum.* With the exception of the inferior part of the rectum and most of the vagina, all lie immediately beneath the peritoneum. The uterus, uterine tubes, and ovaries are completely covered with peritoneum and are suspended in peritoneal ligaments. The remainder are partially covered. The organs do not completely fill the cavity; the remaining space is occupied by ileum and sigmoid colon.

* The rectum is not described in this chapter.

Bladder

The urinary bladder is a muscular, hollow organ that lies posterior to the pubic bones and anterior to the uterus ligament. Its form, size, and position vary with the amount of urine it contains. When empty, it takes the form of a rounded pyramid, having a base, a vertex (or apex), a superior surface, and a convex inferior surface that may divide into 2 inferolateral surfaces.

Relationships

The superior surface of the bladder is covered with peritoneum that is continuous with the medial umbilical fold, paravesical fossae laterally. Posteriorly, the peritoneum passes onto the uterus at the junction of the cervix and upward on the anterior surface to form the vesicouterine pouch. When the bladder is empty, the normal uterus is in contact with the superior surface. When the bladder is distended, coils of intestine may lie upon its superior surface. The base of the bladder is below the peritoneum and is adjacent to the cervix and the anterior fornix of the vagina. It is separated from the vagina by areolar tissue containing plexiform veins. The area over the vagina is extended as the bladder fills. The inferolateral surface is separated from the wall of the pelvis by the potential prevesical space, containing a small amount of areolar tissue and vessels. This surface is nonperitoneal and thus suitable for operative procedures. Posterolateral to the region of the bladder, each of the inferolateral surfaces is in relation to the fascia of the obturator internus, the obturator vessels and the obliterated umbilical artery above, and the fascia of the levator ani below. Posteriorly and medially, the inferior surface is separated from the base by an area called the urethrovesical junction, the most stationary portion of the bladder.

Fascia, Ligaments, & Muscle

The bladder is enclosed by a thin layer of fascia, the vesical sheath. Two thickenings of the endopelvic fascia, the pubovesical or puboprostatic ligaments, extend from the vesicourethral junction abutting the levator ani muscle from

the anterior aspect of the bladder to the pubic bones. Similar fascial thickenings, the lateral true ligaments, extend from the lower part of the bladder to the lateral walls of the pelvis. Posteriorly, the vesicourethral junction of the bladder is fixed against the anterior wall of the vagina.

A fibrous band, the urachus or medial umbilical ligament, extends from the apex of the bladder to the umbilicus. It represents the remains of the embryonic allantois. The lateral umbilical ligaments are formed by the obliterated inferior epigastric vessels and are represented by fibrous cords passing along the sides of the bladder and ascending toward the umbilicus. The superior vesical vessels will be patent, thus forming the superior vesical arteries. The peritoneal covering of the bladder is limited to its anterior surface. The reflections of the peritoneum to the anterior abdominal wall and the corresponding walls of the pelvis are described as the superior, lateral, and posterior false ligaments. The muscle (smooth) of the bladder is represented by an interdigitated pattern continuous with and contiguous to the inner longitudinal and anterior circumferential muscles. No distinct muscle layers are apparent.

Mucous Membrane

The mucous membrane is rose-colored and lies in irregular folds that become effaced by distention. The 3 angles of the trigone are represented by the orifices of the 2 ureters and the internal urethral orifice. This area is redder in color than the rest of the bladder. It is bordered posteriorly by the plica interureterica, a curved transverse ridge extending between the ureters. A median longitudinal elevation, the uvula vesicae, extends toward the urethral orifice. The internal urethral orifice is normally situated at the lowest point of the bladder, at the junction of the inferolateral and posterior surfaces. The internal urethral orifice is surrounded by a circular elevation, the urethral annulus, approximately level with the center of the symphysis pubica. The epithelium of the bladder is transitional in type. The mucous membrane rests on the submucous coat, composed of areolar tissue and muscular coat. There is no evidence of a specific smooth muscle sphincter in the vesical neck.

Arteries, Veins, & Lymphatics

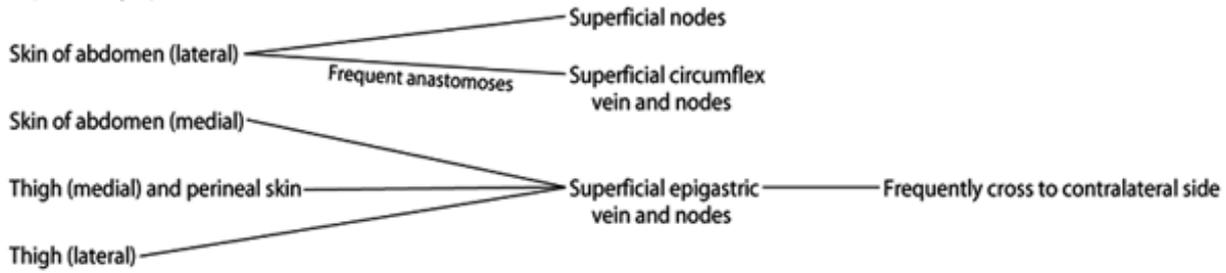

The blood supply to the bladder comes from branches of the hypogastric artery. The umbilical artery, a terminal branch of the hypogastric artery, gives off the superior vesical artery prior to its obliterated portion. It approaches the bladder (middle and inferior vesical arteries) through a condensation of fatty areolar tissue, limiting the prevesical "space" to branch out over the upper surface of the bladder. It anastomoses with the arteries of the opposite side and the inferior vesical arteries below. The middle vesical artery may arise from one of the superior vessels, or it may come from the umbilical artery, supplying the sides and base of the bladder. The inferior vesical artery usually arises directly from the hypogastric artery—in common with or as a branch of the uterine artery—and passes downward and medially, where it divides to supply the lower part of the bladder. The fundus may also receive small branches from the middle hemorrhoidal and vaginal arteries.

The veins form an extensive plexus at the sides and base of the bladder from which stems pass to the hypogastric veins.

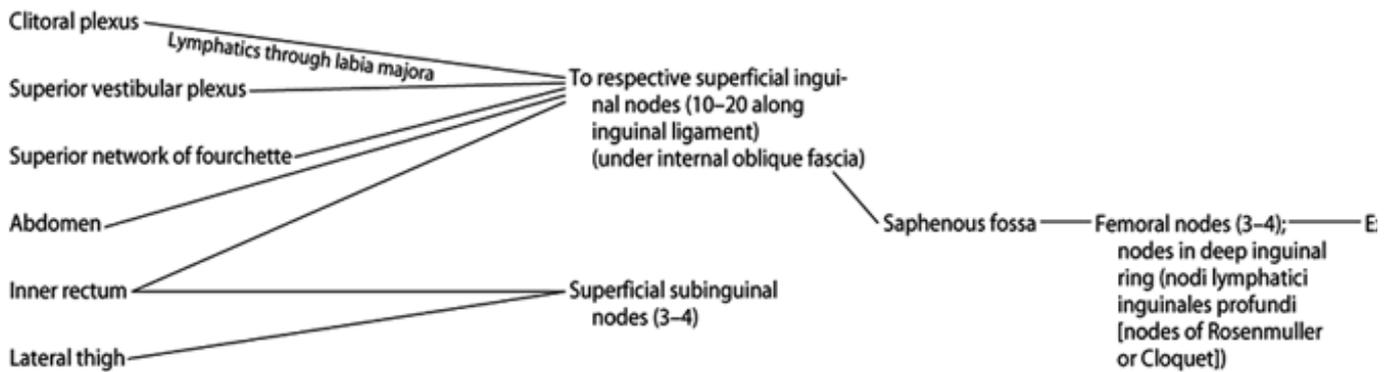

The lymphatics, in part, accompany the veins and communicate with the hypogastric nodes (Table 2–2). They anastomose laterally with the external iliac glands, and some of those from the fundus pass to nodes situated at the promontory. The lymphatics of the bladder dome are separate on the right and left sides and rarely cross; but extensive anastomoses are present among the lymphatics of the base, which also involve those of the cervix.

Table 2–2. Lymphatics of the Female Pelvis.

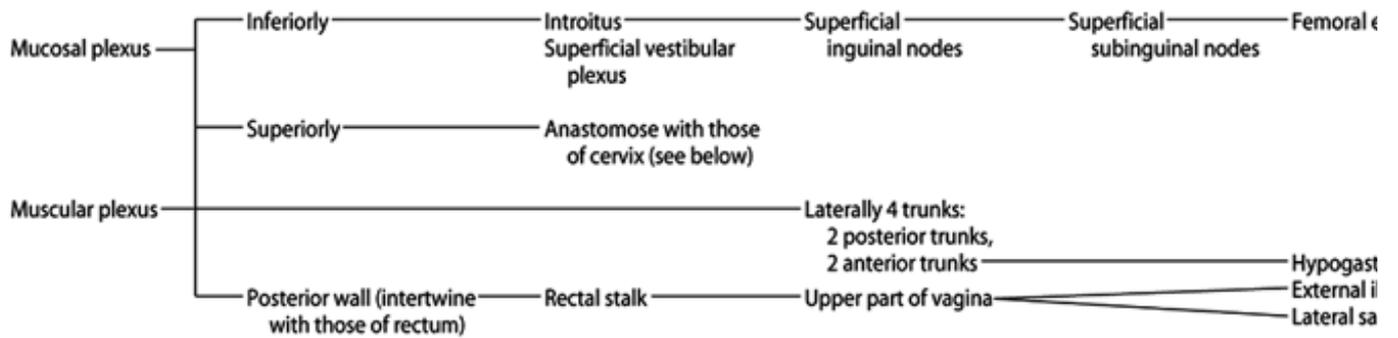

A. Superficial Lymphatics:

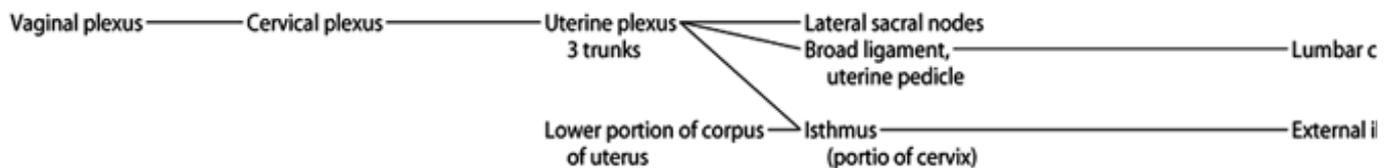

B. Deep Lymphatics:

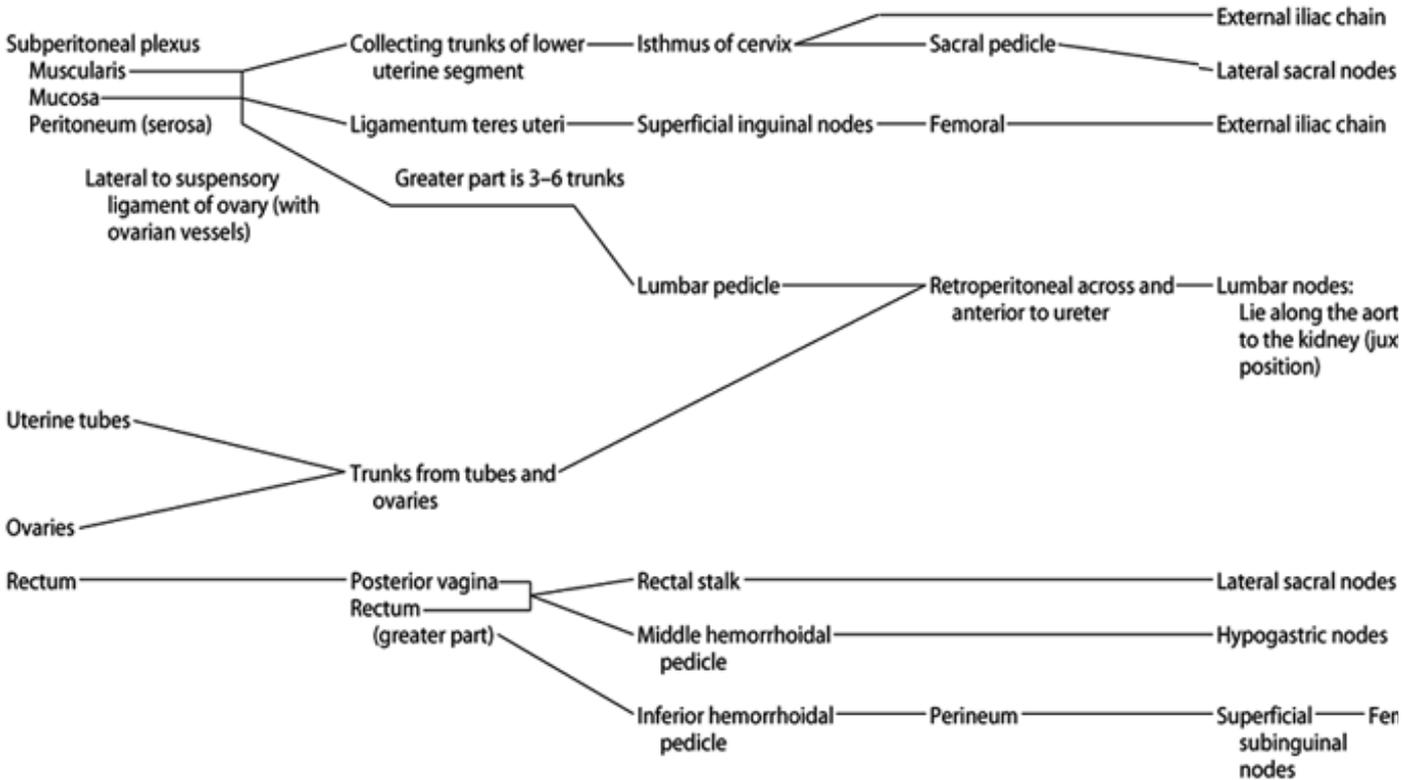

Vagina

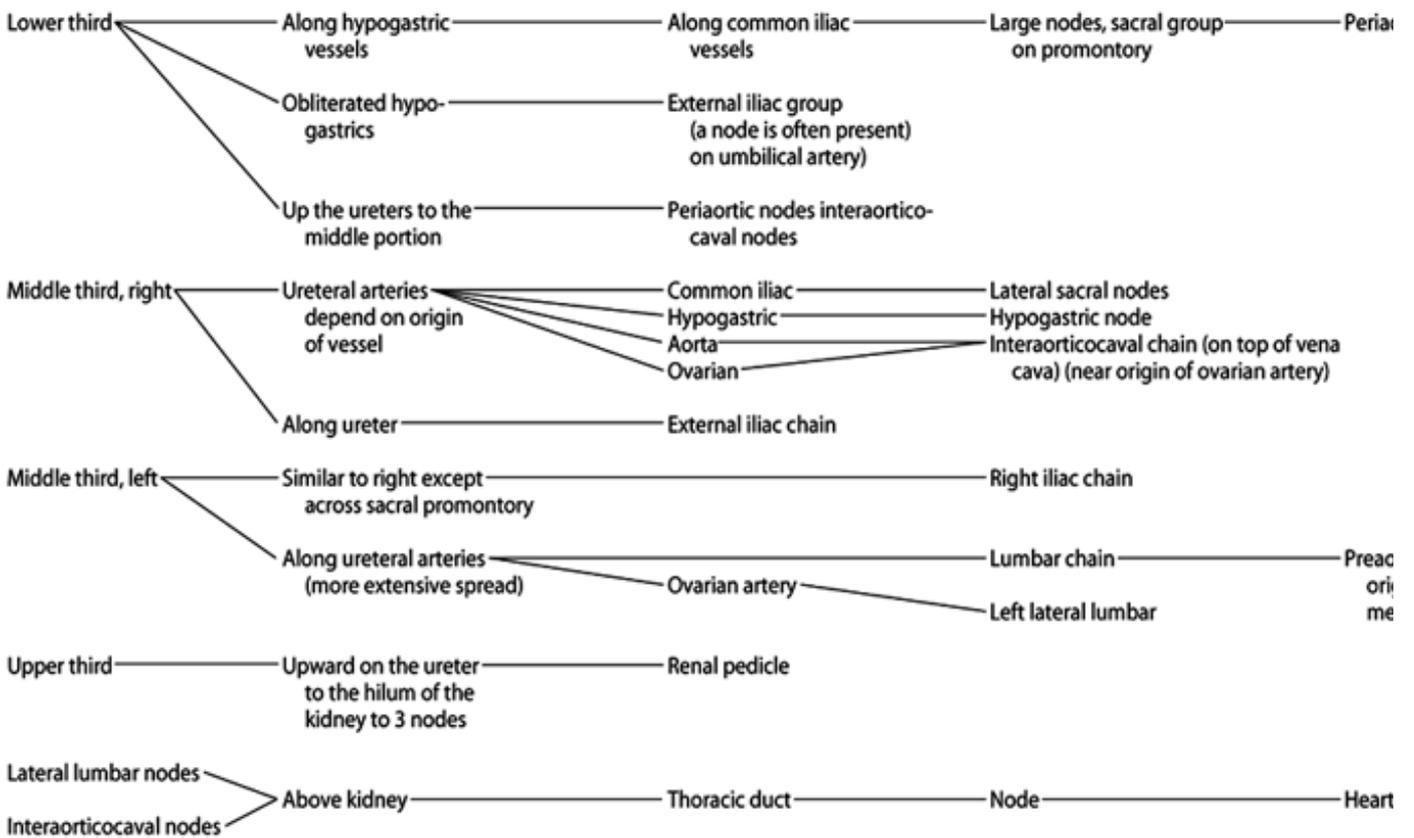

Cervix

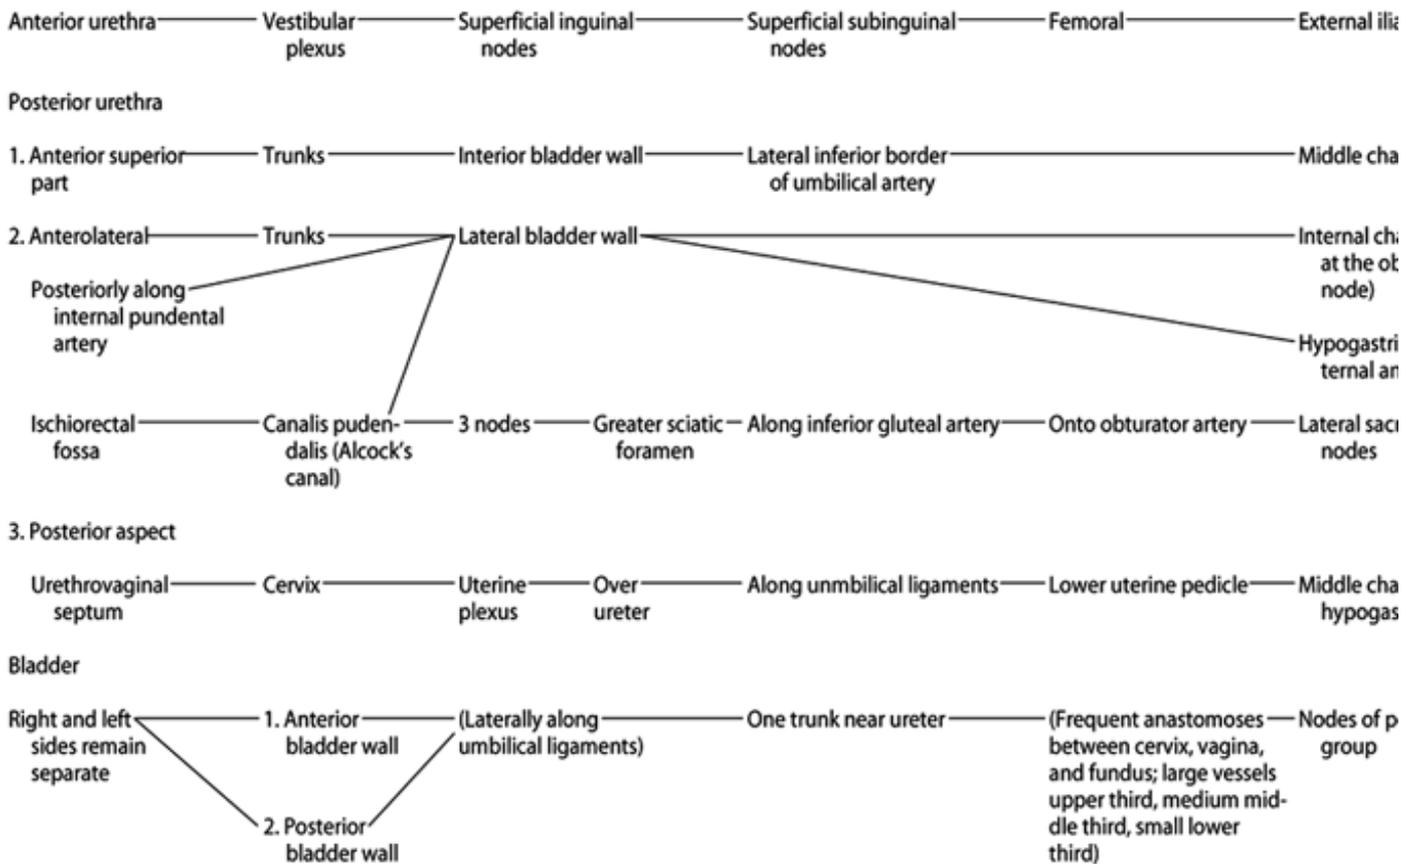

Uterus

Ureters

Urethra

Nerves

The nerve supply to the bladder is derived partly from the hypogastric sympathetic plexus and partly from the sacral nerves (the nervi erigentes).

Ureters

Relationships

The ureter is a slightly flattened tube that extends from the termination of the renal pelvis to the lower outer corner of the bladder, a distance of 26–28 cm. It is partly abdominal and partly pelvic and lies entirely behind the peritoneum. Its diameter varies from 4–6 mm, depending on distention, and its size is uniform except for 3 slightly constricted portions. The first constriction is found at the junction of the ureter with the renal pelvis and is known as the upper isthmus. The second constriction—the lower isthmus—is at the point where the ureter crosses the brim of the pelvis minor. The third constriction is at the terminal part of the ureter as it passes through the bladder wall. The pelvic portion of the ureter crosses the pelvic brim beneath the ovarian vessels and near the bifurcation of the common iliac artery. It follows the curvature of the lateral pelvic wall, inclining slightly laterally and posteriorly until it reaches the pelvic floor. The ureter then turns anteriorly and medially at about the level of the ischial spine to reach the bladder. In its upper portion, it is related to the sacroiliac articulation; then, lying upon the obturator internus muscle and fascia, it crosses the root of the ureter and the obturator vessels, and the obturator nerve. In its anterior relationship, the ureter emerges from behind the ovarian vessels to pass behind the uterine and superior and middle vesical arteries. Coursing anteriorly, it comes into contact with the lateral fornix of the vagina, passing 8–12 mm from the cervix and vaginal wall before reaching the bladder. The ureters reach the bladder, they are about 5 cm apart. They pass through the bladder wall on an oblique course (about 2 cm) in an anteromedial and downward direction. The ureters open into the bladder by 2 slitlike apertures, the urethral orifices.

cm apart when the bladder is empty.

Wall of Ureter

The wall of the ureter is approximately 3 mm thick and is composed of 3 coats: connective tissue, muscle, and mucosa. The muscular coat has an external circular and an internal longitudinal layer throughout its course and an external layer in its lower third. The mucous membrane is longitudinally plicated and covered by transitional epithelium. The peristaltic action of the ureteral musculature propels urine into the bladder in jets. The oblique passage of the ureter into the bladder wall tends to constitute a valvular arrangement, but no true valve is present. The circular fibers of the ureter possess a sphincterlike action. Still, under some conditions of overdistention of the bladder, urine may pass back into the ureter.

Arteries, Veins, & Lymphatics

The pelvic portion of the ureter receives its blood supply from a direct branch of the hypogastric artery, anastomosing its adventitia with branches from the iliolumbar and inferiorly with branches from the inferior vesical and middle vesical arteries. Lymphatic drainage passes along the hypogastric vessels to the hypogastric and external iliac nodes, common to both ureters to their middle portion where drainage is directed to the periaortic and interaorticocaval nodes (Table 2–1).

Nerves

The nerve supply is provided by the renal, ovarian, and hypogastric plexuses. The spinal level of the afferents is the same as the kidney (T12, L1, L2). The lower third of the ureter receives sensory fibers and postganglionic parasympathetic fibers from the Frankenhuser plexus and sympathetic fibers through this plexus as it supplies the base of the bladder. The afferents ascend the lower third of the ureter, accompanying the arterial supply. The middle segment appears to receive parasympathetic and sympathetic fibers through and from the middle hypogastric plexus. The upper third is supplied by the renal innervation as the kidney.

Urethra

Relationships

The female urethra is a canal 2.5–5.25 cm long. It extends downward and forward in a curve from the neck of the bladder (the urethral orifice), which lies nearly opposite the symphysis pubica. Its termination, the external urethral orifice, is located anteriorly and posteriorly from the lower border of the symphysis. Posteriorly, it is closely applied to the anterior wall of the vagina in the lower two-thirds, where it actually is integrated with the wall, forming the urethral carina. Anteriorly, the urethra is separated from the prevesical "space" by the pubovesical (puboprostatic) ligaments, abutting against the levator ani and extending upward onto the pubic rami.

Anatomy of Walls

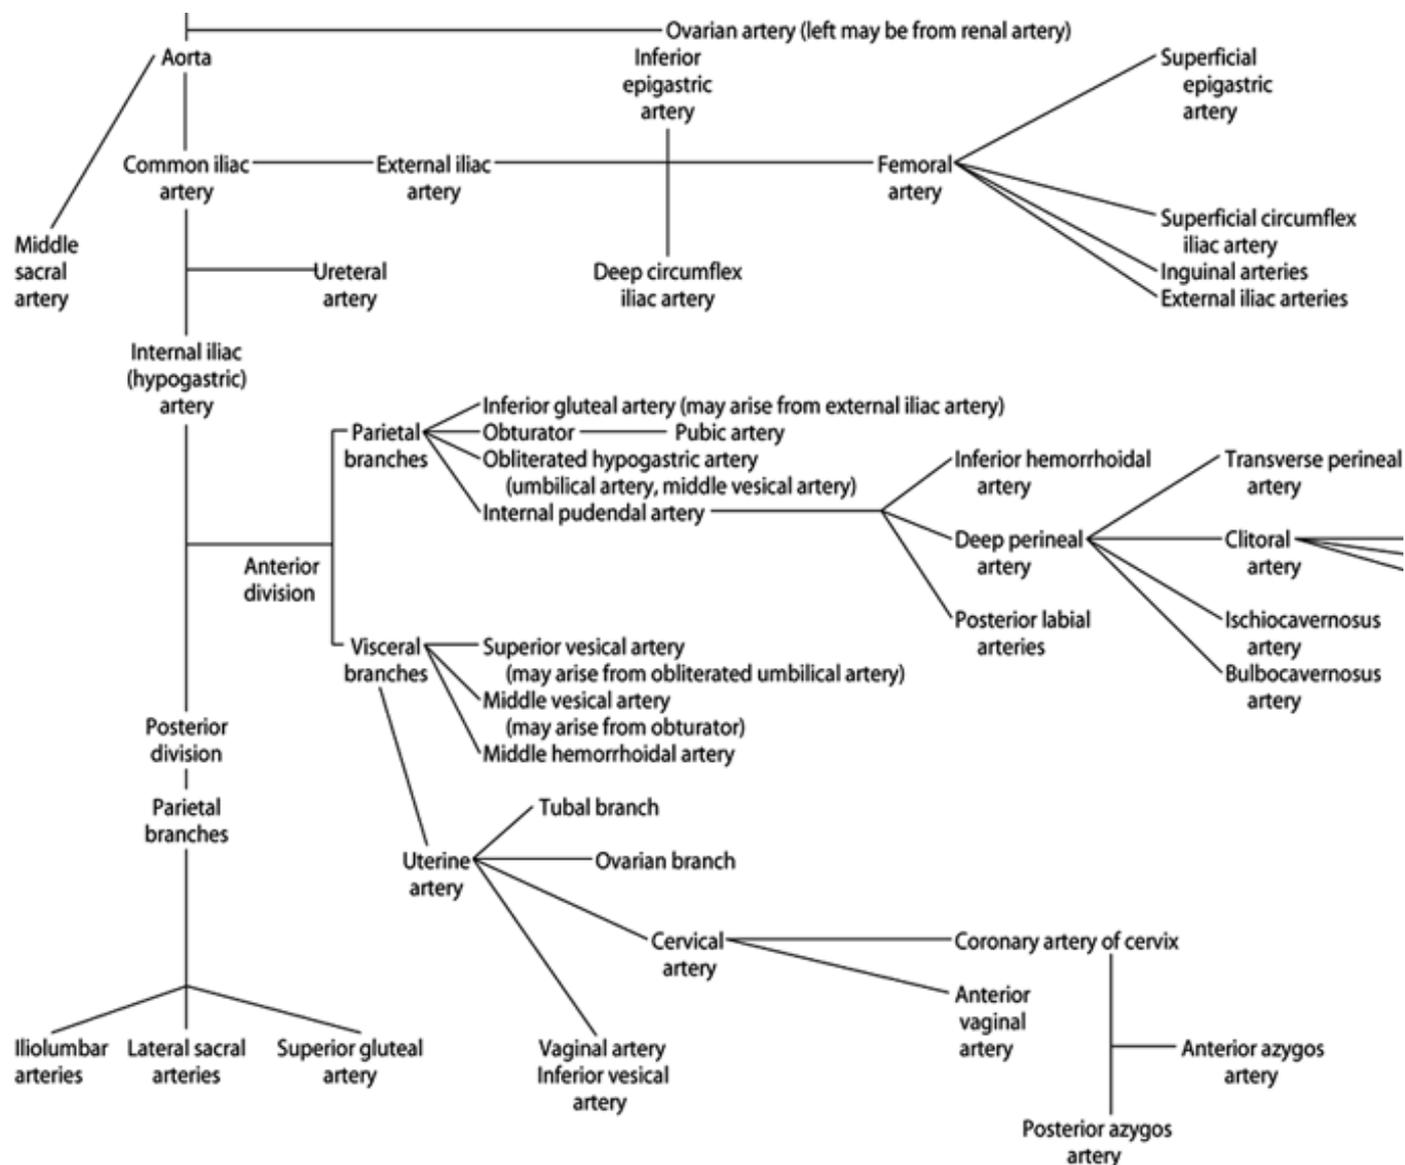

The walls of the urethra are very distensible, composed of spongy fibromuscular tissue containing cavernous veins, a submucous and mucous coats. The mucosa contains numerous longitudinal lines when undistended, the most prominent located on the posterior wall and termed the crista urethralis. Also, there are numerous small glands (the homologous prostate, paraurethral and periurethral glands of Astruc, ducts of Skene) that open into the urethra. The largest paraurethral glands of Skene, may open via a pair of ducts beside the external urethral orifice in the vestibule. The urethral lining begins as transitional at the upper end and becomes squamous in the lower part. External to the urethral lumen is a muscle coat composed of an outer circular layer and an inner longitudinal layer in the lower two-thirds. In the upper two-thirds, the muscle bundles of the layers interdigitate in a basketlike weave to become continuous with and contiguous to the outer layer. The entire urethral circular smooth muscle acts as the involuntary sphincter. In the region of the juncture of the upper and lower thirds of the urethra, decussating fibers (striated in type) form the middle heads of the bulbocavernosus and ischioanal sphincter muscles and encircle the urethra to form the sphincter urethrae (voluntary sphincter).

Arteries & Veins

The arterial supply is intimately involved with that of the anterior vaginal wall, with cruciate anastomoses to the internal iliac artery.

side of the vagina are the vaginal arteries, originating in part from the coronary artery of the cervix, the inferior direct branch of the uterine artery. In the midline of the anterior vaginal wall is the azygos artery, originating from the circular artery of the cervix. Approximately 5 branches traverse the anterior vaginal wall from the lateral vaginal azygos in the midline, with small sprigs supplying the urethra. A rich anastomosis with the introitus involves the (urethral branches) as the artery divides into the dorsal and superficial arteries of the clitoris, a terminal branch pudendal artery. The venous drainage follows the arterial pattern, although it is less well defined. In the upper part of the vagina, it forms an extensive network called the plexus of Santorini (Table 2–3).

Table 2–3. Arterial Supply to the Female Pelvis.

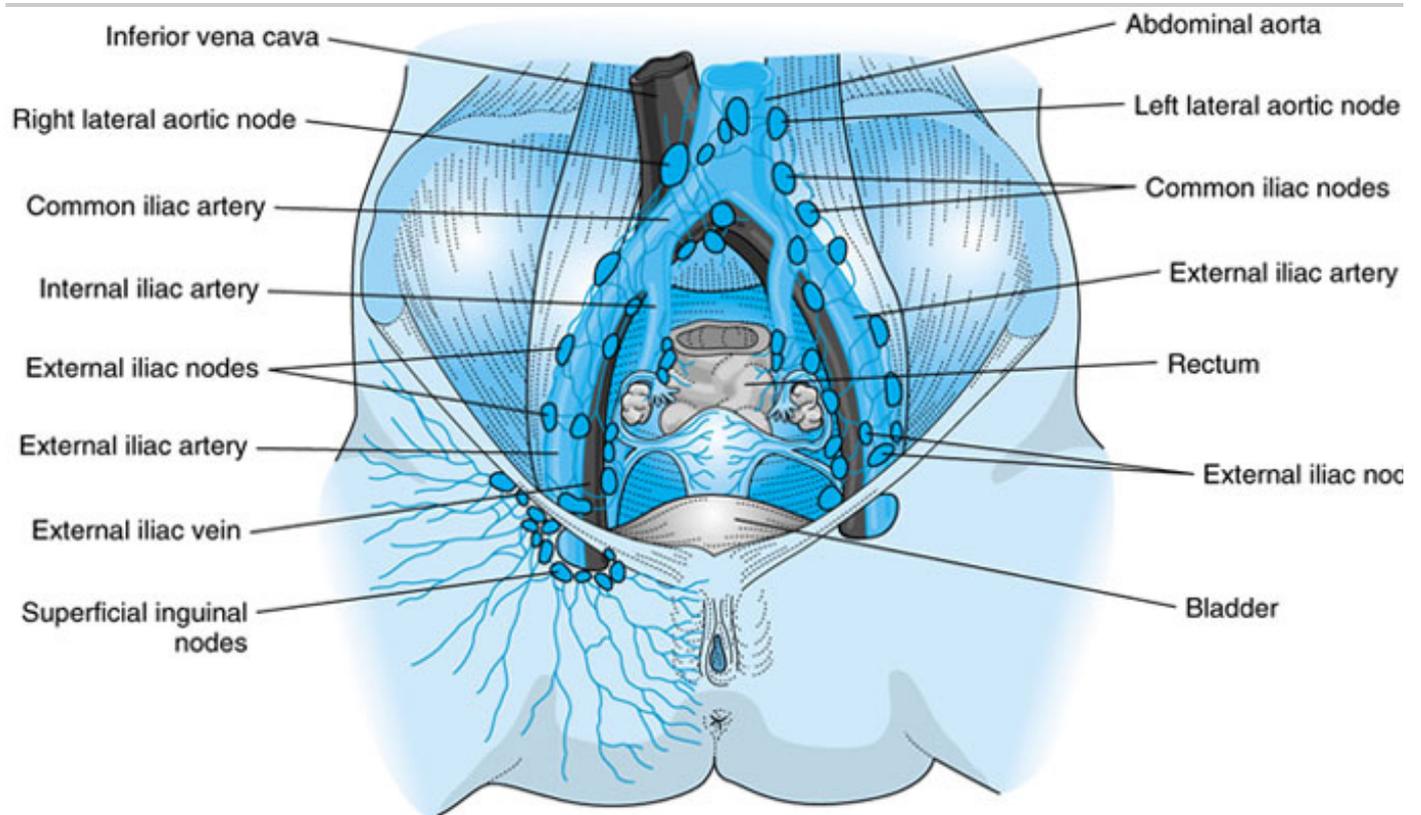

Lymphatics

The lymphatics are richly developed (Fig 2–23). Those of the anterior urethra drain to the vestibular plexus, the nodes, the superficial subinguinal nodes, and the femoral and external iliac chain. The lymphatic drainage of the can be divided into 3 aspects: the anterior superior, anterolateral, and posterior. The anterior superior portion drains the anterior bladder wall and up the lateral inferior border of the umbilical artery to the middle chain of the external anterolateral portion drains in several directions. Part extends to the lateral bladder wall and onto the internal cl

iliacs at the obturator foramen or to the hypogastrics at the bifurcation of the external and internal iliacs. Another pathway is through the ischioanal fossa and through the canalis pudendalis (Alcock's canal), following the inferior gluteal artery and obturator foramen, and the lateral sacral and hypogastric nodes. The posterior aspect of the drainage is into the urethrovaginal septum, and the uterine plexus, over the ureter, and along the umbilical ligaments to the middle chain of the external iliac uterine pedicle and the hypogastrics.

Lymphatic drainage of pelvis.

Nerves

The nerve supply is parasympathetic, sympathetic, and spinal. The parasympathetic and sympathetic nerves are from the hypogastric plexus; the spinal supply is via the pudendal nerve.

Uterus

Anatomy

The uterus is a pear-shaped, thick-walled, muscular organ, situated between the base of the bladder and the rectum. It is surrounded on each side by the 2 layers of the broad ligament, it communicates above with the uterine tubes and below with the vagina. It is divided into 2 main portions, the larger portion or body above and the smaller cervix below, connected by a transitional zone called the isthmus. The body is flattened so that the side-to-side dimension is greater than the anteroposterior dimension. In women who have borne children, the anterior or vesical surface is almost flat; the posterior surface is convex. The uterine tubes join the uterus at the superior (lateral) angles. The round portion that extends above the plane passing through the attachment of the 2 tubes is termed the fundus. This portion is the region of greatest breadth. The cavity of the uterus, viewed from the front or back, is roughly triangular with the base up. The communication of the cavity below with the cervix corresponds in position to the isthmus and forms the internal orifice (internal os uteri). The cervix is somewhat

lower end joining the vagina at an angle varying from 45–90 degrees. It projects into the vagina and is divided into a cervical and a vaginal portion by the line of attachment. About one-fourth of the anterior surface and half of the posterior cervix belong to the vaginal portion. At the extremity of the vaginal portion is the opening leading to the vagina, (external os uteri), which is round or oval before parturition but takes the form of a transverse slit in women who have borne children. It is bounded by anterior and posterior labia. The cavity of the cervix is fusiform in shape, with longitudinal furrows, and extends from the internal to the external orifice.

The size of the uterus varies, under normal conditions, at different ages and in different physiologic states. In the woman who has never borne children, it is approximately 7–8 cm long and 4–5 cm at its widest point. In the prepubertal woman it is considerably smaller. In women who have borne children, it is larger. Its shape, size, and characteristics in the pregnant state become considerably modified depending on the stage of gestation.

Position & Axis Direction

The direction of the axis of the uterus varies greatly. Normally, the uterus forms a sharp angle with the vagina. Its anterior surface lies on the upper surface of the bladder and the body is in a horizontal plane when the woman is standing. At the isthmus, it bends in the area of the isthmus, at which the cervix then faces downward. This position is the normal anteversion of the uterus, although it may be placed backward (retroversion), without angulation (military position), or to one side (lateral version). The forward flexion at the isthmus is referred to as ante flexion, or there may be a corresponding retro flexion. There is no sharp line between the normal and pathologic state of anterior angulation.

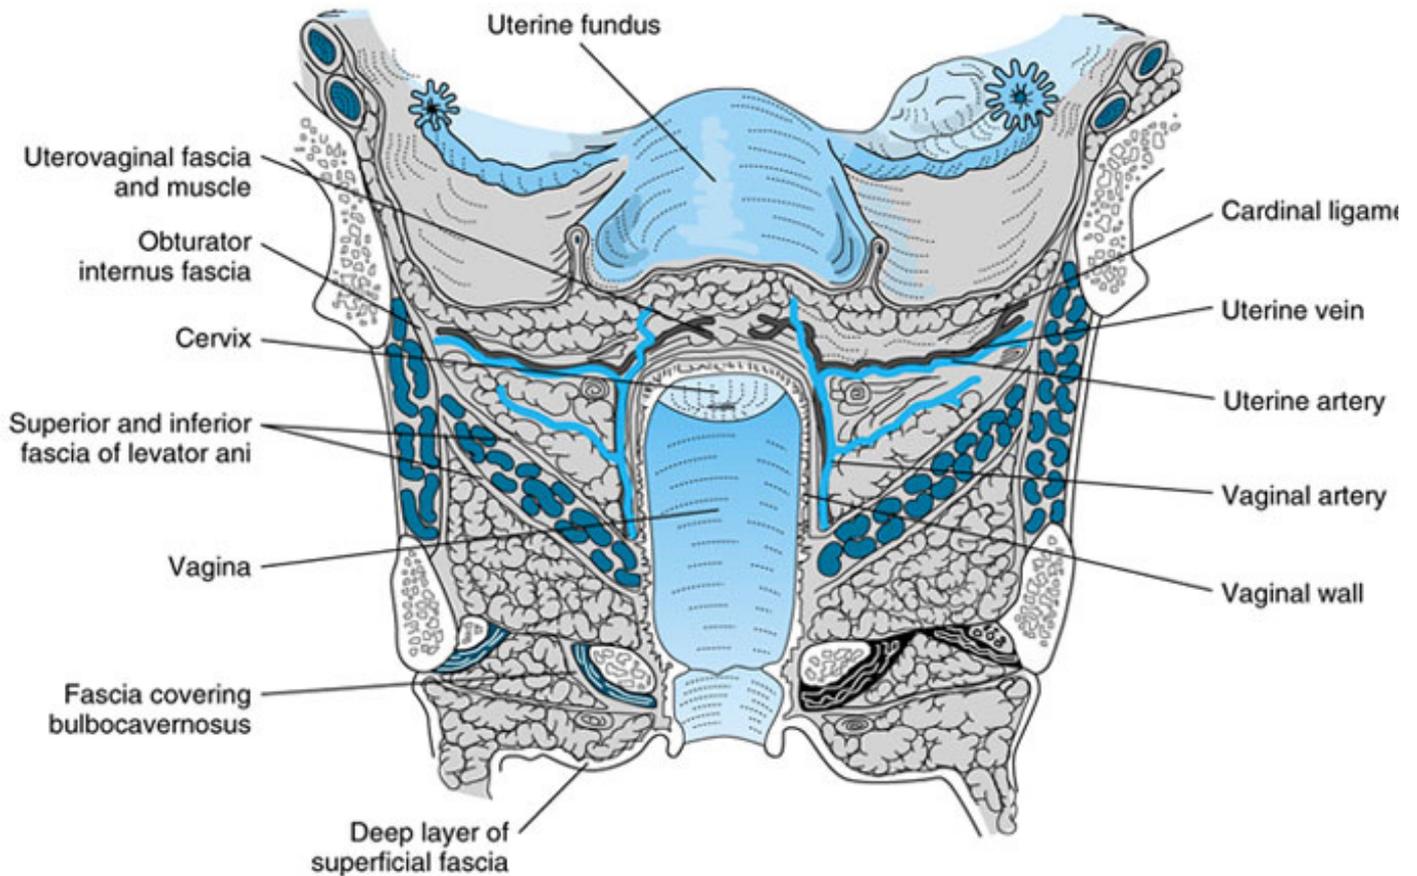

Relationships

Anteriorly, the body of the uterus rests upon the upper and posterior surfaces of the bladder, separated by the upper part of the peritoneum. The whole of the anterior wall of the cervix is below the floor of this pouch, and it is separated from the bladder only by connective tissue. Posteriorly, the peritoneal covering extends down as far as the uppermost part of the vagina; therefore, the entire posterior surface of the uterus is covered by peritoneum, and the convex posterior surface is separated from the rectum by the rectouterine pouch (cul-de-sac or pouch of Douglas). Coils of intestine may rest upon the anterior surface of the body of the uterus and may be present in the rectouterine pouch. Laterally, the uterus is related to the vessels contained within the broad ligament: the uterine tubes, the round ligament and the ligament of the ovary, the uterine veins, and the ureter. The relationships of the ureters and the uterine arteries are very important surgically. The uterine arteries pass to the bladder, run parallel with the cervix for a distance of 8–12 mm. The uterine artery crosses the ureter near the cervix, about 1.5 cm from the lateral fornix of the vagina. In effect, the ureter passes under the uterine artery and flows under a bridge."

Ligaments

Although the cervix of the uterus is fixed, the body is free to rise and fall with the filling and emptying of the bladder. The ligaments supporting the uterus consist of the uterosacral ligaments, the transverse ligaments of the cervix (cardinal supports, ligamentum transversum colli, ligaments of Mackenrodt), the round ligaments, and the broad ligament (2–24). The cervix is embedded in tissue called the parametrium, containing various amounts of smooth muscle. The ligaments of structures continuous with the parametrium and with the wall of the cervix: the uterosacral ligaments and the (cardinal) ligament of the neck, the latter of which is the chief means of support and suspends the uterus from the lesser pelvis. The uterosacral ligaments are, in fact, the inferior posterior folds of peritoneum from the broad ligament. They consist primarily of nerve bundles from the inferior hypogastric plexus and contain preganglionic and postganglionic fibers of the sympathetic lumbar segments, parasympathetic in part from sacral components and in part from sacral spinal segments.

Ligamentous and fascial support of pelvic viscera.

(Redrawn from original drawings by Frank H. Netter, MD, that first appeared in *Ciba Clinical Symposia*, Copyright Pharmaceutical Co. Reproduced with permission.)

The cardinal ligaments are composed of longitudinal smooth muscle fibers originating superiorly from the uterus the vagina, fanning out toward the fascia visceralis to form, with the internal os of the cervix, the primary support. There is a natural defect in the muscle at its sides (hilum of the uterus) and at the cervical isthmus (internal os) vasculature and nerve supply enter the uterus. The round ligaments of the uterus, although forming no real support maintaining the body of the uterus in its typical position over the bladder. They consist of fibrous cords containing (longitudinal) from the outer layer of the corpus. From a point of attachment to the uterus immediately below the ligament, each round ligament extends downward, laterally, and forward between the 2 layers of the mesometrium abdominal inguinal ring that it traverses and the inguinal canal, to terminate in a fanlike manner in the labia majora continuous with connective tissue. The round ligament is the gubernaculum (ligamentum teres uteri), vestigial in appearance accompanied by a funicular branch of the ovarian artery, by a branch from the ovarian venous plexus, and, in its course, by a branch from the inferior epigastric artery, over which it passes as it enters the inguinal ring. Through the inguinal canal, it is accompanied by the ilioinguinal nerve and the external spermatic branch of the genitofemoral nerve.

The broad ligament, consisting of a transverse fold of peritoneum that arises from the floor of the pelvis between the bladder, provides minimal support. In addition to the static support of these ligaments, the pelvic diaphragm provides an indirect and dynamic support. These muscles do not actually come in contact with the uterus, but they support the vagina and maintain the entire pelvic floor in resisting downward pressure. The effectiveness of this support depends on an intact perineum (perineal body, bulbocavernosus muscle and body), for if it is lacerated or weakened will gradually stretch and the uterus will descend. The uterus and its components and the vagina are, in fact, on

Layers of Uterine Wall

The wall of the uterus is very thick and consists of 3 layers: serous, muscular, and mucous. The serous layer (peritoneum) is simply the peritoneal covering. It is thin and firmly adherent over the fundus and most of the body, then thicker and becomes separated from the muscle by the parametrium. The muscular layer (myometrium) is extremely thick, thicker than that of the tubes and vagina. It also extends into the ovarian and round ligaments, into the cardinal ligaments and minimally into the uterosacral ligaments. Two principal layers of the muscular coat can be distinguished: (1) the outer layer is weaker and composed of longitudinal fibers; and (2) a stronger inner layer, the fibers of which are interlaced in two directions, having intermingled within them large venous plexuses. The muscle layer hypertrophies with the increase in size of the sphincter. The cervix, from the internal os distally, progressively loses its smooth muscle, finally to be entirely devoid of muscle and elastic in its distal half. It is, in fact, the "dead-end tendon" of the uterus, at which point, during the onset of labor, both the uterus and the vagina direct their efforts. The mucous layer (endometrium) is soft and spongy tissue resembling embryonic connective tissue. The surface consists of a single layer of ciliated columnar epithelium, which is rather delicate and friable and contains many tubular glands that open into the cavity of the uterus.

Arteries

The blood supply to the uterus is from the uterine and ovarian arteries. As a terminal branch of the hypogastric artery runs downward and medially to cross the ureter near the cervix. It then ascends along the lateral border of the uterus in a tortuous course through the parametrium, giving off lateral branches to both uterine surfaces. Above, it anastomoses with the ovarian artery in the mesometrium, which creates the main accessory source of blood. The uterine arteries and ovaries form a series of arches over the fundus, creating cruciate anastomoses with the opposite side. Branches of the uterine artery (radial) penetrate the myometrium at right angles to terminate in the basilar arterioles for the basilar portion of the spiral arteries and in the spiral arteries of the endometrium. The spiral arteries are tortuous in structure, not because of endometrial contraction, but because, ontogenically, an organ carries its arterial supply with it as it changes size and position. Therefore, the uterus is able to maintain adequate arterial flow to the placenta while it is attached within the uterus. On the other hand, the spiral arteries of the endometrium are a series of small sinusoids that connect to the larger sinusoids of the myometrium, the latter connected to the larger veins of the uterine complex. It is useful here to note the significance of the muscular role of the uterus in preventing venous bleeding during parturition.

The arterial supply to the cervix is primarily through the cervical branches of the right and left uterine arteries, which anastomose around the cervix (coronary artery), creating the azygos artery in the midline anteriorly and posteriorly. Anastomoses between the uterine artery and the vaginal artery on both sides afford cruciate flow on the anterior wall, whereas on the posterior wall anastomoses occur with the right and left middle hemorrhoidal arteries as they supply the wall and the rectum.

Veins

The veins form a plexus and drain through the uterine vein to the hypogastric vein. There are connections with the inferior vena cava and the inferior epigastric by way of the vein accompanying the round ligament.

Lymphatics

Lymphatic drainage involves several chains of lymph nodes (Table 2-2). From the subperitoneal plexus, the lymphatics of the lower uterine segment may drain by way of the cervix to the external iliac chain or by way of the isthmus to the internal iliac chain. Drainage along the round ligament progresses to the superficial inguinal nodes, then to the femoral, and then to the external iliac chain. Drainage laterally to the suspensory ligament of the ovary involves the lumbar pedicle and proceeds in a retroperitoneal manner across and anteriorly to the ureter, to the lumbar nodes (interaorticocaval) that lie along the inferior vena cava inferiorly to the kidney.

Nerves

The pelvic autonomic system can be divided into the superior hypogastric plexus (the presacral plexus and the middle hypogastric plexus), and the inferior hypogastric plexus. The superior hypogastric plexus begins just below the T12 level.

mesenteric artery. It is composed of 1–3 intercommunicating nerve bundles connected with the inferior mesenteric ganglia are an integral part of the plexus. The intermesenteric nerves receive branches from the lumbar sympathetic

SUPERIOR HYPOGASTRIC PLEXUS

The superior hypogastric plexus continues into the midhypogastric plexus. The presacral nerves spread out into level of the first sacral vertebra, with connecting rami to the last of the lumbar ganglia. The greater part of the midhypogastric plexus may be found to the left of the midline.

INFERIOR HYPOGASTRIC PLEXUS

At the first sacral vertebra, this plexus divides into several branches that go to the right and left sides of the pelvis to form the beginning of the right and left inferior hypogastric plexus. The inferior hypogastric plexus, which is the continuation of the midhypogastric plexus, the superior hypogastric plexus, the presacral nerve, and the uterine plexus composed of several parallel nerves on each side. This group of nerves descends within the pelvis in a position posterior to the common iliac artery and anterior to the sacral plexus, curves laterally, and finally enters the sacrouterine fold or the medial section of the primary division of the sacral nerves sends fibers (nervi erigentes) that enter the pelvic plexus through the sacrouterine folds. The plexus now appears to contain both sympathetic (inferior hypogastric plexus) and parasympathetic (nervi erigentes) components.

NERVI ERIGENTES

The sensory components, which are mostly visceral, are found in the nervi erigentes; however, if one takes into account the amount of spinal anesthetic necessary to eliminate uterine sensation, one must assume that there are a number of fibers in the sympathetic component.

COMMON ILIAC NERVES

The common iliac nerves originate separately from the superior hypogastric plexus and descend on the surface of the common iliac vein, one part going through the femoral ring and the remainder following the internal iliac, finally rejoining the internal iliac nerve.

HYPOGASTRIC GANGLION

On either side of the uterus, in the base of the broad ligament, is the large plexus described by Lee and Frankel called hypogastric ganglion. The plexus actually consists of ganglia and nerve ramifications of various sizes, as well as the combined inferior hypogastric plexus and the nervi erigentes. It lies parallel to the lateral pelvic wall, its lateral branches are superficial to the internal iliac and its branches; the ureter occupies a position superficial to the plexus. The middle branch perforates and supplies the plexus, its medial branches supplying the rectal stalk. The greater part of the plexus branches that enter the uterus in the region of the internal os, while another smaller component of the plexus supplies the bladder. The branches of the plexus that supply the uterus enter the isthmus primarily through the sacrouterine ligament. In the isthmus, just outside the entrance to the uterus, ascending rami pass out into the broad ligament and supply the body of the uterus at higher levels—besides supplying the uterine tubes. A part of the inferior hypogastric plexus supplies the uterus without involvement in the pelvic plexus.

Ganglia are in close proximity to the uterine arteries and the ureters, in the adventitia of the bladder and vagina and the vesicovaginal septum. The nerve bundles entering the ganglia contain both myelinated and unmyelinated elements. Lamellae (Vater-Pacini corpuscles) may be found within the tissues and are often observed within nerve bundles; those in the lower divisions of the plexus. Both myelinated and unmyelinated nerves are present within the uterus. Nerves enter along the blood vessels, the richest supply lying in the isthmus portion of the uterus. The fibers following the vessels gradually diminish in number in the direction of the fundus, where the sparsest distribution occurs. The fibers run between muscle bundles, and the nerves frequently branch to form a syncytium before terminating on the sarcoplasm as endings.

Sensory Corpuscles

Vater-Pacini corpuscles (corpuscula lamellosa) are present outside the uterus. Dogiel and Krause corpuscles (corpuscula) appear in the region of the endocervix. They may also be found in the broad ligament along with Vater-Pacini corpuscles.

junction of the uterine arteries with the uterus. These corpuscles may act to modulate the stretch response that stimulates uterine contractions during labor.

The innervation of the cervix shows occasional free endings entering papillae of the stratified squamous epithelium vaginalis. The endocervix contains a rich plexus of free endings that is most pronounced in the region of the internal os. The endocervix and the isthmic portion of the uterus in the nonpregnant state both contain the highest number of nerve fibers of any part of the uterus. The presence here of a lamellar type of corpuscle has already been noted.

Nerves pass through the myometrium and enter the endometrium. A plexus with penetrating fibers involving the region is present in the basal third of the endometrium, with branches terminating in the stroma, in the basal layer at the origin of the spiral arterioles. The outer two-thirds of the endometrium is devoid of nerves.

Uterine (Fallopian) Tubes (Oviducts)

Anatomy

The uterine tubes serve to convey the ova to the uterus. They extend from the superior angles of the uterus to the ovaries, running in the superior border of the broad ligament (mesosalpinx). The course of each tube is nearly horizontal and slightly backward. Upon reaching the lower (uterine) pole of the ovary, the tube turns upward, parallel with the mesovarian (mesovarian) border, then arches backward over the upper pole and descends posteriorly to terminate in contact with the ovarian surface. Each tube is 7–14 cm long and may be divided into 3 parts: isthmus, ampulla, and infundibulum. The narrow and nearly straight portion immediately adjoining the uterus. It has a rather long intramural course, and the uterine ostium, is approximately 1 mm in diameter. Following the isthmus is the wider, more tortuous ampulla, which terminates in a funnel-like dilatation, the infundibulum. The margins of the infundibulum are fringed by numerous finger-like processes, the fimbriae, the longest of which, the fimbria ovarica, is attached to the ovary. The funnel-shaped part of the infundibulum, the abdominal ostium, is about 3 mm in diameter and actually leads into the peritoneal cavity, although it is closely applied to the surface of the ovary during ovulation.

Layers of Wall

The wall of the tube has 4 coats: serous (peritoneal), subserous or adventitial (fibrous and vascular), muscular, and mucous. The tube is enclosed within a peritoneal covering except along a small strip on its lower surface, where the mesosalpinx is attached. The margins of the infundibulum and the fimbriae, this peritoneal covering becomes directly continuous with the lining the interior of the tube. The subserous tissue is lax in the immediate vicinity of the tube. The blood and nerves run within this layer. The muscular coat has an outer longitudinal and an inner circular layer of smooth muscle fibers and is continuous with that of the uterus at the uterine end of the tube. The mucous coat is ciliated columnar epithelium with longitudinal folds, simple in the region of the isthmus but becoming higher and more complex in the ampulla. The cilia extend outward into the fimbriae. The ciliary motion is directed toward the uterus.

Ligament

The infundibulum is suspended from the pelvic brim by the infundibulopelvic ligament (suspensory ligament of the ovary). The portion of the tube may adjoin the tip of the appendix and fuse with it.

Arteries & Veins

The blood supply to the tubes is derived from the ovarian and uterine arteries. The tubal branch of the uterine artery runs along the lower surface of the uterine tube as far as the fimbriated extremity and may also send a branch to the ligament of the ovary. The ovarian branch of the uterine artery runs along the attached border of the ovary and gives off a tubal branch. The two arteries form a cruciate anastomosis in the mesosalpinx. The veins accompany the arteries.

Lymphatics

The lymphatic drainage occurs through trunks running retroperitoneally across and anterior to the ureter, into the thorax along the aorta, and inferior to the kidney.

Nerves

The nerve supply is derived from the pelvic plexuses (parasympathetic and sympathetic) and from the ovarian plexus. The nerves of the ampulla are given off from the branches passing to the ovary, whereas those of the isthmus come from the uterine branches. The nerve fibers enter the muscularis of the tube through the mesosalpinx to form a reticular network among the smooth muscle cells.

Ovaries

Anatomy

The ovaries are paired organs situated close to the wall on either side of the pelvis minor, a little below the brim of the lesser pelvis. They are 2.5–5 cm in length, 1.5–3 cm in breadth, and 0.7–1.5 cm in width, weighing about 4–8 g. The ovary has 2 surfaces, lateral and medial; 2 borders, anterior or mesovarian and posterior or free; and 2 poles, upper or tubal and lower or uterine. In the normal position, the long axis of the ovary is nearly vertical, but it bends somewhat medially at the lower end so that the lower pole tends to point toward the uterus. The medial surface is rounded and bears numerous scars or elevations that mark the position of developing follicles and sites of ruptured ones.

Relationships

The upper portion of this surface is overhung by the fimbriated end of the uterine tube, and the remainder lies in contact with the posterior surface of the sigmoid intestine. The lateral surface is similar in shape and faces the pelvic wall, where it forms a distinct depression, the ovarian fossa. This fossa is lined by peritoneum and is bounded above by the external iliac vessels and below by the obturator foramen. Its posterior boundary is formed by the ureter and uterine artery and vein, and the pelvic attachment of the broad ligament is located anteriorly. The mesovarian or anterior border is fairly straight and provides attachment for the mesovarian fold by which the ovary is attached to the posterosuperior layer of the broad ligament. Because the vessels, nerves, and lymphatics enter the ovary through this border, it is referred to as the hilum of the ovary. Anterior to the hilum are the embryonic mesonephros and female germ cell ducts. The posterior or free border is more convex and broader and is directed freely toward the rectouterine pouch. The upper or tubal pole is large and rounded. It is overhung closely by the infundibulum of the uterine tube and is connected with the pelvic brim by the suspensory ligament of the ovary, a peritoneal fold. The lower or uterine pole is smaller and directed toward the uterus. It serves as the attachment of the ligament of the ovary proper.

Mesovarium

The ovary is suspended by means of the mesovarium, the suspensory ligament of the ovary, and the ovarian ligament. The mesovarium consists of 2 layers of peritoneum, continuous with both the epithelial coat of the ovary and the posterior layer of the broad ligament. It is short and wide and contains branches of the ovarian and uterine arteries, with the pampiniform plexus of veins, and the lateral end of the ovarian ligament. The suspensory ligament of the ovary is a layer of peritoneum and is actually the upper lateral corner of the broad ligament, which becomes confluent with the posterior layer at the pelvic brim. It attaches to the mesovarium as well as to the peritoneal coat of the infundibulum medially, both the ovary and the tube. It contains the ovarian artery, veins, and nerves after they pass over the pelvic brim. The ovarian ligament is a band of connective tissue, with numerous small muscle fibers, which connects the 2 layers of the broad ligament on the boundary line between the mesosalpinx and the mesometrium, connecting the uterine pole of the ovary with the lateral wall of the uterus. It is attached just below the uterine tube and above the round ligament of the uterus and is continuous with the latter.

Structure of Ovary

The ovary is covered by cuboid or low columnar epithelium and consists of a cortex and a medulla. The medulla is composed of connective tissue fibers, smooth muscle cells, and numerous blood vessels, nerves, lymphatic vessels, and supp. The cortex is composed of a fine areolar stroma, with many vessels and scattered follicles of epithelial cells within which are definitive ova (oocytes) in various stages of maturity. The more mature follicles enlarge and project onto the free surface of the ovary, where they are visible to the naked eye. They are called graafian follicles. When fully mature, the follicle ruptures, discharging the ovum and becoming transformed into a corpus luteum. The corpus luteum, in turn, is later replaced by scar tissue.

corpus albicans.

Arteries

The ovarian artery is the chief source of blood for the ovary. Though both arteries may originate as branches of aorta, the left frequently originates from the left renal artery; the right, less frequently. The vessels diverge from they descend. Upon reaching the level of the common iliac artery, they turn medially over that vessel and ureter tortuously into the pelvis on each side between the folds of the suspensory ligament of the ovary into the mesovarium. An additional blood supply is formed from anastomosis with the ovarian branch of the uterine artery, which courses along the lateral border of the ovary. Blood vessels that enter the hilum send out capillary branches centrifugally.

The veins follow the course of the arteries and, as they emerge from the hilum, form a well-developed plexus (the ovarian plexus) between the layers of the mesovarium. Smooth muscle fibers occur in the meshes of the plexus, giving it the appearance of erectile tissue.

Lymphatics

Lymphatic channels drain retroperitoneally, together with those of the tubes and part of those from the uterus, into lymph nodes along the aorta inferior to the kidney. The distribution of lymph channels in the ovary is so extensive that the lymphatic system may also provide additional fluid to the ovary during periods of preovulatory follicular swelling.

Nerves

The nerve supply of the ovaries arises from the lumbosacral sympathetic chain and passes to the gonad along with the ovarian artery.

Vagina

The vagina is a strong canal of muscle approximately 7.5 cm long that extends from the uterus to the vestibule of the external genitalia, where it opens to the exterior. Its long axis is almost parallel with that of the lower part of the sacrum. The cervix of the uterus projects into the upper portion of the vagina at an angle of 45–90 degrees. Because the cervix of the uterus projects into the upper portion of the vagina, the anterior wall of the vagina is 1.5–2 cm shorter than the posterior wall. The circular cul-de-sac formed around the cervix is the vaginal fornix and is divided into 4 regions: the anterior fornix, the posterior fornix, and 2 lateral fornices. Toward its lower end, the vagina pierces the urogenital diaphragm and is surrounded by the 2 bulbocavernosus muscles and bodies, which act as a sphincter (sphincter vaginae). In the virginal state, an incomplete fold of highly vascular tissue and mucous membrane, the hymen, closes the external orifice.

Relationships

Anteriorly, the vagina is in close relationship to the bladder, ureters, and urethra in succession. The posterior fornix is related to the peritoneum of the rectovaginal pouch, which may contain coils of intestine. Below the pouch, the vagina rests on the rectum, separated from it by a thin layer of areolar connective tissue. Toward the lower end of the vagina, the wall curves back sharply, and the distance between the vagina and rectum greatly increases. This space, filled with muscle fibers, connective tissue, and fat, is known as the perineal body. The lateral fornix lies just under the root of the broad ligament at a distance of 1 cm from the point where the uterine artery crosses the ureter. The remaining lateral vaginal wall is related to the anterior portion of the levator ani. The vagina is supported at the introitus by the bulbocavernosus muscles and lower third by the levator ani (puborectalis), and superiorly by the transverse (cardinal) ligaments of the uterus. The epoophori longitudinalis (duct of Gartner), the remains of the lower portion of the Wolffian duct (mesonephric duct), is found on the sides of the vagina as a minute tube or fibrous cord. These vestigial structures often become cystic or translucent areas.

Wall Structure

The vaginal wall is composed of a mucosal layer and a muscular layer. The smooth muscle fibers are indistinctly arranged in 3 layers: an outer longitudinal layer, circumferential layer, and a poorly differentiated inner longitudinal layer. In the

circumferential fibers envelop the urethra. The submucous area is abundantly supplied with a dense plexus of lymphatics. The mucous layer shows many transverse and oblique rugae, which project inward to such an extent that a transverse section resembles an H-shaped slit. On the anterior and posterior walls, these ridges are more prominent. The anterior column forms the urethral carina at its lower end, where the urethra slightly invaginates the anterior wall. The mucosa of the vagina is lined throughout by stratified squamous epithelium. Even though the vagina has no glands, a secretion is present. It consists of cervical mucus, desquamated epithelium, and, with sexual stimulation, a discharge of leukocytes.

Arteries & Veins

The chief blood supply to the vagina is through the vaginal branch of the uterine artery. After forming the coronary artery of the cervix, it passes medially, behind the ureter, to send 5 main branches onto the anterior wall. These branches anastomose with the azygos artery (originating midline from the coronary artery of the cervix) and coronary artery to supply the anterior vaginal wall and the lower two-thirds of the urethra. The uterine artery eventually anastomoses with the branch of the clitoral artery. The posterior vaginal wall is supplied by branches of the middle and inferior hemorrhoidal arteries, traversing toward the midline to join the azygos artery from the coronary artery of the cervix. These branches then anastomose with the perineum to the superficial and deep transverse perineal arteries.

The veins follow the course of the arteries.

Lymphatics

The lymphatics are numerous mucosal plexuses, anastomosing with the deeper muscular plexuses (Table 2–2). The superficial group of lymphatics joins those of the cervix and may follow the uterine artery to terminate in the external iliac nodes. The middle group anastomoses with the uterine plexus. The middle group of lymphatics, which drain the greater part of the vagina, anastomoses with the vaginal arteries to the hypogastric channels. In addition, there are lymph nodes in the rectovaginal septum that are responsible for drainage of the rectum and part of the posterior vaginal wall. The inferior group of lymphatics for the perineum anastomoses between the right and left sides and either courses upward to anastomose with the middle group or downward and drains to the inguinal nodes.

Nerves

The innervation of the vagina contains both sympathetic and parasympathetic fibers. Only occasional free nerve endings are noted in the mucosa; no other types of nerve endings are noted.

STRUCTURES LINING THE PELVIS

The walls of the pelvis minor are made up of the following layers: (1) the peritoneum, (2) the subperitoneal or fibroareolar layer, (3) the fascial layer, (4) the muscular layer, and (5) the osseoligamentous layer (not further described). The anatomy of the floor of the pelvis is comparable to that of the walls except for the absence of an osseoligamentous layer.

Peritoneum

The peritoneum presents several distinct transverse folds that form corresponding fossae on each side. The most variable fold, the transverse vesical, extends from the bladder laterally to the pelvic wall. It is not the superficial definitive structure. Behind it lies the broad ligament, which partially covers and aids in the support of the uterus.

Ligaments

The broad ligament extends from the lateral border on either side of the uterus to the floor and side walls of the pelvis. It is composed of 2 layers, anterior and posterior, the anterior facing downward and the posterior facing upward, corresponding to the position of the uterus. The inferior or "attached" border of the broad ligament is continuous with the parietal peritoneum on the floor and on the side walls of the pelvis. Along this border, the posterior layer continues laterally and posteriorly to the region of the sacrum, forming the uterosacral fold. Another fold—the rectouterine fold—frequently passes from the anterior surface of the cervix to the rectum in the midline. The anterior layer of the broad ligament is continuous laterally with the parietal peritoneum on the border with the peritoneum of the paravesical fossae and continuous medially with peritoneum on the upper surface of the bladder.

Both layers of the attached border continue up the side walls of the pelvis to join with a triangular fold of peritoneum at the brim of the pelvis to form the suspensory ligament of the ovary or infundibular ligament. This ligament contains vessels and nerves. The medial border of the broad ligament on either side is continuous with the peritoneal covering of the uterine surfaces. The 2 layers of the ligament separate to partially contain the uterus, and the superior or "free" border is laterally continuous with the suspensory ligament of the ovary, envelops the uterine tube.

The broad ligament can be divided into regions as follows: (1) a larger portion, the mesometrium, which is associated with the lateral border of the uterus; (2) the mesovarium, the fold that springs from the posterior layer of the broad ligament; (3) the mesosalpinx, which is associated with the uterine tube in the region of the free border. The superior border of the broad ligament has been referred to as the suspensory ligament of the ovary, or infundibulopelvic ligament, and it suspends the infundibulum as well as the ovary.

Fossae & Spaces

Corresponding to the peritoneal folds are the peritoneal fossae. The prevesical or retropubic space is a potential space crossed by the transverse vesical fold. It is situated in front of the bladder and behind the pubis. When the bladder is displaced posteriorly, it becomes an actual space, anteriorly continuous from side to side and posteriorly limited by a condensed areolar tissue extending from the base of the bladder to the side wall of the pelvis. The vesicouterine pouch is a space between the anterior surface of the body of the uterus and the upper surface of the bladder when the uterus is in an anteфлекed position. In the bottom of this pouch, the peritoneum is reflected from the bladder onto the uterus at the cervix and corpus. Therefore, the anterior surface of the cervix is below the level of the peritoneum and is connected to the bladder by condensed areolar tissue. The peritoneum on the posterior surface of the body of the uterus extends onto the cervix and onto the posterior fornix of the vagina. It is then reflected onto the anterior surface of the rectum in a narrow cul-de-sac continuous with the pararectal fossa of either side. The entire space, bounded anteriorly by the fornix in the midline, the uterosacral folds laterally, and the rectum posteriorly, is the rectouterine pouch or cul-de-sac of Douglas).

Subperitoneal & Fascial Layers

The subperitoneal layer consists of loose, fatty areolar tissue underlying the peritoneum. External to the subperitoneal layer of fascia lines the wall of the pelvis, covering the muscles and, where these are lacking, blending with the periosteum of the pelvic bones. This layer is known as the parietal pelvic fascia and is subdivided into the obturator fascia, the fascia of the diaphragm, and the fascia of the piriformis. The obturator fascia is of considerable thickness and covers the obturator foramen. Traced forward, it partially blends with the periosteum of the pubic bone and assists in the formation of the lesser sciatic foramen. Traced upward, it is continuous at the arcuate line with the iliac fascia. Inferiorly, it extends nearly to the ischiopubic arch, where it is attached to the bone. In this lower region, it also becomes continuous with a double sheet of fascia, the fasciae of the urogenital diaphragm, passing across the anterior part of the pelvic outlet. A narrow portion of the parietal pelvic fascia covers the piriform and coccygeus muscles in the posterior pelvic wall. Medial parietal fascia blends with the periosteum of the sacrum around the margins of the anterior sacral foramina and covers the branches of the sacral plexus. Visceral pelvic fascia denotes the fascia in the bottom of the pelvic bowl, which invests the organs and forms a number of supports that suspend the organs from the pelvic walls. These supports arise in the obturator part of the parietal fascia, along or near the arcus tendineus. This arc or line extends from a point near the symphysis pubica to the root of the spine of the ischium. From this common origin, the fascia spreads inward, dividing into a number of parts classified as either investing (endopelvic) fascia or suspensory and diaphragmatic.

Muscular Layer

The muscles of the greater pelvis are the psoas major and iliacus. Those of the lesser pelvis are the piriformis, coccygeus, and levator ani; they do not form a continuous layer.

Greater Pelvis

PSOAS MAJOR

The fusiform psoas major muscle originates from the 12th thoracic to the fifth lumbar vertebrae. Parallel fibers run nearly vertically along the side of the vertebral bodies and extend along the border of the minor pelvis, beneath the inguinal ligament, and on toward insertion in the thigh. The medial border inserts into the lesser trochanter, whereas the lateral border shares its tendon with the iliacus muscle. Together with the iliacus, it is the most powerful flexor of the thigh, an abductor and medial rotator of the femur when the foot is off the ground and free and as a medial rotator when the foot is on the ground and fixed. The psoas component flexes the spine and the pelvis and abducts the lumbar region of the spine. The psoas has more fibers than the iliacus, gives a quicker but weaker pull.

ILIACUS

The fan-shaped iliacus muscle originates from the iliac crest, the iliolumbar ligament, the greater part of the iliac sacroiliac ligaments, and frequently the ala of the sacrum. It also originates from the ventral border of the ilium anterior spines. It is inserted in a penniform manner on the lateral surface of the tendon that emerges from the inguinal ligament and directly on the femur immediately distal to the lesser trochanter. The lateral portion of the iliacus from the ventral border of the ilium is adherent to the direct tendon of the rectus femoris and the capsule of the

Lesser Pelvis

PIRIFORMIS

The piriformis has its origin from the lateral part of the ventral surface of the second, third, and fourth sacral vertebrae, the posterior border of the greater sciatic notch, and from the deep surface of the sacrotuberous ligament near the lesser sciatic foramen. Its fiber bundles pass through the greater sciatic foramen to insert upon the anterior and inner portion of the upper border of the lesser trochanter. The piriformis acts as an abductor, lateral rotator, and weak extensor of the thigh.

OBTURATOR INTERNUS

The obturator internus arises from the pelvic surface of the pubic rami near the obturator foramen, the pelvic surface of the ischium between the foramen and the greater sciatic notch, the deep surface of the obturator internus fascia, which bounds the canal for the obturator vessels and nerves, and the pelvic surface of the obturator membrane. The fibers converge toward the lesser sciatic notch, where they curve laterally to insert into the trochanteric fossa of the femur. The obturator internus is a powerful lateral rotator of the thigh. When the thigh is bent at a right angle, the muscle serves as a weak extensor.

COCCYGEUS

The coccygeus muscle runs from the ischial spine and the neighboring margin of the greater sciatic notch to the sacral vertebrae and the coccyx. A large part of the muscle is aponeurotic. It supports the pelvic and abdominal wall and possibly flexes and abducts the coccyx.

LEVATOR ANI

The levator ani muscle forms the floor of the pelvis and the roof of the perineum. It is divisible into 3 portions: (1) the iliococcygeus, (2) the pubococcygeus, and (3) the puborectalis.

Iliococcygeus

The iliococcygeus arises from the arcus tendineus, which extends from the ischial spine to the superior ramus of the obturator canal and for a variable distance downward below the obturator canal. Its insertion is into the lateral margin of the raphe that extends from the tip of the coccyx to the rectum. Many fiber bundles cross the median line.

Pubococcygeus

The pubococcygeus arises from the inner surface of the os pubis, the lower margin of the symphysis pubica to the lesser sciatic foramen and the arcus tendineus as far backward as the origin of the iliococcygeus. It passes backward, downward, and under the urogenital organs and the rectum, inserting into the anterior sacrococcygeal ligament, the deep part of the anococcygeal muscle, and each side of the rectum. The pubococcygeus lies to some extent on the pelvic surface of the insertion of the

Puborectalis

The puborectalis arises from the body and descending ramus of the pubis beneath the origin of the pubococcygeus and

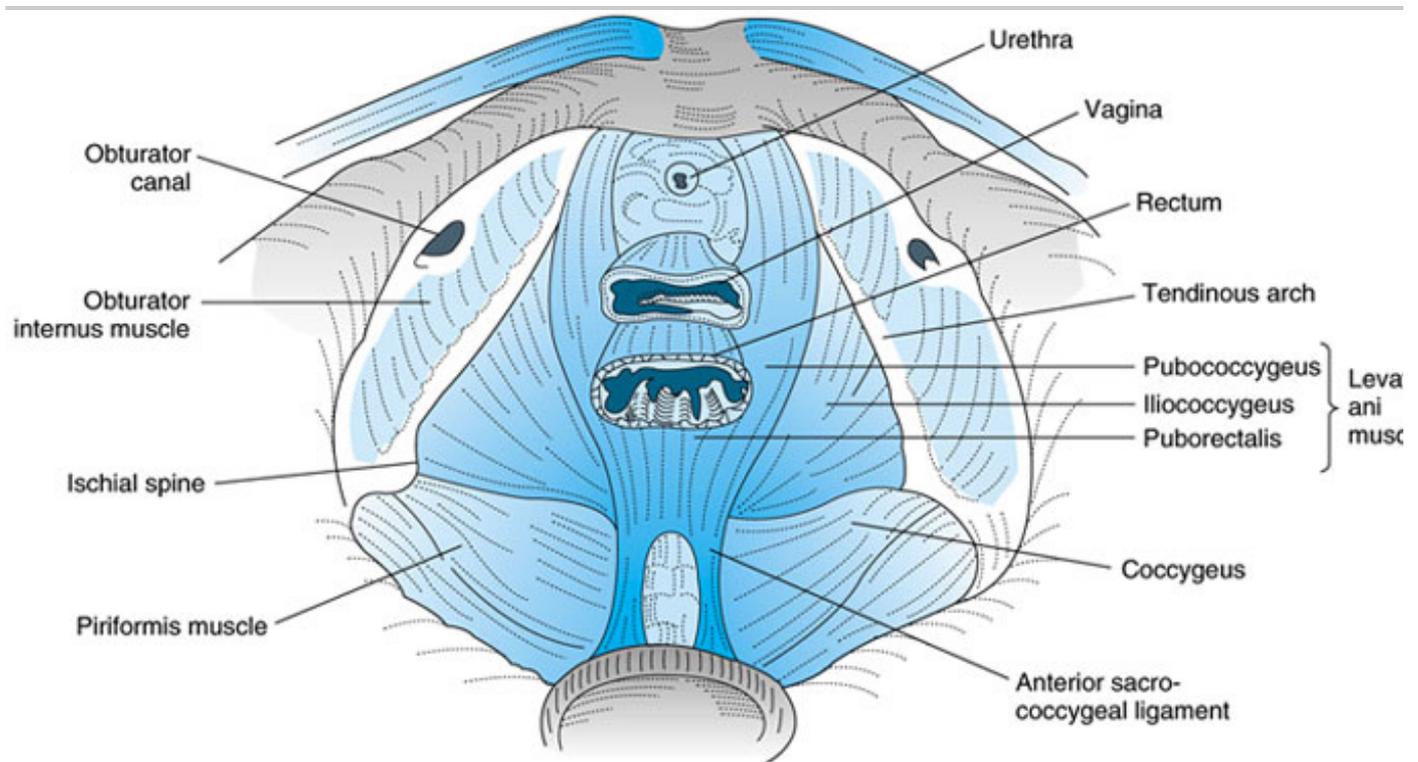

part of the obturator fascia, and the fascia covering the pelvic surface of the urogenital diaphragm. Many of the interdigitate with those of the opposite side, and they form a thick band on each side of the rectum behind which side are inserted into the anococcygeal raphe.

The levator ani serves to slightly flex the coccyx, raise the anus, and constrict the rectum and vagina. It resists pressure that the thoracoabdominal diaphragm exerts on the viscera during inspiration.

Pelvic Diaphragm

The pelvic diaphragm (Fig 2–25) extends from the upper part of the pelvic surface of the pubis and ischium to the coccyx. It passes through it. The pelvic diaphragm is formed by the levator ani and coccygeus muscles and covering fascia. Diaphragmatic fasciae cloaking the levator ani arise from the parietal pelvic fascia (obturator fascia), the muscular layer between the fasciae. As viewed from above, the superior fascia is the best developed and is reflected onto the rectum. The "rectal sheath." The coccygeus muscle forms the deeper portion of the posterolateral wall of the ischioanal fossa. The diaphragm presents a hiatus anteriorly, occupied by the vagina and urethra. The pelvic diaphragm is the main support of the pelvic floor; it suspends the rectum and indirectly supports the uterus.

Figure 2–25.

Pelvic diaphragm from above.

Arteries & Veins

The blood supply to the muscles lining the pelvis is primarily from branches of the hypogastric artery, accompanied by contributions from the external iliac artery. The iliolumbar branch of the hypogastric artery runs upward and laterally to the common iliac artery, then beneath the psoas muscle to the superior aperture of the pelvis minor, where it divides into lumbar branches. The iliac supplies both the iliacus and psoas muscles. It passes laterally beneath the psoas and, perforating the iliacus, ramifies in the iliac fossa between the muscle and the bone. It supplies a nutrient artery to the iliacus and then divides into several branches that can be traced as follows: (1) upward toward the sacroiliac synchondrosis

anastomose with the last lumbar artery, (2) laterally toward the crest of the ilium to anastomose with the lateral gluteal arteries, and (3) medially toward the pelvis minor to anastomose with the deep circumflex iliac from the lumbar branch ascends beneath the psoas and supplies that muscle along with the quadratus lumborum. It then the last lumbar artery.

Another branch of the hypogastric artery, the lateral sacral artery, may be represented as 2 distinct vessels. It is in front of the sacrum and turns downward to run parallel with the sympathetic trunk. Crossing the slips of origin of the muscle, it sends branches to that muscle. On reaching the coccyx, it anastomoses in front of the bone with the right and with the inferior lateral sacral artery of the opposite side. The obturator artery usually arises from the hypogastric occasionally it may stem from the inferior epigastric or directly from the external iliac artery. It runs forward and below the brim of the pelvis, lying between the peritoneum and endopelvic fascia. Passing through the obturator foramen and divides into anterior and posterior branches that curve around the margin of the obturator foramen beneath the obturator externus muscle.

When the obturator artery arises from the inferior epigastric or external iliac artery, its proximal relationships are altered, the vessel coursing near the femoral ring where it may be endangered during operative procedures. The obturator artery runs around the medial margin of the obturator foramen and anastomoses with both its posterior and the medial circumflex artery. It supplies branches to the obturator muscles. The internal pudendal artery is a terminal hypogastric artery that arises opposite the piriform muscle and accompanies the inferior gluteal artery downward along the border of the greater sciatic foramen. It leaves the pelvis between the piriform and coccygeus muscles, passing the greater sciatic foramen to enter the ischioanal fossa through the small sciatic foramen. Then, running forward through the canal (Alcock's canal) in the obturator fascia, it terminates by dividing into the perineal artery and the artery of the clitoris.

Within the pelvis, the artery lies anterior to the piriform muscle and the sacral plexus of nerves, lateral to the inferior gluteal artery. Among the small branches that it sends to the gluteal region are those that accompany the nerve to the piriform muscle. Another of its branches, the inferior hemorrhoidal artery, arises at the posterior part of the ischioanal fossa. Upon reaching the obturator fascia, it immediately breaks up into several branches. Some of them run medially toward the rectum and levator ani muscle. The superior gluteal artery originates as a short trunk from the lateral and back part of the ilium associated in origin with the iliolumbar and lateral sacral and sometimes with the inferior gluteal or with the inferior internal pudendal. It leaves the pelvis through the greater sciatic foramen above the piriform muscle, beneath the greater sciatic foramen of the superior gluteal nerve. Under cover of the gluteus maximus muscle, it breaks into a superficial and a deep branch.

The deep portion further divides into superior and inferior branches. The inferior branch passes forward between the gluteus medius and minimus toward the greater trochanter, where it anastomoses with the ascending branch of the lateral circumflex iliac artery. The superior gluteal artery supplies branches to the obturator internus, the piriformis, the levator ani, and the coccygeus muscles and to the greater sciatic foramen. The deep circumflex iliac artery arises from the side of the external iliac artery either opposite the epigastric or a little anterior to that vessel. It courses laterally behind the inguinal ligament, lying between the fascia transversalis and the peritoneum in the fibrous canal formed by the union of the fascia transversalis with the iliac fascia. It sends off branches that supply the iliopsoas muscles, as well as a cutaneous branch that anastomoses with the superior gluteal artery.

PLACENTA*

* This section is contributed by Robert C. Goodlin, MD.

At term, the normal placenta is a blue-red, rounded, flattened, meaty discoid organ 15–20 cm in diameter and weighs 400–600 g, or about one-sixth the normal weight of the newborn. The umbilical cord arises from almost the fetal surface of the placenta, seemingly at random. The fetal membranes arise from the placenta at its margin. In multiple pregnancy, one or more placentas may be present depending upon the number of ova implanted and the type of twinning that occurs. The placenta is derived from both maternal and fetal tissue. At term, about four-fifths of the placenta is fetal in origin.

The maternal portion of the placenta amounts to less than one-fifth of the total placenta by weight. It is composed of sheets of decidua basalis, remnants of blood vessels, and, at the margin, spongy decidua. Irregular grooves or clefts separate the maternal portion from the fetal portion.

placenta into cotyledons. The maternal surface is torn from the uterine wall at birth and as a result is rough, red. The fetal portion of the placenta is composed of numerous functional units called villi. These are branched terminal circulation and provide for transfer of metabolic products. The villous surface, which is exposed to maternal blood as 12 m² (130 square feet). The fetal capillary system within the villi is almost 50 km (27 miles) long. Most villi are in intervillous spaces, but an occasional anchor villus attaches the placenta to the decidua basalis. The fetal surface is covered by amniotic membrane and is smooth and shiny. The umbilical cord vessels course over the fetal surface of the placenta.

Placental Types

CIRCUMVALLATE (CIRCUMMARGINATE) PLACENTAS

In about 1% of cases, the delivered placenta shows a small central chorionic plate surrounded by a thick whitish ring composed of a double fold of amnion and chorion with fibrin and degenerated decidua in between. This circumvallate predispose to premature marginal separation and second-trimester antepartum bleeding (Fig 2–26). This uncommon placenta is of uncertain origin. It is associated with increased rates of slight to moderate antepartum bleeding, early perinatal death. Older multiparas are more prone to its development. Low-birth-weight infants and extrachorial are related.

Figure 2–26.

Marked circumvallate or extrachorial placenta.

SUCCENTURIATE LOBE

Occasionally there may be an accessory cotyledon, or succenturiate lobe, with vascular connections to the main placenta. A succenturiate lobe may not always deliver with the parent placenta during the third stage of labor. This can lead to postpartum hemorrhage. If a careful examination of the delivered membranes reveals torn vessels, immediate manual removal of the uterus is indicated for removal of an accessory lobe (Fig 2–27).

Figure 2–27.

All rights reserved.

Succenturiate placenta.

BIPARTITE PLACENTA

A bipartite placenta is an uncommon variety. The placenta is divided into 2 separate lobes but united by primary membranes. Retention of one lobe after birth will cause hemorrhagic and septic complications. Examine the vasculature and the completeness of membranes of a small placenta for evidence of a missing lobe, and recover the adherent placenta (Fig 2–28).

Figure 2–28.

All rights reserved.

Bipartite placenta.

MARGINAL INSERTION OF CORD (BATTLEDORE PLACENTA)

The umbilical cord may be found inserted into the chorionic plate at almost any point, but when it inserts at the edge, it is sometimes called a battledore placenta (Fig 2–29).

Figure 2–29.

Copyright ©2006 by The McGraw-Hill Companies, Inc.
All rights reserved.

Marginal insertion of battledore placenta.

PLACENTA MEMBRANACEA

This type of placenta is one in which the decidua capsularis is so well vascularized that the chorion laeve does not are maintained. Hence, the entire fetal envelope is functioning placenta.

PLACENTA ACCRETA

In rare cases, the placenta is abnormally adherent to the myometrium, presumably because it developed where deficiency of decidua. Predisposing factors include placenta previa in one-third of cases, previous cesarean in on dilatation and curettage (D&C) in one-fourth, and grand multiparity. The adherence may be partial or total. Rare may invade the myometrium deeply (placenta increta) or even perforate the uterus (placenta percreta). When a to remove a placenta accreta manually, hemorrhage may be severe. The treatment is hysterectomy.

PLACENTA PREVIA

This abnormality is discussed in Chapter 20.

MULTIPLE PREGNANCY PLACENTA

In fraternal twins, the placentas may be 2 distinct entities or fused. There are 2 distinct chorions and amnions. In identical twins, the picture may be more confusing. Depending upon the time of division of the fertilized ovum, 1 placentas and number of membranes will vary. If the division occurs soon after fertilization, 2 distinct placentas membranes are the result. From that point on, many variations (eg, monochorionic monoamniotic fused placenta, interchange of blood supply) may occur. Further variations may be noted when triplets or more are derived from the presence of identical twins is suspected, it is always wise to clamp the cord on the placental side at the time the infant to minimize the chance of exsanguination of the uterine twin.

Current OB/GYN >Chapter 3. The Role of Imaging Techniques in Gynecology>

CASE REPORT

C.O. is a 29-year-old white woman who presented with a history of infertility for several years, followed by a history of recurrent pregnancy losses.

Her past medical and surgical histories were negative. Gynecologically, she was remarkable in that she reported severe dysmenorrhea for several years that was relieved by nonsteroidal anti-inflammatory drugs. Her gynecologist found a low luteal phase progesterone level and treated her with 50 mg of clomiphene citrate on days 5–9 of the cycle.

She responded well to the medication, with a subsequent conception. The pregnancy resulted in a spontaneous abortion 5 weeks later. No dilatation and curettage (D&C) was required, and the patient recovered well. She still was unable to conceive on her own and was again given clomiphene citrate therapy. Again, she conceived and had a spontaneous abortion—this time at 7 weeks' gestation. No D&C was performed.

The patient was evaluated for recurrent pregnancy losses. Karyotype was normal for both partners. Hormonal evaluation was normal with the exception of a low midluteal phase progesterone level. Immunologic and infective screening failed to reveal a cause for the recurrent losses. The hysterosalpingogram (HSG) demonstrated a midline filling defect similar to that shown in Figure 3–1.

Figure 3–1.

Mullerian anomaly as demonstrated by hysterosalpingogram.

(Reproduced, with permission, from Doyle MB: Magnetic resonance imaging in Mullerian fusion defects. *J Reprod Med* 1992; 37:33.)

The patient was informed of the results and the potential for future miscarriages. The need for further evaluation and possible repair performed hysteroscopically or abdominally, together with its risks and benefits, was carefully explained to the patient. She elected to try clomiphene citrate therapy one more time and hoped to avoid surgery.

At 8 weeks' gestation, vaginal ultrasonography (US) revealed positive fetal cardiac activity in an ovulation induced by clomiphene citrate. While still taking micronized progesterone 100 mg 3 times daily, she was referred to her gynecologist for routine obstetric care.

At 12 weeks' gestation, the patient had an incomplete abortion that required a D&C. She recovered uneventfully and later returned to the office for further evaluation and treatment.

Several months were allowed to lapse before a hysteroscopy/laparoscopy was performed, which revealed a broad-based intrauterine septum and stage I endometriosis. To evaluate the depth and width of the septum, a LaparoScan (EndoMedix, Irvine, CA) laparoscopic 7.5-Hz probe was used during the procedure. The septum was removed with a hysteroscopic resectoscope loop on a 40-W setting. After the resection, the ultrasonic probe was

again used to measure the thickness of the myometrium and to verify the resection of the septum. A 30-mL 18F Foley catheter with the distal tip resected was placed in the fundus and inflated. The patient was discharged and placed on therapy consisting of a broad-spectrum antibiotic and conjugated estrogen 2.5 mg daily.

DISCUSSION

The new millennium saw a proliferation of imaging techniques used in medical practice. Research into the development, refinement, and application of imaging in gynecology is apparent in the literature.

The HSG has been considered the gold standard for imaging the uterine corpus for benign disorders (submucous myomas, submucous polyps, localization of tubal occlusion, and evaluation of müllerian fusion defects) and malignant disease (endometrial carcinoma).

In the case reported, the standard scout film was obtained, and the cervix was prepared after the following were assured: position of the uterus, absence of pelvic tenderness, and negative pregnancy test. The water-soluble contrast medium was injected into the uterine cavity, and oblique and anteroposterior films were obtained. These films showed a midline uterine filling defect of the type usually seen with septate or bicornuate uteri.

US performed on this patient during her pregnancies failed to show the filling defect. If suspected, the septum might have been encountered by more careful scanning. The scans of the last pregnancy revealed only an eccentrically placed pregnancy that might have been seen ultrasonographically even in normally structured uteri. Although not helpful at this point, ultrasonographic examination of the uterus between conceptions might have been helpful if used with a distending medium. This is especially useful in patients allergic to iodine contrast medium (Table 3–1). This technique of ultrasonic HSG is performed by occluding the cervix with a uterine injector and distending the uterus. The method can demonstrate the separate cavities as well as the possible difference between the septate and the bicornuate uterus while demonstrating tubal patency. The technique was adopted for this patient during her uterine septum resection, with the addition of ultrasonic contrast between the endometrial cavity and septum and the myometrium. Readers are referred to the many fine texts on diagnostic pelvic ultrasound for instruction and further discussion of these techniques. The development of "sonicated" contrast solutions may add greatly to the usefulness of US.

Table 3–1. Indications for Saline Infusion Sonohysterosalpingogram.

Abnormal x-ray hysterosalpingogram

Abnormal uterine bleeding

Allergies to iodine dyes

Amenorrhea

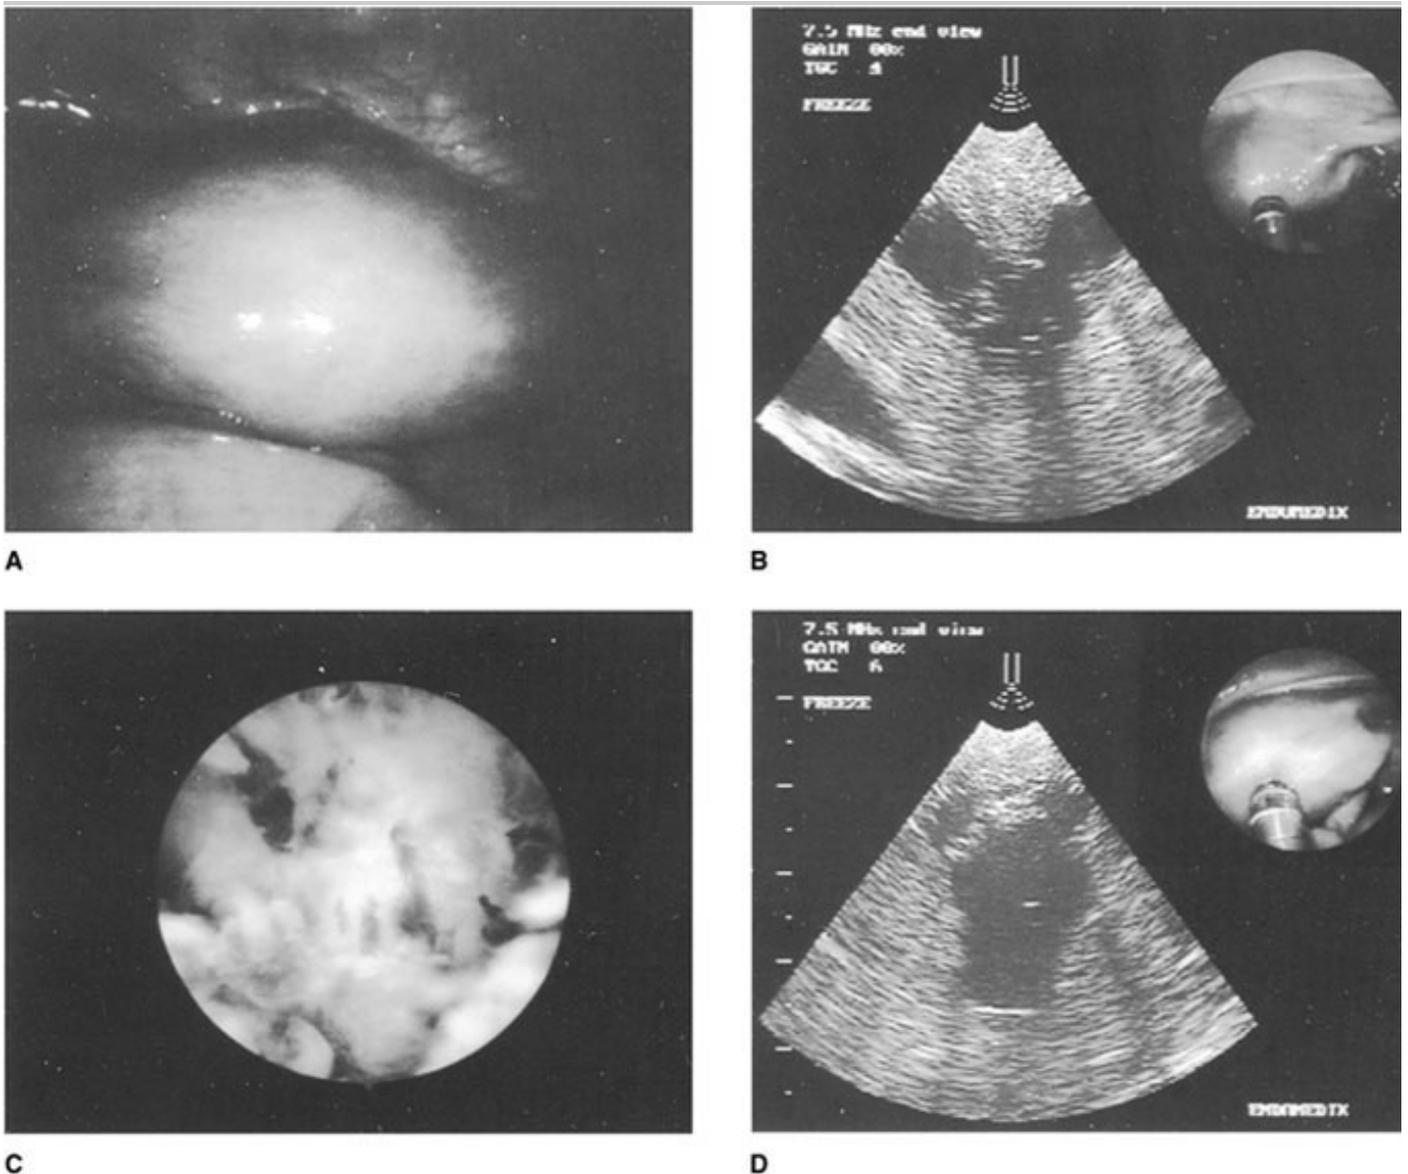

Infertility

Using 2 video cameras (1 for the resectoscope and the other for the laparoscope and the LaparoScan laparoscopic ultrasound probe), all aspects of the surgery were evaluated. This setup allowed the operating surgeon adequate visualization of the uterine cavity during the resection and enabled other personnel in the operating room to follow the progress of surgery. The laparoscopic video allowed for careful monitoring of the uterine surface and assured the surgeon that there would be less likelihood of a uterine perforation, a complication that could result in bowel

injury.

The laparoscopic ultrasound probe with a picture within a picture was useful because it allowed visualization of the 2 separate cavities and measurement of the length and width of the septum. It also enabled the operator to demonstrate the complete removal of the septum (Fig 3–2).

IMAGING OF THE UTERUS & CERVIX

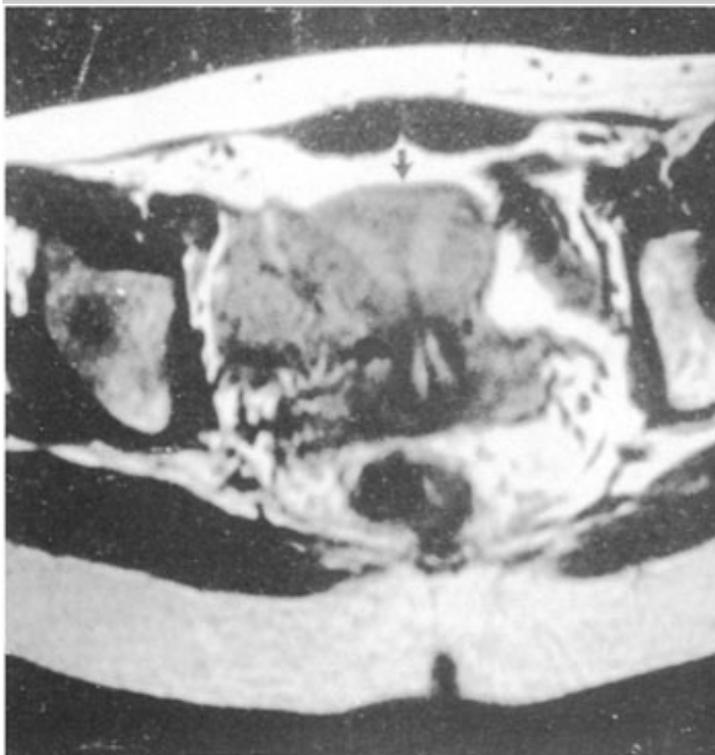

Plain radiographs are rarely the test of choice for identifying gynecologic pathology, but they can be used to detect calcified leiomyomas as well as an intrauterine device (IUD). Such films can help determine if an IUD has been

expelled from the uterine cavity or has penetrated the uterine wall and migrated to an ectopic location.

Pelvic US plays a significant role in the diagnosis of uterine leiomyomas (submucosal, intramural, and subserosa and polyps. Occasionally, the detection and localization of myomas, assessment of size, and their differential diagnosis are difficult. In these circumstances it is sometimes useful to perform magnetic resonance imaging (MRI) of the pelvis. MRI produces images with excellent soft-tissue resolution. MRI can be used for evaluation of congenital abnormalities of the uterus, leiomyomas, adenomyosis, gestational trophoblastic disease, and endometrial carcinoma diagnosis and staging. MRI can accurately measure the volume of the myoma, which aid in determining whether medical management of myomas has resulted in shrinkage or whether conservatively treated myomas are growing. Malignant degeneration of myomas visualized by MRI as described by some authors allows for early and appropriate intervention.

MRI can effectively discern between the septate and the bicornuate uterus, thus avoiding the more costly laparoscopy. MRI may provide a clear anatomic picture of complicated müllerian fusion defects (didelphys with transverse vaginal septum or noncommunicating uterine segment) and allow for proper planning of surgical repair. If pelvic MRI had been performed on the patient in the opening case report, the image probably would have appeared the same as the MRI shown in Figure 3–3. (See review of MRI findings of müllerian fusion defects in Table 3–2.)

Currently, histopathologic evaluation of colposcopic biopsies is required to diagnose cervical cancer and its precursor lesions. However, the technique is expensive and often requires a waiting period before histopathology results are available and necessary treatment can be scheduled. Several new imaging techniques that evaluate the cervical epithelium are under investigation. Optical techniques, such as elastic backscattering and fluorescence Raman spectroscopies, have been used to noninvasively examine tissue morphology and the biochemical composition of the cervix. Optical coherence tomography (OCT) is a noninvasive imaging technique that uses coherent light to form images of subsurface tissue structures with 10- to 20- μ m resolution and up to 1-mm depth. A study by Zuluaga et al showed that simple quantitative analysis of images obtained with an OCT system can be used for noninvasive evaluation of normal and abnormal cervical tissue in vivo. Optical coherence tomographic imaging could have broad applications for screening and detection of cervical malignancies and their precursors. It also may aid in surgical planning by allowing surgeons to identify margins in vivo without obtaining frozen sections.

IMAGING OF THE ENDOMETRIUM

Pelvic ultrasound has been used to evaluate the uterine cavity, and endometrial thickness has been used as a marker for endometrial pathology. The following guidelines should be used to obtain interobserver consistency in the evaluation of the endometrium. Obtain measurements from the midfundal region in the sagittal plane. Obtain the maximal double-thickness dimension, remembering to exclude the hypoechoic area between the myometrium and the endometrium. Any fluid between the anterior and posterior walls should be subtracted from the total measurement. Endometrial thickness ranges from 4–8 mm during the follicular phase. The uterine lining ranges from 7–14 mm during the luteal phase and has a uniform echogenic appearance.

Premenopausal women should be evaluated during the early follicular phase, immediately following the menses when the endometrium has a uniform linear appearance.

Menopausal women usually have an endometrial stripe less than 4 mm. Menopausal women on hormone replacement therapy (HRT) may have an endometrial thickness exceeding 8 mm and a small amount of fluid (< 5 mm).

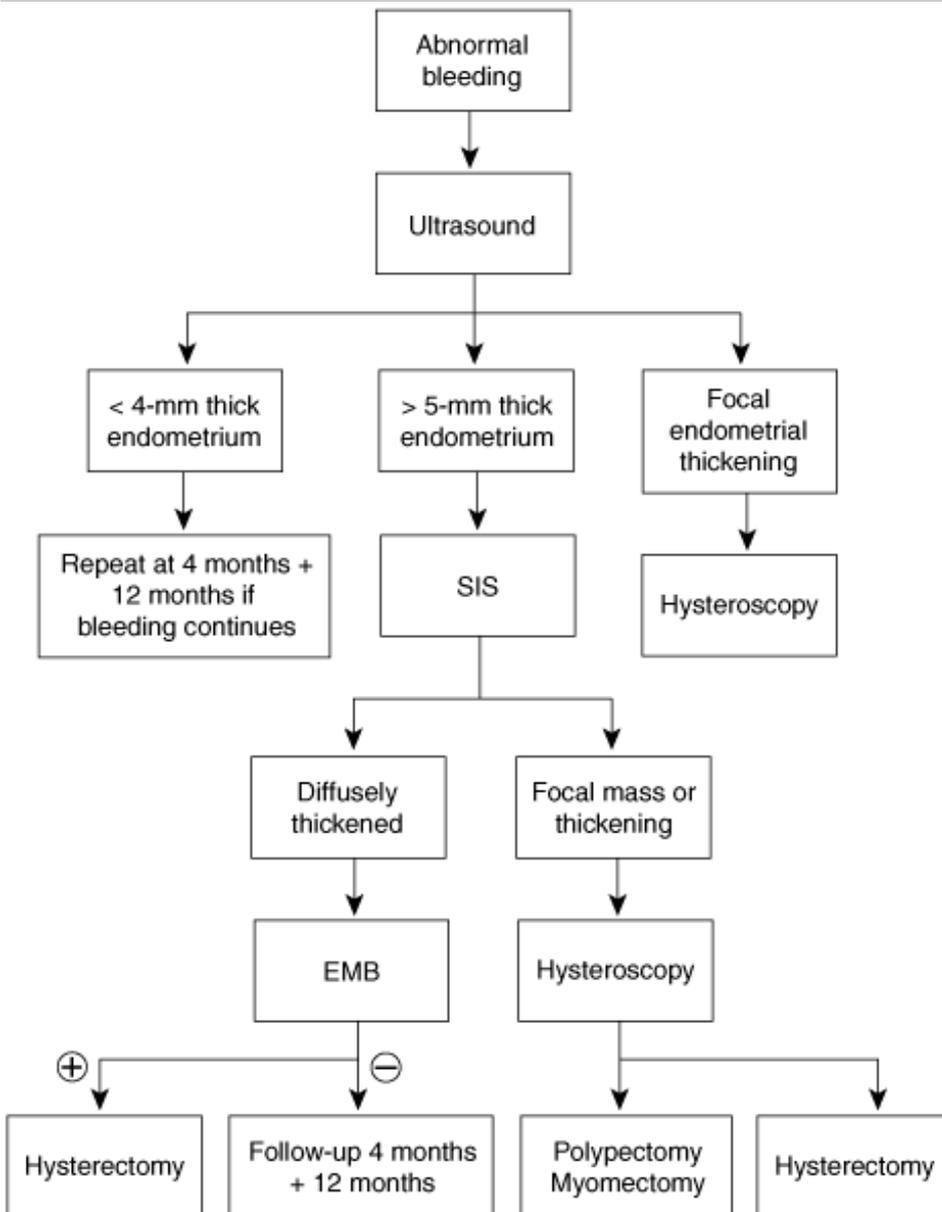

Approximately one-fifth of patients with abnormal uterine bleeding have submucous myomas and/or polyps. The lesions may be detected by irregularities in the endometrial stripe or by saline infusion sonohysterography (SIS), a technique that involves saline infusion to distend the uterine cavity. Using SIS, a polyp appears as a smoothly marginated focal lesion that protrudes into the endometrial cavity. A study comparing transvaginal sonography with SIS for detection of endometrial polyps found SIS had significantly greater sensitivity (93% versus 65%) and specificity (94% versus 76%) than transvaginal sonography alone.

The sensitivity and specificity rates of ultrasound in detecting endometrial pathology reportedly increase when color flow and power Doppler imaging are used. However, tissue sampling would be required to make a definitive diagnosis and to rule out malignancy in any patient not on HRT with a hyperechogenic endometrial stripe greater than 4 mm.

Three-dimensional ultrasonography (3-D US) has been studied for evaluation of the endometrium. The ability of 3-D US to produce coronal images of the cornua may increase slightly the sensitivity of SIS for detecting lesions in this location that otherwise might be difficult to evaluate. Endometrial abnormalities that can be seen in women

with congenital malformations of the uterus may be imaged to greater advantage with 3-D US techniques. Three dimensional ultrasonography has also been demonstrated to be a valid measurement technique for assessing volume. However, hysteroscopy likely will become the new gold standard for evaluating the endometrium because of the ability of hysteroscopy to visualize directly the endometrium and perform biopsies as indicated. The technique may become more cost-effective as use of office hysteroscopy becomes more widespread. Evaluation the endometrium using transvaginal sonography as the initial screening tool, followed by endometrial biopsy or possibly hysteroscopy, is likely to become the standard of care (Fig 3–4).

IMAGING OF THE OVARIES

Approximately 12,000 women in the United States die annually of ovarian cancer. Unfortunately, the ability of the pelvic examination to detect early ovarian malignancy is poor. Cancer antigen (CA)-125 monoclonal marker for ovarian cancer also is a poor predictor of early cases.

The flat plate of the abdomen may still be useful in the diagnosis of dermoid cysts of the ovary, which are identified by the presence of calcified teeth. However, cystic and solid structures of the ovary now are better evaluated by transabdominal ultrasonography, transvaginal ultrasonography (TVUS), computed tomography (CT) and MRI.

US is frequently used in the evaluation of ovarian pathology. TVUS combined with color flow and Doppler can be used for evaluation of blood flow to the adnexal structures and for diagnosis of ovarian torsion. Venous and lymphatic flow is occluded in early torsion, but arterial flow may be present. Arterial flow ceases completely later in the torsion. Torsion is diagnosed by Doppler study showing no venous or arterial flow, but a study showing arterial blood flow does not necessarily rule out the diagnosis.

In an attempt to discriminate between malignant and benign adnexal masses, morphologic criteria have been assigned to increase suspicion concerning ultrasound findings when ovarian cancer is suspected. Cysts larger than 4 cm, solid and cystic components, septa, and papillary nodules have all been described (Fig 3–5). In addition, Doppler flow studies have been used to distinguish between benign and malignant masses (Table 3–3).

CT may be useful for preoperative staging of ovarian cancer or for planning second-look procedures. CT may be useful for biopsy and drainage in patients with benign-appearing adnexal masses (ovarian cysts or tubo-ovarian abscesses). Contraindications to needle biopsy and drainage include lack of a safe unobstructed path for the needle, bleeding disorders, and lack of a motivated patient. Three-dimensional ultrasonography can be useful in the evaluation of gynecologic diseases. It can reconstruct any plane of interest and is particularly valuable in visualizing abnormalities in the coronal plane. In addition, 3-D US is better able to measure volumes than is 2-dimensional ultrasonography and therefore is helpful when evaluating patients with conditions ranging from fibroids to infertility. CT can be used in conjunction with pelvic US to diagnose and manage several conditions, such as pelvic inflammatory disease, adnexal torsion, ovarian vein thrombosis, and hemorrhagic ovarian cysts. In addition, MRI has been shown to be particularly useful in the evaluation of ovarian vein thrombosis.

IMAGING OF THE FALLOPIAN TUBES

Endoscopic techniques provide the best direct evaluation of the patency and architecture of the fallopian tubes. HSG provides the best indirect evaluation of tubal function. HSG allows demonstration of tubal patency and visualization of tubal rugations while avoiding the more costly laparoscopic surgery. Some disadvantages of HSG are pelvic infection, dye allergies, failure to detect adnexal adhesions, and false-positive results for tubal occlusion. Hysterosalpingo-contrast sonography and MRI are alternatives to laparoscopy, as women with normal findings probably have a normal pelvis. For example, transvaginal sonography may detect dilated fallopian tubes and tubo-ovarian complexes. (See the sections on pelvic inflammatory disease and tubo-ovarian abscess in Chapter 41 for more on the radiographic diagnosis and management of these conditions.)

IMAGING IN ECTOPIC PREGNANCY

Adnexal sonography is a valuable tool in assessing women with suspected ectopic pregnancy (Table 3–4). When human chorionic gonadotropin (hCG) levels reach 6500 mIU/mL, most normal intrauterine pregnancies can be

detected as a gestational sac by transabdominal US. However, the sonographic appearance of a pseudogestational sac should not be confused with the gestational sac. In the latter, a double-ring sign resulting from the decidua parietalis is seen abutting the decidua capsularis.

TVUS, on the other hand, has the advantage of earlier and better localization of the pregnancy, with less pelvic discomfort because the bladder is not painfully distended. An hCG level of 1000–2000 mIU/mL is the discriminatory zone in which an intrauterine pregnancy can be detected by TVUS. The double-ring sign and/or the yolk sac must be identified to ensure that the pregnancy is intrauterine. When an intrauterine pregnancy is not visualized on TVUS and the hCG level exceeds 1000–2000 mIU/mL, then suspicion for an ectopic pregnancy should be high. Also, multiple gestations may take several more days to be identified, and heterotopic pregnancies are encountered more frequently in patients using assisted reproductive techniques. Transvaginal sonography may also detect dilated fallopian tubes and tubo-ovarian complexes.

CONCLUSION

The imaging techniques prevalent today have proved to be valuable tools in the diagnosis and early treatment of benign and malignant gynecologic disorders. To provide the patient with the highest level of medical care, the contemporary practicing gynecologist must constantly keep abreast of the new developments and applications of diagnostic imaging.

No matter what technology is used today and in the future, the goal will always be the same: to provide quick, low-risk, accurate diagnosis of gynecologic conditions while keeping in mind the cost-effectiveness of the care delivered.

Current OB/GYN >Chapter 4. Embryology of the Urogenital System & Congenital Anomalies of the Female Genital Tract >

EMBRYOLOGY OF THE UROGENITAL SYSTEM & CONGENITAL ANOMALIES OF GENITAL TRACT: INTRODUCTION

In the urogenital system, knowledge of the embryology is crucial in understanding the functions and interconnections of the reproductive and urologic systems. The adult genital and urinary systems are distinct in both function and anatomy, but in the male urethra, where the two systems are interconnected. During development, these two systems are closely associated. A developmental overlap of these systems occurs 4–12 weeks after fertilization. The complexity of development is evident by the incomplete separation of the 2 systems found in some congenital anomalies. For the sake of clarity, the embryology of each system separately, rather than following a strict developmental chronology.

In view of the complexity and duration of differentiation and development of the genital and urinary systems, the incidence of malformations involving these systems is one of the highest (10%) of all body systems. Etiologies of congenital anomalies are sometimes categorized on the basis of genetic, environmental, or genetic-plus-environmental (so-called polygenic) factors. Known genetic and inheritance factors reportedly account for about 20% of anomalies detected at birth, for nearly 5%, and environmental factors for nearly 10%. The significance of these statistics must be viewed against the fact that (1) an estimated one-third to one-half of human zygotes are lost during the first week of gestation and (2) the cause of many anomalies is unknown. Even so, congenital malformations remain a matter of concern because they are detected at birth and 20% of perinatal deaths are purportedly due to congenital anomalies.

The inherent pattern of normal development of the genital system can be viewed as one directed toward somatic masculinization. This development is directed by factors for "maleness." The presence and expression of a Y chromosome (and its testis-determining factor) in the normal 46,XY karyotype of somatic cells directs differentiation toward a testis, and normal development of the testis produces male hormones for the selection and differentiation of the genital ducts. When male hormones are present, the mesonephros persists; when male hormones are not present, the "female" paramesonephric (Müllerian) ducts persist. Normal female development and masculinization of the external genitalia is also a result of the respective timely absence or presence of androgen.

An infant usually is reared as female or male according to the appearance of the external genitalia. However, gender is not always immediately discernible, and the choice of sex of rearing can be an anxiety-provoking consideration. Unfortunately, it is apparent, later clinical presentation may unmask disorders of sexual differentiation that can lead to problems with social adjustment. Whether a somatic disorder is detected at birth or later, investigative backtracking through the developmental process is necessary for proper diagnosis and treatment.

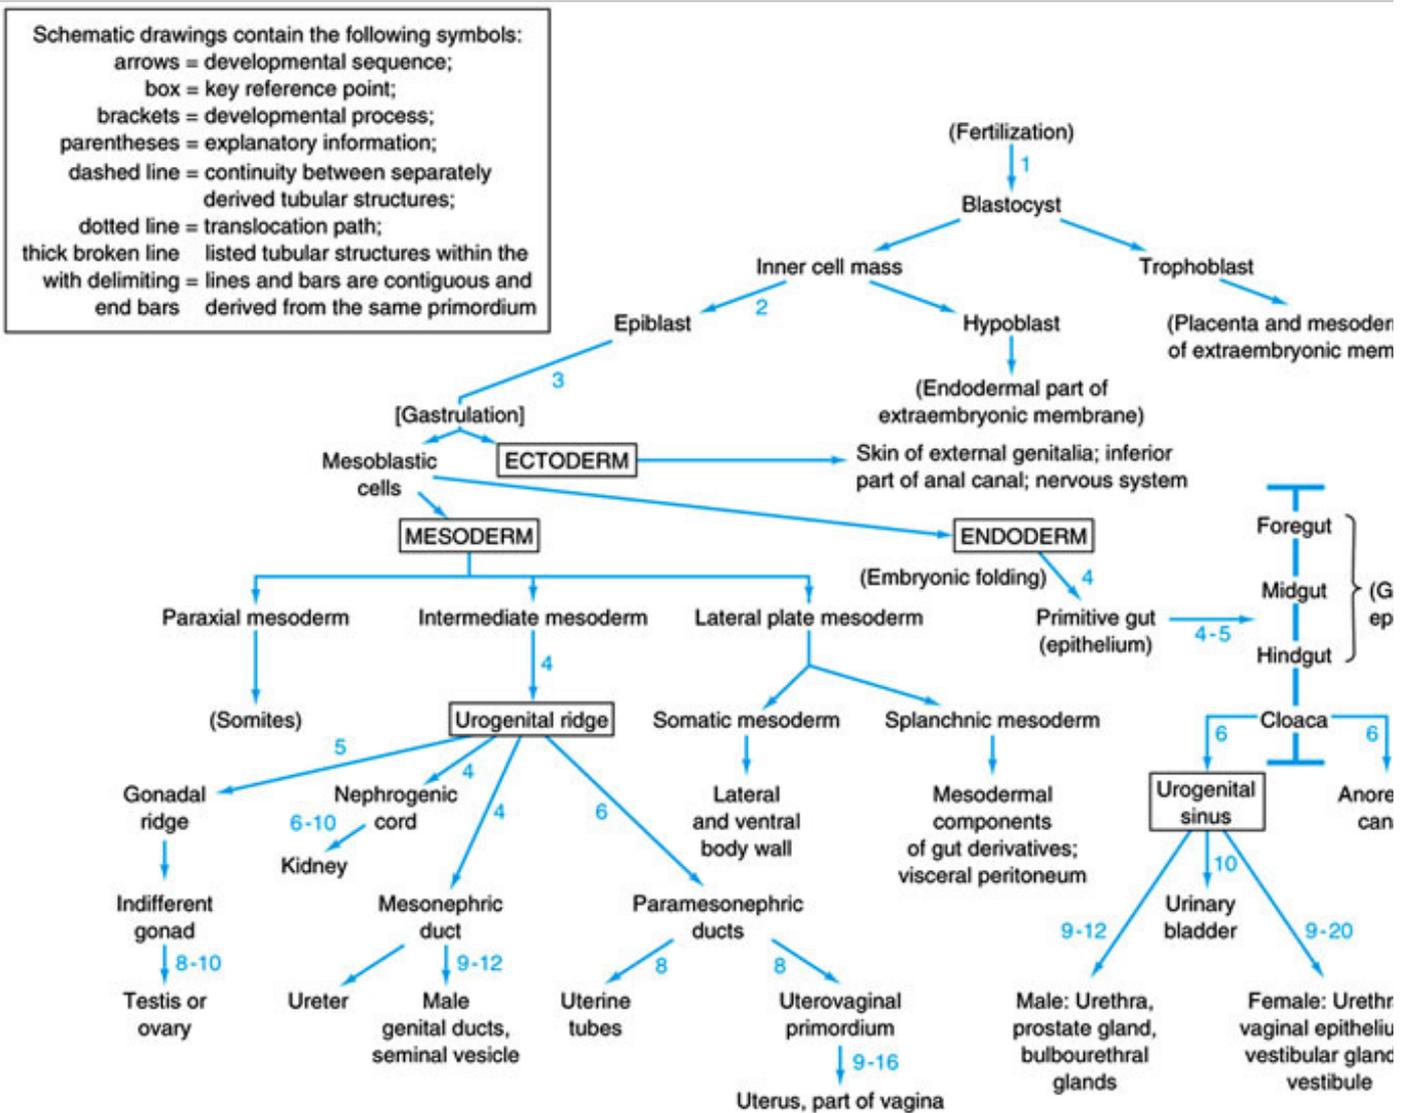

OVERVIEW OF THE FIRST FOUR WEEKS OF DEVELOPMENT *

*Embryonic or fetal ages given in this chapter are relative to the time of fertilization and should be considered estimates, not absolutes.

Transformation of the bilaminar embryonic disk into a trilaminar disk composed of ectoderm, mesoderm, and endoderm (the three embryonic germ layers) occurs during the third week by a process called gastrulation (Fig 4–1). During this process, the thickening of epiblast, the primitive streak, elongates through the midline of the disk. Some epiblastic cells become the notochord, which migrate peripherally between the epiblast and hypoblast, forming a middle layer of embryonic mesoderm.

migrate into the hypoblastic layer and form embryonic endoderm, which displaces the hypoblastic cells. The r becomes the embryonic ectoderm.

Figure 4-1.

Schematic overview of embryonic development of progenitory urinary and genital tissues and structures consider embryonic ectoderm, mesoderm, or endoderm. Numbers indicate the weeks after fertilization when the indicated occurs.

By the end of the third week, 3 clusters of mesoderm are organized on both sides of the midline neural tube. For clusters are paraxial mesoderm, which forms much of the axial skeleton; intermediate mesoderm, which is urogenital ridge and, hence, much of the reproductive and excretory systems (Fig 4-2); and lateral plate mesoderm, which takes part in body cavity formation. Rarely, degeneration of the primitive streak is incomplete after the fourth week, and remnants form a teratoma in the sacrococcygeal region of the fetus (more common in females than in males). The intermediate mesoderm is located between the paraxial and lateral plate mesoderm and is the origin of the urogenital ridge, reproductive and excretory systems (Fig 4-2). The primitive streak regresses after the fourth week. Rarely, degeneration is incomplete, and presumptive remnants form a teratoma in the sacrococcygeal region of the fetus (more common in females than in males).

males).

Schematic drawing of formation of the definitive kidney and its collecting ducts. The pronephric duct is probably participates in all 3 urinary systems, as its caudal portion continues to grow and is called the mesonephric duct v system develops. (Explanatory symbols are given in Fig 4–1.)

Weeks 4 through 8 of development are called the embryonic period (the fetal period is from week 9 to term) major internal and external structures, including the 2 primary forerunners of the urogenital system (urogenital begins during this time. During this period the embryo is most likely to develop major congenital or acquired mc response to the effects of various agents. During the fourth week, the shape of the embryo changes from that o

of a crescentic cylinder. The change results from "folding," or flexion, of the embryonic disk in a ventral direction in transverse and longitudinal planes. Flexion occurs as midline structures (neural tube and somites) develop and more lateral tissues (ectoderm, 2 layers of lateral plate mesoderm enclosing the coelom between them, and endoderm) undergo transverse folding, the lateral tissues on each side of the embryo curl ventromedially and join the respective tissues creating a midline ventral tube (the endoderm-lined primitive gut), a mesoderm-lined coelomic cavity (the primitive cavity), and the incomplete ventral and lateral body wall. Concurrent longitudinal flexion ventrally of the caudal end establishes the pouchlike distal end, or cloaca, of the primitive gut as well as the distal attachment of the cloaca: the allantois of the sac (Fig 4–3).

Figure 4–3.

Early stage in the formation of the mesonephric kidneys and their collecting ducts in the urogenital ridge. The center is the nephrogenic cord, in which the mesonephric tubules are forming. The mesonephric ducts grow toward (arrows) the cloaca. About 5 weeks' gestation.

A noteworthy point (see The Gonads) is that the primordial germ cells of the later-developing gonad initially are in the urogenital sinus and later migrate to the gonadal primordia. Subsequent partitioning of the cloaca during the sixth week results in the anorectal canal and the urogenital sinus, the progenitor of the urinary bladder, urethra, vagina, and other genital structures (see Table 4–1; see Subdivision of the Cloaca & Formation of the Urogenital Sinus).

Embryonic folding also moves the intermediate mesoderm—the forerunner of the urogenital ridge—to its characteristic locations as bilateral longitudinal bulges in the dorsal wall of the new body cavity and lateral to the dorsal mesenteries. By the end of the fourth week of development, the principal structures (urogenital ridge and cloaca) and tissues of the urogenital system are present.

THE URINARY SYSTEM

Three excretory "systems" form successively, with temporal overlap, during the embryonic period. Each system "organ," but the 3 systems share anatomic continuity through development of their excretory ducts. The 3 systems are derivatives of the urogenital ridge (Figs 4–2 and 4–3), part of which becomes a longitudinal mass, the nephrogenic ridge. The first system, the pronephros, or organ of the first system, exists rudimentarily, is nonfunctional, and regresses during the fourth week. The second system, the mesonephros, or organ of the second system, exists rudimentarily, is nonfunctional, and regresses during the fourth week. The developing pronephric ducts continue to grow and become the mesonephric ducts of the subsequent kidney, the paired mesonephroi exist during 4–8 weeks as simplified morphologic versions of the third, or permanent, set of ducts. They have transient excretory function. Although the mesonephroi degenerate, some of its tubules, called epigenital tubules, persist to participate in formation of the gonad and male ductuli efferentes (Fig 4–4). The permanent kidney, the metanephros, forms in response to an inductive influence of a diverticulum of the mesonephric ducts during the fifth week and continues to develop until 10–13 weeks.

Figure 4–4.

All rights reserved.

Schematic drawing of the formation of the gonads and genital ducts.

Differentiation of the caudal segment of the mesonephric ducts results in (1) incorporation of part of the ducts into the urogenital sinus (early vesicular trigone, see following text), and (2) formation of a ductal diverticulum, which is the precursor of the definitive kidney. If male sex differentiation occurs, the major portion of each duct becomes the deferens, and ejaculatory duct. Only small vestigial remnants of the duct sometimes persist in the female (Gartepoophoron).

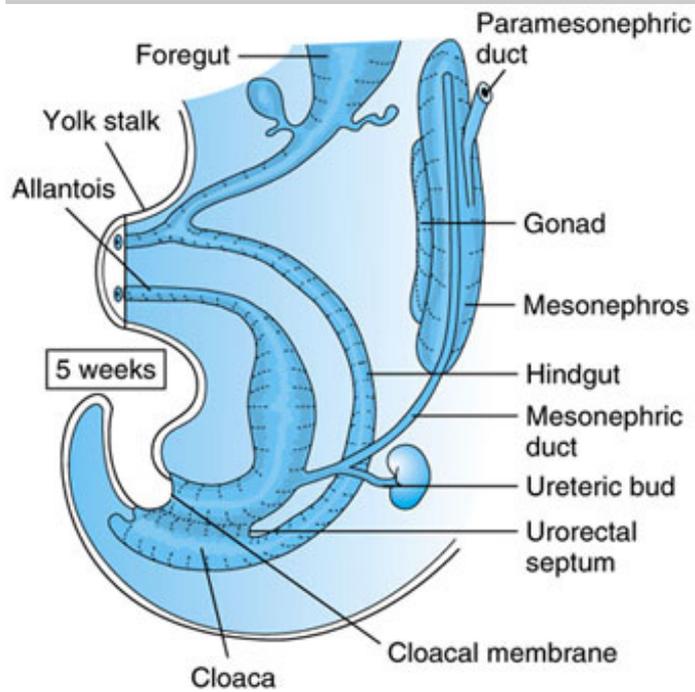

Metanephros (Definitive Kidney)

COLLECTING DUCTS

By the end of the fifth week, a ureteric bud, or metanephric diverticulum, forms on the caudal part of the mesonephros. The bud gives rise to the collecting tubules, calices, renal pelvis, and ureter (Fig 4-2). The stalk of the ureter is the part of the duct that remains between the stalk and the cloaca. The expanded tip, or the ureter, when the ductal segment between the stalk and the cloaca becomes incorporated into the wall of the metanephros, a derivative of the partitioned cloaca, see text that follows; Figs 4-5, 4-6, 4-7, and 4-8). The expanded tip, or

into the adjacent metanephric mesoderm (blastema) and subdivides successively into 12–15 generations of tubules. From weeks 10–14, dilatation of the early generations of tubular branches successively produces the major calices, and the minor calices, while the middle generations form the medullary collecting tubules. The last set of collecting tubules grow centrifugally into the cortical region of the kidney between weeks 24 and 36.

Nephrons

Continued maintenance of the intimate relationship of the metanephric blastema and ampulla is necessary for the formation of definitive excretory units (nephrons), which starts at about the eighth week. Formation of urine purportedly begins when an estimated 20% of the nephrons are morphologically mature.

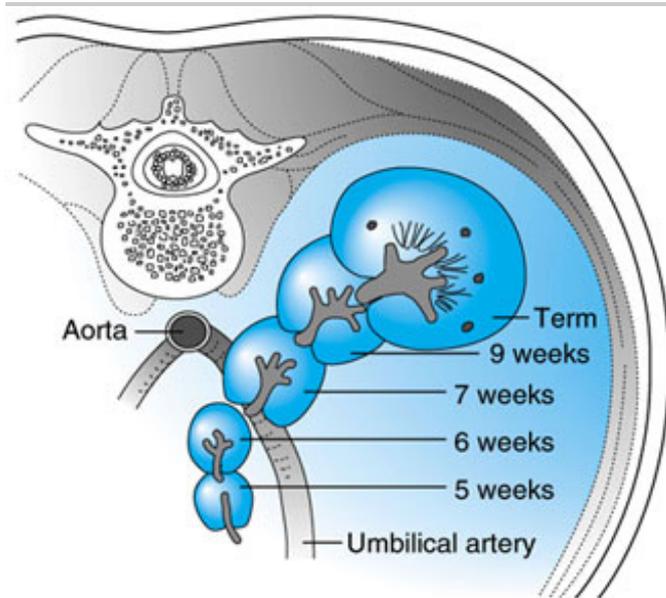

The last month of gestation is marked by interstitial growth, hypertrophy of existing components of uriniferous tubules, and disappearance of bud primordia for collecting tubules. Opinions differ about whether formation of nephrons ceases at 32 weeks or postnatally during the first several months. If the ureteric bud fails to form, or undergoes early degeneration into the nephrogenic mesoderm, aberrations of nephrogenesis result. These may be nonthreatening (unilateral or even fatal (bilateral renal agenesis, polycystic kidney)).

POSITIONAL CHANGES

Figure 4–9 illustrates relocation of the kidney to a deeper position within the posterior body wall, as well as the medial rotation of the organ on its longitudinal axis. Rotation and lateral positioning probably are facilitated by the developing axial structures (axial skeleton and muscles). The "ascent" of the kidney between weeks 5 and 8 can be attributed largely to longitudinal growth of the rest of the lumbosacral area and to the reduction of the rather sharp curvature of the embryo. Some migration of the kidney may also occur. Straightening of the curvature also may be attributable to growth, especially the development of the infraumbilical abdominal wall. As the kidney moves into its final position (by the 12th week), its arterial supply shifts to successively higher aortic levels. Ectopic kidneys can result from abnormal migration beginning at the seventh week, the "ascending" metanephroi closely approach each other near the aortic bifurcation. The close apposition

developing kidneys can lead to fusion of the lower poles of the kidneys, resulting in formation of a single horseshoe kidney which would be arrested by the stem of the inferior mesenteric artery. Infrequently, a pelvic kidney results from a kidney that has descended from beneath the umbilical artery, which restricts passage out of the pelvis.

THE GENITAL SYSTEM

Sexual differentiation of the genital system occurs in a basically sequential order: genetic, gonadal, ductal, and external genitalia. The sex of the individual is determined at fertilization by the complement of sex chromosomes (ie, XY specifies a genotypic male and XX a female). Morphologic indications of the sex of the developing embryo do not appear until about the eighth or ninth week; there is a so-called indifferent stage, when morphologic identity of sex is not clear or when preferential differentiation has not been imposed on the sexless primordia. This is characteristic of early developmental stages for the gonads, ducts, and external genitalia. When the influence of genetic sex has been expressed on the indifferent gonad, gonadal sex is established. In the male, the SRY gene in the short arm of the Y chromosome of normal genetic males is the candidate for the gene encoding for the testis-determining factor (TDF). TDF initiates a chain of events that transforms the indifferent gonad into a testis with its subsequent production of antimüllerian hormone and testosterone, which influence "maleness" (see Testis). Normal genetic females do not have the SRY gene, and the early undifferentiated mesonephric duct (presumptive gonad) does not produce the TDF (see Ovary).

The testis and ovary are derived from the same primordial tissue, but histologically visible differentiation toward male or female occurs. An "ovary" is first recognized by the absence of testicular histogenesis (eg, thick tunica albuginea, absence of germ cells entering meiotic prophase between the 8th and about the 11th week). The different primary genital ducts exist in each embryo during overlapping periods, but establishment of male or female ductal sex depends on the presence or absence, respectively, of testicular products and the sensitivity of tissues to these products. The 2 primary testicular androgenic steroids (testosterone and nonsteroidal antimüllerian hormone) (see Testis). Stimulation by testosterone leads to the persistence and differentiation of the "male" mesonephric ducts (wolffian ducts), whereas antimüllerian hormone causes regression of the "female" paramesonephric ducts (müllerian ducts). Absence of these hormones in a nonaberrant condition leads to regression of müllerian ducts and regression of wolffian ducts, ie, initiation of development of the uterus and uterine tubes. External genitalia subsequently develops according to the absence or presence of androgen. Thus, the inherent pattern of development of the genital system is determined by the presence or absence of androgen.

genital system can be viewed as one directed toward somatic "femaleness" unless the system is dominated by "maleness" (eg, gene expression of the Y chromosome, androgenic steroids, and antimüllerian hormone).

THE GONADS

Indifferent (Sexless) Stage

Gonadogenesis temporally overlaps metanephrogenesis and interacts with tissues of the mesonephric system. It is summarized schematically in Fig 4–4.

Around the fifth week, the midportion of each urogenital ridge thickens as cellular condensation forms the gonad. For several weeks, this ridge is an undifferentiated cell mass, lacking either testicular or ovarian morphology. As shown in Fig 4–4, the gonad consists of (1) primordial germ cells, which translocate into the ridge, and a mixture of somatic cells derived from (2) coelomic epithelial cells, (3) condensation of the underlying mesenchyme of part of the urogenital ridge, and (4) mesonephric-derived cells.

The end of the gonadal indifferent stage in the male is near the middle of the seventh week, when a basal lamina epithelium and the developing tunica albuginea separates the coelomic epithelium from the developing testicular cords. In the female, this stage ends around the ninth week, when the first oogonia enter meiotic prophase.

Primordial germ cells, presumptive progenitors of the gametes, become evident in the late third to early fourth week. They migrate from the wall of the yolk sac and the mesenchyme around the allantois. The allantois is a caudal diverticulum of the yolk sac that invaginates into the primitive umbilical stalk and, after embryonic flexion, is adjacent proximally to the cloacal hindgut. The germ cells translocate from the allantoic region (about the middle of the fourth week) to the urogenital ridge (between the fourth and late in the sixth week). It is not known whether primordial germ cells must be present in the gonadal ridge to form a functional gonad to occur. The initial stages of somatic development appear to occur independently of the germ cells. Later in the male testis, but not in the ovary, is known to occur in the absence of germ cells. The germ cells appear to have some degree of differentiation at certain stages of development.

Testis

During early differentiation of the testis, there are condensations of germ cells and somatic cells, which have been organized into cords, or sheets. These groups are at first distributed throughout the gonad and then become more organized into cords. The cords begin to form centrally and are arranged somewhat perpendicular to the long axis of the gonad. As these cords differentiate into Sertoli cells. The first characteristic feature of male gonadal sex differentiation is evident when the tunica albuginea begins to form in the mesenchymal tissue underlying the coelomic epithelium. Eventually, the development of tissue causes the developing testicular cords to be separated from the surface epithelium and placed deeper in the gonad. The surface epithelium re-forms a basal lamina and later thins to a mesothelial covering of the gonad. The cords thicken peripherally and thicken as their cellular organization becomes more distinct. A basal lamina eventually develops although it is not known if the somatic cells, germ cells, or both are primary contributors to the lamina.

Throughout gonadal differentiation, the developing testicular cords appear to maintain a close relationship to the mesonephric-derived cell mass. An interconnected network of cords, rete cords, develops in this cell mass and eventually forms the testis. The rete testis joins centrally with neighboring epigenital mesonephric tubules, which become the efferent ducts. The rete testis with the epididymis, a derivative of the mesonephric duct. With gradual enlargement of the testis and mesonephros, a cleft forms between the 2 organs, slowly creating the mesentery of the testis, the mesorchium.

The differentiating testicular cords are made up of primordial germ cells (primitive spermatogonia) and somatic cells (sustentacular cells, or Sertoli cells). Some precocious meiotic activity has been observed in the fetal testis, but usually does not begin until puberty; the cause of this delay is unknown. Besides serving as "supporting cells" for spermatogonia, Sertoli cells also produce the glycoprotein antimüllerian hormone (also called müllerian-inhibiting substance). Antimüllerian hormone causes regression of the paramesonephric (müllerian) ducts, apparently during a very discrete period of sensitivity in male fetuses. At puberty, the seminiferous cords mature to become the seminiferous tubules, and the

spermatogonia mature.

Shortly after the testicular cords form, the steroid-producing interstitial (Leydig) cells of the extracordal compartment differentiate from stromal mesenchymal cells, probably due to antimüllerian hormone. Mesonephric-derived cells are the source of Leydig cells. Steroidogenic activity of Leydig cells begins near the tenth week. High levels of testosterone are maintained through weeks 16–18. Steroid levels are somewhat in accordance with changes in the concentration of Leydig cells. Both the number of cells and the level decrease around the fifth month.

Ovary

DEVELOPMENT

In the normal absence of the Y chromosome or the sex-determining region of the Y chromosome (SRY gene; sex-determining region Y), the somatic sex cords of the indifferent gonad do not produce TDF. In the absence of TDF, differentiation of the gonad, and subsequent production of antimüllerian hormone and testosterone do not occur (see Testis). The indifferent gonad develops into an ovary. Complete ovarian differentiation seems to require two X chromosomes (XO females exhibit ovarian dysgenesis, with precociously degenerated germ cells and no follicles and are present as gonadal "streaks"). The first recognition of an ovary is around weeks 9–10, based on the temporal absence of testicular-associated features (most prominently, the testicular cords) and the presence of early meiotic activity in the germ cells.

Early differentiation toward an ovary involves mesonephric-derived cells "invading" the basal region (adjacent to the region of the gonad; central and basal regions represent the primitive "medullary" region of the gonad). At the time of invasion, the cells are displaced somewhat peripherally into the "cortical" region of the gonad. Some of the central mesonephric cords of the mesonephric system that subsequently forms a network of cords (intraovarian rete cords) extending to the primitive cortex. The cords extend peripherally between germ clusters, several epithelial cell proliferations extend centrally, and some mixing of germ cells apparently takes place around the germ cell clusters. These early cordlike structures are more irregularly distributed than in the testis and not distinctly outlined. The cords open into clusters of germ cells, but all germ cells are not confined to the cords. Germ cells that begin meiosis are located in the innermost part of the cortex and are the first germ cells to contact the intraovarian rete cords. Folliculogenesis begins in the innermost part of the cortex when the central somatic cells of the cord contact a germ cell while an intact basal lamina is laid down. These somatic cells are morphologically similar to the mesonephric cells of the intraovarian rete cords associated with the oocytes and apparently differentiate into the presumptive granulosa cells. Folliculogenesis continues peripherally. Between weeks 12 and 20 of gestation, proliferative activity causes the cords to become a thickened, irregular multilayer of cells. In the absence of a basal lamina, the cords and apparent epithelial cells of underlying tissues. These latter cortical cords often retain a connection to and appear similar to the surface epithelium. The epithelium of these cords probably differentiates into granulosa cells and contributes to folliculogenesis, although this occurs only in the outer part of the cords. Follicles fail to form in the absence of oocytes or with precocious loss of oocytes not encompassed by follicular cells degenerate.

Stromal mesenchymal cells, connective tissue, and somatic cells of cords not participating in folliculogenesis form the stroma of the late fetal ovary. Individual primordial follicles containing diplotene oocytes populate the inner and outer cortex. The rete ovarii may persist, along with a few vestiges of mesonephric tubules, as the vestigial epoophoron near the mesonephros. In the male, to the testicular mesorchium, the mesovarium eventually forms as a gonadal mesentery between the ovary and the mesonephros. Postnatally, the epithelial surface of the ovary consists of a single layer of cells continuous with peritoneal mesothelium at the hilum. A thin, fibrous connective tissue, the tunica albuginea, forms beneath the surface epithelium and separates the surface from the follicles.

ANOMALIES OF THE OVARIES

Anomalies of the ovaries encompass a broad range of developmental errors from complete absence of the ovaries to hyperplasia of the ovaries. The many variations of gonadal disorders usually are subcategorized within classifications of disorders of the sex chromosomes. Unfortunately, there is little consensus for a major classification, although most include pathogenetic considerations.

of the different classifications are offered in the references to this chapter.

Congenital absence of the ovary (no gonadal remnants found) is very rare. Two types have been considered, a definition, agenesis implies that the primordial gonad did not form in the urogenital ridge, whereas agonadism gonads that may have formed initially and subsequently degenerated. It can be difficult to distinguish one type from the other on a practical basis. For example, a patient with female genital ducts and external genitalia and a 46,XY karyotype could have gonadal agenesis or agonadism. In the latter condition, the gonad may form but undergo early degeneration and no virilizing expression is made. *Whenever congenital absence of the ovaries is suspected, careful examination of the external genitalia, and the genital ducts must be performed.*

Descriptions of agonadism usually have indicated that the external genitalia are abnormal (variable degree of fusiform swellings) and that either very rudimentary ductal derivatives are present or there are no genital ducts. The cause is unknown, although several explanations have been suggested, such as (1) failure of the primordial gonad to form or (2) partial differentiation and then regression and absorption of testes (accounting for the presence of müllerian ducts but lack of stimulation of mesonephric, or wolffian, ducts). Explanations that include teratogenic causes are more likely candidates in view of the associated incidence of nonsexual somatic anomalies with the disorder. The streak gonad is a product of primordial gonadal formation and subsequent failure of differentiation, which can occur at various stages. It appears as a fibrouslike cord of mixed elements (lacking germ cells) located parallel to a uterine tube. Streak gonadism is associated with gonadal dysgenesis and a 45,XO karyotype (Turner's syndrome; distinctions are drawn between Turner's syndrome and gonadal dysgenesis when consideration is given to the various associated somatic anomalies of gonadal dysgenesis). How the disorder is consequent to genetic mutation or hereditary disease other than the anomalous karyotype.

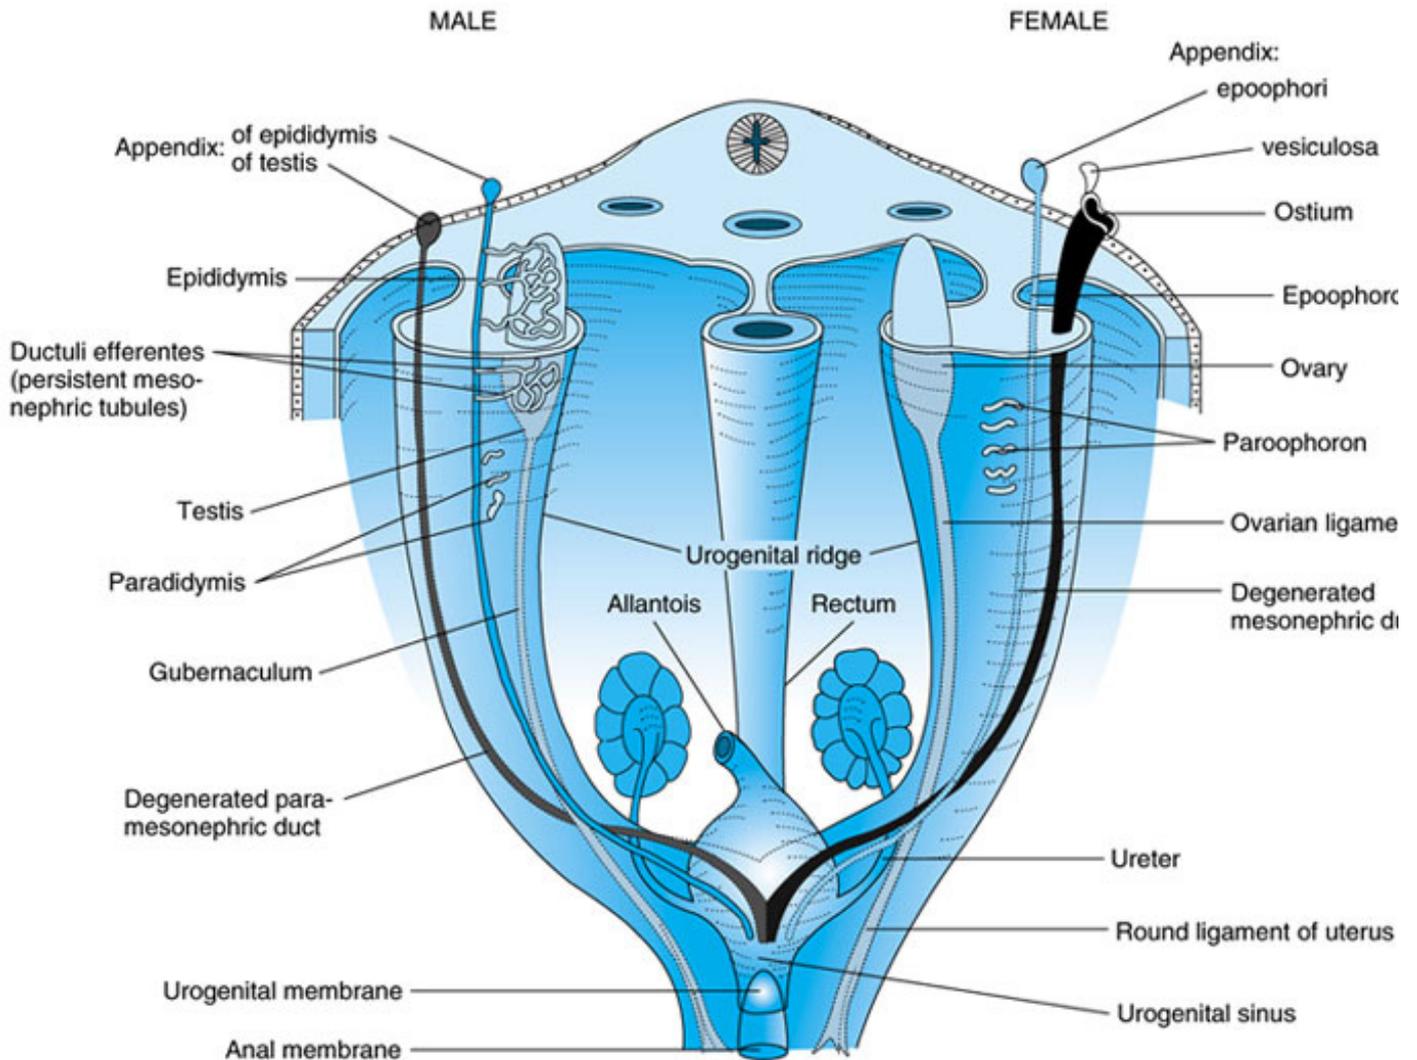

Ectopic ovarian tissue occasionally can be found as accessory ovarian tissue or as supernumerary ovaries. The former is a product of disaggregation of the embryonic ovary, and the latter may arise from the urogenital ridge as independent structures.

SUBDIVISION OF THE CLOACA & FORMATION OF THE UROGENITAL SINUS

The endodermally lined urogenital sinus is derived by partitioning of the endodermal cloaca. It is the precursor of the urinary and genital structures specific to each sex (Fig 4-1). The cloaca is a pouchlike enlargement of the hindgut and is formed by the process of "folding" of the caudal region of the embryonic disk between 4 and 5 weeks (Overview of the First Four Weeks of Development; Figs 4-1 and 4-3). During the "tail-fold" process, the posterior wall of the allantoic diverticulum of the yolk sac, becomes an anterior extension of the cloaca (Figs 4-3 and 4-5). Soon after, the cloaca receives posterolaterally the caudal ends of the paired mesonephric ducts and hence becomes a junctional chamber between the hindgut, and the ducts. A cloacal membrane, composed of ectoderm and endoderm, is the caudal limit of the hindgut and temporarily separates the cloacal cavity from the extraembryonic confines of the amniotic cavity (Fig 4-5).

Between weeks 5 and 7, 3 wedges of splanchnic mesoderm, collectively called the urorectal septum, proliferate in the caudal region of the embryo to eventually subdivide the cloaca (Figs 4-5, 4-6, 4-7, and 4-8). The superior fold, called the Tourneux fold, is in the angle between the allantois and the primitive hindgut, and it proliferates caudally into the wall of the cloaca (Fig 4-5). The other 2 mesodermal wedges, called the Rathke folds, proliferate in the right and left wall adjacent to the cloacal membrane, these laterally placed folds grow toward each other and the Tourneux fold. While creating a urorectal septum, the once single chamber is subdivided into the primitive urogenital sinus (ventral chamber) and the anal canal of the hindgut (dorsally; Figs 4-6, 4-7, and 4-8). The mesonephric ducts and allantois then open into the primitive urogenital sinus. The primordialium of the fused paramesonephric ducts will contact the sinus wall between the mesonephric ducts early in development. However, it can be noted that the junctional point of fusion of the cloacal membrane and urorectal septum creates a primitive perineum (later differentiation creates the so-called perineal body of tissue) and subdivides the cloaca into the urogenital sinus (anteriorly) and the anal membrane (posteriorly; Figs 4-5, 4-8, 4-10, and 4-20).

THE GENITAL DUCTS

Indifferent (Sexless) Stage

Two pairs of genital ducts are initially present in both sexes: (1) the mesonephric (wolffian) ducts, which give rise to the seminal vesicles; and (2) the paramesonephric (müllerian) ducts, which form the oviduct and vagina. When the adult structures are described as derivatives of embryonic ducts, this refers to the epithelial lining and connective tissues of the differentiating structures originate from splanchnic mesoderm and mesonephros. Mesonephric ducts are originally the excretory ducts of the mesonephric "kidneys" (see previous text), and they regress during the embryonic period, about 2 weeks before development of paramesonephric ducts (weeks 6–10). The 2 pairs of genital ducts have an anatomic relationship in their bilateral course through the urogenital ridge. At their caudal limit, both sets of ducts contact the urogenital sinus (Figs 4–5, 4–6, and 4–10). *Determination of the ductal sex of the genital ducts will continue differentiation rather than undergo regression) is established initially by the gonadal sex and the influence of hormones.*

Formation of each paramesonephric duct begins early in the sixth week as an invagination of coelomic epithelium at the cranial end of the urogenital ridge and adjacent to each mesonephric duct. The free edges of the invaginated ep

duct except at the site of origin, which persists as a funnel-shaped opening, the future ostium of the oviduct. The paramesonephric duct grows caudally through the mesenchyme of the urogenital ridge and laterally parallel to and inferiorly, the paramesonephric duct has a caudomedial course, passing ventral to the mesonephric duct. As it bends at the caudal portion of the urogenital ridge, the paramesonephric duct then lies medial to the mesonephric duct and lies in close apposition to its counterpart from the opposite side (Fig 4–10). At approximately the eighth week, the right and left ducts fuse medially and their lumens coalesce to form a single cavity. This conjoined portion of the paramesonephric ducts becomes the uterovaginal primordium, or canal.

Male: Genital Ducts

MESONEPHRIC DUCTS

The mesonephric ducts persist in the male and, under the stimulatory influence of testosterone, differentiate into the epididymis, ductus deferens, and ejaculatory ducts. Near the cranial end of the duct, some of the mesonephric tubules (epididymic tubules) of the mesonephric kidney persist lateral to the developing testis. These tubules form a coiled epididymis, between the duct and the rete testis (Fig 4–10). The cranial portion of each duct becomes the convoluted epididymis. The ductus deferens forms when smooth muscle from adjacent splanchnic mesoderm is added to the mesonephric duct. The seminal vesicle develops as a lateral bud from each mesonephric duct just distal to the urogenital sinus (Fig 4–7). The terminal segment of the duct between the sinus and seminal vesicle forms the ampulla and becomes encased by the developing prostate gland early in the 12th week (see Differentiation of the Urogenital System). The ampulla of the duct may persist cranially near the head of the epididymis as the appendix epididymis, whereas remnants near the inferior pole of the testis and tail of the epididymis may persist as the paradidymis (Fig 4–10).

PARAMESONEPHRIC DUCTS

The paramesonephric ducts begin to undergo morphologic regression centrally (and progress cranially and caudally) to meet the urogenital sinus caudally (approximately the start of the ninth week). Regression is effected by nonsteroidal antiandrogens produced by the differentiating Sertoli cells slightly before androgen is produced by the Leydig cells (see Testis). The regression begins from the time of early testicular differentiation until birth (ie, not only during the period of regression of the duct). However, ductal sensitivity to antimüllerian hormone in the male seems to exist for only a short "critical" time period, the signs of ductal regression. Vestigial remnants of the cranial end of the ducts may persist as the appendix testis, or hydatid of Morgagni, near the testis (Fig 4–10). Caudally, a ductal remnant is considered to be part of the prostatic utricle of the seminal vesicle and urethra.

RELOCATION OF THE TESTES AND DUCTS

Around weeks 5–6, a bandlike condensation of mesenchymal tissue in the urogenital ridge forms near the caudal end. Distally, this gubernacular precursor tissue grows into the area of the undifferentiated tissue of the anterior abdominal wall. Proximally, the gubernaculum contacts the mesonephric duct when the mesonephros regresses and the duct to form. By the start of the fetal period, the mesonephric duct begins differentiation and the gubernaculum adheres to the duct, which lies in the mesorchium of the testis. The external genitalia differentiate over the seventh to the 12th week, the testis is near the deep inguinal ring, and the gubernaculum is virtually at the inferior pole of the testis in the mesenchyme of the scrotal swellings, distally.

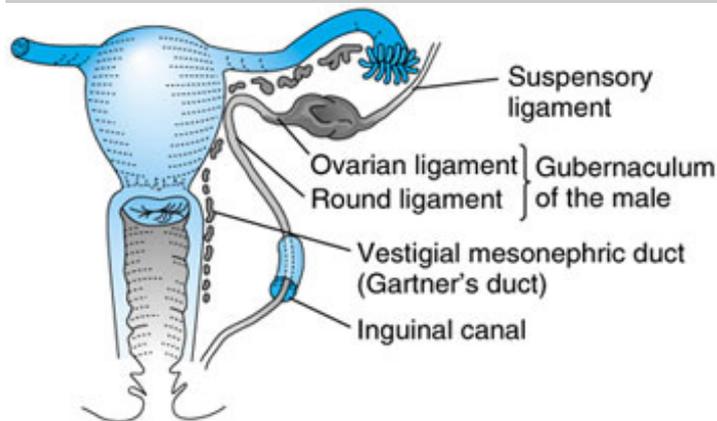

Although the testis in early development is near the last thoracic segment, it is still close to the area of the developing gubernaculum. With rapid growth of the lumbar region and "ascent" of the metanephric kidney, the testis remains relatively immobile near the gubernaculum, although there is the appearance of a lengthy transabdominal "descent" from an upper abdominal level. The gubernaculum descends through the inguinal canal around the 28th week and into the scrotum about the 32nd week. Testicular descent is complete by the 36th week. The testis is located on the dorsal body wall and retains its origin during the transabdominal and pelvic descent. The mesonephric duct follows the descent of the testis and hence passes anterior to the ureter, which follows the retroperitoneal course of the kidney (Fig 4–10).

Female: Uterus and Uterine Tubes

MESONEPHRIC DUCTS

Virtually all portions of these paired ducts degenerate in the female embryo, with the exception of the most caudal ureteric bud and the cloaca, which is later incorporated into the posterior wall of the urogenital sinus (Figs 4–5 and 4–6). Regression begins just after gonadal sex differentiation and is finished near the onset of the fetal period. Tubular vestiges of mesonephric duct (Fig 4–11) may persist to variable degrees parallel with the vagina and uterus. Other mesonephric remnants of the duct or tubules may persist in the broad ligament (epoophoron).

Figure 4–11.

Female genital tract. Gubernacular derivatives and mesonephric vestiges are shown.

PARAMESONEPHRIC DUCTS

Differentiation of müllerian ducts in female embryos produces the uterine tubes, uterus, and probably the fibromyometrium. In contrast to the ductal/gonadal relationship in the male, ductal differentiation in the female does not require the formation of the paramesonephric ducts during the second half of the embryonic period [the (Sexless) Stage]. By the onset of the fetal period, the 2 ducts are joined caudally in the midline, and the fused Y-shaped ductal structure is the uterovaginal primordium (Fig 4–8). The nonfused cranial part of each paramesonephric duct forms the uterine tubes (oviducts), and the distal end of this segment remains open and will form the ostium of the fallopian tube. Early in the ninth week, the uterovaginal primordium contacts medianly the dorsal wall of the urogenital sinus. This contact occurs at a median position between the bilateral openings of the mesonephric ducts, which joined the dorsal wall during the embryonic period. A subdivision of the urogenital sinus from the cloaca occurred (Figs 4–8 and 4–9). A ventral protrusion of the dorsal wall of the urogenital sinus forms at the area of contact of the uterovaginal primordium with the wall and between the openings of the mesonephric ducts. In reference to its location, this protrusion is called the sinusal tubercle (sinus tubercle, paramesonephric tubercle). This tubercle may consist of several types of epithelia derived from the different ducts as well as from the wall of the urogenital sinus. Shortly after the sinusal tubercle forms, midline fusion of the middle and caudal portions of the paramesonephric ducts occurs. The vertical septum (apposed walls of the fused ducts) within the newly established uterovaginal primordium degenerates, forming a cavity or canal (Fig 4–12). The solid tip of this primordium continues to grow caudally, while a mesenchymal thickening surrounds the cervical region of the uterovaginal primordium. The primordium gives rise to the fundus, body, and cervix of the uterus. The endometrial stroma and smooth muscle of the uterus are derived from adjacent splanchnic mesenchyme. The epithelium of the cervix forms from the lower aspect of the paramesonephric duct. The epithelium of the various components of the uterus covers the 3 trimesters of gestation. The basic structure is generated during the first trimester. The initial formation of glands and muscular layer occurs near midgestation, whereas mucinous cervical glands form during the third trimester.

Sagittal cutaway view of female urogenital sinus and uterovaginal primordium (fused paramesonephric ducts). See the tenth week.

The formation of the vagina is discussed in Differentiation of the Urogenital Sinus, even though the question of whether the vaginal epithelium is a sinusal or paramesonephric derivative (or both) has not been resolved. The fibromuscular wall of the vagina is considered to be derived from the uterovaginal primordium (Fig 4–13).

Schematic drawing of differentiation of urogenital sinus and paramesonephric ducts in the female; formation of uterine tubes, uterus, and vagina. (Explanatory symbols are given in Fig 4–1.)

RELOCATION OF THE OVARIES AND FORMATION OF LIGAMENTS

Transabdominal "descent" of the ovary, unlike that of the testis, is restricted to a relatively short distance, presumably because of attachment of the gubernaculum to the paramesonephric duct. Hence, relocation of the ovary appears as a passive rotatory movement of the ovary as its mesentery is drawn by the twist of the developing ductal mesentery in the lumbosacral region of the fetus. The ovarian vessels (like the testicular vessels) originate or drain during development of the gonad, the arteries from the aorta just inferior to the renal arteries and the veins to the left cava from the right gonad.

Initial positioning of the ovary on the anteromedial aspect of the urogenital ridge is depicted in Fig 4–10, as is the position of the paramesonephric duct lateral to the degenerating mesonephros, the ovary, and the urogenital mesentery. The space between the ridge and the dorsal body wall represents the first mesenteric support for structures developing in the urogenital ridge. Alterations within the urogenital ridge eventually result in formation of contiguous double-layered mesenteries separating the unfused segments of the paramesonephric ducts. Enlargement of the ovary and degeneration of the adjacent mesonephros result in the separated layers of coelomic mesothelium fusing into near apposition, establishing the mesentery of the ovary, the mesonephros degenerating along the region of differentiation of the unfused cranial segment of the paramesonephric duct.

mesosalpinx. Caudally, growth and fusion ventromedially of these bilateral ducts "sweep" the once medially attached ducts toward the midline. These bilateral mesenteries merge over the fused uterovaginal primordium and extend to form a continuous double-layered "drape," the mesometrium of the broad ligament, between the upper pole and the posterolateral body wall. This central expanse of mesentery creates the rectouterine and vesicouterine pouches. The fusion of the ducts also alters the previous longitudinal orientation of the upper free segments of the ducts (the transverse orientation). During this alteration, the attached mesovarium is drawn from a medial relationship into a lateral relationship with the paramesonephric mesentery of the mesosalpinx and the mesometrium.

The suspensory ligament of the ovary, through which the ovarian vessels, nerves, and lymphatics traverse, is formed by degeneration of the mesonephric tissue and regression of the urogenital ridge adjacent to the ovary reduce this fold.

The round ligament of the uterus and the proper ovarian ligament are both derivatives of the gubernaculum, a mesenchymal condensation at the caudal end of the mesonephros and extends over the initially short distance to the body wall (see Relocation of the Testes and Ducts). As the gonad enlarges and the mesonephric tissue degenerates, the gubernaculum appears to "shift" to the inferior aspect of the ovary. Distally, growth of the fibrous gubernaculum extends to the inguinal region. However, the midportion of the gubernaculum becomes attached, inexplicably, to the paramesonephric duct at the uterotubal junction. Formation of the uterovaginal primordium by caudal fusion of the paramesonephric ducts and the gubernaculum attached medially within the cover of the encompassing mesentery of the structures (ie, the paramesonephric ligament). This fibrous band of connective tissue eventually becomes 2 ligaments.

Cranially, the band is the proper ligament of the ovary, extending between the inferior pole of the ovary and the broad ligament just inferior to the oviduct. Caudally, it continues as the uterine round ligament from a point just inferior to the broad ligament and extending through the inguinal canal to the labium majus.

ANOMALIES OF THE UTERINE TUBES (OVIDUCTS, FALLOPIAN TUBES)

The uterine tubes are derivatives of the cranial segments of the paramesonephric (müllerian) ducts, which differentiate between the sixth and ninth weeks (Fig 4–10). Ductal formation begins with invagination of the coelomic epithelium into the coelomic bay. The initial depression remains open to proliferate and differentiate into the ostium (Fig 4–10). Variable duplication of the ostium sometimes occur; in such cases, the leading edges of the initial ductal groove present completely or anomalous proliferation of epithelium around the opening occurred.

Absence of a uterine tube is very rare when otherwise normal ductal and genital derivatives are present. This is associated with (1) ipsilateral absence of an ovary and (2) ipsilateral unicornuate uterus (and probable anomalies of the external genitalia). Bilateral absence of the uterine tubes is most frequently associated with lack of formation of the uterus and anomalies of the external genitalia. Interestingly, absence of the derivatives of the lower part of the müllerian ducts with persistence of the upper part is more frequently than the reverse condition. This might be expected, as the müllerian ducts form in a craniocaudal direction.

Partial absence of a uterine tube (middle or caudal segment) also has been reported. The cause of partial absence of a uterine tube several theories have been advanced. One theory holds that when the unilateral anomaly coincides with ipsilateral absence of an ovary, a "vascular accident" might occur following differentiation of the ducts and ovaries. Obviously, various factors resulting in unilateral atresia could be proposed. From a different perspective, bilateral absence of the uterine tubes as an associated anomaly with external phenotype is characteristic of testicular feminization syndrome (nonpersistence of the rest of the paramesonephric ducts, anomalous external genitalia, hypoplastic male genital ducts, and testicular differentiation with usual ectopic location).

ANOMALIES OF THE UTERUS

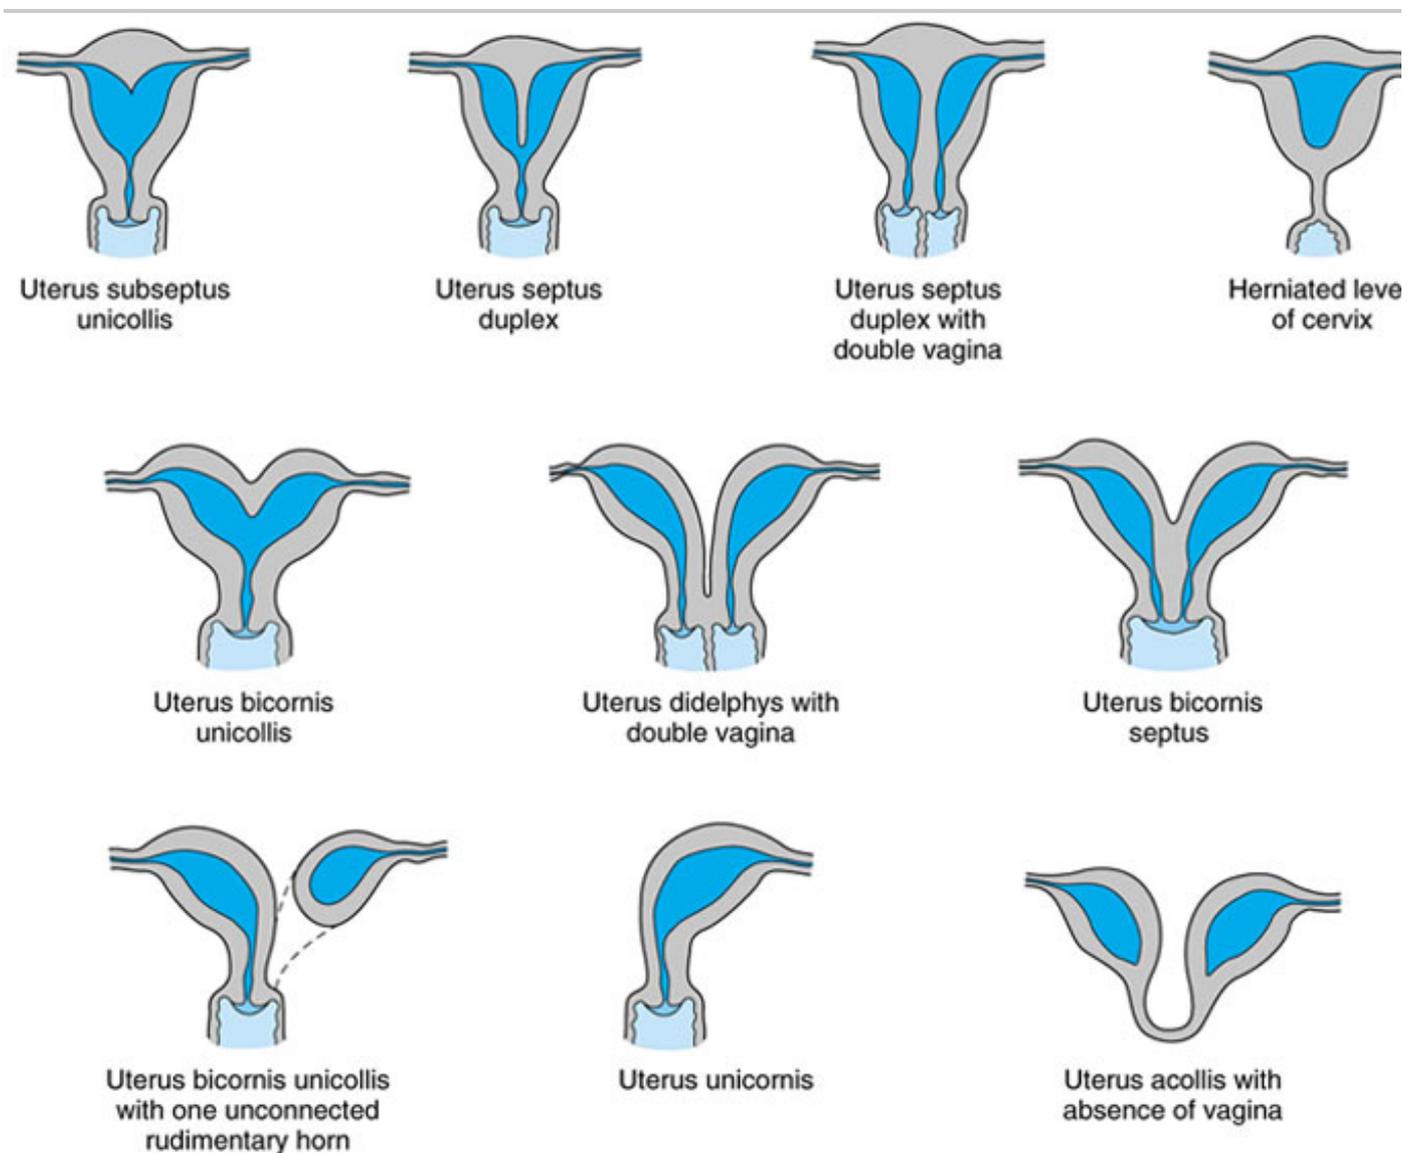

The epithelium of the uterus and cervix and the fibromuscular wall of the vagina are derived from the paramesonephric ducts, the caudal ends of which fuse medially to form the uterovaginal primordium. Most of the primordium gives rise to the uterine tube. Subsequently, the caudal tip of the primordium contacts the pelvic part of the urogenital sinus, and the interaction of the two (the bulbs) and primordium leads to differentiation of the vagina. Various steps in this sequential process can go awry, resulting in (1) partial failure of one or both ducts to form (agenesis), (2) lack of or incomplete fusion of the caudal segments of

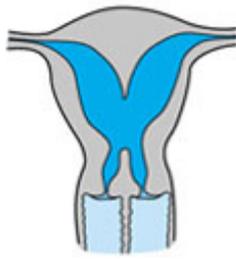

(abnormal uterovaginal primordium), or (3) failure of development *after* successful formation (aplasia or hypoplasia). Anomalies may occur because of the number of sites for potential error, the complex interactions necessary for Müllerian derivatives, and the duration of the complete process.

Complete agenesis of the uterus is very rare, and associated vaginal anomalies are usually expected. Also, a unilateral associated structural or positional abnormality of the kidney has been reported; there has been speculation the cases may be in the development of the urinary system and then in the formation of the paramesonephric ducts.

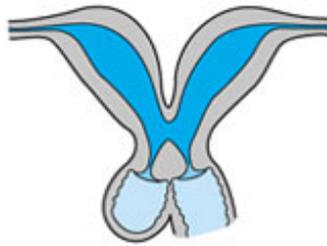

Aplasia of the paramesonephric ducts (Müllerian aplasia) is more common than agenesis and could occur after formation of the primordium with the urogenital sinus. A rudimentary uterus or a vestigial uterus (ie, varying degrees of development) is most frequently accompanied by partial or complete absence of the vagina. As in uterine agenesis, a kidney is frequently associated with uterine aplasia (in about 40% of cases). Uterine hypoplasia variably yields an infantile uterus and is associated with normal or abnormal uterine tubes and ovaries. Unilateral agenesis or aplasia results in uterus unicornis, whereas unilateral hypoplasia may result in a rudimentary horn that may or may not be connected to the "normal" horn (uterus bicornis unicollis with one unconnected rudimentary horn; Fig 4–14). The status of the cervix must be considered for potential hematometra, or blood in the uterus that cannot exit, at puberty.

Uterine anomalies.

(*Redrawn and reproduced, with permission, from Toaff R: A major genital malformation: Communicating uteri. 1974;43:221.)

Anomalous unification caudally of the paramesonephric ducts results in many uterine malformations (Fig 4–14; defective fusion is estimated to be 0.1–3% of females. Furthermore, faulty unification of the ducts has been cited responsible for most anomalies of the female genital tract. Partial or complete retention of the apposed walls of the ducts produce slight (uterus subseptus unicollis) to complete (uterus bicornis septus) septal defects in the uterine unification of the paramesonephric ducts can result in a double uterus (uterus didelphys) with either a single

ANOMALIES OF THE CERVIX

Because the cervix forms as an integral part of the uterus, cervical anomalies are often the same as uterine anomalies. Hypoplasia of the cervix is rarely found with a normal uterovaginal tract. The cervix appears as a fibrous junction between the uterine corpus and the vagina.

DIFFERENTIATION OF THE UROGENITAL SINUS

Until differentiation of the genital ducts begins, the urogenital sinus appears similar in both sexes during the embryonic period. For purposes of describing the origin of sinus derivatives, the sinus can be divided into 3 parts: (1) the dilated segment superior to the entrance of the mesonephric ducts; (2) the pelvic part, or the narrowed tubular level of the mesonephric ducts and the inferior segment; and (3) the phallic part, often referred to as the definitive (anteroposteriorly elongated, transversely flattened inferiormost segment) (Fig 4–8). The urogenital membrane is the inferior limit of the phallic part. The superior limit of the vesical part becomes delimited by conversion of the notochord into a thick fibrous cord, the urachus, by about 12 weeks. After differentiation of the vesical part of the sinus to form the urinary bladder, the urachus maintains its continuity between the apex of the bladder and the umbilical cord as the median umbilical ligament. Various anomalies of urachal formation can present as urachal fistula, cyst,

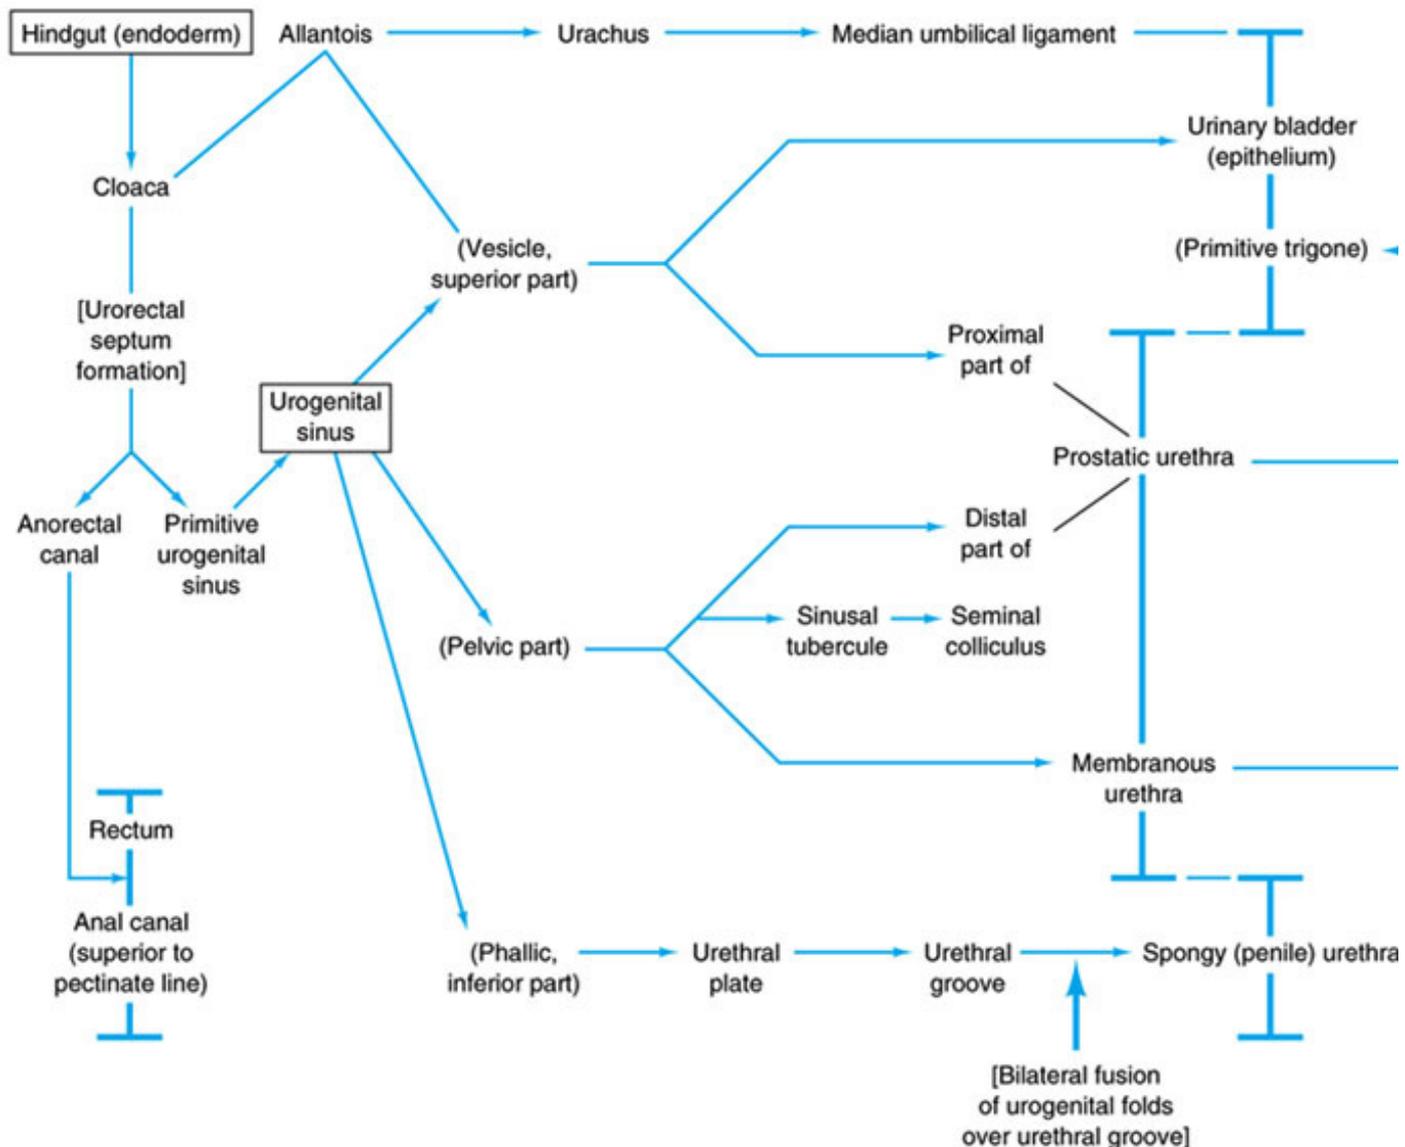

the degree of patency that persists during obliteration of the allantois.

In both sexes, the caudal segments of each mesonephric duct between the urogenital sinus and the level of the metanephric diverticulum (or ureteric bud) become incorporated into the posterocaudal wall of the vesical part (sinus (Figs 4–5 and 4–6). As the dorsal wall of the bladder grows and "absorbs" these caudal segments, the ureters move closer to the bladder and eventually open directly and separately into it, dorsolateral to the mesonephric ducts (the mesodermal segment of mesonephric duct incorporated into the bladder defines the epithelium of the trigone of the bladder; this mesodermal epithelium is secondarily replaced by the endodermal epithelium of the sinus of the bladder. After the remainder of each mesonephric duct (ie, the portion that was cranial to the metanephric diverticulum) is joined to the pelvic part of the urogenital sinus. Thereafter, the ducts either degenerate (in females) or undergo differentiation.

Male: Urinary Bladder and Urethra

(Fig 4–15) The urogenital sinus gives rise to the endodermal epithelium of the urinary bladder, the prostatic anlage, and most of the spongy (penile) urethra (except the glandular urethra). Outgrowths from its derivatives produce the prostate and bulbourethral glands (Fig 4–15). The prostatic urethra receives the ejaculatory ducts (derived from the mesonephric ducts) and arises from 2 parts of the urogenital sinus. The portion of this urethral segment superior to the ejaculatory ducts is the inferiormost area of the vesical part of the sinus. The lower portion of the prostatic urethra is derived from the pelvic part of the sinus at the entrance of the ducts and including the region of the sinusal tubercle—the latter apparently forming the seminal vesicle. At the 12th week, endodermal outgrowths of the prostatic urethra form the prostatic anlage, the prostatic buds, from which the epithelium of the prostate will arise. Differentiation of splanchnic mesoderm contributes other components to the prostatic anlage and connective tissue), as is the case for mesodermal parts of the urinary bladder. The pelvic part of the sinus also gives rise to the epithelium of the membranous urethra, which later yields endodermal buds for the bulbourethral glands. The dorsal wall of the urogenital sinus proliferates anteriorly as the external genitalia form (during weeks 9–12) and results in the spongy part as the endodermal epithelium of the spongy (penile) urethra (the distal glandular urethra is derived from the mesonephric ducts).

Schematic drawing of male differentiation of the urogenital sinus; formation of urinary bladder and urethra. (Exp in Fig 4-1.)

Female: Urinary Bladder, Urethra, and Vagina

DEVELOPMENT

Differentiation of the female sinus is schematically presented in Fig 4-13 and illustrated in Figs 4-8, 4-12, 4-16. In contrast to sinusual differentiation in the male, the vesical part of the female urogenital sinus forms the epithelium of the urinary bladder and the proximal part of the urethra. Derivatives of the pelvic part of the sinus include the epithelium of the vagina, the greater vestibular pouch, and the labia minora. Controversy exists about how the vagina is formed, mainly because of a lack of consensus about the origin and precursory tissues (mesodermal paramesonephric duct, endodermal urogenital sinus, or even mesonephric duct). The current theory is that 2 endodermal outgrowths, the sinovaginal bulbs, of the dorsal wall of the pelvic part of the urogenital sinus grow to and join with the caudal tip of the uterovaginal primordium (fused paramesonephric ducts) in the area of the vaginal opening. This cellular mass at the end of the primordium occludes the inferior aspect of the canal, creating an endoderm-mesoderm wall of the uterovaginal primordium. Eventually, the vaginal segment grows, approaching the vestibular opening. The process of growth has been described either as "downgrowth" of the vaginal segment away from the uterine canal.

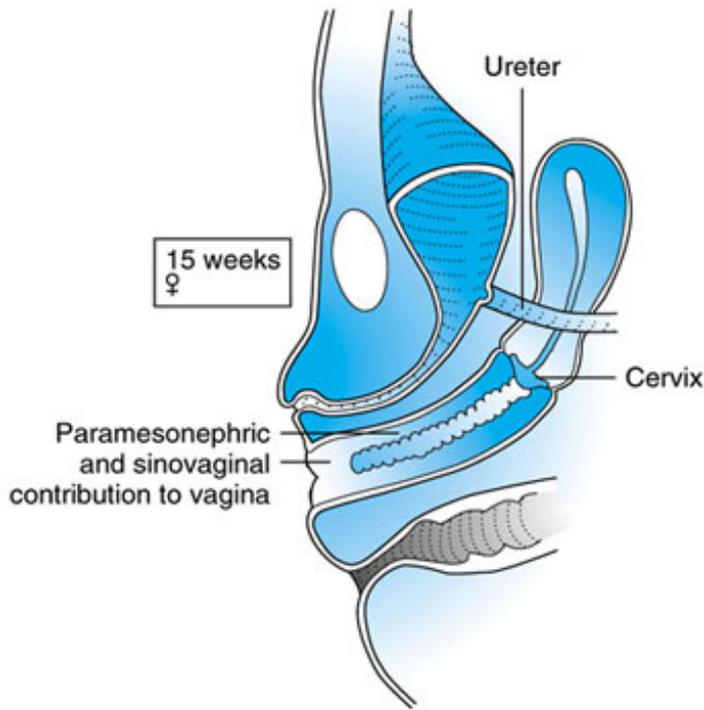

sinus or, more commonly, as "upgrowth" of the segment away from the sinus and toward the uterovaginal cana vaginal segment is extended between the paramesonephric-derived cervix and the sinus-derived vestibule (Figs Near the fifth month, the breakdown of cells centrally in the vaginal plate creates the vaginal lumen, which is de remaining cells of the plate as the epithelial lining of the vagina. The solid vaginal fornices become hollow soon a vaginal lumen is complete. The upper one-third to four-fifths of the vaginal epithelium has been proposed to aris primordium, whereas the lower two-thirds to one-fifth has been proposed as a contribution from the sinovaginal **Figure 4–16.**

Sagittal cutaway view of differentiated urogenital sinus and precanalization stage of vaginal development. The diagram illustrates several theories about the relative contributions of paramesonephric ducts and sinovaginal bulbs to the vagina.

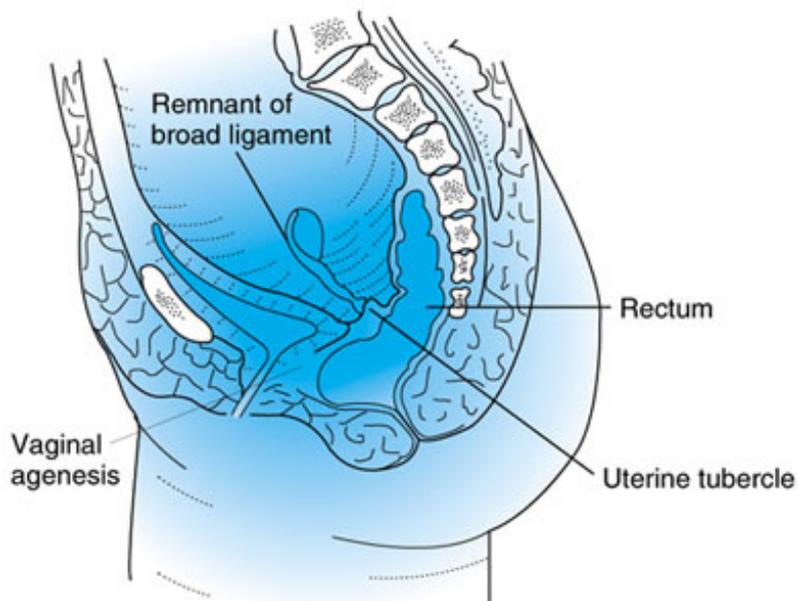

The fibromuscular wall of the vagina is derived from the uterovaginal primordium. The cavities of the vagina are temporarily separated by the thin hymen, which probably is a mixture of tissue derived from the vaginal plate and a sinus tubercle. With concurrent differentiation of female external genitalia, inferior closure of the sinus does not occur at the same week of development, as it does in the male. Instead, the remainder of the pelvic part and all of the inferior part of the urogenital sinus expand to form the vestibule of the vagina. Presumably, the junctional zone of pigmentation on the labia minora is a distinction between endodermal derivation from the urogenital sinus (medially) and ectodermal skin (laterally).

ANOMALIES OF THE VAGINA

The vagina is derived from interaction between the uterovaginal primordium and the pelvic part of the urogenital sinus (see Urogenital Development). The causes of vaginal anomalies are difficult to assess because integration of the uterovaginal primordium and the urogenital sinus in the normal differentiation of the vagina remains a controversial subject. Furthermore, an account of certain anomalous vaginal presentations, as with many anomalies of the external genitalia, would have to include factors of endocrine and genetic origin as well.

The incidence of absence of the vagina due to suspected vaginal agenesis is about 0.025%. Aggenesis may be due to failure of the uterovaginal primordium to contact the urogenital sinus. The uterus is usually absent (Fig 4–18). Ovarian agenesis is associated with vaginal agenesis. The presence of greater vestibular glands has been reported with presumed vaginal agenesis, which emphasizes the complexity of differentiation of the urogenital sinus.

Figure 4–18.

Midsagittal view of vaginal agenesis and uterine agenesis with normal ovaries and oviducts.

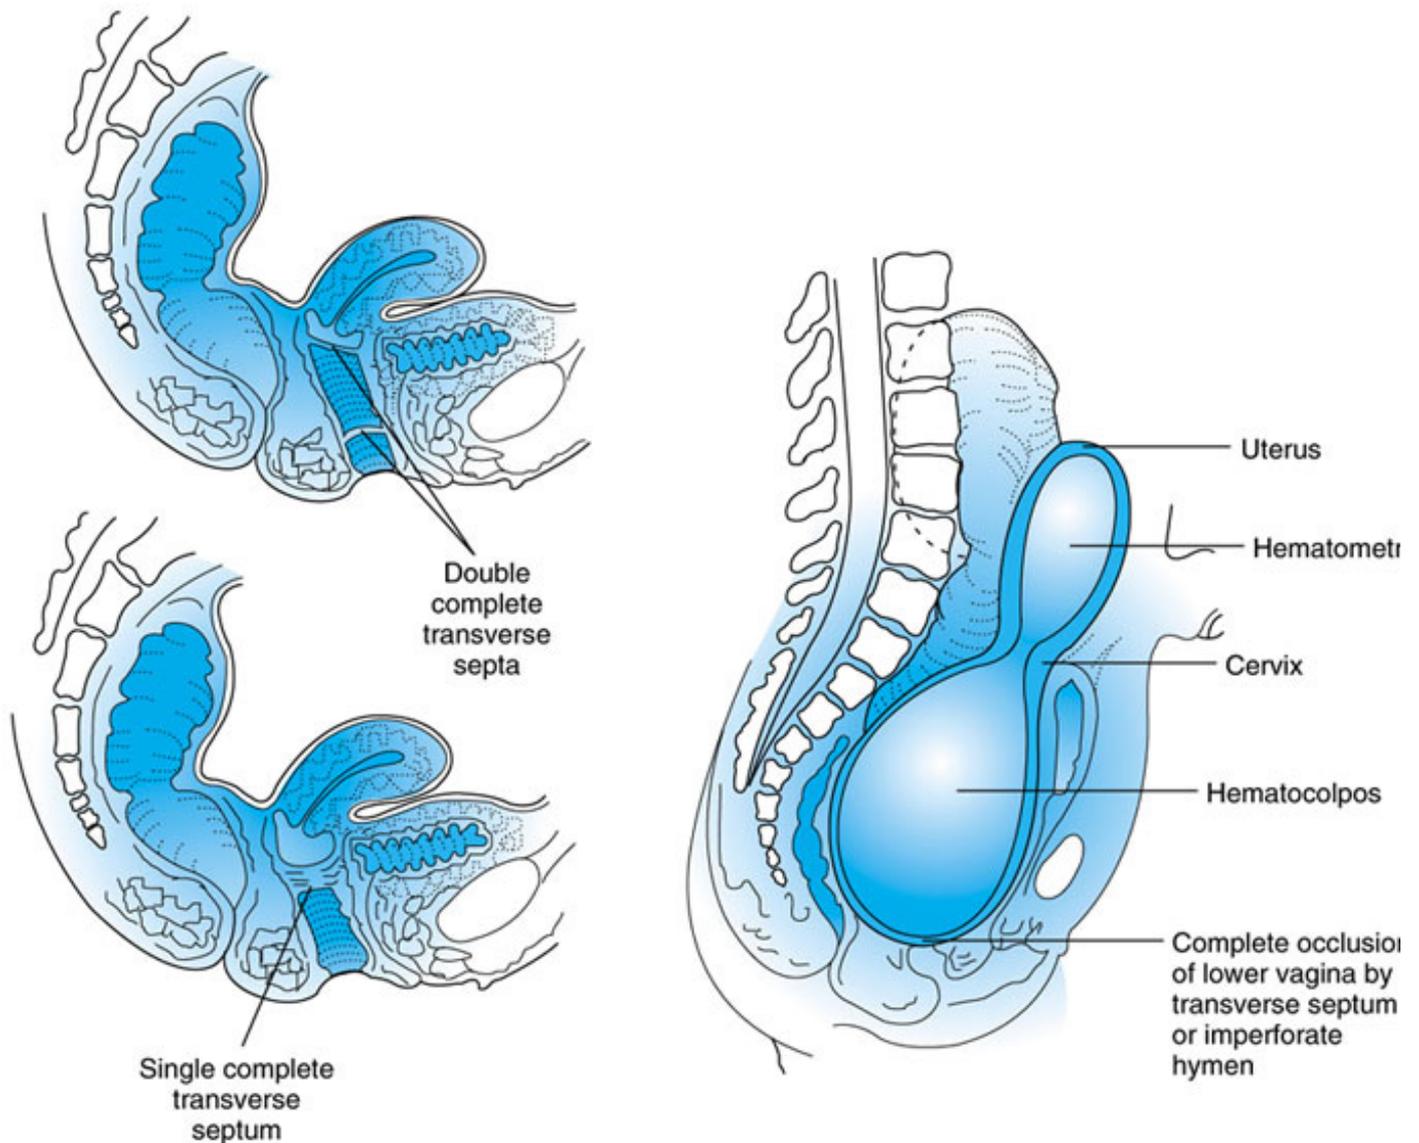

(Reproduced, with permission, from Ingram JM: The Ingram technique for the management of vaginal agenesis *Surgeon* 1981;2:1.)

Vaginal atresia, on the other hand, is considered when the lower portion of the vagina consists merely of fibrocontiguous superior structures (the uterus, in particular) are well differentiated (perhaps because the primary contribution to the vagina). In müllerian aplasia almost all of the vagina and most of the uterus are absent (Rokitansky syndrome, with a rudimentary uterus of bilateral, solid muscular tissue, was considered virtually the same as that with absence of the vagina (and normal external genitalia) are considered to have müllerian aplasia rather than vaginal atresia).

Other somatic anomalies are sometimes associated with müllerian aplasia, suggesting multiple malformation syndromes are much more prevalent than middle ear anomalies, eg, müllerian aplasia associated with Klippel-Feil syndrome (cervical vertebrae) is more common than müllerian aplasia associated with Klippel-Feil syndrome plus middle ear deafness). Winter's syndrome, which is thought to be autosomal recessive, is evidenced by middle ear anomalies (those in the triad above), renal agenesis or hypoplasia, and vaginal atresia (rather than aplasia of the paramesonephros). Dysgenesis (partial absence) of the vagina and hypoplasia (reduced caliber of the lumen) have also been described.

Transverse vaginal septa (Fig 4–19) are probably not the result of vaginal atresia but rather of incomplete canalization or discrete fusion of sinus and primordial (ductal) derivatives. Alternative explanations are likely because the location of septa is not consistent. A rare genetic linkage has been demonstrated. A single septum or multiple septa can occur. The location may vary in upper or lower segments of the lumen. Longitudinal vaginal septa can also occur. A variety of explanations have been advanced, including true duplication of vaginal primordial tissue, anomalous differentiation of the uterovaginal primordium, variation of the caudal fusion of the müllerian ducts, persistence of vaginal plate epithelium, and anomalous mesoderm. A transverse septum creates the potential for various occlusive manifestations, including hematometra, or hematocolpos, depending on the composition and location of the trapped fluid.

Figure 4–19.

Transverse vaginal septa.

Abnormalities of the vagina are often associated with anomalies of the urinary system and the rectum because the urogenital sinus is involved in formation of the bladder and urethra as well as the vagina and vestibule. Furthermore, if the cloaca into the sinus and the anorectal canal is faulty, then associated rectal defects can occur. Compound anomalies of the tract or rectum. The urethra may open into the vaginal wall; even a single vesicovaginal cavity has been described. The vagina can open into a persistent urogenital sinus, as in certain forms of female pseudohermaphroditism. Associated anomalies include vaginorectal fistula, vulvovaginal anus, rectosigmoidal fistula, and vaginosigmoidal cloaca (in the absence of Cloacal Dysgenesis).

ANOMALIES OF THE HYMEN

The hymen is probably a mixture of tissue derived from remains of the sinusal tubercle and the vaginal plate. It normally perforates by puberty, although an imperforate hymen is not rare. The imperforate condition can be the result of lack of central degeneration or the result of inflammatory occlusion after perforation. Obstruction of menstrual flow is the first sign (Fig 4-19).

CLOACAL DYSGENESIS (INCLUDING PERSISTENCE OF THE UROGENITAL SINUS)

Anomalous partitioning of the cloaca by abnormal development of the urorectal septum is rare, at least based on literature. As anticipated from a developmental standpoint, the incidence of associated genitourinary anomalies in cloacal or anorectal malformations are summarized in Table 4–3.

Table 4–3. Cloacal Malformations.

Vestibule

Deformed; flanked by labia; clitoris in front, fourchette behind; anterior vestibule short, shallow, and moist; single posterior half of vestibule (common conduit for urine, cervical mucus, and feces).

Bladder/urethra

Anterior; directed cranially and ventrally.

Vagina

Opens into the vault of cloaca.

Anus/rectum

Enters at highest and most posterior point; orifice is in midline and stenotic.

Disposition

Lengths of urethra and vagina are inversely proportionate to length of cloacal canal.

Rectovaginal Fistula

Vestibule

Normal anatomy (2 orifices: urethral & vaginal).

Bladder/urethra

Normal.

Vagina

May be septate or normal.

Anus/rectum

Internal in the midposterior vaginal wall.

Disposition

Anus absent from perineum.

Rectovestibular Fistula

Vestibule

Contains rectum, otherwise normal.

Urethra

Normal.

Vagina

Normal.

Anus/rectum

Small, sited at the fossa navicularis.

Disposition

Rectum is parallel with both vagina and urethra.

Covered Anus

Vestibule

Normal.

Urethra

Normal.

Vagina

(Probably normal.)

Anus

At any point between the normal site and the fourchette; anocutaneous; anovulvar.

Disposition

Genital folds are abnormally fused anterior and posterior to common orifice and give rise to hypertrophied perineum.

Ectopic Anus

Vestibule

Normal.

Urethra

Normal.

Vagina

Normal.

Anus

Anterior to the normal site; normal function.

Disposition

Fault lies in the development of the perineum.

	Rectocloacal Fistula

Modified and reproduced, with permission, from Okonkwo JEN, Crocker KM: Cloacal dysgenesis. *Obstet Gynecol*

Rectocloacal fistula with a persistent cloaca provides a common canal or outlet for the urinary, genital, and distinction between a canal and an outlet is one of depth (deep versus very shallow, respectively) of the persistent cloaca and, thus, the length of the individual urethral and vaginal canals emptying into the cloaca. The inverse ratio (or length) of the cloaca and length of the vaginal and urethral canals is probably a reflection of the time when a urorectal septum occurs. Although the bladder, the vagina, and the rectum can empty into a common cloaca as unusual variations of persistent cloaca can also occur.

For example, the vagina and rectum develop, but the urinary bladder does not develop as a separate entity from vagina and rectum open separately into a "urinary bladder," which has ureters entering posterolaterally to the vagina (the "anatomic trigone" of the bladderlike structure). The external orifice from the base of this cloacal "bladder" is the urogenital sinus. One explanation for this variant might be that arrest of formation of the urorectal septum occurs much earlier than development of distal portions of the 3 tracts (urethra, vagina, and anorectum) to a more advanced (but still incomplete) urorectal septal formation ceases. The anomaly is probably rare.

With a rectovaginal fistula, the vestibule may appear anatomically normal, but the anus does not appear in the female. This anomaly probably results from anorectal agenesis due to incomplete subdivision of the cloaca (similar agenesis in the male is rectourethral fistula). The development of the anterior aspect of the vagina completes the separation of the ureters from the rectum; there is not a persistent urogenital sinus. Anorectal agenesis is reputedly the most common type of anorectal malformation. Rectovaginal, anovestibular (or rectovestibular; Table 4–3), and anoperineal fistulas account for other types of malformations.

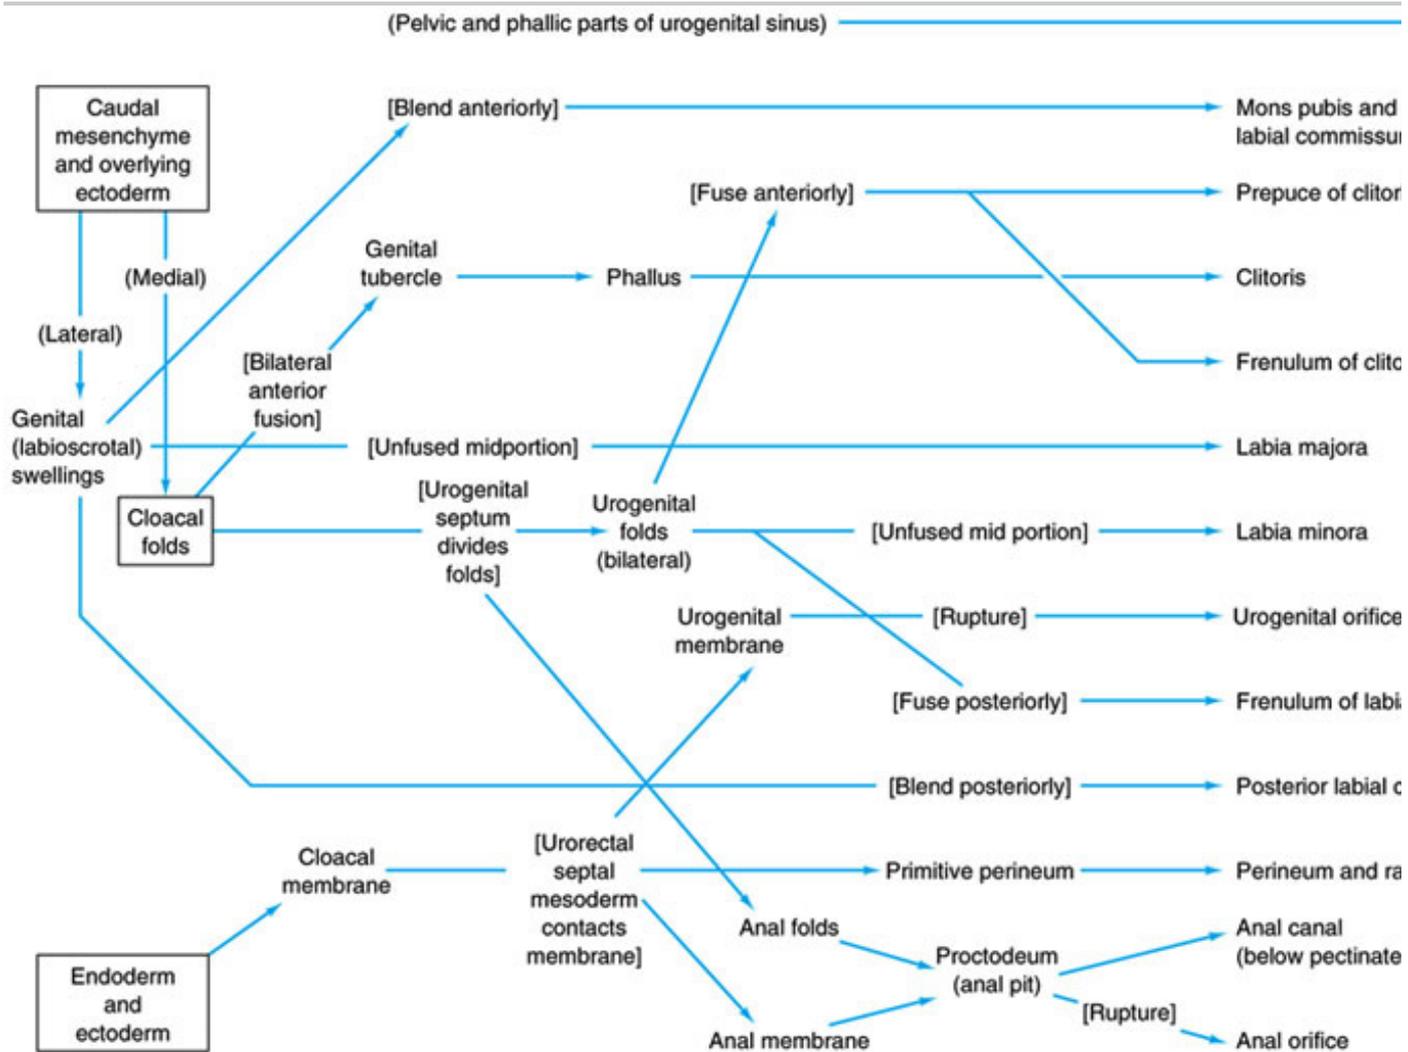

In the absence of the anorectal defect (normal anal presentation) but presence of a persistent urogenital sinus, various irregularities of the urethra and genitalia can appear. The relative positions of urethral and vaginal orifices can even change as the child grows. In the discussion of anomalies of the labia majora, there may be persistent urogenital sinus or pseudohermaphroditism due to congenital adrenal hyperplasia. The vagina opens into the persisting pelvic part of the urogenital sinus with the phallic part of the sinus to the external surface at the urogenital opening. The sinus can be deep and narrow, approximating the size of a urethra, or it can be relatively shallow.

Urinary tract disorders associated with persistent urogenital sinus include duplication of the ureters, unilateral ureteral atresia, and lack of or abnormal ascent of the kidneys. Variations in the anomalies of derivatives of the urogenital sinus are related in part to the time of arrest of normal differentiation and development of the urogenital sinus, as well as to factors associated with abnormal sexual differentiation, such as the variable degrees of response to adrenal androgen excess and hyperplasia.

THE EXTERNAL GENITALIA

Undifferentiated Stage

The external genitalia begin to form early in the embryonic period, shortly after development of the cloaca. The

Development of external genitalia. A: Before sexual differentiation and just after the urorectal septum divides the cloacal membrane (anteriorly) and the anal membrane (posteriorly). B: Male differentiation at about 10 weeks and near term, respectively. The urogenital folds fuse ventrally over the spongy urethra and close the inferior phallic part of the urogenital sinus. The glandular urethra forms by invagination of ectoderm from the tip of the glans. C and E: Female differentiation at about 10 weeks and near term, respectively. There is little difference in the appearance of female and male external genitalia. The urogenital folds fuse only at their posterior extremes, while the unfused remainder differentiates into the labia minora. (See also Figs 4–20 and 4–21).

By the seventh week, the urorectal septum subdivides the bilayered (ectoderm and endoderm) cloacal membrane (anteriorly) and the anal membrane (posteriorly). The area of fusion of the urorectal septum and the anal membrane becomes the primitive perineum, or perineal body. With formation of the perineum, the cloacal folds are divided into urogenital folds adjacent to the urogenital membrane and anal folds around the anal membrane. As the mesonephros thickens and elongates between the perineum and the phallus, the urogenital membrane sinks deeper into the folds. Within a week, this membrane ruptures, forming the urogenital orifice and, thus, opening the urogenital system. Similar thickening of the anal folds creates a deep anal pit, in which the anal membrane breaks down to establish the anal canal (Figs 4–20 and 4–21).

Subsequent masculinization or feminization of the external genitalia is a consequence of the respective presence

and the androgenic sensitivity or insensitivity of the tissues. The significance of both of these factors (availability sensitivity of target tissue) is exemplified by the rare condition (about 1 in 50,000 "females") of testicular fem are present (usually ectopic) and produce testosterone and antimüllerian hormone. The antimüllerian hormone sup uterus and uterine tubes (from the paramesonephric ducts), whereas testosterone supports male differentiation to form the epididymis and ductus deferens. The anomalous feminization of the external genitalia is considered insensitivity of the precursor tissues consequent to an abnormal androgen receptor or postreceptor mechanism :

Male

Early masculinization of the undifferentiated or indifferent genitalia takes place during the first 3 weeks of the fe and is caused by androgenic stimulation. The phallus and urogenital folds gradually elongate to initiate developr subjacent endodermal lining of the inferior part (phallic) of the urogenital sinus extends anteriorly along with the an endodermal plate, the urethral plate. The plate deepens into a groove, the urethral groove, as the uroger urethral folds) thicken on each side of the plate. The urethral groove extends into the ventral aspect of the de bilateral urethral folds slowly fuse in a posterior to anterior direction over the urethral groove to form the spong thereby closing the urogenital orifice (Figs 4–15 and 4–20). The line of fusion becomes the penile raphe on the penis.

As closure of the urethral folds approaches the glans, the external urethral opening on this surface is eliminated ectodermal glandular plate invaginates the tip of the penis. Canalization of the plate forms the distal end of t glandular urethra. Thus, the external urethral meatus becomes located at the tip of the glans when closure of completed (Fig 4–20). The prepuce is formed slightly later by a circular invagination of ectoderm at the tip of t cylindrical ectodermal plate then cleaves to leave a double-layered fold of skin extending over the glans.

While the cloacal folds and phallic urogenital sinus were differentiating into the penis and the urethra, the genit: swellings of the undifferentiated stage were enlarging lateral to the cloacal folds. Medial growth and fusion of the the scrotum and scrotal raphe around the 12th week virtually complete the differentiation of the male extern: 4–22).

Female

DEVELOPMENT OF EXTERNAL GENITALIA

Feminization of the external genitalia proceeds in the absence of androgenic stimulation (or nonresponsiveness) primary distinctions in the general process of feminization versus masculinization are (1) the lack of continued g (2) the near absence of fusion of the urogenital folds and the labioscrotal swellings. Female derivatives of the in: for the external genitalia are virtually homologous counterparts of the male derivatives. Formation of the female presented in Fig 4–21.

The growth of the phallus slows relative to that of the urogenital folds and labioscrotal swellings and becomes th anterior extreme of the urogenital folds fuses superior and inferior to the clitoris, forming the prepuce and fren respectively. The midportions of these folds do not fuse but give rise to the labia minora. Lack of closure of the orifice patent and results in formation of the vestibule of the vagina from the inferior portion of the pelvic part urogenital sinus at about the fifth month (Fig 4–21). Derivatives of the vesical part of the sinus (the urethra) a the pelvic part of the sinus (vagina and greater vestibular glands) then open separately into the vestibule. T minora is formed by fusion of the posterior ends of the urogenital folds. The mesoderm of the labioscrotal swell the ectoderm and remains virtually unfused to create the labia majora lateral to the labia minora. The swelling to form the anterior labial commissure and the tissue of the mons pubis, while the swellings posteriorly less labial commissure. The distal fibers of the round ligament of the uterus project into the tissue of the labia maj

ANOMALIES OF THE LABIA MINORA

In otherwise normal females, 2 somewhat common anomalies occur—labial fusion and labial hypertrophy. True l developmental defect in the normally unfused midportions of the urogenital folds is purportedly less frequent th

inflammatory-type reactions. Labial hypertrophy can be unilateral or bilateral and may require surgical correction.

ANOMALIES OF THE LABIA MAJORA

The labia majora are derived from the bilateral genital (labioscrotal) swellings, which appear early in the embryonic period and fuse centrally during subsequent sex differentiation in the fetal period. Anomalous conditions include hypoplastic labia as well as different gradations of fusion of the labia majora. Abnormal fusion (masculinization) of labioscrotal females is most commonly associated with ambiguous genitalia of female pseudohermaphroditism consequent to 17 α -hydroxylase deficiency (adrenogenital syndrome). Over 90% of females with congenital adrenal hyperplasia have a steroid 17 α -hydroxylase deficiency (autosomal recessive), resulting in excess adrenal androgen production. This enzyme deficiency has been the most common cause of ambiguous genitalia in genetic females." Associated anomalies include clitoral hypertrophy and urogenital sinus. Formation of a penile urethra is extremely rare.

ANOMALIES OF THE CLITORIS

Clitoral agenesis is extremely rare and is due to lack of formation of the genital tubercle during the sixth week of development. It could also result from atresia of the genital tubercle. The tubercle forms by fusion of the anterior segments of the labia minora; rarely, these anterior segments fail to fuse, and a bifid clitoris forms. This anomaly also occurs when unification of the folds is restricted by exstrophy of the cloaca or bladder. Duplication of the genital tubercle with consequent bifid clitoris is equally rare. Clitoral hypertrophy alone is not common but may be associated with various intersex conditions.

ANOMALIES OF THE PERINEUM

The primitive perineum originates at the area of contact of the mesodermal urorectal septum and the endoderm cloacal membrane (at 7 weeks). During normal differentiation of the external genitalia in the fetal period, the perineum separates the urogenital folds and ruptured urogenital membrane from the anal folds and ruptured anal membrane, and develops the perineal body. Malformations of the perineum are rare and usually associated with malformations of the urogenital tract consequent to abnormal development of the urorectal septum. Imperforate anus has an incidence of 1 in 5000. The simplest form (rare) is a thin membrane over the anal canal (the anal membrane failed to rupture at the end of the fetal period). Anal stenosis can arise by posterior deviation of the urorectal septum as the septum approaches the cloacal membrane to be smaller (with a relatively increased anogenital distance through the perineum). Anal agenesis and ectopic anus is considered to be a urorectal septal defect. The incidence of agenesis with a fistula is only slightly higher than that of fistula. In females, the fistula commonly may be located in the perineum (perineal fistula) or may open into the vestibule of the vagina (anovestibular fistula; see Cloacal Dysgenesis).

Current OB/GYN >Chapter 5. Genetic Disorders & Sex Chromosome Abnormalities>Genetic Disorders>

MENDELIAN LAWS OF INHERITANCE

Types of Inheritance

Autosomal Dominant

In autosomal dominant inheritance, it is assumed that a mutation has occurred in 1 gene of an allelic pair and the presence of this new gene produces enough of the changed protein to give a different phenotypic effect. Environment must also be considered because the effect may vary under different environmental conditions. The following are characteristic of autosomal dominant inheritance:

1. The trait appears with equal frequency in both sexes.
2. For inheritance to take place, at least 1 parent must have the trait unless a new mutation has just occurred.
3. When a homozygous individual is mated to a normal individual, all offspring will carry the trait. When a heterozygous individual is mated to a normal individual, 50% of the offspring will show the trait.
4. If the trait is rare, most persons demonstrating it will be heterozygous (Table 5–1).

Table 5–1. Examples of Autosomal Dominant Conditions and Traits.

Achondroplasia

Acoustic neuroma

Aniridia

Cataracts, cortical and nuclear

Chin fissure

Color blindness, yellow-blue

Craniofacial dysostosis

Deafness (several forms)

Dupuytren's contracture

Ehlers-Danlos syndrome

Facial palsy, congenital

Huntington's chorea

Hyperchondroplasia

Intestinal polyposis

Keloid formation

Lipomas, familial

Marfan's syndrome

Mitral valve prolapse

Muscular dystrophy

Neurofibromatosis (Recklinghausen's disease)

Night blindness

Pectus excavatum

Adult polycystic renal disease

Tuberous sclerosis

Von Willebrand's disease

Wolff-Parkinson-White syndrome (some cases)

Autosomal Recessive

The mutant gene will not be capable of producing a new characteristic in the heterozygous state in this circumstance under customary environmental conditions—ie, with 50% of the genetic material producing the normal protein, the phenotypic effect will not be different from that of the normal trait. When the environment is manipulated, the recessive trait occasionally becomes dominant. The characteristics of this form of inheritance a

as follows:

1. The characteristic will occur with equal frequency in both sexes.
2. For the characteristic to be present, both parents must be carriers of the recessive trait.
3. If both parents are homozygous for the recessive trait, all offspring will have it.
4. If both parents are heterozygous for the recessive trait, 25% of the offspring will have it.
5. In pedigrees showing frequent occurrence of individuals with rare recessive characteristics, consanguinity is often present (Table 5–2).

Table 5–2. Examples of Autosomal Recessive Conditions and Traits.

Acid maltase deficiency

Albinism

Alkaptonuria

Argininemia

Ataxia-telangiectasia

Bloom's syndrome

Cerebrohepatorenal syndrome

Chloride diarrhea, congenital

Chondrodystrophia myotonia

Color blindness, total

Coronary artery calcinosis

Cystic fibrosis

Cystinosis

Cystinuria

Deafness (several types)

Dubowitz's syndrome

Dysautonomia

Fructose-1,6-diphosphatase deficiency

Galactosemia

Gaucher's disease

Glaucoma, congenital

Histidinemia

Homocystinuria

Laron's dwarfism

Maple syrup urine disease

Mucopolipidosis I, II, III

Mucopolysaccharidosis I-H, I-S, III, IV, VI, VII

Muscular dystrophy, autosomal recessive type

Niemann-Pick disease

Phenylketonuria

Sickle cell anemia

17 α -Hydroxylase deficiency

18-Hydroxylase deficiency

21-Hydroxylase deficiency

Tay-Sachs disease

Wilson's disease

X-Linked Recessive

This condition occurs when a gene on the X chromosome undergoes mutation and the new protein formed as a result of this mutation is incapable of producing a change in phenotype characteristic in the heterozygous state. Because the male has only 1 X chromosome, the presence of this mutant will allow for expression should it occur in the male. The following are characteristic of this form of inheritance:

1. The condition occurs more commonly in males than in females.
2. If both parents are normal and an affected male is produced, it must be assumed that the mother is a carrier of the trait.
3. If the father is affected and an affected male is produced, the mother must be at least heterozygous for the trait.
4. A female with the trait may be produced in 1 of 2 ways. (A) She may inherit a recessive gene from both her mother and her father; this suggests that the father is affected and the mother is heterozygous. (B) She may inherit a recessive gene from 1 of her parents and may express the recessive characteristic as a function of the Lyon hypothesis; this assumes that all females are mosaics for their functioning X chromosome. It is theorized that this occurs because at about the time of implantation, each cell in the developing female embryo selects 1 X chromosome as its functioning X and that all progeny cells thereafter use this X chromosome as their functioning chromosome. The other X chromosome becomes inactive. Because this selection is done on a random basis, it is conceivable that some females will be produced who will be using primarily the X chromosome bearing the recessive gene. Thus, a genotypically heterozygous individual may demonstrate a recessive characteristic phenotypically on this basis (Table 5–3).

Table 5–3. Examples of X-Linked Recessive Conditions and Traits.

Androgen insensitivity syndrome (complete and incomplete)

Color blindness, red-green

Diabetes insipidus (most cases)

Fabry's disease

Glucose-6-phosphate dehydrogenase deficiency

Gonadal dysgenesis (XY type)

Gout (certain types)

Hemophilia A (factor VIII deficiency)

Hemophilia B (factor IX deficiency)

Hypothyroidism, X-linked infantile

Hypophosphatemia

Immunodeficiency, X-linked

Lesch-Nyhan syndrome

Mucopolysaccharidosis II

Muscular dystrophy, adult and childhood types

Otopalatodigital syndrome

Reifenstein's syndrome

X-Linked Dominant

In this situation, the mutation will produce a protein that, when present in the heterozygous state, is sufficient to cause a change in characteristic. The following are characteristic of this type of inheritance:

1. The characteristic occurs with the same frequency in males and females.
2. An affected male mated to a normal female will produce the characteristic in 50% of the offspring.
3. An affected homozygous female mated to a normal male will produce the affected characteristic in all offspring.
4. A heterozygous female mated to a normal male will produce the characteristic in 50% of the offspring.
5. Occasional heterozygous females may not show the dominant trait on the basis of the Lyon hypothesis (Table 5–4).

Table 5–4. Examples of X-Linked Dominant Conditions and Traits.

Acro-osteolysis, dominant type

Cervico-oculo-acoustic syndrome

Hyperammonemia

Orofaciodigital syndrome I

Applications of Mendelian Laws

Identification of Carriers

When a recessive characteristic is present in a population, carriers may be identified in a variety of ways. If the gene is responsible for the production of a protein (eg, an enzyme), the carrier often possesses 50% of the amount of the substance present in homozygous normal persons. Such a circumstance is found in galactosemia, where the carriers will have approximately half as much galactose-1-phosphate uridyltransferase activity in red cells as do noncarrier normal individuals.

At times, the level of the affected enzyme may be only slightly below normal, and a challenge with the substance to be acted upon may be required before the carrier can be identified. An example is seen in carriers of phenylketonuria, in whom the deficiency in phenylalanine hydroxylase is in the liver cells, and serum levels may not be much lower than normal. Nonetheless, when the individual is given an oral loading dose of phenylalanine plasma phenylalanine levels may remain high because the enzyme is not present in sufficient quantities to act upon this substance properly.

In still other situations where the 2 alleles produce different proteins that can be measured, a carrier state will have 50% of the normal protein and 50% of the other protein. Such a situation is seen in sickle cell trait, where one gene is producing hemoglobin A and the other hemoglobin S. Thus, the individual has half the amount of hemoglobin A as a normal person and half the hemoglobin S of a person with sickle cell anemia. An interesting and important problem involves the detection of carriers of cystic fibrosis. This is the most common autosomal recessive disease in Caucasian populations of European background, occurring in 1 in 2500 births in such populations but found in the carrier state in 1 in 25 Americans. By 1990, over 230 alleles of the single gene responsible have been discovered. The gene is known as the cystic fibrosis transmembrane conductance regulator (CFTR), and the most common mutation, delta F508, accounts for about 70% of all mutations, with 5 specific point mutations accounting for over 85% of cases. Because so many alleles are present, population screening poses logistical problems that have yet to be worked out. Most programs screen for the most common mutations using DNA replication and amplification studies.

Polygenic Inheritance

Polygenic inheritance is defined as the inheritance of a single phenotypic feature as a result of the effects of many genes. Most physical features in humans are determined by polygenic inheritance. Many common malformations are determined in this way also. For example, cleft palate with or without cleft lip, clubfoot, anencephaly, meningomyelocele, dislocation of the hip, and pyloric stenosis each occur with a frequency of 0.5–2 per 1000 in white populations. Altogether, these anomalies account for slightly less than half of single primary defects noted early in infancy. They are present in siblings of affected infants—when both parents are normal—at a rate of 2–5%. They are also found more commonly among relatives than in the general population. The increase in incidence is not environmentally induced because the frequency of such abnormalities in monozygotic twins is 4–8 times that of dizygotic twins and other siblings. The higher incidence in monozygotic twins is called concordance.

Sex also plays a role. Certain conditions appear to be transmitted by polygenic inheritance and are passed on more frequently by the mother who is affected than by the father who is affected. Cleft lip occurs in 6% of the offspring of women with cleft lip, as opposed to 2.8% of offspring of men with cleft lip.

Many racial variations in diseases are believed to be transmitted by polygenic inheritance, making racial background a determinant of how prone an individual will be to a particular defect. In addition, as a general rule the more severe a defect, the more likely it is to occur in subsequent siblings. Thus, siblings of children with bilateral cleft lip are more likely to have the defect than are those of children with unilateral cleft lip.

Environment undoubtedly plays a role in polygenic inheritance, because seasonal variations alter some defects and their occurrence rate from country to country in similar populations.

EPIGENETIC

Epigenetic is the regulation of gene expression not encoded in the nucleotide sequence of the gene. Gene expression can either be turned on or off by DNA methylation or histone modification (methylation, acetylation, phosphorylation, ubiquitination, or ADP-ribosylation). Epigenetic can subsequently be inherited by its descendant.

Genomic Imprinting

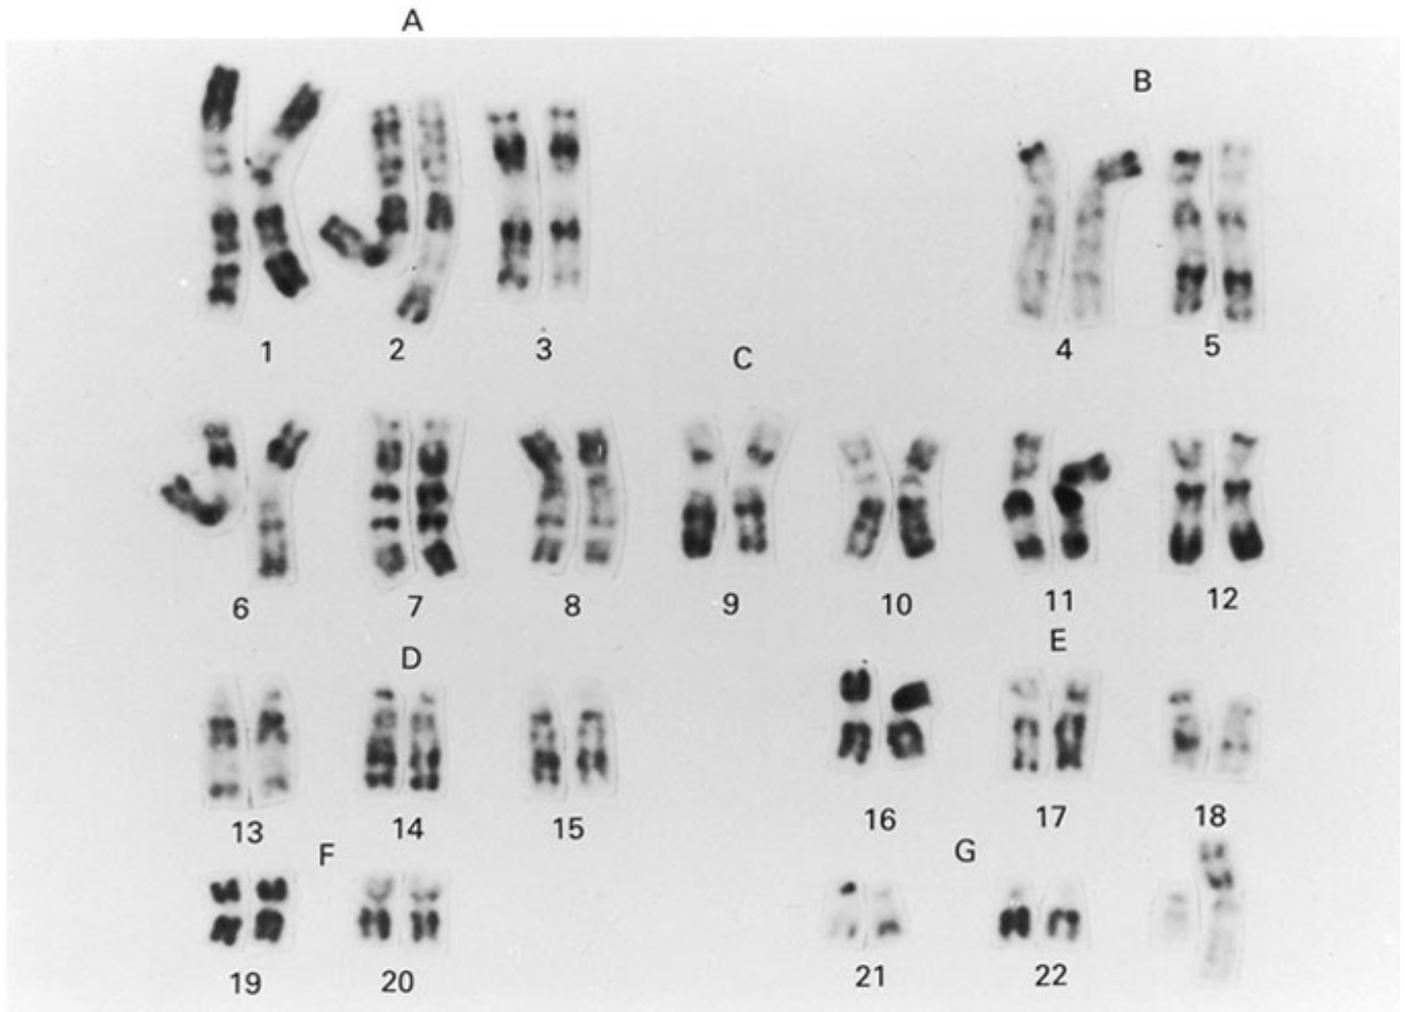

Genomic imprinting is an epigenetic process by which the male and female genomes are differently expressed. The imprinting mark on genes is either by DNA methylation or histone modification. The imprinting patterns are different according to the parental origin of the genes. Genomic imprints are erased in primordial germ cells and re-established again during gametogenesis. The imprinting process is completed by the time of round spermatid formation in males and at ovulation of metaphase-II oocytes in females. The imprinted genes survive the global waves of DNA demethylation and remethylation during early embryonic development. In normal children, 1 set of chromosomes is derived from the father and the other from the mother. If both sets of chromosomes are from only 1 parent, the imprinted gene expression will be unbalanced. Prader-Willi syndrome and Angelman syndrome are examples of imprinting disorders. In Prader-Willi syndrome, both 15q13 regions are from the father, whereas in Angelman syndrome both 15q13 regions are from the mother.

CYTOGENETICS

Identification of Chromosomes

In 1960, 1963, 1965, and 1971, international meetings were held in Denver, London, Chicago, and Paris, respectively, for the purpose of standardizing the nomenclature of human chromosomes. These meetings resulted in a decision that all autosomal pairs should be numbered in order of decreasing size from 1 to 22. Autosomes are divided into groups based on their morphology, and these groups are labeled by the letters A–G. Thus, the A group is comprised of pairs 1–3; the B group, pairs 4 and 5; the C group, pairs 6–12; the D group, pairs 13–15; the E group, pairs 16–18; the F group, pairs 19 and 20; and the G group, pairs 21 and 22. The sex chromosomes are labeled X and Y, the X chromosome being similar in size and morphology to the number 7 pair and thus frequently included in the C group (C-X) and the Y chromosome being similar in morphology and size to the G group (G-Y) (Fig 5–1).

Figure 5–1.

Karyotype of a normal male demonstrating R banding.

The short arm of a chromosome is labeled p and the long arm q. If a translocation occurs in which the short arm of a chromosome is added to another chromosome, it is written p+. If the short arm is lost, it is p-. The same can be said for the long arm (q+ and q-).

It has been impossible to separate several chromosome pairs from one another on a strictly morphologic basis because the morphologic variations have been too slight. However, there are other means of identifying each chromosome pair in the karyotype. The first of these is the incorporation of ³H-thymidine, known as the autoradiographic technique. This procedure involves the incorporation of radioactive thymidine into growing cells in tissue culture just before they are harvested. Cells that are actively undergoing DNA replication will pick up the radioactive thymidine, and the chromosomes will demonstrate areas of activity. Each chromosome will incorporate thymidine in a different pattern, and several chromosomes can therefore be identified by their labeling pattern. Nonetheless, with this method it is not possible to identify each chromosome, although it is possible to identify chromosomes involved in pathologic conditions, eg, D₁ trisomy and Down syndrome.

Innovative staining techniques have made it possible to identify individual chromosomes in the karyotype and to identify small anomalies that might have evaded the observer using older methods. These involve identification of chromosome banding by a variety of staining techniques, at times with predigestion with proteolytic agents. Some of the more commonly used techniques are the following:

Q banding: Fixed chromosome spreads are stained without any pretreatment using quinacrine mustard, quinacrine, or other fluorescent dyes and observed with a fluorescence microscope.

G banding: Preparations are incubated in a variety of saline solutions using any 1 of several pretreatments and stained with Giemsa's stain.

R banding: Preparations are incubated in buffer solutions at high temperatures or at special pH and stained with Giemsa's stain. This process yields the reverse bands of G banding (Fig 5–1).

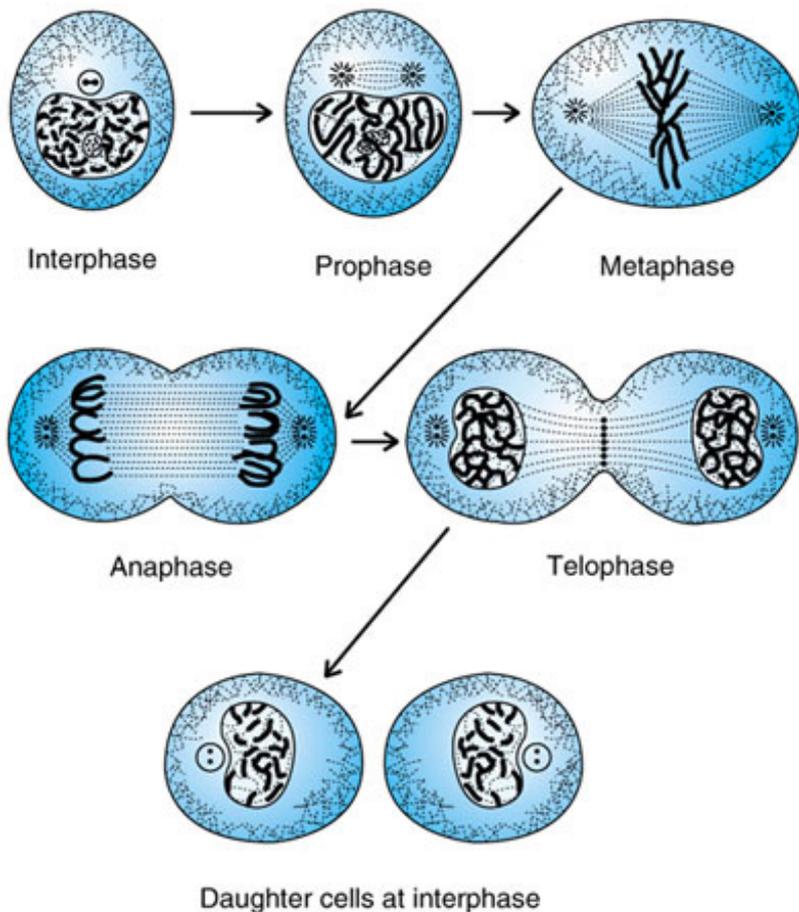

C banding: Preparations are either heated in saline to temperatures just below boiling or treated with certain alkali solutions and then stained with Giemsa's stain. This process causes prominent bands to develop in the region of the centromeres.

Cell Division

Each body cell goes through successive stages in its life cycle. As a landmark, cell division can be considered as the beginning of a cycle. Following this, the first phase, which is quite long but depends on how rapidly the particular cell is multiplying, is called the G_1 stage. During this stage, the cell is primarily concerned with carrying out its function. Following this, the S stage, or period of DNA synthesis, takes place. Next there is a somewhat shorter stage, the G_2 stage, during which time DNA synthesis is completed and chromosome replication begins. Following this comes the M stage, when cell division occurs.

Somatic cells undergo division by a process known as mitosis (Fig 5–2). This is divided into 4 periods. The first prophase, during which the chromosome filaments shorten, thicken, and become visible. At this time they can be seen to be composed of 2 long parallel spiral strands lying adjacent to one another and containing a small clear structure known as the centromere. As prophase continues, the strands continue to unwind and may be recognized as chromatids. At the end of prophase, the nuclear membrane disappears and metaphase begins. The stage is heralded by the formation of a spindle and the lining up of the chromosomes in pairs on the spindle. Following this, anaphase occurs, at which time the centromere divides and each daughter chromatid goes to 1 of the poles of the spindle. Telophase then ensues, at which time the spindle breaks and cell cytoplasm divides. A nuclear membrane now forms, and mitosis is complete. Each daughter cell has received chromosome material equal in amount and identical to that of the parent cell. Because each cell contains 2 chromosomes of each pair and a total of 46 chromosomes, a cell is considered to be diploid. Occasionally, an error takes place on the spindle, and instead of chromosomes dividing, with identical chromatids going to each daughter cell, an extra chromatid goes to 1 daughter cell and the other lacks that particular member. After completion of cell division, this leads to a trisomic state (an extra dose of that chromosome) in 1 daughter cell and a monosomic state (a missing dose of the chromosome) in the other daughter cell. Any chromosome in the karyotype may be involved in such a process, which is known as mitotic nondisjunction. If these cells thrive and produce their own progeny, a new cell line is established within the individual. The individual then has more than 1 cell line and is known as a mosaic. A variety of combinations and permutations have occurred in humans.

Figure 5–2

Mitosis of a somatic cell.

Germ cells undergo division for the production of eggs and sperm by a process known as meiosis. In the female is known as oogenesis and in the male as spermatogenesis. The process that produces the egg and the sperm for fertilization essentially reduces the chromosome number from 46 to 23 and changes the normal diploid cell to an haploid cell, i.e., a cell that has only 1 member of each chromosome pair. Following fertilization and the fusion of the 2 pronuclei, the diploid status is reestablished.

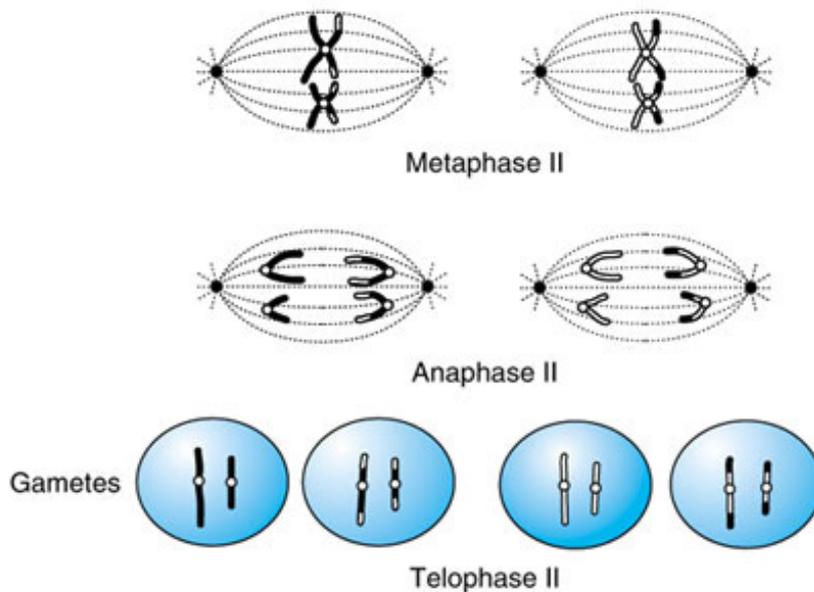

Meiosis can be divided into several stages (Fig 5-3). The first is prophase I. Early prophase is known as the leptotene stage, during which chromatin condenses and becomes visible as a single elongated threadlike structure. This is followed by the zygotene stage, when the single threadlike chromosomes migrate toward the equatorial plate of the nucleus. At this stage, homologous chromosomes become arranged close to one another to form bivalents that exchange materials at several points known as synapses. In this way, genetic material located on 1 member of a pair is exchanged with similar material located on the other member of a pair. Next comes the pachytene stage in which the chromosomes contract to become shorter and thicker. During this stage, each chromosome splits longitudinally into 2 chromatids united at the centromere. Thus, the bivalent becomes a structure composed of 4 closely opposed chromatids known as a tetrad. The human cell in the pachytene stage demonstrates 23 tetrads. This stage is followed by the diplotene stage, in which the chromosomes of the bivalent are held together only at certain points called bridges or chiasmata. It is at these points that crossover takes place. The sister chromatids are joined at the centromere so that crossover can only take place between chromatids of homologous chromosomes and not between identical sister chromatids. In the case

of males, the X and Y chromosomes are not involved in crossover. This stage is followed by the last stage of prophase, known as diakinesis. Here the bivalents contract, and the chiasmata move toward the end of the chromosome. The homologs pull apart, and the nuclear membrane disappears. This is the end of prophase I. **Figure 5–3.**

FIRST MEIOTIC DIVISION

SECOND MEIOTIC DIVISION

Meiosis in the human.

Metaphase I follows. At this time, the bivalents are now highly contracted and align themselves along the equatorial plate of the cell. Paternal and maternal chromosomes line up at random. This stage is then followed by anaphase I and telophase I, which are quite similar to the corresponding events in mitosis. However, the difference is that in meiosis the homologous chromosomes of the bivalent pair separate and not the sister

chromatids. The homologous bivalents pull apart, 1 going to each pole of the spindle, following which 2 daughter cells are formed at telophase I.

Metaphase, anaphase, and telophase of meiosis II take place next. A new spindle forms in metaphase, the chromosomes align along the equatorial plate, and, as anaphase occurs, the chromatids pull apart, 1 each going to a daughter cell. This represents a true division of the centromere. Telophase then supervenes, with reconstitution of the nuclear membrane and final cell division. At the end, a haploid number of chromosomes is present in each daughter cell (Fig 5-3). In the case of spermatogenesis, both daughter cells are similar, forming 2 separate sperms. In the case of oogenesis, only 1 egg is produced, the nuclear material of the other daughter cell being present and intact but with very little cytoplasm, this being known as the polar body. A polar body is formed at the end of meiosis I and the end of meiosis II. Thus, each spermatogonium produces 4 sperms at the end of meiosis, whereas each oogonium produces 1 egg and 2 polar bodies.

Nondisjunction may also occur in meiosis. When it does, both members of the chromosome pair go to 1 daughter cell and none to the other. If the daughter cell that receives the entire pair is the egg, and fertilization ensues, a triple dose of the chromosome, or trisomy, will occur. If the daughter cell receiving no members of the pair is fertilized, a monosomic state will result. In the case of autosomes, this is lethal, and a very early abortion will follow. In the case of the sex chromosome, the condition may not be lethal, and examples of both trisomy and monosomy have been seen in humans. Any chromosome pair may be involved in trisomic or monosomic conditions.

Abnormalities in Chromosome Morphology & Number

As has been stated, nondisjunction may give rise to conditions of trisomy. In these cases, the morphology of the chromosome is not affected, but the chromosome number is. Be this as it may, breaks and rearrangements in chromosomes may have a variety of results. If 2 chromosomes undergo breaks and exchange chromatin material between them, the outcome is 2 morphologically new chromosomes known as translocations. If a break in a chromosome takes place and the fragment is lost, deletion has occurred. If the deletion is such that the cell cannot survive, the condition may be lethal. Nonetheless, several examples of deleted chromosomes in individuals who have survived have been identified. If a break takes place at either end of a chromosome and the chromosome heals by having the 2 ends fuse together, a ring chromosome is formed. Examples of these have been seen clinically in all of the chromosomes of the karyotype, and generally they exhibit a variety of phenotypic abnormalities.

At times a chromosome will divide by a horizontal rather than longitudinal split of the centromere. This leaves each daughter cell with a double dose of 1 of the arms of the chromosome. Thus, 1 daughter cell receives both long arms and the other both short arms of the chromosome. Such a chromosome is referred to as an isochromosome, the individual being essentially trisomic for 1 arm and monosomic for the other arm of the chromosome. Examples of this abnormality have been seen in humans.

Another anomaly that has been recognized is the occurrence of 2 breaks within the chromosome and rotation of the center fragment 180 degrees. Thus, the realignment allows for a change in morphology of the chromosome although the original number of genes is preserved. This is called an inversion. At meiosis, however, the chromosome has difficulty in undergoing chiasm formation, and abnormal rearrangements of this chromosome, leading to partial duplications and partial losses of chromatin material, do take place. This situation may lead to several bizarre anomalies. If the centromere is involved in the inversion, the condition is called a pericentric inversion.

Breaks occasionally occur in 2 chromosomes, and a portion of 1 broken chromosome is inserted into the body of another, leading to a grossly abnormal chromosome. This is known as an insertion and generally leads to gross anomalies at meiosis.

Methods of Study

Sex Chromatin (X-Chromatin) Body (Barr Body)

The X-chromatin body was first seen in the nucleus of the nerve cell of a female cat in 1949 by Barr and Bertram. It has been found to be the constricted, nonfunctioning X chromosome. As a general rule, only 1 X chromosome functions in a cell at a given time. All other X chromosomes present in a cell may be seen as X-chromatin bodies in a resting nucleus. Thus, if one knows the number of X chromosomes, one can anticipate that the number of Barr bodies will be 1 less. If one counts the number of Barr bodies, the number of X chromosomes can be determined by adding 1.

Drumsticks on Polymorphonuclear Leukocytes

Small outpouchings of the lobes of nuclei in polymorphonuclear leukocytes of females have been demonstrated to be the X-chromatin body in this particular cell. Hence, leukocyte preparations may be used to detect X-chromatin bodies in much the same way as buccal cells are used.

Chromosome Count

In the karyotypic analysis of a patient, it is the usual practice to count 20–50 chromosome spreads for chromosome number. The purpose of this practice is to determine whether mosaicism exists because if a mosaic pattern does exist, there will be at least 2 cell lines of different counts. Photographs are made of representative spreads, and karyotypes are constructed so that the morphology of each chromosome can be studied.

Banding Techniques

As previously described, it is possible after appropriate pretreatment to stain metaphase spreads with special stains and construct a karyotype that demonstrates the banding patterns of each chromosome. In this way, it is possible to identify with certainty every chromosome in the karyotype. This is of value with problems such as translocations and trisomic conditions. Another use depends on the fact that most of the long arm of the Y chromosome is heterochromic and stains deeply with fluorescent stains. Thus, the Y chromosome can be identified at a glance, even in the resting nucleus.

APPLIED GENETICS & TERATOLOGY

Chromosomes & Spontaneous Abortion

An entirely new approach to reproductive biology problems became available with the advent of tissue culture and cytologic techniques that made it possible to culture cells from any tissue of the body and produce karyotypes that could be analyzed. In the early 1960s, investigators in a number of laboratories began to study chromosomes of spontaneous abortions and demonstrated that the earlier the spontaneous abortion occurred, the more likely it was due to a chromosomal abnormality. It is now known that in spontaneous abortions occurring in the first 8 weeks, the fetuses have about a 50% incidence of chromosome anomalies.

Of abortuses that are abnormal, approximately one-half are trisomic, suggesting an error of meiotic nondisjunction. One-third of abortuses with trisomy have trisomy 16. Although this abnormality does not occur in liveborn infants, it apparently is a frequent problem in abortuses. The karyotype 45,X occurs in nearly one-fourth of chromosomally abnormal abortuses. This karyotype occurs about 24 times more frequently in abortuses than in liveborn infants, a fact that emphasizes its lethal nature. Over 15% of chromosomally abnormal abortuses have polyploidy (triploidy or tetraploidy). These lethal conditions are seen only in abortuses except in extremely rare circumstances and are due to a variety of accidents, including double fertilization and a number of meiotic errors. Finally, a small number of chromosomally abnormal abortuses have unbalanced translocations and other anomalies.

Recurrent Pregnancy Loss

Couples who experience habitual abortion constitute about 0.5% of the population. The condition is defined as 2 or more spontaneous abortions. Several investigators have studied groups of these couples using banding techniques and have found that 10–25% of them have a chromosome anomaly in either the male or female partner. Those seen are 47,XXX, 47,XYY, and a variety of balanced translocation carriers. Those with sex chromosome abnormalities frequently demonstrate other nondisjunctional events. Chromosome anomalies are thus a major cause of habitual abortion, and the incorporation of genetic evaluation into such a work-up is potentially fruitful.

Lippman-Hand and Bekemans reviewed the world literature and studied the incidence of balanced translocation carriers among 177 couples who had 2 or more spontaneous abortions. These studies suggest that in 2–3% of couples experiencing early fetal loss, 1 partner will have balanced translocations. This percentage is not markedly increased when more than 2 abortions occur. Females had a somewhat higher incidence of balanced translocations than did males.

Chromosomal Disorders

This section is devoted to a brief discussion of various autosomal abnormalities. Table 5–5 summarizes some of the autosomal abnormalities that have been diagnosed. They are represented as syndromes, together with some of the signs typical of these conditions. In general, autosomal monosomy is so lethal that total loss of a chromosome is rarely seen in an individual born alive. Only a few cases of monosomy 21–22 have been reported to date, which attests to the rarity of this disorder. Trisomy may occur with any chromosome. The 3 most common trisomic conditions seen in living individuals are trisomies 13, 18, and 21. Trisomy of various C group chromosomes has been reported sporadically. The most frequently reported is trisomy 8. Generally, trisomy of other chromosomes must be assumed to be lethal, because they occur only in abortuses, not in living individuals. To date, trisomy of every autosome except chromosome 1 has been seen in abortuses.

Table 5–5. Autosomal Disorders.

Monosomy

Monosomy 21–22

Moderate mental retardation, antimongoloid slant of eyes, flared nostrils, small mouth, low-set ears, spade hand

Trisomy

Trisomy 13

Trisomy D: the "D₁" syndrome

Severe mental retardation, congenital heart disease (77%), polydactyly, cerebral malformations (especially aplasia of olfactory bulbs), eye defects, low-set ears, cleft lip and palate, low birth weight. Characteristic dermatoglyphic pattern.

Trisomy 18

Trisomy E: the "E" syndrome, Edward's syndrome

Severe mental retardation, long narrow skull with prominent occiput, congenital heart disease, flexion deformities of fingers, narrow palpebral fissures, low-set ears, harelip and cleft palate. Characteristic dermatoglyphics, low birth weight.

Trisomy 21

Down syndrome

Mental retardation, brachycephaly, prominent epicanthal folds. Brushfield spots, poor nasal bridge development, congenital heart disease, hypotonia, hypermobility of joints, characteristic dermatoglyphics.

Translocations

15/21

Down syndrome

Same as trisomy 21.

21/21

Down syndrome

Same as trisomy 21.

21/22

Down syndrome

Same as trisomy 21.

Deletions

Short arm chromosome 4(4p-)

Wolf's syndrome

Severe growth and mental retardation, midline scalp defects, seizures, deformed iris, beak nose, hypospadias.

Short arm chromosome 5(5p-)

Cri-du-chat syndrome

Microcephaly, catlike cry, hypertelorism with epicanthus, low-set ears, micrognathism, abnormal dermatoglyphic low birth weight.

Long arm chromosome 13(13q-)

...

Microcephaly, psychomotor retardation, eye and ear defects, hypoplastic or absent thumbs.

Short arm chromosome 18(18p-)

...

Severe mental retardation, hypertelorism, low-set ears, flexion deformities of hands.

Long arm chromosome 18(18q-)

...

Severe mental retardation, microcephaly, hypotonia, congenital heart disease; marked dimples at elbows, shoulders, and knees.

Long arm chromosome 21(21q-)

...

Associated with chronic myelogenous leukemia.

Type	Synonym	Signs

Translocations can occur between any 2 chromosomes of the karyotype, and a variety of phenotypic expressions may be seen after mediocre arrangements. Three different translocation patterns have been identified in Down syndrome: 15/21, 21/21, and 21/22.

Deletions may also occur with respect to any chromosome in the karyotype and may be brought about by a translocation followed by a rearrangement in meiosis, which leads to the loss of chromatin material, or by a simple loss of the chromatin material following a chromosome break. Some of the more commonly seen deletion patterns are listed in Table 5-5.

The most frequent abnormality related to a chromosome abnormality is Down syndrome. Down syndrome serves as an interesting model for the discussion of autosomal diseases. The 21 trisomy type is the most common form and is responsible for approximately 95% of Down syndrome patients. There is a positive correlation between the frequency of Down syndrome and maternal age. Babies with Down syndrome are more often born to teenage mothers and even more frequently to mothers over 35. Although the reason for these findings is not entirely clear, it may be that, in older women at least, the egg has been present in prophase of the first meiotic division from the time of fetal life and that as the egg ages there is a greater tendency for nondisjunction to occur, leading to trisomy. A second theory is that coital habits are more erratic in both the very young and the older mothers, and this may lead to an increased incidence of fertilization of older eggs. This theory maintains that these eggs may be more likely to suffer nondisjunction or to accept abnormal sperm. Be this as it may, the incidence of Down syndrome in the general population is approximately 1 in 600 deliveries and at age 40 approximately 1 in 100 deliveries. At age 45, the incidence is approximately 1 in 40 deliveries (Table 5-6). The other 5% of Down syndrome patients are the result of translocations, the most common being the 15/21 translocation, but examples of 21/21 and 21/22 have been noted. In the case of 15/21, the chance of recurrence in a later pregnancy is

theoretically 25%. In practice, a rate of 10% is observed if the mother is the carrier. When the father is the carrier, the odds are less because there may be a selection not favoring the sperm carrying both the 15/21 translocation and the normal 21 chromosome. In the case of 21/21 translocation, there is no chance for formation of a normal child because the carrier will contribute either both 21s or no 21 and, following fertilization, will produce either a monosomic 21 or trisomic 21. With regard to 21/22 translocation, the chance of producing a baby with Down syndrome is 1 in 2.

Maternal Age	Down Syndrome	Edward's Syndrome (Trisomy 18)	Patau's Syndrome (Trisomy 13)	XXY	XYY	Turner's Syndrome Genotype	Other Clinically Significant Abnormality ¹	Total

¹ XXX is excluded.

² Calculation of the total at each age assumes rate for autosomal aneuploidies is at the midpoints of the ranges given.

³ No range may be constructed for those under 20 years by the same methods as for those 20 and over.

Reproduced with permission, from Hook EB: Rates of chromosome abnormalities at different maternal ages. *Obstet Gynecol* 1981;58:282.

In general, other trisomic states occur with greater frequency in older women, and the larger the chromosome involved, the more severe the syndrome. Because trisomy 21 involves the smallest of the chromosomes, the phenotypic problems of Down syndrome are the least severe, and a moderate life expectancy may be anticipated. Even these individuals will be grossly abnormal, however, because of mental retardation and defects in other organ systems. The average life expectancy of patients with Down syndrome is much lower than for the general population.

Prenatal Diagnosis

Currently the most common use for applied genetics in obstetrics and gynecology is in prenatal counseling, screening, and diagnosis. Prenatal diagnosis first came into use in 1977 with the discovery of the significance of serum α -fetoprotein (AFP). The United Kingdom Collaboration Study found that elevated AFP in maternal serum drawn between 16 and 18 weeks of gestation correlated with an increased incidence of neural tube defects (NTD). Since that time, much research effort has been aimed at perfecting the technique. We now can screen not only for NTDs but also for trisomy 21 and trisomy 18. In addition, cystic fibrosis, sickle cell disease, and Huntington's disease, as well as many inborn errors of metabolism and other genetic disorders, can now be identified prenatally.

Neural Tube Disease

Most neural tube diseases, eg, anencephaly, spina bifida, and meningomyelocele, are associated with a multifactorial inheritance pattern. The frequency of their occurrence varies in different populations (eg, rates as high as 10 per 1000 births in Ireland and as low as 0.8 per 1000 births in the western United States). Ninety percent are index cases, ie, they occur spontaneously without previous occurrence in a family. In general, if a couple has a child with such an anomaly, the chance of producing another affected child is 2–5%. If they have 2 such children, the risk can be as high as 10%. However, other diagnostic possibilities involving different modes of inheritance should be considered. Siblings also run greater risks of having affected children, with the highest risk being to female offspring of sisters and the lowest to male offspring of brothers. Maternal serum screening is now available to all mothers between 16 and 20 weeks of gestation. If an elevation of 2.5 or more standard deviations above the mean is noted, amniocentesis for AFP should be done along with a careful ultrasound study of the fetus for structural anomalies. Evidence for an NTD noted on ultrasound and suspected by amniotic fluid AFP elevation of 3.0 or more standard deviations indicates a diagnosis of an NTD and allows for appropriate counseling and decision making for the parents.

Maternal serum AFP screening detects about 85% of all open NTDs, thus allowing detection of 80% of all open NTDs and 90% of all anencephalic infants. Serum AFP screening does not detect skin-covered lesions or the closed form of NTDs. Thus, most encephaloceles may be missed.

Approximately 5–5.5% of women screened will have abnormally elevated values (≥ 2.5 times the mean). Most of these will be false-positive results (a repeat test should determine this) due to inaccurate dating of gestational age, multiple gestation, fetal demise or dying fetus, or a host of other structural abnormalities. In most cases, repeat AFP testing and ultrasound examination will identify the problem. If the serum AFP level remains elevated and ultrasound examination does not yield a specific diagnosis, amniotic fluid AFP levels should be measured as well as amniotic fluid acetylcholinesterase levels. Further testing and counseling may be necessary before a final diagnosis can be made. When the correct gestational age is used, the false-positive rate for second-trimester maternal screening is 3–4%.

Chromosomal Abnormalities

In 1984, maternal serum AFP levels were found to be lower in patients who delivered infants with Down syndrome. Using the AFP value with maternal age, 25–30% of fetuses with Down syndrome were detected prenatally. In 1988, 2 additional tests were added to the maternal AFP: human chorionic gonadotropin (hCG) and unconjugated estriol (uE_3). Using the "triple screen" a 60% detection rate for Down syndrome was accomplished. In addition, the use of uE_3 allowed for detection of trisomy 18.

Fetuses with Down syndrome have low maternal AFP, low uE_3 , and high hCG. Fetuses with trisomy 18 have low values across all of the serum markers. The false-positive rate for women less than 35 years of age is 5%. Above this age cutoff the false-positive rate is increased. The definitive diagnosis of a chromosomal abnormality must be confirmed with a fetal karyotype.

The risk of fetal trisomies increases with increasing maternal age. At age 35 the risk of a trisomy is approximately 1 in 200. At age 40 the risk is 1 in 20 (Table 5–6). Prior to the discovery of serum markers, advanced maternal

age was used to guide which women received fetal karyotyping. Trisomies, however, are not the only abnormalities increased in this population of women. Sex chromosome aneuploidies (47,XXY and 47,XXX) also occur at an increased rate in women 35 years of age and older. Despite the advances in serum screening, fetal karyotyping continues to be the gold standard for prenatal testing in this group of women. The use of maternal serum screening in this subset of women is hindered by a high false-positive rate, less than 100% detection rate for trisomy 18 and 21, and the lack of ability to screen for the sex chromosome aneuploidies.

Cystic Fibrosis

Cystic fibrosis affects 1 in 3300 individuals of European descent in the United States. The carrier frequency is 1 in 29 for North Americans of European descent and Ashkenazi Jewish descent and 1 in 60 for African Americans. A deletion of phenylalanine at position 508 of the CFTR gene on chromosome 7 leads to the disease. All individuals with a family history of cystic fibrosis or a high carrier frequency should be offered carrier testing. For couples who are both carriers of the defective allele, fetal testing may be provided.

Future Advances in Prenatal Screening

In the detection of certain trisomies, the triple-marker screen provides better sensitivity than any single marker alone. Nonetheless, the detection rate for trisomy 18 and trisomy 21 still remains quite low. According to the Serum Urine and Ultrasound Screening Study (SURUSS), integration of nuchal translucency measurement and pregnancy-associated plasma protein-A (PAPP-A) in the first trimester improves screening. This information in conjunction with early second-trimester measurement of AFP, uE_3 , free β -hCG (or total hCG), and inhibin-A with maternal age provides the most effective method for screening of Down Syndrome, with an 85% detection rate and 0.9% false-positive rate. As the field of prenatal diagnostics continues to evolve, higher detection rates with lower false-positive rates can be expected. With continued research and advancing technology, prenatal screening may move into the first trimester. It may involve new markers (proform of eosinophil major basic protein [proMBP], nasal bone) and may even involve markers taken in both the first and second trimesters.

Fetal Karyotyping

AMNIOCENTESIS

Amniocentesis for prenatal diagnosis of genetic diseases is an extremely useful tool in the following circumstances or classes of patients:

1. Maternal age 35 years or above
2. Previous chromosomally abnormal child
3. Three or more spontaneous abortions
4. Patient or husband with chromosome anomaly
5. Family history of chromosome anomaly
6. Possible female carrier of X-linked disease
7. Metabolic disease risk (because of previous experience or family history)
8. NTD risk (because of previous experience or family history)
9. Positive second-trimester maternal serum screen

Currently, so many metabolic diseases can be diagnosed prenatally by amniocentesis that when the history elicits the possible presence of a metabolic disease, it is prudent to check with a major center to ascertain the availability of a diagnostic method.

Amniocentesis generally is carried out at 15 to 17 weeks of gestation but can be offered earlier (12–14 weeks). The underlying risk of amniocentesis when performed at 15 weeks of gestation and beyond is increased risk of

miscarriage. This risk is estimated at 1 in 200 (0.5%), which is approximately the risk of Down syndrome in a 31-year-old woman. When amniocentesis is performed prior to 15 weeks the miscarriage rate is slightly increased. Table 5–7 lists some of the conditions that now can be diagnosed prenatally by biochemical means.

Table 5–7. Examples of Hereditary Diseases Diagnosable Prenatally.

Lipidoses: Gaucher's, Tay-Sachs, Fabry's, etc.

Mucopolysaccharidoses: Hurler's, Hunter's, etc.

Aminoacidurias: Cystinosis, homocystinuria, maple syrup urine disease, etc.

Diseases of carbohydrate metabolism: Glucose-6-phosphate dehydrogenase deficiency, glycogen storage diseases, etc.

Miscellaneous: Adrenogenital syndrome, Lesch-Nyhan syndrome, sickle cell disease, cystic fibrosis, Huntington's disease, etc.

CHORIONIC VILLUS SAMPLING

Chorionic villus sampling (CVS) is a technique used in the first trimester to obtain villi for cytogenetic testing. Most commonly, it is performed transcervically; however, transabdominal routes may also be attempted. The value of CVS is that it can be performed earlier in the pregnancy, and thus the decision of pregnancy termination can be made earlier. The downfall of CVS, however, is a slightly higher miscarriage rate of 1–5% and an association with distal limb defects. These risks appear to be dependent on operator experience, and lower numbers have been reported when CVS is performed between 10 and 12 weeks of gestation.

Karyotyping & Fluorescence In Situ Hybridization Analysis

Once the fetal cells are obtained they must be processed. Formal karyotyping should be performed on all specimens. This involves culturing the cells, replication, and eventually karyotyping. The entire process often takes 10–14 days until the final report becomes available. Fortunately, a quicker analysis can be obtained for some of the most common chromosomal anomalies.

The fluorescence in situ hybridization (FISH) study is a rapid assay for the detection of specific chromosomal aneuploidies using fluorescent-labeled DNA probes. Currently, probes exist for chromosomes 13, 18, 21, and 22 as well as the X and Y sex chromosomes among others. The average time to obtain a result is 24 hours. However, certain chromosomal probes may return as quickly as 4 hours. The more rapid turnaround time can be attained because the probes are mixed with uncultured amniocytes obtained from amniotic fluid or cells from CVS. If a patient is late in gestation or if the ultrasound is highly suggestive of a certain chromosomal composite, FISH analysis may be an appropriate study. With the development of multicolor FISH, all human chromosomes are painted in 24 different colors, allowing identification of chromosome rearrangement.

Single Gene Defects

If 1 parent is affected and the condition is caused by an autosomal dominant disorder, the chances are 1 in 2 that a child will be affected. If both parents are carriers of an autosomal recessive condition, the chances are 1 in 4 that the child will be affected and 1 in 2 that the child will be a carrier. Carrier status of both parents can be assumed if an affected child has been produced or if a carrier testing program is available and such testing determines that both parents are carriers. Tay-Sachs disease and sickle cell disease detection programs are

examples of the latter possibility.

When carrier testing is available and the couple is at risk, as with Tay-Sachs disease in Jewish couples and sickle cell disease in blacks, the physician should order these carrier tests before pregnancy is undertaken, or immediately if the patient is already pregnant. When parents are carriers and pregnancy has been diagnosed, prenatal diagnostic testing is indicated if a test is available. If a physician does not know whether or not a test exists or how to obtain the test, the local genetic counseling program, local chapter of the National Foundation/March of Dimes, or state health department should be called for consultation. These sources may be able to inform the physician about new research that may have produced a prenatal test. A new test may be like because this area of research is very dynamic. If genetic counseling services are readily available, patients with specific problems should be referred to those agencies for consultation. It is impossible for a physician to keep track of all of the current developments in the myriad conditions caused by single gene defects.

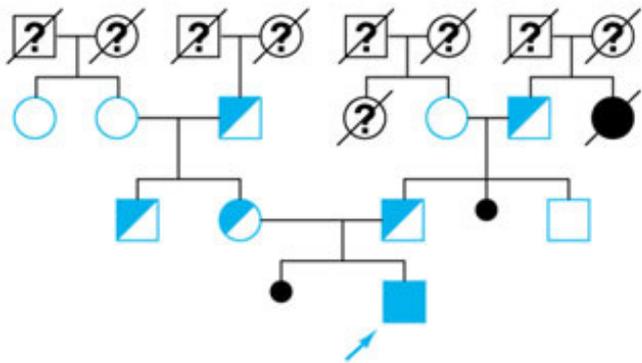

X-linked traits are frequently amenable to prenatal diagnostic testing. When such tests are not available, the couple has the option of testing for the sex of the fetus. If a fetus is noted to be a female, the odds are overwhelming that it will not be affected, although a carrier state may be present. If the fetus is a male, the chances are 1 in 2 that it will be affected. With this information, the couple can decide whether or not to continue the pregnancy in the case of a male fetus. Again, checking with genetic counseling agencies may reveal a prenatal diagnostic test that has only recently been described or information such as gene linkage studies that may apply to the individual case.

All options should be presented in a nonjudgmental fashion with no attempt to persuade, based on the best information available at the time. The couple should be encouraged to decide on a course of action that suits the particular needs. If the decision is appropriate, it should be supported by the physician and the genetic counselor. Very rarely, the patient will make a decision the physician regards as unwise or unrealistic. Such a decision may be based on superstition, religious or mystical beliefs, simple naivete, or even personality disorder. The physician should make every attempt to clarify the issues for the patient. Rarely, other resources such as family members or spiritual leaders may be consulted in strict confidence. The physician and the genetic counselor must clearly set forth the circumstances of the problem in the record, in case the patient undertakes a course of action that ends in tragedy and perhaps attempts to blame the professional counselors for not preventing it.

Genetic Counseling

Genetic counseling involves interaction between the physician, the family, and the genetic counselor. It is the physician's responsibility to utilize the services of the genetic consultant in the best interest of the patient. The genetic counselor will take a formal family history and construct a family tree (Fig 5–4). The assessment of the underlying general population risk of a disease and the specific family risk should be provided. When a specific diagnosis is known in the proband and the relatives are dead or otherwise not available, the counselor may ask to see photographs, which may show characteristics of the suspected condition. In many cases, when the pedigree is constructed, the inheritance pattern can be determined. If this can be done, the relative risks that future progeny will be affected can be estimated. This pedigree information is also useful in discussing the case with a genetic counselor.

THE CHROMOSOMAL BASIS OF SEX DETERMINATION

Syngamy

The sex of the fetus normally is determined at fertilization. The cells of normal females contain 2 X chromosome those of normal males contain 1 X and 1 Y. During meiotic reduction, half of the male gametes receive a Y chromosome and the other half an X chromosome. Because the female has 2 X chromosomes, all female gametes contain an X chromosome. If a Y-bearing gamete fertilizes an ovum, the fetus is male; conversely, if an X-bearing gamete fertilizes an ovum, the fetus is female.

Arithmetically, the situation described previously should yield a male/female sex ratio of 100—the sex ratio being defined as 100 times the number of males divided by the number of females. However, for many years, the male/female sex ratio of the newborns in the white population has been approximately 105. Apparently the sex ratio at fertilization is even higher than at birth; most data on the sex of abortuses indicate a preponderance of males.

Abnormalities of Meiosis and Mitosis

The discussion in this section is limited to anomalies of meiosis and mitosis that result in some abnormality in the sex chromosome complement of the embryo.

Chromosome studies in connection with various clinical conditions suggest that errors in meiosis and mitosis do indeed occur. These errors result in any of the following principal effects: (1) an extra sex chromosome, (2) an absent sex chromosome, (3) 2 cell lines having different sex chromosomes and arising by mosaicism, (4) 2 cell lines having different sex chromosomes and arising by chimerism, (5) a structurally abnormal sex chromosome, and (6) a sex chromosome complement inconsistent with the phenotype.

By and large, an extra or a missing sex chromosome arises as the result of an error of disjunction in meiosis I or in either the male or the female. In meiosis I, this means that instead of each of the paired homologous sex

chromosomes going to the appropriate daughter cell, both go to 1 cell, leaving that cell with an extra sex chromosome and the daughter cell with none. Failure of disjunction in meiosis II simply means that the centromere fails to divide normally.

A variation of this process, known as anaphase lag, occurs when 1 of the chromosomes is delayed in arriving at the daughter cell and thus is lost. Theoretically, chromosomes may be lost by failure of association in prophase and by failure of replication, but these possibilities have not been demonstrated.

Persons who have been found to have 2 cell lines apparently have experienced problems in mitosis in the very early stage of embryogenesis. Thus, if there is nondisjunction or anaphase lag in an early (first, second, or immediately subsequent) cell division in the embryo, mosaicism may be said to exist. In this condition, there are cell lines; 1 has a normal number of sex chromosomes, and the other is deficient in a sex chromosome or has an extra number of sex chromosomes. A similar situation exists in chimerism, except that there may be a difference in the sex chromosome: 1 may be an X and 1 may be a Y. This apparently arises by dispermy, by the fertilization of a double oocyte, or by the fusion, very early in embryogenesis, of 2 separately fertilized oocytes. Each of these conditions has been produced experimentally in animals.

Structural abnormalities of the sex chromosomes—deletion of the long or short arm or the formation of an isochromosome (2 short arms or 2 long arms)—result from injury to the chromosomes during meiosis. How such injuries occur is not known, but the results are noted more commonly in sex chromosomes than in autosomes—perhaps because serious injury to an autosome is much more likely to be lethal than injury to an X chromosome, and surviving injured X chromosomes would therefore be more common.

The situation in which there is a sex chromosome complement with an inappropriate genotype arises in special circumstances of true hermaphroditism and XX males (see later sections).

The X Chromosome in Humans

At about day 16 of embryonic life, there appears on the undersurface of the nuclear membrane of the somatic cells of human females a structure 1 μ m in diameter known as the X-chromatin body. There is genetic as well as cytogenetic evidence that this is 1 of the X chromosomes (the only chromosome visible by ordinary light microscopy during interphase). In a sense, therefore, all females are hemizygous with respect to the X chromosome. However, there are genetic reasons for believing that the X chromosome is not entirely inactivated during the process of formation of the X-chromatin body. In normal females, inactivation of the X chromosome during interphase and its representation as the X-chromatin body are known as the Lyon phenomenon (for Mary Lyon, a British geneticist). This phenomenon may involve, at random, either the maternal or the paternal X chromosome. Furthermore, once the particular chromosome has been selected early in embryogenesis, it is always the same X chromosome that is inactivated in the progeny of that particular cell. Geneticists have found that the ratio of maternal to paternal X chromosomes inactivated is approximately 1:1.

The germ cells of an ovary are an exception to the X inactivation concept in that X inactivation does not characterize the meiotic process. Apparently, meiosis is impossible without 2 genetically active X chromosomes. Although random structural damage to 1 of the X chromosomes seems to cause meiotic arrest, oocyte loss, and therefore failure of ovarian development, an especially critical area necessary for oocyte development has been identified on the long arm of the X. This essential area involves almost all of the long arm and has been specifically located from Xq13 to Xq26. If this area is broken in 1 of the X chromosomes as in a deletion or translocation, oocyte development does not occur. However, a few exceptions to this rule have been described.

It is a curious biologic phenomenon that if 1 of the X chromosomes is abnormal, it is always this chromosome that is genetically inactivated and becomes the X-chromatin body, regardless of whether it is maternal or paternal in origin. Although this general rule seems to be an exception to the randomness of X inactivation, this is more apparent than real. Presumably, random inactivation does occur, but the disadvantaged cells—ie, those left with

damaged active X—do not survive. Consequently, the embryo develops only with cells with a normal active X chromosome (X-chromatin body) (Fig 5–5).

Relation of X-chromatin body to the possible sex chromosome components.

If there are more than 2 X chromosomes, all X chromosomes except 1 are genetically inactivated and become X chromatin bodies; thus, in this case, the number of X-chromatin bodies will be equal to the number of X chromosomes minus 1. This type of inactivation applies to X chromosomes even when a Y chromosome is present, eg, in Klinefelter's syndrome.

Although the X chromosomes are primarily concerned with the determination of femininity, there is abundant genetic evidence that loci having to do with traits other than sex determination are present on the X chromosome. Thus, in the catalog of genetic disorders given in the 10th edition of *Mendelian Inheritance in Man*, 320 traits are listed as more or less definitely X-linked. Substantial evidence for X linkage has been found for about 160 of the traits; the rest are only suspected of having this relationship. Hemophilia, color blindness, childhood muscular dystrophy (Duchenne's dystrophy), Lesch-Nyhan syndrome, and glucose-6-phosphate dehydrogenase deficiency are among the better known conditions controlled by loci on the X chromosome. These entities probably arise from the expression of a recessive gene due to its hemizygous situation in males.

X-linked dominant traits are infrequent in humans. Vitamin D-resistant rickets is an example.

At least 1 disorder can be classified somewhere between a structural anomaly of the X chromosome and a single gene mutation. X-linked mental retardation in males is associated with a fragile site at q26, but a special culture medium is required for its demonstration. Furthermore, it has been shown that heterozygote female carriers for this fragile site have low IQ test scores.

The Y Chromosome in Humans

Just as the X chromosome is the only chromosome visible by ordinary light microscopy during interphase, the Y chromosome is the only chromosome visible in interphase, after exposure to quinacrine compounds, by fluorescence microscopy. This is a very useful diagnostic method.

In contrast to the X chromosome, few traits have been traced to the Y chromosome except those having to do with testicular formation and those at the very tip of the short arm, homologous with those at the tip of the short arm of the X. Possession of the Y chromosome alone, ie, without an X chromosome, apparently is lethal, because such a case has never been described.

Present on the Y chromosome is an area that produces a factor which allows for testicular development. This factor is termed testis-determining factor (TDF). Without the presence of TDF normal female anatomy will develop. When TDF is present, testicular development occurs with subsequent differentiation of Sertoli cells. The Sertoli cells in turn produce a second factor central to male differentiation, müllerian-inhibiting factor (MIF), also termed antimüllerian factor (AMF). The presence of MIF causes the regression of the müllerian ducts and thereby allows for the development of normal internal male anatomy.

ABNORMAL DEVELOPMENT

Ovarian Agenesis–Dysgenesis

In 1938, Turner described 7 girls 15–23 years of age with sexual infantilism, webbing of the neck, cubitus valgus, and retardation of growth. A survey of the literature indicates that "Turner's syndrome" means different things to different writers. After the later discovery that ovarian streaks are characteristically associated with the clinical entity described by Turner, "ovarian agenesis" became a synonym for Turner's syndrome. After discovery of the absence of the X-chromatin body in such patients, the term ovarian agenesis gave way to "gonadal dysgenesis," "gonadal agenesis," or "gonadal aplasia."

Meanwhile, some patients with the genital characteristics mentioned previously were shown to have a normally positive X-chromatin count. Furthermore, a variety of sex chromosome complements have been found in connection with streak gonads. As if these contradictions were not perplexing enough, it has been noted that streaks are by no means confined to patients with Turner's original tetrad of infantilism, webbing of the neck, cubitus valgus, and retardation of growth but may be present in girls with sexual infantilism only. Since Turner's original description, a host of additional somatic anomalies (varying in frequency) have been associated with his original clinical picture; these include shield chest, overweight, high palate, micrognathia, epicanthal folds, low-set ears, hypoplasia of nails, osteoporosis, pigmented moles, hypertension, lymphedema, cutis laxa, keloids, coarctation of the aorta, mental retardation, intestinal telangiectasia, and deafness.

For our purposes, the eponym Turner's syndrome will be used to indicate sexual infantilism with ovarian streaks, short stature, and 2 or more of the somatic anomalies mentioned earlier. In this context, terms such as ovarian agenesis, gonadal agenesis, and gonadal dysgenesis lose their clinical significance and become merely descriptive of the gonadal development of the person. At least 21 sex chromosome complements have been associated with streak gonads (Fig 5–6), but only about 9 sex chromosome complements have been associated with Turner's syndrome. However, approximately two-thirds of patients with Turner's syndrome have a 45,X chromosome complement, whereas only one-fourth of patients without Turner's syndrome but with streak ovaries have a 45,X chromosome complement.

The 21 sex chromosome complements that have been found in patients with streak gonads.

Karyotype–phenotype correlations in the syndromes associated with ovarian agenesis are not completely satisfactory. Nonetheless, if gonadal development is considered as 1 problem and if the somatic difficulties associated with these syndromes are considered as a separate problem, one can make certain correlations.

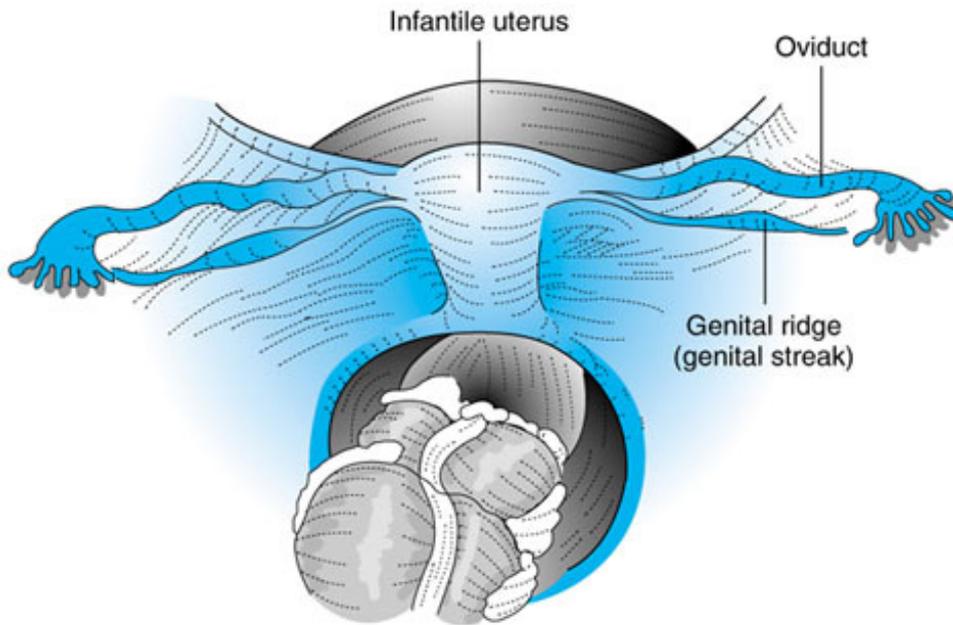

With respect to failure of gonadal development, it is important to recall that diploid germ cells require 2 normal active X chromosomes. This is in contrast to the somatic cells, where only 1 sex chromosome is thought to be genetically active, at least after day 16 of embryonic life in the human, when the X-chromatin body first appears in the somatic cells. It is also important to recall that in 45,X persons no oocytes persist, and streak gonads are the rule. From these facts, it can be inferred that failure of gonadal development is not the result of a specific sex chromosome defect but rather of the absence of 2 X chromosomes with the necessary critical zones.

Karyotype–phenotype correlations with respect to somatic abnormalities are even sketchier than the correlations with regard to gonadal development. However, good evidence shows that monosomy for the short arm of the X chromosome is related to somatic difficulties, although some patients with long-arm deletions have somatic abnormalities.

History of Gonadal Agenesis

The histologic findings in these abnormal ovaries in patients with gonadal streaks are essentially the same regardless of the patient's cytogenetic background (Fig 5–7).

Figure 5–7.

Gonadal streaks in a patient with the phenotype of Turner's syndrome.

(Redrawn and reproduced, with permission, from Jones HW Jr, Scott WW: *Hermaphroditism, Genital Anomalies and Related Endocrine Disorders*, 2nd ed. Williams & Wilkins, 1971.)

Fibrous tissue is the major component of the streak. It is indistinguishable microscopically from that of the normal ovarian stroma. The so-called germinal epithelium, on the surface of the structure, is a layer of low cuboid cells; this layer appears to be completely inactive.

Tubules of the ovarian rete are invariably found in sections taken from about the midportion of the streak.

In all patients who have reached the age of normal puberty, hilar cells are also demonstrated. The number of hilar cells varies among patients. In those with some enlargement of the clitoris, hilar cells are present in large numbers. These developments may be causally related. Nevertheless, hilar cells are also found in many normal ovaries. The origin of hilar cells is not precisely known, but they are associated with development of the medulla portion of the gonad. Their presence lends further support to the concept that in ovarian agenesis the gonad develops along normal lines until just before the expected appearance of early oocytes. In all cases in which sections of the broad ligament have been available for study, it has been possible to identify the mesonephric duct and tubules—broad ligament structures found in normal females.

Clinical Findings

SYMPTOMS AND SIGNS

In Newborn Infants

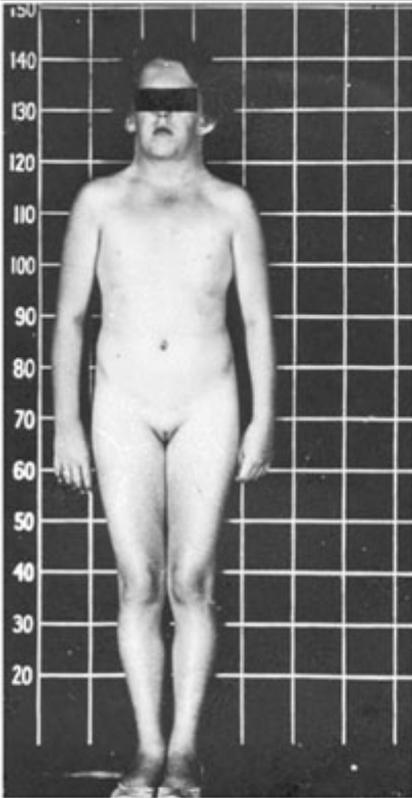

The newborn with streak ovaries often shows edema of the hands and feet. Histologically, this edema is associated with large dilated vascular spaces. With such findings, it is obviously desirable to obtain a karyotype. However, some children with streak ovaries—particularly those who have few or no somatic abnormalities—cannot be recognized at birth.

In Adolescents

The arresting and characteristic clinical finding in many of these patients is their short stature. Typical patients seldom attain a height of 1.5 m (5 ft) (Fig 5–8). In addition, sexual infantilism is a striking finding. As mentioned earlier, a variety of somatic abnormalities may be present; by definition, if 2 or more of these are noted, the

patient may be considered to have Turner's syndrome. Most of these patients have only 1 normal X chromosome and two-thirds of them have no other sex chromosome. Patients of normal height without somatic abnormalities may also have gonadal streaks. Under these circumstances, there is likely to be a cell line with 2 normal sex chromosomes but often a second line with a single X. The internal findings are exactly the same as in patients with classic Turner's syndrome, however.

Patient with Turner's syndrome.

(Reproduced, with permission, from Jones HW Jr, Scott WW: *Hermaphroditism, Genital Anomalies and Related Endocrine Disorders*, 2nd ed. Williams & Wilkins, 1971.)

LABORATORY FINDINGS

An important finding in patients of any age—but especially after expected puberty, ie, about 12 years—is elevation of total gonadotropin production. From a practical point of view, ovarian failure in patients over age 15 cannot be considered a diagnostic possibility unless the serum follicle-stimulating hormone level is more than 50 mIU/mL and luteinizing hormone level is more than 90 mIU/mL.

Nongonadal endocrine functions are normal. Urinary excretion of estrogens is low, and the maturation index and other vaginal smear indices are shifted well to the left.

Treatment

Substitution therapy with estrogen is necessary for development of secondary characteristics.

Therapy with growth hormone will increase height. Whether ultimate height will be greater than it otherwise would be is uncertain, but current evidence suggests that it will be.

The incidence of malignant degeneration is increased in the gonadal streaks of patients with a Y chromosome, as compared with normal males. Surgical removal of streaks from all patients with a Y chromosome is recommended.

True Hermaphroditism

By classic definition, true hermaphroditism exists when both ovarian and testicular tissue can be demonstrated in a patient. In humans, the Y chromosome carries genetic material that normally is responsible for testicular development; this material is active even when multiple X chromosomes are present. Thus, in Klinefelter's syndrome, a testis develops with up to 4 Xs and only 1 Y. Conversely (with rare exceptions), a testis has not been observed to develop in the absence of the Y chromosome. The exceptions are found in true hermaphrodites and XX males, in whom testicular tissue has developed in association with an XX sex chromosome complement.

Clinical Findings

SYMPTOMS AND SIGNS

No exclusive features clinically distinguish true hermaphroditism from other forms of intersexuality. Hence, the diagnosis must be entertained in an infant with any form of intersexuality, except only those with a continuing virilizing influence, eg, congenital adrenal hyperplasia. Firm diagnosis is possible after the onset of puberty, when certain clinical features become evident, but the diagnosis can and should be made in infancy.

In the past, most true hermaphrodites have been reared as males because they have rather masculine-appearing external genitalia (Fig 5–9). Nevertheless, with early diagnosis, most should be reared as females.

Figure 5–9.

External genitalia of a patient with true hermaphroditism.

(Reproduced, with permission, from Jones HW Jr, Scott WW: *Hermaphroditism, Genital Anomalies and Related Endocrine Disorders*, 2nd ed. Williams & Wilkins, 1971.)

Almost all true hermaphrodites develop female-type breasts. This helps to distinguish male hermaphroditism from true hermaphroditism, because few male hermaphrodites other than those with familial feminizing hermaphroditism develop large breasts.

Many true hermaphrodites menstruate. The presence or absence of menstruation is partially determined by the development of the uterus; many true hermaphrodites have rudimentary or no development of the müllerian duct (Fig 5–10).

Figure 5–10.

Internal genitalia of a patient with true hermaphroditism.

(Reproduced, with permission, from Jones HW Jr, Scott WW: *Hermaphroditism, Genital Anomalies and Related Endocrine Disorders*, 2nd ed. Williams & Wilkins, 1971.)

A few patients who had a uterus and menstruated after removal of testicular tissue have become pregnant and delivered normal children.

SEX CHROMOSOME COMPLEMENTS

Most true hermaphrodites have X-chromatin bodies and karyotypes that are indistinguishable from those of normal females. In contrast to these, a few patients who cannot be distinguished clinically from other true hermaphrodites have been reported to have a variety of other karyotypes—eg, several chimeric persons with karyotypes of 46,XX/46,XY have been identified.

In true hermaphrodites, the testis is competent in its müllerian-suppressive functions, but an ovotestis may behave as an ovary insofar as its müllerian-suppressive function is concerned. The true hermaphroditic testis or ovotestis is as competent to masculinize the external genitalia as is the testis of a patient with the virilizing type of male hermaphroditism. This is unrelated to karyotype.

Deletion mapping by DNA hybridization has shown that most (but not all) XX true hermaphrodites have Y-specific sequences. Abnormal crossover of a portion of the Y chromosome to the X in meiosis may explain some cases. This latter is further supported by the finding of a positive H-Y antigen assay in some patients with 46,XX true hermaphroditism.

In general, the clinical picture of true hermaphroditism is not compatible with the clinical picture in other kinds of gross chromosomal anomalies. For example, very few true hermaphrodites have associated somatic anomalies, and mental retardation almost never occurs.

Treatment

The principles of treatment of true hermaphroditism do not differ from those of the treatment of hermaphroditism in general. Therapy can be summarized by stating that surgical removal of contradictory organs is indicated, and

the external genitalia should be reconstructed in keeping with the sex of rearing. The special problem in this group is how to establish with certainty the character of the gonad. This is particularly difficult in the presence of an ovotestis, because its recognition by gross characteristics is notoriously inaccurate, and one must not remove too much of the gonad for study. In some instances the gonadal tissue of 1 sex is completely embedded within a gonadal structure primarily of the opposite sex.

Klinefelter's Syndrome

This condition, first described in 1942 by Klinefelter, Reifstein, and Albright, occurs only in apparent males. As originally described, it is characterized by small testes, azoospermia, gynecomastia, relatively normal external genitalia, and otherwise average somatic development. High levels of gonadotropin in urine or serum are characteristic.

Clinical Findings

SYMPTOMS AND SIGNS

By definition, this syndrome applies only to persons reared as males. The disease is not recognizable before puberty except by routine screening of newborn infants. Most patients come under observation at 16–40 years of age.

Somatic development during infancy and childhood may be normal. Growth and muscular development may also be within normal limits. Most patients have a normal general appearance and no complaints referable to this abnormality, which is often discovered during the course of a routine physical examination or an infertility study.

In the original publication by Klinefelter and coworkers, gynecomastia was considered an essential part of the syndrome. Since then, however, cases without gynecomastia have been reported.

The external genitalia are perfectly formed and in most patients are quite well developed. Erection and intercourse usually are satisfactory.

There is no history of delayed descent of the testes in typical cases, and the testes are in the scrotum. Neither is there any history of testicular trauma or disease. Although a history of mumps orchitis is occasionally elicited, the disease has not been correlated with the syndrome. However the testes are often very small in contrast to the size of the genitalia (about 1.5 x 1.5 cm).

Psychological symptoms are often present. Most studies of this syndrome have been performed in psychiatric institutions. The seriousness of the psychological disturbance seems to be partly related to the number of extra chromosomes—eg, it is estimated that about one-fourth of XXY patients have some degree of mental retardation.

LABORATORY FINDINGS

One of the extremely important clinical features of Klinefelter's syndrome is the excessive amount of pituitary gonadotropin found in either urine or serum assay.

The urinary excretion of neutral 17-ketosteroids varies from relatively normal to definitely subnormal levels. There is a rough correlation between the degree of hypogonadism as judged clinically and a low 17-ketosteroid excretion rate.

HISTOLOGIC AND CYTOGENETIC FINDINGS

Klinefelter's syndrome may be regarded as a form of primary testicular failure.

Several authors have classified a variety of forms of testicular atrophy as subtypes of Klinefelter's syndrome. Be this as it may, Klinefelter believed that only those patients who have a chromosomal abnormality could be said to have this syndrome. Microscopic examination of the adult testis shows that the seminiferous tubules lack epithelium and are shrunken and hyalinized. They contain large amounts of elastic fibers, and Leydig cells are present in large numbers.

Males with positive X-chromatin bodies are likely to have Klinefelter's syndrome. The nuclear sex anomaly reflects a basic genetic abnormality in sex chromosome constitution. All cases studied have had at least 2 X chromosomes and 1 Y chromosome. The most common abnormality in the sex chromosome constitution is XXY, but the literature also records XXXY, XXYY, XXXXY, and XXXYY, and mosaics of XX/XXY, XY/XXY, XY/XXXY, and XXXY/XXXXY. In all examples except the XX/XXY mosaic, a Y chromosome is present in all cells. From these patterns, it is obvious that the Y chromosome has a very strong testis-forming impulse, which can operate in spite of the presence of as many as 4 X chromosomes.

Thus, patients with Klinefelter's syndrome will have not only a positive X-chromatin body but also a positive Y-chromatin body.

The abnormal sex chromosome constitution causes differentiation of an abnormal testis, leading to testicular failure in adulthood. At birth or before puberty, such testes show a marked deficiency or absence of germinal cells.

By means of nursery screening, the frequency of males with positive X-chromatin bodies has been estimated to 2.65 per 1000 live male births.

Treatment

There is no treatment for the 2 principal complaints of these patients: infertility and gynecomastia. No pituitary preparation has been effective in the regeneration of the hyalinized tubular epithelium or the stimulation of gametogenesis. Furthermore, no hormone regimen is effective in treating the breast hypertrophy. When the breasts are a formidable psychological problem, surgical removal may be a satisfactory procedure. In patients who have clinical symptoms of hypogonadism, substitution therapy with testosterone is an important physiologic and psychological aid. Donor sperm may be offered for treatment of infertility.

Double-X Males

A few cases of adult males with a slightly hypoplastic penis and very small testes but no other indication of abnormal sexual development have been reported. These males are sterile. Unlike those with Klinefelter's syndrome, they do not have abnormal breast development. They are clinically very similar to patients with Del Castillo's syndrome (testicular dysgenesis). Nevertheless, the XX males have a positive sex chromatin and a normal female karyotype. These may be extreme examples of the sex reversal that usually is partial in true hermaphroditism.

Multiple-X Syndromes

The finding of more than 1 X-chromatin body in a cell indicates the presence of more than 2 X chromosomes in that particular cell. In many patients, such a finding is associated with mosaicism, and the clinical picture is controlled by this fact—eg, if 1 of the strains of the mosaicism is 45,X, gonadal agenesis is likely to occur. There also are persons who do not seem to have mosaicism but do have an abnormal number of X chromosomes in all cells. In such persons, the most common complement is XXX (triplo-X syndrome), but XXXX (tetra-X syndrome) and XXXXX (penta-X syndrome) have been reported.

An additional X chromosome does not seem to have a consistent effect on sexual differentiation. The body proportions of these persons are normal, and the external genitalia are normally female. A number of such persons have been examined at laparotomy, and no consistent abnormality of the ovary has been found. In a few cases, the number of follicles appeared to be reduced, and in at least 1 case the ovaries were very small and the ovarian stroma poorly differentiated. About 20% of postpubertal patients with the triplo-X syndrome report various degrees of amenorrhea or some irregularity in menstruation. For the most part, however, these patients have a normal menstrual history and are of proved fertility.

Almost all patients known to have multiple-X syndromes have some degree of mental retardation. A few have mongoloid features. (The mothers of these patients tended to be older than the mothers of normal children, as in

true with Down syndrome.) Perhaps these findings are in part circumstantial, as most of these patients were discovered during surveys in mental institutions. The important clinical point is that mentally retarded infants should have chromosomal study.

Uniformly, the offspring of triplo-X mothers have been normal. This is surprising, because theoretically in such cases meiosis should produce equal numbers of ova containing 1 or 2 X chromosomes, and fertilization of the abnormal XX ova should give rise to XXX and XXY individuals. Nevertheless, the triplo-X condition seems selective for normal ova and zygotes.

The diagnosis of this syndrome is made by identifying a high percentage of cells with double X-chromatin bodies in the buccal smear and by finding 47 chromosomes with a karyotype showing an extra X chromosome in all cells cultured from the peripheral blood. It should be noted that in the examination of the buccal smear, some cells have a single X-chromatin body. Hence, based on the chromatin examination, one might suspect XX/XXX mosaicism. Actually, in triplo-X patients, only a single type of cell can be demonstrated in cultures of cells from peripheral blood. The absence of the second X-chromatin body in some of the somatic cells may result from the time of examination of the cell (during interphase) and from the spatial orientation, which could have prevented visualization of the 2 X-chromatin bodies (adjacent to the nuclear membrane). In this syndrome, the number of cells containing either 1 or 2 X-chromatin bodies is very high—at least 60–80%, as compared with an upper limit of about 40% in normal females.

Female Hermaphroditism Due to Congenital Adrenal Hyperplasia

Essentials of Diagnosis

- Female pseudohermaphroditism, ambiguous genitalia with clitoral hypertrophy, and, occasionally, persistent urogenital sinus.
- Early appearance of sexual hair; hirsutism, dwarfism.
- Urinary 17-ketosteroids elevated; pregnanetriol may be increased.
- Elevated serum 17-hydroxyprogesterone level.
- Occasionally associated with water and electrolyte imbalance—particularly in the neonatal period.

General Considerations

Female hermaphroditism due to congenital adrenal hyperplasia is a clearly delineated clinical syndrome. The syndrome has been better understood since the discovery that cortisone may successfully arrest virilization. The problem usually is due to a deficiency of a gene required for 21-hydroxylation in the biosynthesis of cortisol.

If the diagnosis is not made in infancy, an unfortunate series of events ensues. Because the adrenals secrete an abnormally large amount of virilizing steroid even during embryonic life, these infants are born with abnormal genitalia (Fig 5–11). In extreme cases, there is fusion of the scrotolabial folds and, in rare instances, even formation of a penile urethra. The clitoris is greatly enlarged so that it may be mistaken for a penis (Fig 5–12). The gonads are palpable within the fused scrotolabial folds, and their absence has sometimes given rise to the mistaken impression of male cryptorchidism. Usually, there is a single urinary meatus at the base of the phallus, and the vagina enters the persistent urogenital sinus as noted in Figure 5–13.

(Redrawn and reproduced, with permission, from Verkauf BS, Jones HW Jr: Masculinization of the female genital in congenital adrenal hyperplasia. *South Med J* 1970; 63: 634.)

During infancy, provided there are no serious electrolyte disturbances, these children grow more rapidly than normal. For a time, they greatly exceed the average in both height and weight. Unfortunately, epiphyseal closure occurs by about age 10, and as a result these people are much shorter than normal as adults (Fig 5–14).

Figure 5–14.

Untreated adult with virilizing adrenal hyperplasia. Note the short stature and the relative shortness of the limbs

(Reproduced, with permission, from Jones HW Jr, Scott WW: *Hermaphroditism, Genital Anomalies and Related Endocrine Disorders*, 2nd ed. Williams & Wilkins, 1971.)

The process of virilization begins at an early age. Pubic hair may appear as early as age 2 years but usually somewhat later. This is followed by growth of axillary hair and finally by the appearance of body hair and a beard which may be so thick as to require daily shaving. Acne may develop early. Puberty never ensues. There is no breast development. Menstruation does not occur. During the entire process, serum adrenal androgens and 17-hydroxyprogesterone levels are abnormally high.

Although our principal concern here is with this abnormality in females, it must be mentioned that adrenal hyperplasia of the adrenogenital type may also occur in males, in whom it is called macrogenitosomia precox. Sexual development progresses rapidly, and the sex organs attain adult size at an early age. Just as in the female sexual hair and acne develop unusually early, and the voice becomes deep. The testes are usually in the scrotum however, in early childhood they remain small and immature, although the genitalia are of adult dimensions. In adulthood, the testes usually enlarge and spermatogenesis occurs, allowing impregnation rates similar to those of a control population. Somatic development in the male corresponds to that of the female; as a child, the male exceeds the average in height and strength, but (if untreated) as an adult he is stocky, muscular, and well below average height.

Both the male and the female with this disorder—but especially the male—may have the complicating problem of electrolyte imbalance. In infancy, it is manifested by vomiting, progressive weight loss, and dehydration and may be fatal unless recognized promptly. The characteristic findings are an exceedingly low serum sodium level, low

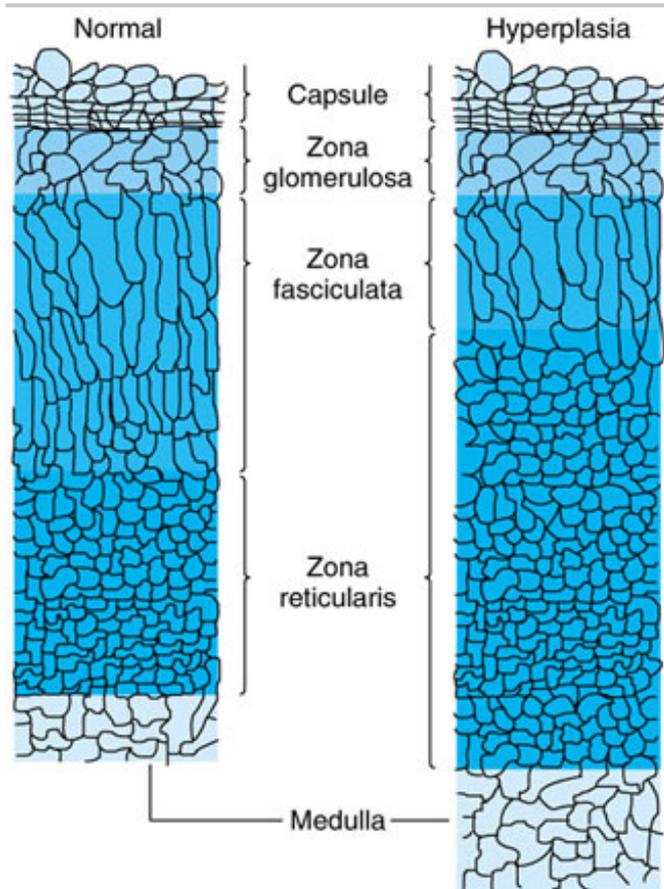

CO₂ -combining power level, and high potassium level. The condition is sometimes misdiagnosed as congenital pyloric stenosis.

A few of these patients have a deficiency in 11-hydroxylation that is associated with hypertension in addition to virilization.

Adrenal Histology

The adrenal changes center on a reticular hyperplasia, which becomes more marked as the patient grows older. In some instances, the glomerulosa may participate in the hyperplasia, but the fasciculata is greatly diminished in amount or entirely absent. Lipid studies show absence of fascicular and glomerular lipid but an abnormally strong lipid reaction in the reticularis (Fig 5–15).

Figure 5–15.

Copyright ©2006 by The McGraw-Hill Companies, Inc.
All rights reserved.

Normal adrenal architecture and adrenal histology in congenital virilizing adrenal hyperplasia. Note the great relative increase in the zona reticularis.

Ovarian Histology

The ovarian changes can be summarized by stating that in infants, children, and teenagers, there is normal follicular development to the antrum stage but no evidence of ovulation. With increasing age, less and less follicular activity occurs, and primordial follicles disappear. This disappearance must not be complete, however, because cortisone therapy, even in adults, usually results in ovulatory menstruation after 4–6 months of treatment.

Developmental Anomalies of the Genital Tubercle & Urogenital Sinus Derivatives

The phallus is composed of 2 lateral corpora cavernosa, but the corpus spongiosum is normally absent. The external urinary meatus is most often located at the base of the phallus (Fig 5–11). An occasional case may be seen in which the urethra does extend to the end of the clitoris (Fig 5–12). The glans penis and the prepuce are present and indistinguishable from these structures in the male. The scrotolabial folds are characteristically fused in the midline, giving a scrotumlike appearance with a median perineal raphe; however, they seldom enlarge to normal scrotal size. No gonads are palpable within the scrotolabial folds. When the anomaly is not severe (eg, in patients with postnatal virilization), fusion of the scrotolabial folds is not complete, and by gentle retraction it is often possible to locate not only the normally located external urinary meatus but also the orifice of the vagina.

An occasional patient has no communication between the urogenital sinus and the vagina. In no case does the vagina communicate with that portion of the urogenital sinus that gives rise to the female urethra or the prostatic urethra. Instead, the vaginal communication is via caudal urogenital sinus derivatives; thus, fortunately, the sphincter mechanism is not involved, and the anomalous communication is with that portion of the sinus that develops as the vaginal vestibule in the female and the membranous urethra in the male. From the gynecologist point of view, it is much more meaningful to say that the vagina and (female) urethra enter a persistent urogenital sinus than to say that the vagina enters the (membranous [male]) urethra. This conclusion casts some doubt on the embryologic significance of the prostatic utricle, which is commonly said to represent the homologue of the vagina in the normal male.

Hormone Changes

Important and specific endocrine changes occur in congenital adrenal hyperplasia of the adrenogenital type. The ultimate diagnosis depends on demonstration of these abnormalities.

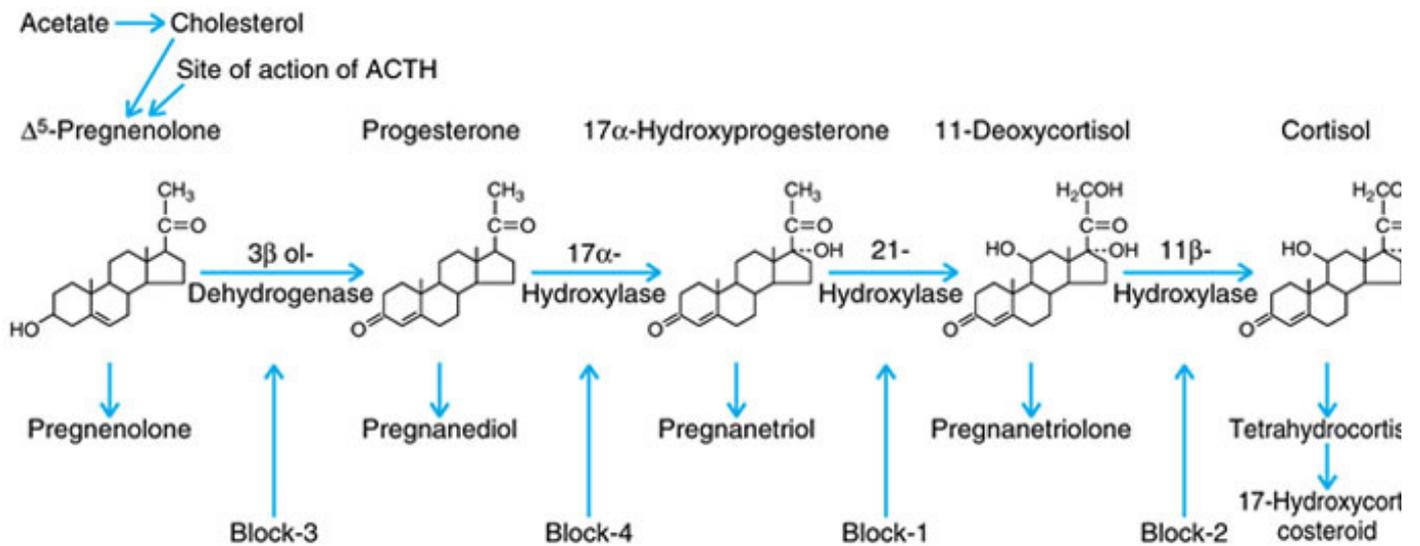

URINARY ESTROGENS

The progressive virilization of female hermaphrodites caused by adrenal hyperplasia would suggest that estrogen secretion in these patients is low, and this hypothesis is further supported by the atrophic condition of both the ovarian follicular apparatus and the estrogen target organs. Actually, the determination of urinary estrogens, both fluorometrically and biologically, indicates that it is elevated.

SERUM STEROIDS

The development of satisfactory radioimmunoassay techniques for measuring steroids in blood serum has resulted in an increased tendency to measure serum steroids rather than urinary metabolites in diagnosing the condition and monitoring therapy. Serum steroid profiles of many patients with this disorder show that numerous defects in the biosynthesis of cortisol may occur. The most common defect is at the 21-hydroxylase step. Less frequent defects are at the 11-hydroxylase step and the 3 β -ol-dehydrogenase step. Rarely, the defect is at the 17-hydroxylase step. In the most common form of the disorder—21-hydroxylase deficiency—the serum 17-hydroxyprogesterone level and, to a lesser extent, the serum progesterone level are elevated. This is easily understandable when it is recalled that 17-hydroxyprogesterone is the substrate for the 21-hydroxylation step (Fig 5–16). Likewise, in the other enzyme defects, the levels of serum steroid substrates are greatly elevated.

Enzymatic steps in cortisol synthesis. Localization of defects in congenital adrenal hyperplasia.

Pathogenesis of Virilizing Adrenal Hyperplasia

The basic defects in congenital virilizing adrenal hyperplasia are 1 or more enzyme deficiencies in the biosynthesis of cortisol (Fig 5–16). With the reduced production of cortisol, normal feedback to the hypothalamus fails, with the result that increased amounts of adrenocorticotropic hormone (ACTH) are produced. This excess production of ACTH stimulates the deficient adrenal gland to produce relatively normal amounts of cortisol—but also stimulates production of abnormally large amounts of estrogen and androgens by the zona reticularis. In this overproductive state, a biologic preponderance of androgens causes virilization. These abnormal sex steroids suppress the gonadotropin so that untreated patients never reach puberty and do not menstruate.

Therefore, the treatment of this disorder consists in part of the administration of sufficient exogenous cortisol to suppress ACTH production to normal levels. This in turn should reduce overstimulation of the adrenal so that the adrenal will cease to produce abnormally large amounts of estrogen and androgen. The gonadotropins generally return to normal levels, with consequent feminization of the patient and achievement of menstruation.

The pathogenesis of the salt-losing type of adrenal hyperplasia involves a deficiency in aldosterone production.

Diagnosis

Hermaphroditism due to congenital adrenal hyperplasia must be suspected in any infant born with ambiguous or abnormal external genitalia. It is exceedingly important that the diagnosis be made at a very early age if undesirable disturbances of metabolism are to be prevented.

All patients with ambiguous external genitalia should have an appraisal of their chromosomal characteristics. In instances of female pseudohermaphroditism due to congenital hyperplasia, the chromosomal composition is that of a normal female. A pelvic ultrasound in the newborn to determine the presence of a uterus is very helpful and, if positive, strongly suggests a female infant.

The critical determinations are those of the urinary 17-ketosteroid and serum 17-hydroxyprogesterone levels. If these are elevated, the diagnosis must be either congenital adrenal hyperplasia or tumor. In the newborn, the latter is very rare, but in older children and adults with elevated 17-ketosteroids the possibility of tumor must be considered. One of the most satisfactory methods of making this differential diagnosis is to attempt to suppress the excess androgens by administration of dexamethasone. In an adult or an older child, a suitable test dose of

dexamethasone is 1.25 mg/45 kg (100 lb) body weight, given orally for 7 consecutive days. In congenital adrenal hyperplasia, there should be suppression of the urinary 17-ketosteroids on the seventh day of the test to less than 1 mg/24 h; in the presence of tumor, either there will be no effect or the 17-ketosteroid levels will rise.

Determination of urinary dehydroepiandrosterone (DHEA) or serum dehydroepiandrosterone sulfate (DHEAS) levels can also be helpful in differentiating congenital adrenal hyperplasia from an adrenal tumor. Levels in patients with congenital adrenal hyperplasia may be up to double the normal amount, whereas an adrenal tumor is usually associated with levels that are much higher than double the normal level.

Determination of the serum sodium and potassium levels and CO_2 -combining power is also important to ascertain whether electrolyte balance is seriously disturbed.

Treatment

The treatment of female hermaphroditism due to congenital adrenal hyperplasia is partly medical and partly surgical. Originally, cortisone was administered; today, it is known that various cortisone derivatives are at least effective. It is most satisfactory to begin treatment with relatively large doses of hydrocortisone divided in 3 doses orally for 7–10 days to obtain rapid suppression of adrenal activity. In young infants, the initial dose is about 25 mg/d; in older patients, 100 mg/d. After the output of 17-ketosteroids has decreased to a lower level, the dose should be reduced to the minimum amount required to maintain adequate suppression. This requires repeated measurements of plasma 17 α -hydroxyprogesterone in order to individualize the dose.

It has been found that even with suppression of the urinary 17-ketosteroids to normal levels, the more sensitive serum 17-hydroxyprogesterone level may still be elevated. It seems difficult and perhaps undesirable to suppress the serum 17-hydroxyprogesterone values to normal because to do so may require doses of hydrocortisone that tend to cause cushingoid symptoms.

In the treatment of newborns with congenital adrenal hyperplasia who have a defect of electrolyte regulation, it is usually necessary to administer sodium chloride in amounts of 4–6 g/d, either orally or parenterally, in addition to cortisone. Furthermore, fludrocortisone acetate usually is required initially. The dose is entirely dependent on the levels of the serum electrolytes, which must be followed serially, but it is generally 0.05–0.1 mg/d.

In addition to the hormone treatment of this disorder, surgical correction of the external genitalia is usually necessary.

During acute illness or other stress, as well as during and after an operation, additional hydrocortisone is indicated to avoid the adrenal insufficiency of stress. Doubling the maintenance dose is usually adequate in such circumstances.

Female Hermaphroditism Without Progressive Masculinization

Females with no adrenal abnormality may have fetal masculinization of the external genitalia with the same anatomic findings as in patients with congenital virilizing adrenal hyperplasia. Unlike patients with adrenogenital syndrome, patients without adrenal abnormality do not have elevated levels of serum steroids or urinary 17-ketosteroids, nor do they show precocious sexual development or the metabolic difficulties associated with adrenal hyperplasia as they grow older. At onset of puberty, normal feminization with menstruation and ovulation may be expected.

The diagnosis of female hermaphroditism not due to adrenal abnormality depends on the demonstration of a 46, XX karyotype and the finding of normal levels of serum steroids or normal levels of 17-ketosteroids in the urine. If fusion of the scrotolabial folds is complete, it is necessary to determine the exact relationship of the urogenital sinus to the urethra and vagina and to demonstrate the presence of a uterus by rectal examination or ultrasonography or endoscopic observation of the cervix. When there is a high degree of masculinization, the differential diagnosis between this condition and true hermaphroditism may be very difficult; an exploratory

laparotomy may be required in some cases.

Classification

Patients with this problem may be seen because of a variety of conditions.

1. Exogenous androgen:

a. Maternal ingestion of androgen

b. Maternal androgenic tumor

c. Luteoma of pregnancy

d. Adrenal androgenic tumor

2. Idiopathic: No identifiable cause.

3. Special or nonspecific: The same as condition 2 except that it is associated with various somatic anomalies and with mental retardation.

4. Familial: A very rare anomaly.

Male Hermaphroditism

Persons with abnormal or ectopic testes may have external genitalia so ambiguous at birth that the true sex is not identifiable (Fig 5-17). At puberty, these persons tend to become masculinized or feminized depending on factors to be discussed. Thus, the adult habitus of these persons may be typically male, ie, without breasts, or typically female, with good breast development. In some instances, the external genitalia may be indistinguishable from those of a normal female; in others, the clitoris may be enlarged; and in still other instances there may be fusion of the labia in the midline, resulting in what seems to be a hypospadiac male. A deep or shallow vagina may be present. A cervix, a uterus, and uterine tubes may be developed to varying degrees; however, müllerian structures are often absent. Mesonephric structures may be grossly or microscopically visible. Body hair may be either typically feminine in its distribution and quantity or masculine in distribution and of sufficient quantity as to require plucking or shaving if the person is reared as a female. In a special group, axillary and pubic hair is congenitally absent. Although there is a well-developed uterus in some instances, all patients so far reported have been amenorrheic—in spite of the interesting theoretic possibility of uterine bleeding from endometrium stimulated by estrogen of testicular origin. There is no evidence of adrenal malfunction. In the feminized group, and less frequently in the nonfeminized group, there is a strong familial history of the disorder. Male hermaphrodites reared as females may marry and be well adjusted to their sex role. Others, especially when there has been equivocation regarding sex of rearing in infancy, may be less than attractive as women because of indecisive therapy. Psychiatric studies indicate that the best emotional adjustment comes from directing endocrine, surgical, and psychiatric measures toward improving the person's basic characteristics. Fortunately, this is consonant with the surgical and endocrine possibilities for those reared as females, because current operative techniques can produce more satisfactory feminine than masculine external genitalia. Furthermore, the testes of male hermaphrodites are nonfunctional as far as spermatogenesis is concerned. Only about one-third of male hermaphrodites are suitable for rearing as males.

(Reproduced, with permission, from Jones HW Jr, Scott WW: *Hermaphroditism, Genital Anomalies and Related Endocrine Disorders*, 2nd ed. Williams & Wilkins, 1971.)

Classification

Since about 1970, considerable progress has been made in identifying specific metabolic defects that are etiologically important for the various forms of male hermaphroditism. Details are beyond the scope of this text. Nevertheless, it is important to point out that all cases of male hermaphroditism have a defect in either the biologic action of testosterone or the MIF of the testis. Furthermore, it now seems apparent that nearly all—if not all—of these defects have a genetic or cytogenetic background. The causes and pathogenetic mechanisms of the defects may vary, but the final common pathway is 1 of the 2 problems just mentioned; in the adult a study of serum gonadotropins and serum steroids, including the intermediate metabolites of testosterone, can often pinpoint a defect in the biosynthesis of testosterone. In other cases, the end-organ action of testosterone may be defective. In children, the defect is sometimes more difficult to determine before gonadotropin levels rise at puberty, but one may suspect a problem by observing abnormally high levels of steroids that act as substrates in the metabolism of testosterone. A working classification of male hermaphroditism is as follows:

I. Male hermaphroditism due to a central nervous system defect

A. Abnormal pituitary gonadotropin secretion

B. No gonadotropin secretion

II. Male hermaphroditism due to a primary gonadal defect

A. Identifiable defect in biosynthesis of testosterone

1. Pregnenolone synthesis defect (lipoid adrenal hyperplasia)

2. 3β -Hydroxysteroid dehydrogenase deficiency

3. 17α -Hydroxylase deficiency

4. $17,20$ -Desmolase deficiency

5. 17β -Ketosteroid reductase deficiency

B. Unidentified defect in androgen effect

C. Defect in duct regression (Figs 5–18 and 5–19)

D. Familial gonadal destruction

E. Leydig cell agenesis

F. Bilateral testicular dysgenesis

III. Male hermaphroditism due to peripheral end-organ defect

A. Androgen insensitivity syndrome (Fig 5–20)

1. Androgen-binding protein deficiency

2. Unknown deficiency

B. 5α -Reductase deficiency

C. Unidentified abnormality of peripheral androgen effect

IV. Male hermaphroditism due to Y chromosome defect

A. Y chromosome mosaicism (asymmetric gonadal differentiation) (Fig 5–21)

B. Structurally abnormal Y chromosome

C. No identifiable Y chromosome

Differential Diagnosis in Infants with Ambiguous Genitalia

Accurate differential diagnosis is possible in most patients with ambiguous genitalia (Table 5–8). This requires a complex history of the mother's medication use, a complex sex chromosome study, rectal examination for the presence or absence of a uterus, measurement of serum steroid levels, pelvic ultrasonography, and information about other congenital anomalies. The following disorders, however, do not yield to differentiation by the parameters given in Table 5–8: (1) idiopathic masculinization, (2) the "special" forms of female hermaphroditism (3) 46,XX true hermaphroditism, and, occasionally, (4) the precise type of male hermaphroditism. For these differentiations, laparotomy may be necessary for diagnosis and for therapy.

Treatment of Hermaphroditism

The sex of rearing is much more important than the obvious morphologic signs (external genitalia, hormone dominance, gonadal structure) in forming the gender role. Furthermore, serious psychological consequences ma

result from changing the sex of rearing after infancy. Therefore, it is seldom proper to advise a change of sex at infancy to conform to the gonadal structure of the external genitalia. Instead, the physician should exert efforts to complete the adjustment of the person to the sex role already assigned. Fortunately, most aberrations of sexual development are discovered in the newborn period or in infancy, when reassignment of sex causes few problems.

Regardless of the time of treatment (and the earlier the better), the surgeon should reconstruct the external genitalia to correspond to the sex of rearing. Any contradictory sex structures that may function to the patient's disadvantage in the future should be eradicated. Specifically, testes should always be removed from male hermaphrodites reared as females, regardless of hormone production. In cases of testicular feminization, orchiectomy is warranted because a variety of tumors may develop in these abnormal testes if they are retained but the orchiectomy may be delayed until after puberty in this variety of hermaphroditism.

In virilized female hermaphroditism due to adrenal hyperplasia, suppression of adrenal androgen production by use of cortisone from an early age will result in completely female development. It is no longer necessary to explore the abdomen and the internal genitalia in this well-delineated syndrome. The surgical effort should be confined to reconstruction of the external genitalia along female lines.

Patients with streak gonads or Turner's syndrome, who are invariably reared as females, should be given exogenous estrogen when puberty is expected. Those hermaphrodites reared as females who will not become feminized also require estrogen to promote the development of the female habitus, including the breasts. In patients with a well-developed system, cyclic uterine withdrawal bleeding can be produced even though reproduction is impossible. Estrogen should be started at about age 12 and may be given as conjugated estrogen 1.5 mg/d orally (or its equivalent). In some patients, after a period of time this dosage may have to be increased for additional breast development. In patients without ovaries who have uteri and in male hermaphrodites in the same condition, cyclic uterine bleeding can often be induced by the administration of estrogen for 3 weeks of each month. In other instances, this may be inadequate to produce a convincing "menstrual" period; if so, the 3 weeks of estrogen can be followed by 3–4 days of progestin (eg, medroxyprogesterone acetate) orally or a single injection of progesterone. Prolonged estrogen therapy increases the risk of subsequent development of adenocarcinoma of the corpus, so periodic endometrial sampling is mandatory in such patients.

Reconstruction of Female External Genitalia

The details of the operative reconstruction of abnormal external genitalia are beyond the scope of this chapter. However, it should be emphasized that the procedure should be carried out at the earliest age possible so as to enhance the desired psychological, social, and sexual orientation of the patient and to facilitate adjustment by the parents. Sometimes the reconstruction can be done during the neonatal period. In any case, operation should not be delayed beyond the first several months of life. From a technical point of view, early operation is possible in all but the most exceptional circumstances.

Current OB/GYN >Chapter 6. Physiology of Reproduction in Women >

PHYSIOLOGY OF REPRODUCTION IN WOMEN: INTRODUCTION

This chapter is concerned with the function of the female reproductive system from birth through puberty and adulthood to the menopause.

After birth, the gonads are quiescent until they are activated by gonadotropins from the pituitary to bring about the final maturation of the reproductive system. This period of final maturation is known as adolescence. It is often called puberty, although strictly defined, puberty is the period when the endocrine and gametogenic functions of the gonads first develop to the point where reproduction is possible. In girls, the first event is thelarche, the development of breasts, followed by pubarche, the development of axillary and pubic hair, and then menarche, the first menstrual period. The initial periods are generally anovulatory, and regular ovulation begins about 1 year later. In contrast to the situation in adulthood, removal of the gonads during the period from soon after birth to puberty causes little or no increase in gonadotropin secretion, so gonadotropin secretion is not being held in check by the gonadal hormones. In children between the ages of 7 and 10, a slow increase in estrogen and androgen secretion precedes the more rapid rise in the early teens (Fig 6–1).

Figure 6–1.

Changes in plasma hormone concentrations during puberty in boys (top) and girls (bottom). Stage 1 of puberty is preadolescence in both sexes. In boys, stage 2 is characterized by beginning enlargement of the testes, stage 3 by penile enlargement, stage 4 by growth of the glans penis, and stage 5 by adult genitalia. The stages of puberty in girls are summarized in Fig 6–3.

(Reproduced, with permission, from Grumbach MM: Onset of puberty. In: Berenberg SR [editor]: *Puberty: Biologic and Psychosocial Components*. HE Stenfoert Kroese BV, 1975.)

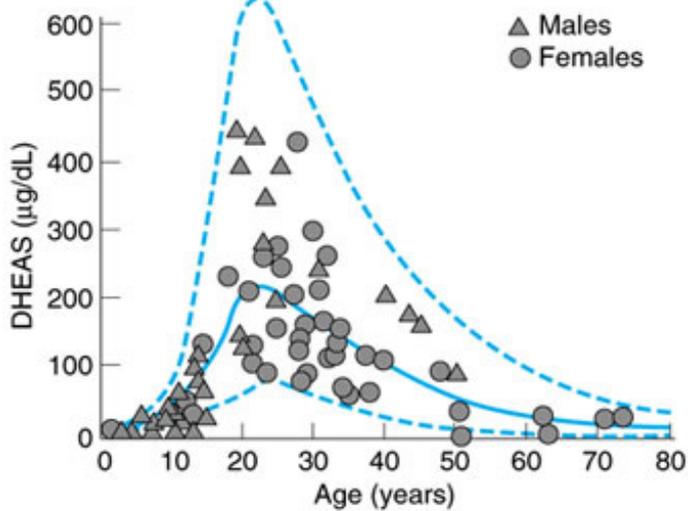

This chapter is based in large part on Chapter 23 in Ganong WF: *Review of Medical Physiology*, 22nd ed. McGraw Hill, 2005.

PUBERTY

The age at the time of puberty is variable; in Europe and the United States, it has been declining at the rate of 1 month per decade for more than 175 years. In the United States in recent years, puberty has generally been occurring between the ages of 8 and 13 in girls and 9 and 14 in boys.

Another event that occurs in humans at the time of puberty is an increase in the secretion of adrenal androgens (Fig 6–2). The onset of this increase is called adrenarche. It occurs at age 8–10 years in girls and 10–12 years in boys. Dehydroepiandrosterone (DHEA) values peak at about 25 years of age and are slightly higher in boys. They then decline slowly to low values after the age of 60.

Figure 6–2.

Change in serum dehydroepiandrosterone sulfate (DHEAS) with age. The middle line is the mean, and the dashed lines identify 1.96 standard deviations.

(Reproduced, with permission, from Smith MR et al: A radioimmunoassay for the estimation of serum dehydroepiandrosteronesulfate in normal and pathological sera. Clin Chim Acta 1975; 65:5.)

The increase in adrenal androgen secretion at adrenarche occurs without any changes in the secretion of cortisol or adrenocorticotropic hormone (ACTH). Adrenarche is probably due to a rise in the lyase activity of a 17 α -hydroxylase. Thereafter, there is a gradual decline in this activity as plasma adrenal androgen secretion declines to low levels in old age.

The adrenal androgens contribute significantly to the growth of axillary and pubic hair. The breasts develop under the influence of the ovarian hormones estradiol and progesterone, with estradiol primarily responsible for the growth of ducts and progesterone primarily responsible for the growth of lobules and alveoli. The sequence of changes that occur at puberty in girls is summarized in Fig 6–3.

Figure 6–3.

Copyright ©2006 by The McGraw-Hill Companies, Inc.
All rights reserved.

Sequence of events at adolescence in girls. A: Stage 1: Preadolescent; elevation of breast papillae only. Stage 2: Breast bud stage (may occur between ages 8 and 13); elevation of breasts and papillae as small mounds, with enlargement of areolar diameter. Stage 3: enlargement and elevation of breasts and areolas with no separation contours. Stage 4: Areolas and papillae project from breast to form a secondary mound. Stage 5: Mature; projection of papillae only, with recession of areolas into general contour of breast. B: Stage 1: Preadolescent; no pubic hair. Stage 2: Sparse growth along labia of long, slightly pigmented, downy hair that is straight or slightly curled (may occur between ages 8 and 14). Stage 3: Darker, coarser, more curled hair growing sparsely over pubic area. Stage 4: Resembles adult in type but covers smaller area. Stage 5: Adult in quantity and type.

(Redrawn, with permission, from Tanner JM: *Growth at Adolescence*, 2nd ed. Blackwell, 1962.)

Control of the Onset of Puberty

A neural mechanism is responsible for the onset of puberty. In children, the gonads can be stimulated by gonadotropins, the pituitary contains gonadotropins, and the hypothalamus contains gonadotropin-releasing hormone (GnRH). However, the gonadotropins are not secreted. In immature monkeys, normal menstrual cycle can be brought on by pulsatile injection of GnRH, and the cycles persist as long as the pulsatile injection is continued. In addition, GnRH is secreted in a pulsatile fashion in adults. Thus, it seems clear that during the period from birth to puberty, a neural mechanism is operating to prevent the normal pulsatile release of GnRH. The nature of the mechanism inhibiting the GnRH pulse generator is unknown.

Relation to Leptin

It has been argued for some time that normally a critical body weight must be reached for puberty to occur. Thus, for example, young women who engage in strenuous athletics lose weight and stop menstruating. So do girls who

anorexia nervosa. If these girls start to eat and gain weight, they menstruate again, ie, they "go back through puberty." It now appears that leptin, the satiety-producing hormone secreted by fat cells, may be the link between body weight and puberty. Obese ob/ob mice that cannot make leptin are infertile, and their fertility is restored by injections of leptin. Leptin treatment also induces precocious puberty in immature female mice. However, how leptin fits into the overall control of puberty remains to be determined.

Sexual Precocity

The major causes of precocious sexual development in humans are listed in Table 6–1. Early development of secondary sexual characteristics without gametogenesis is caused by abnormal exposure of immature males to androgen or of females to estrogen. This syndrome should be called precocious pseudopuberty to distinguish from true precocious puberty due to an early but otherwise normal pubertal pattern of gonadotropin secretion from the pituitary (Fig 6–4).

Table 6–1. Classification of the Causes of Precocious Sexual Development in Humans

True precocious puberty

Constitutional

Cerebral: Disorders involving posterior hypothalamus

Tumors

Infections

Developmental abnormalities

Gonadotropin-independent precocity

Precocious pseudopuberty

(no spermatogenesis or ovarian development)

Adrenal

Congenital virilizing adrenal hyperplasia (without treatment in males; following cortisone treatment in females)

Constitutional precocious puberty in a 3¹/₂-year-old girl. The patient developed pubic hair and started to menstruate at the age of 17 months.

(Reproduced, with permission, from Jolly H: *Sexual Precocity*. Thomas, 1955.)

In 1 large series of cases, precocious puberty was the most frequent endocrine symptom of hypothalamic disease. It is interesting that in experimental animals and humans, lesions of the ventral hypothalamus near the infundibulum cause precocious puberty. The effect of the lesions may be due to interruption of neural pathways that produce inhibition of the GnRH pulse generator. Pineal tumors are sometimes associated with precocious puberty, but there is evidence that these tumors are associated with precocious puberty only when there is secondary damage to the hypothalamus. Precocity due to this and other forms of hypothalamic damage probably occurs with equal frequency in both sexes, although the constitutional form of precocious puberty is more common in girls. In addition, it has now been proved that precocious gametogenesis and steroidogenesis can occur without the pubertal pattern of gonadotropin secretion (gonadotropin-independent precocity). At least in some cases of this condition, the sensitivity of luteinizing hormone (LH) receptors to gonadotropins is increased because of an

activating mutation in the G protein that couples receptors to adenyl cyclase.

Delayed or Absent Puberty

The normal variation in the age at which adolescent changes occur is so wide that puberty cannot be considered to be pathologically delayed until menarche has failed to occur by the age of 17. Failure of maturation due to panhypopituitarism is associated with dwarfing and evidence of other endocrine abnormalities. Patients with the XO chromosomal pattern and gonadal dysgenesis are also dwarfed. In some individuals, puberty is delayed and menarche does not occur (primary amenorrhea), even though the gonads are present and other endocrine functions are normal.

REPRODUCTIVE FUNCTION AFTER SEXUAL MATURITY

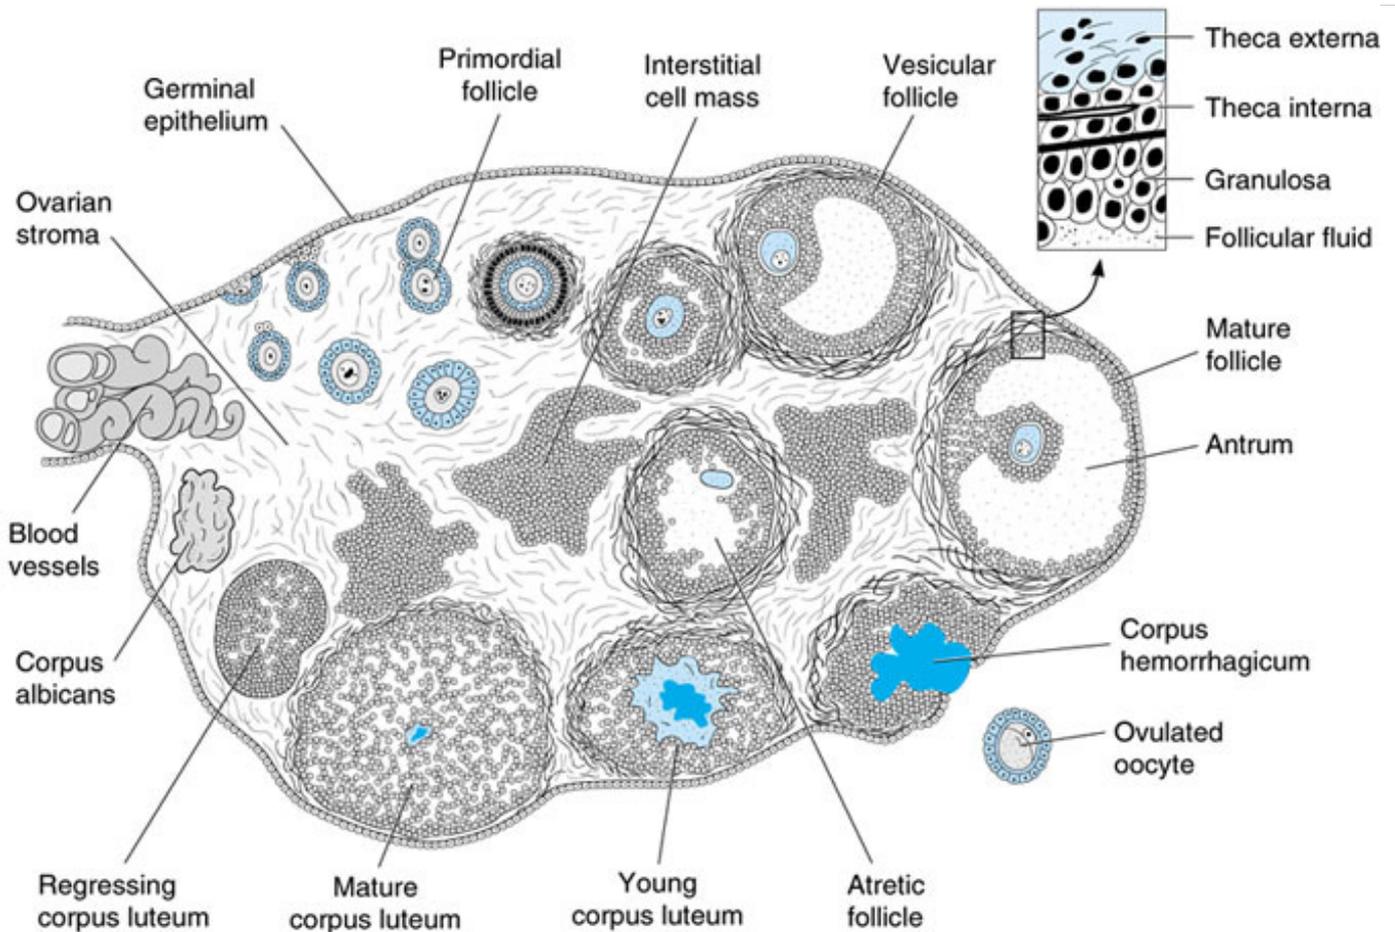

Menstrual Cycle

The anatomy of the reproductive system of adult women is described in Chapter 2. Unlike the reproductive system of men, this system shows regular cyclic changes that teleologically may be regarded as periodic preparation for fertilization and pregnancy. In primates, the cycle is a menstrual cycle, and its most conspicuous feature is the periodic vaginal bleeding that occurs with shedding of the uterine mucosa (menstruation). The length of the cycle is notoriously variable, but the average figure is 28 days from the start of 1 menstrual period to the start of the next. By common usage, the days of the cycle are identified by number, starting with the first day of menstruation.

Ovarian Cycle

From the time of birth, there are many primordial follicles under the ovarian capsule. Each contains an immature ovum (Fig 6–5). At the start of each cycle, several of these follicles enlarge and a cavity forms around the ovum (antrum formation). This cavity is filled with follicular fluid. In humans, 1 of the follicles in 1 ovary starts to grow rapidly on about the sixth day and becomes the dominant follicle. The others regress, forming atretic follicles. It is not known how 1 follicle is singled out for development during this follicular phase of the menstrual cycle, but it seems to be related to the ability of the follicle to secrete the estrogen inside it that is needed for final maturation. When women are given highly purified human pituitary gonadotropin preparations by injection, many follicles develop simultaneously.

Figure 6–5.

(After Patten B, Eakin RM. Reproduced, with permission, from Gorbman A, Bern H: *Textbook of Comparative Endocrinology*. Wiley, 1962.)

The structure of a mature ovarian follicle (graafian follicle) is shown in Fig 6-5. The cells of the theca interna of the follicle are the primary source of circulating estrogens. The follicular fluid has a high estrogen content, and much of this estrogen comes from the granulosa cells.

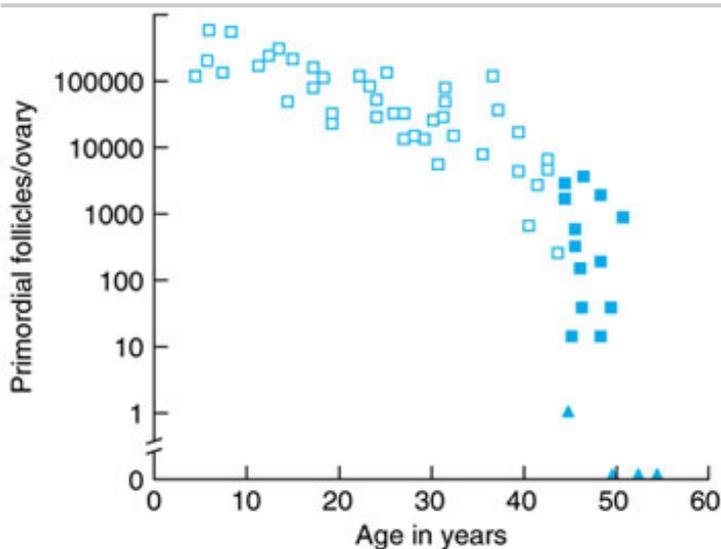

At about the 14th day of the cycle, the distended follicle ruptures, and the ovum is extruded into the abdominal cavity. This is the process of ovulation. The ovum is picked up by the fimbriated ends of the uterine tubes (oviducts) and transported to the uterus. Unless fertilization occurs, the ovum degenerates or is passed on through the uterus and out the vagina.

The follicle that ruptures at the time of ovulation promptly fills with blood, forming what is sometimes called a corpus hemorrhagicum. Minor bleeding from the follicle into the abdominal cavity may cause peritoneal irritant and fleeting lower abdominal pain ("mittelschmerz"). The granulosa and theca cells of the follicle lining promptly begin to proliferate, and the clotted blood is rapidly replaced with yellowish, lipid-rich luteal cells, forming the corpus luteum. This is the luteal phase of the menstrual cycle, during which the luteal cells secrete estrogens and progesterone. Growth of the corpus luteum depends on its developing an adequate blood supply, and there

evidence that vascular endothelial growth factor (VEGF) is essential for this process. If pregnancy occurs, the corpus luteum persists, and there are usually no more menstrual periods until after delivery. If there is no pregnancy, the corpus luteum begins to degenerate about 4 days before the next menses (day 24 of the cycle) and is eventually replaced by fibrous tissue, forming a corpus albicans.

In humans, no new ova are formed after birth. During fetal development, the ovaries contain over 7 million germ cells; however, many undergo involution before birth, and others are lost after birth. At the time of birth, there are approximately 2 million primordial follicles containing ova, but approximately 50% of these are atretic. The million or so ova that are normal undergo the first part of the first meiotic division at about this time and enter a stage of arrest in prophase in which those that survive persist until adulthood. Atresia continues during development, and the number of ova in both the ovaries at the time of puberty is less than 300,000 (Fig 6–6). Normally, only 1 of these ova per cycle (or about 500 in the course of a normal reproductive life) is stimulated to mature; the remainder degenerate. Just before ovulation, the first meiotic division is completed. One of the daughter cells, the secondary oocyte, receives most of the cytoplasm, while the other, the first polar body, fragments and disappears. The secondary oocyte immediately begins the second meiotic division, but this division stops at metaphase and is completed only when a sperm penetrates the oocyte. At that time, the second polar body is cast off, and the fertilized ovum proceeds to form a new individual. The arrest in metaphase is due, at least in some species, to formation in the ovum of the protein pp39^{mos}, which is encoded by the *c-mos* proto-oncogene. When fertilization occurs, the pp39^{mos} is destroyed within 30 minutes by calpain, a calcium-dependent cysteine protease.

Uterine Cycle

The events that occur in the uterus during the menstrual cycle terminate in the menstrual flow. By the end of ea

menstrual period, all but the deep layer of the endometrium has sloughed. Under the influence of estrogens from the developing follicles, the endometrium regenerates from the deep layer and increases rapidly in thickness during the period from the fifth to 16th days of the menstrual cycle. As the thickness increases, the uterine glands are drawn out so that they lengthen (Fig 6–7), but they do not become convoluted or secrete to any degree. The endometrial changes are called proliferative, and this part of the menstrual cycle is sometimes called the proliferative phase. It is also called the preovulatory or follicular phase of the cycle. After ovulation, the endometrium becomes more highly vascularized and slightly edematous under the influence of estrogen and progesterone from the corpus luteum. The glands become coiled and tortuous (Fig 6–7), and they begin to secrete a clear fluid. Consequently, this phase of the cycle is called the secretory or luteal phase. Late in the luteal phase, the endometrium, like the anterior pituitary, produces prolactin, but the function of this endometrial prolactin is unknown.

Figure 6–7.

Changes in the endometrium during the menstrual cycle.

(Reproduced, with permission, from Ganong WF: *Review of Medical Physiology*, 22nd ed. McGraw-Hill, 2005.)

The endometrium is supplied by 2 types of arteries. The superficial two-thirds of the endometrium that is shed during menstruation, the stratum functionale, is supplied by long, coiled spiral arteries, whereas the deep layer, the stratum basale, which is not shed, is supplied by short, straight basilar arteries.

When the corpus luteum regresses, hormonal support for the endometrium is withdrawn. The endometrium becomes thinner, which adds to the coiling of the spiral arteries. Foci of necrosis appear in the endometrium, and these coalesce. There is, in addition, necrosis of the walls of the spiral arteries, leading to spotty hemorrhages that become confluent and produce the menstrual flow.

Vasospasm occurs and probably is produced by locally released prostaglandins. There are large quantities of prostaglandins in the secretory endometrium and in menstrual blood, and infusions of prostaglandin F_{2a} (PGF_{2a}) produce endometrial necrosis and bleeding. One theory of the onset of menstruation holds that in necrotic endometrial cells, lysosomal membranes break down with the release of enzymes that foster the formation of prostaglandins from cellular phospholipids.

From the point of view of endometrial function, the proliferative phase of the menstrual cycle represents the restoration of epithelium from the preceding menstruation, and the secretory phase represents the preparation of the uterus for implantation of the fertilized ovum. The length of the secretory phase is remarkably constant, at about 14 days, and the variations seen in the length of the menstrual cycle are mostly due to variations in the

length of the proliferative phase. When fertilization fails to occur during the secretory phase, the endometrium is shed, and a new cycle starts.

Normal Menstruation

Menstrual blood is predominantly arterial, with only 25% of the blood being of venous origin. It contains tissue debris, prostaglandins, and relatively large amounts of fibrinolysin from the endometrial tissue. The fibrinolysin lyses clots, so menstrual blood does not normally contain clots unless the flow is excessive.

The usual duration of the menstrual cycle is 3–5 days, but flows as short as 1 day and as long as 8 days can occur in normal women. The average amount of blood lost is 30 mL but normally may range from slight spotting to 80 mL. Loss of more than 80 mL is abnormal. Obviously, the amount of flow can be affected by various factors, including thickness of the endometrium and medications and diseases that affect the clotting mechanism. After menstruation, the endometrium regenerates from the stratum basale.

Anovulatory Cycles

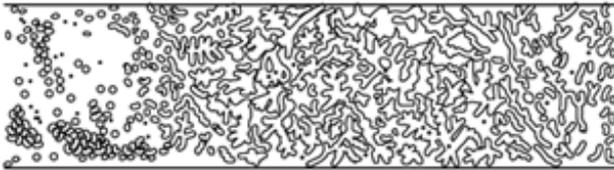

In some instances, ovulation fails to occur during the menstrual cycle. Such anovulatory cycles are common for the first 12–18 months after menarche and again before the onset of menopause. When ovulation does not occur, no corpus luteum is formed, and the effects of progesterone on the endometrium are absent. Estrogens continue to cause growth, however, and the proliferative endometrium becomes thick enough to break down and begin to slough. The time it takes for bleeding to occur is variable, but it usually occurs less than 28 days from the last menstrual period. The flow is also variable and ranges from scanty to relatively profuse.

Cyclic Changes in the Uterine Cervix

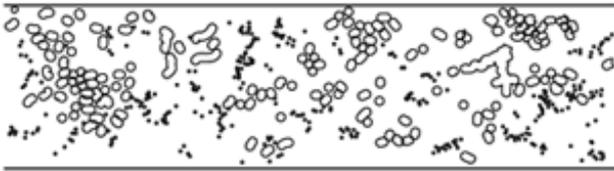

Although it is contiguous with the body of the uterus, the cervix of the uterus is different in a number of ways. The mucosa of the uterine cervix does not undergo cyclic desquamation, but there are regular changes in the cervical mucus. Estrogen makes the mucus thinner and more alkaline, changes that promote the survival and transport of sperm. Progesterone makes it thick, tenacious, and cellular. The mucus is thinnest at the time of ovulation, and its elasticity, or *spinnbarkeit*, increases so that by midcycle, a drop can be stretched into a long, thin thread that may be 8–12 cm or more in length. In addition, it dries in an arborizing, fernlike pattern when a thin layer is spread on a slide (Fig 6–8). After ovulation and during pregnancy, it becomes thick and fails to form the fern pattern.

Vaginal Cycle

Under the influence of estrogens, the vaginal epithelium becomes cornified, and cornified epithelial cells can be identified in the vaginal smear. Under the influence of progesterone, a thick mucus is secreted, and the epithelium proliferates and becomes infiltrated with leukocytes. The cyclic changes in the vaginal smear in rats are particularly well known. The changes in humans and other species are similar but unfortunately not so clear-cut. However, the increase in cornified epithelial cells is apparent when a vaginal smear from an adult woman in the follicular phase of the menstrual cycle is compared, for example, with a smear taken from a prepubescent female (Fig 6–9).

Bottom: Left to right: Epithelial maturation at birth; atrophic cell picture in childhood; beginning of estrogenic influence in puberty; complete maturation in the reproductive period; regression in old age.

Cyclic Changes in the Breasts

Although lactation normally does not occur until the end of pregnancy, there are cyclic changes in the breasts during the menstrual cycle. Estrogens cause proliferation of mammary ducts, whereas progesterone causes growth of lobules and alveoli (see Actions of Progesterone). The breast swelling, tenderness, and pain experienced by many women during the 10 days preceding menstruation probably are due to distention of the ducts, hyperemia and edema of the interstitial tissue of the breasts. All of these changes regress, along with the symptoms, during menstruation.

Cyclic Changes in Other Body Functions

In addition to cyclic breast swelling and tenderness, there is usually a small increase in body temperature during the luteal phase of the menstrual cycle. This change in body temperature (see Indicators of Ovulation) probably is due to the thermogenic effect of progesterone.

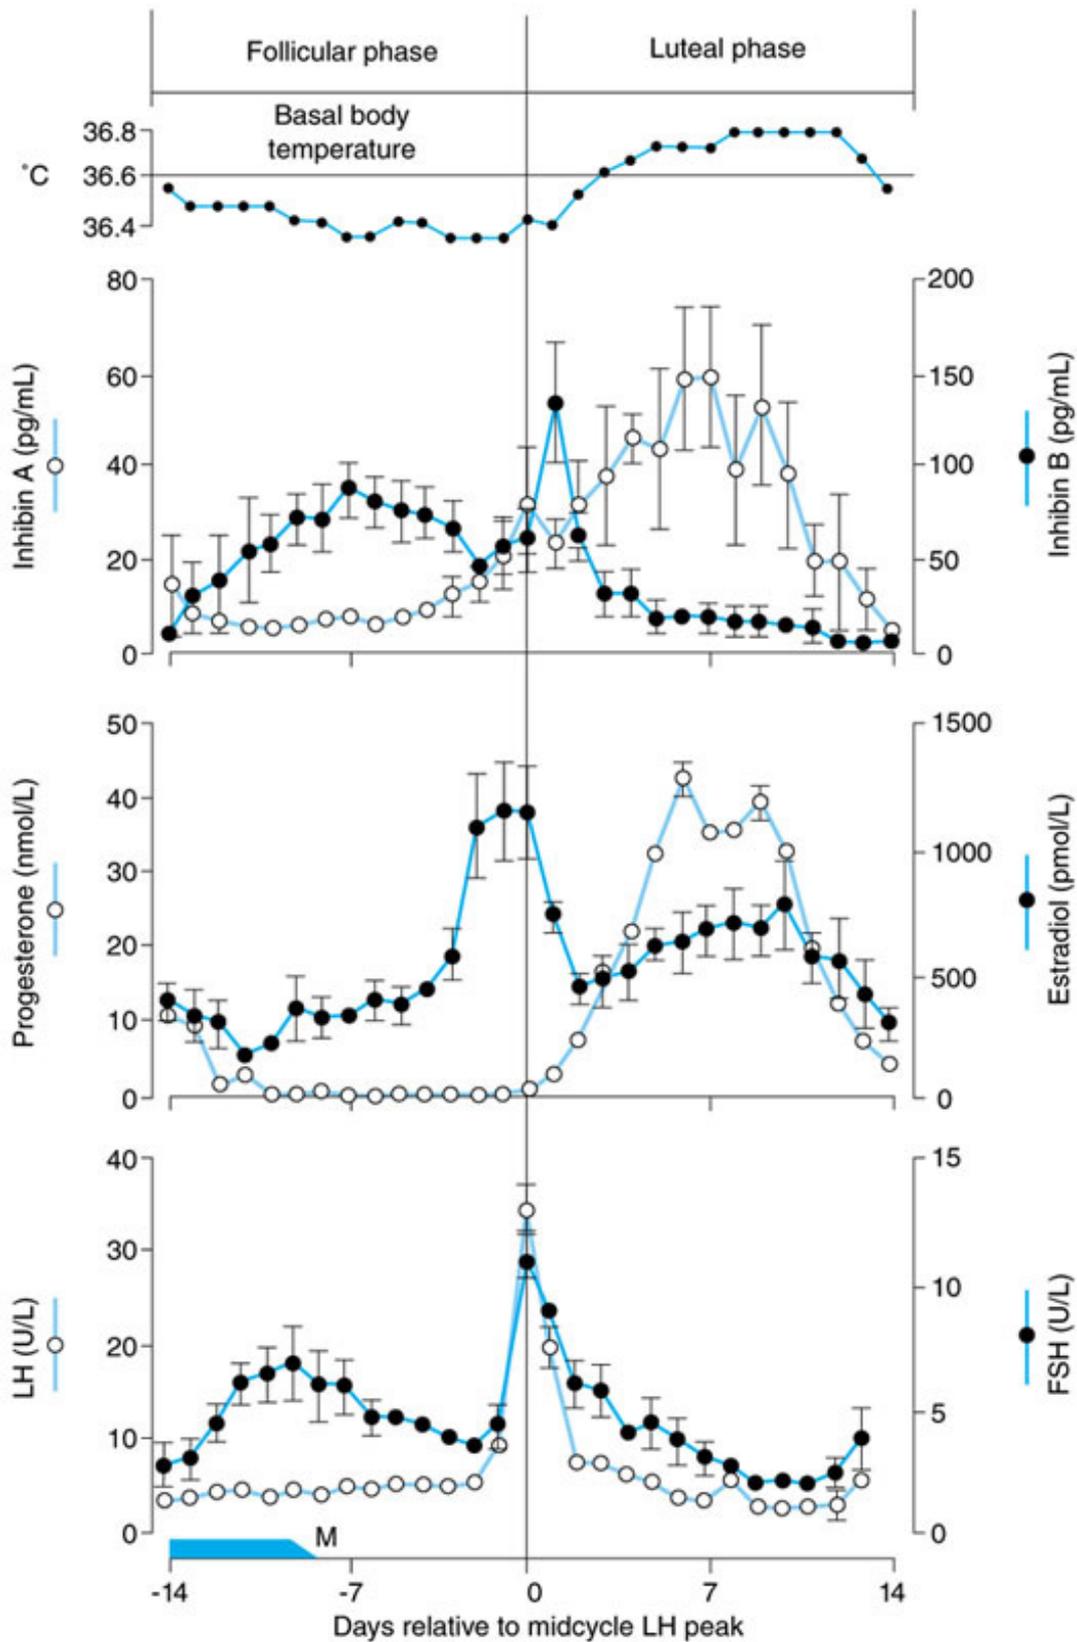

Changes during Sexual Intercourse

During sexual excitation, the vaginal walls become moist as a result of transudation of fluid through the mucous membrane. A lubricating mucus is secreted by the vestibular glands. The upper part of the vagina is sensitive to stretch, while tactile stimulation from the labia minora and clitoris adds to the sexual excitement. The stimuli are reinforced by tactile stimuli from the breasts and, as in men, by visual, auditory, and olfactory stimuli; eventually the crescendo or climax known as orgasm may be reached. During orgasm, there are autonomically mediated rhythmic contractions of the vaginal wall. Impulses also travel via the pudendal nerves and produce rhythmic contractions of the bulbocavernosus and ischiocavernosus muscles. The vaginal contractions may aid in the transport of spermatozoa but are not essential for it, as fertilization of the ovum is not dependent on orgasm.

Indicators of Ovulation

Knowing when during the menstrual cycle ovulation occurs is important in increasing fertility or, conversely, in contraception. A convenient but retrospective indicator of the time of ovulation is a rise in the basal body temperature (Fig 6–10). Accurate temperatures can be obtained by using a thermometer that is able to measure temperature precisely between 96 and 100 F. The woman should take her temperature orally, vaginally, or rectally in the morning before getting out of bed. The cause of the temperature change at the time of ovulation is unknown but probably is due to the increase in progesterone secretion, as progesterone is thermogenic. A rise in urinary LH occurs during the rise in circulating LH that causes ovulation, and this increase can be measured as another indicator of ovulation. Kits using dipsticks or simple color tests for detection of urinary LH are available for home use.

(Reproduced, with permission, from Ganong WF: *Review of Medical Physiology*, 22nd ed. McGraw-Hill, 2005.)

Ovulation normally occurs about 9 hours after the peak of the LH surge at midcycle (Fig 6–10). The ovum lives approximately 72 hours after it is extruded from the follicle but probably is fertilizable for less than half this time. In a study of the relationship of isolated intercourse to pregnancy, 36% of women had a detected pregnancy following intercourse on the day of ovulation, but with intercourse on days after ovulation, the percentage was zero. Isolated intercourse on the first and second days before ovulation led to pregnancy in about 36% of the women. A few pregnancies resulted from isolated intercourse on day 3, 4, or 5 before ovulation, although the percentage was much lower, ie, 8% on day 5 before ovulation. Thus, some sperm can survive in the female genital tract and produce fertilization for up to 120 hours before ovulation, but the most fertile period is clearly 48 hours before ovulation. However, for those interested in the "rhythm method" of contraception, it should be noted that there are rare but documented cases in the literature of pregnancy resulting from isolated coitus on every day of the cycle.

OVARIAN HORMONES

Chemistry, Biosynthesis, & Metabolism of Estrogens

The naturally occurring estrogens are 17β -estradiol, estrone, and estriol (Fig 6–11). They are C_{18} steroids, ie, they do not have an angular methyl group attached to the 10 position or a Δ^4 -3-keto configuration in the A ring. They are secreted primarily by the granulosa and the thecal cells of the ovarian follicles, the corpus luteum, and the placenta. The biosynthetic pathway involves their formation from androgens. They are also formed by aromatization of androstenedione in the circulation. Aromatase (CYP19) is the enzyme that catalyzes the conversion of androstenedione to estrone (Fig 6–11). It also catalyzes the conversion of testosterone to estradiol. **Figure 6–11.**

Biosynthesis and metabolism of estrogens.

(Reproduced, with permission, from Ganong WF: *Review of Medical Physiology*, 22nd ed. McGraw-Hill, 2005.)

Theca interna cells have many LH receptors, and LH acts on them via cyclic adenosine 3',5'-monophosphate (cAMP) to increase conversion of cholesterol to androstenedione. Some of the androstenedione is converted to estradiol, which enters the circulation. The theca interna cells also supply androstenedione to the granulosa cells. The granulosa cells only make estradiol when provided with androgens (Fig 6–12), and they secrete the estradiol that they produce into the follicular fluid. They have many follicle-stimulating hormone (FSH) receptors, and FSH facilitates the secretion of estradiol by acting via cyclic AMP to increase the aromatase activity in these cells. Mature granulosa cells also acquire LH receptors, and LH stimulates estradiol production.

Interactions between theca and granulosa cells in estradiol synthesis and secretion.

(Reproduced, with permission, from Ganong WF: *Review of Medical Physiology*, 22nd ed. McGraw-Hill, 2005.)

The stromal tissue of the ovary also has the potential to produce androgens and estrogens. However, it probably does so in insignificant amounts in normal premenopausal women. 17β -Estradiol, the major secreted estrogen, is in equilibrium in the circulation with estrone. Estrone is further metabolized to estriol (Fig 6–11), probably mainly in the liver. Estradiol is the most potent estrogen of the three, and estriol is the least potent.

Two percent of the circulating estradiol is free. The remainder is bound to protein: 60% to albumin and 38% to the same gonadal steroid-binding globulin (GBG) that binds testosterone (Table 6–2).

In the liver, estrogens are oxidized or converted to glucuronide and sulfate conjugates. Appreciable amounts are secreted in the bile and reabsorbed in the bloodstream (enterohepatic circulation). There are at least 10 different metabolites of estradiol in human urine.

Secretion of Estrogens

The concentration of estradiol in plasma during the menstrual cycle is shown in Fig 6–10. Almost all of the estrogen comes from the ovary. There are 2 peaks of secretion: 1 just before ovulation and 1 during the midluteal phase. The estradiol secretion rate is 36 $\mu\text{g}/\text{d}$ (133 nmol/d) in the early follicular phase, 380 $\mu\text{g}/\text{d}$ just before ovulation, and 250 $\mu\text{g}/\text{d}$ during the midluteal phase (Table 6–3). After menopause, estrogen secretion declines to low levels. For comparison, the estradiol production rate in men is about 50 $\mu\text{g}/\text{d}$ (184 nmol/d).

Sex Steroids	Early Follicular	Preovulatory	Midluteal

Modified and reproduced, with permission, from Yen SSC, Jaffe RB: *Reproductive Endocrinology*, 3rd ed. Saunders 1991.

Effects on Female Genitalia

Estrogens facilitate the growth of the ovarian follicles and increase the motility of the uterine tubes. Their role in the cyclic changes in the endometrium, cervix, and vagina is discussed above. They increase uterine blood flow and have important effects on the smooth muscle of the uterus. In immature and ovariectomized females, the uterus is small and the myometrium atrophic and inactive. Estrogens increase the amount of uterine muscle and its content of contractile proteins. Under the influence of estrogens, the myometrium becomes more active and excitable, and action potentials in the individual muscle fibers are increased. The "estrogen-dominated" uterus is also more sensitive to oxytocin.

Prolonged treatment with estrogens causes endometrial hypertrophy. When estrogen therapy is discontinued, there is some sloughing and withdrawal bleeding. Some "breakthrough" bleeding may also occur during prolonged treatment with estrogens.

Effects on Endocrine Organs

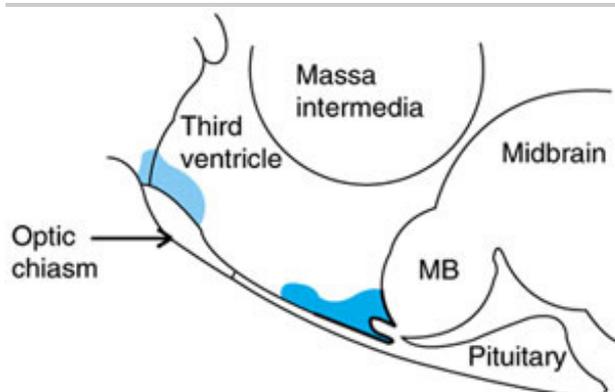

Estrogens decrease FSH secretion. In some circumstances, estrogens inhibit LH secretion (negative feedback); in others, they increase LH secretion (positive feedback). Estrogens also increase the size of the pituitary. Women are sometimes given large doses of estrogens for 4–6 days to prevent conception during the fertile period (postcoital or "morning-after" contraception). In this instance, pregnancy probably is prevented by interference with implantation of the fertilized ovum rather than by changes in gonadotropin secretion.

Estrogens cause increased secretion of angiotensinogen and thyroid-binding globulin. They exert an important protein anabolic effect in chickens and cattle, possibly by stimulating the secretion of androgens from the adrenals; estrogens have been used commercially to increase the weight of domestic animals. They cause epiphyseal closure in humans.

Effects on the Central Nervous System

Estrogens are responsible for estrus behavior in animals, and they may increase libido in humans. They apparently exert this action by a direct effect on certain neurons in the hypothalamus (Fig 6–13).

Figure 6–13.

The implants that stimulate sex behavior are located in the suprachiasmatic area above the optic chiasm, whereas ovarian atrophy is produced by implants in the arcuate nucleus and surrounding ventral hypothalamus just above the pituitary stalk. MB, mamillary body.

(Reproduced, with permission, from Ganong WF: *Review of Medical Physiology*, 22nd ed. McGraw-Hill, 2005.)

Estrogens increase the proliferation of dendrites on neurons and the number of synaptic knobs in rats. In humans they have been reported to slow the progression of Alzheimer's disease, but this role of estrogens remains

controversial.

Effects on the Breasts

Estrogens produce duct growth in the breasts and are largely responsible for breast enlargement at puberty in girls. Breast enlargement that occurs when estrogen-containing skin creams are applied locally is due primarily to systemic absorption of the estrogen, although a slight local effect is also produced. Estrogens are responsible for the pigmentation of the areolas. Pigmentation usually becomes more intense during the first pregnancy than it does at puberty.

Effects on Female Secondary Sex Characteristics

The body changes that develop in girls at puberty—in addition to enlargement of the breasts, uterus, and vagina—are due in part to estrogens, which are the "feminizing hormones," and in part simply to the absence of testicular androgens. Women have narrow shoulders and broad hips, thighs that converge, and arms that diverge (wide carrying angle). This body configuration, plus the female distribution of fat in the breasts and buttocks, also seen in castrated males. In women, the larynx retains its prepubertal proportions and the voice is high-pitched. There is less body hair and more scalp hair, and the pubic hair generally has a characteristic flattop pattern (female escutcheon). Growth of pubic and axillary hair in the female is due primarily to androgens rather than estrogens, although estrogen treatment may cause some hair growth. The androgens are produced by the adrenal cortex and, to a lesser extent, by the ovaries.

Other Actions of Estrogens

Normal women retain salt and water and gain weight just before menstruation. Estrogens can cause some degree of salt and water retention. However, aldosterone secretion is slightly elevated in the luteal phase, and this also contributes to premenstrual fluid retention.

Estrogens make sebaceous gland secretions more fluid and thus counter the effect of testosterone and inhibit formation of comedones ("blackheads") and acne. The liver palms, spider angiomas, and slight breast enlargement seen in advanced liver disease are due to increased circulating estrogens. The increase appears to be due to decreased hepatic metabolism of androstenedione, making more of this androgen available for conversion to estrogens.

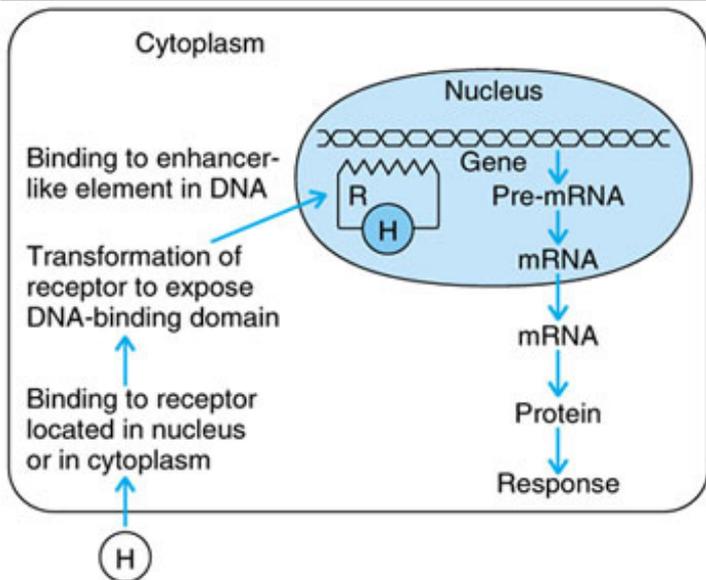

Estrogens have a significant plasma cholesterol-lowering action. They produce vasodilation and inhibit vascular smooth muscle proliferation, possibly by increasing the local production of nitric oxide (NO). Estrogen has also been shown to prevent expression of factors important in the initiation of atherosclerosis. These actions may account for the low incidence of myocardial infarction and other complications of atherosclerotic-vascular disease in premenopausal women. There is considerable evidence that small doses of estrogen may reduce the incidence of cardiovascular disease after menopause. However, some recently published data do not support this conclusion and additional research is needed. Large doses of oral estrogens also promote thrombosis, apparently because they reach the liver in high concentrations in the portal blood and alter hepatic production of clotting factors.

Mechanism of Action

The 2 principal types of nuclear estrogen receptors are estrogen receptor- α (ER- α), which is encoded by a gene on chromosome 6, and estrogen receptor- β (ER- β), which is encoded by a gene on chromosome 14. Both are members of the nuclear receptor superfamily, which includes receptors for many different steroids. After binding estrogen, the nuclear receptors dimerize and bind to DNA, altering its transcription (Fig 6–14). Some tissues contain 1 type or the other, but there is also overlap, with some tissues containing both ER- α and ER- β . ER- α is found primarily in the uterus, kidneys, liver, and heart, whereas ER- β is found primarily in the ovaries, prostate, lungs, gastrointestinal tract, hemopoietic system, and central nervous system. The receptors also form heterodimers, with ER- α binding to ER- β . Male and female mice in which the gene for ER- α has been knocked out

are sterile, develop osteoporosis, and continue to grow because their epiphyses do not close. ER- β female knockouts are infertile, but ER- β male knockouts are fertile even though they have hyperplastic prostates and lots of fat. Thus, the actions of the estrogen receptors are complex, multiple, and varied. However, this is not surprising because it is now known that both receptors exist in various isoforms and, like thyroid receptors, can bind to various activating and stimulating factors.

Mechanism of action of steroid hormones. The estrogen, progestin, androgen, glucocorticoid, mineralocorticoid, and 1,25-dihydroxycholecalciferol receptors have different molecular weights, but all have a ligand-binding domain and a DNA-binding domain that is exposed when the ligand binds. The receptor–hormone complex then binds to DNA, producing increased or decreased transcription. H, hormone; R, receptor.

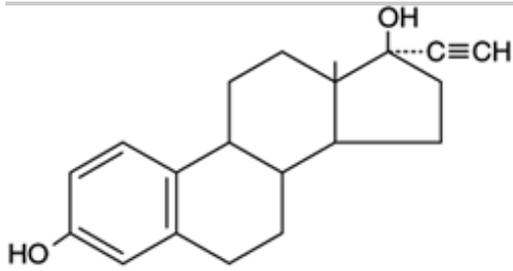

(Reproduced, with permission, from Ganong WF: *Review of Medical Physiology*, 22nd ed. McGraw-Hill, 2005.)

Most of the actions of estrogens are genomic, ie, mediated by actions on the nucleus. However, some effects are so rapid that it is difficult to believe they are mediated via increased expression of mRNAs. These include effects on neuronal discharge in the brain and possibly feedback effects on gonadotropin secretion. Their existence has led to the hypothesis that, in addition to genomic actions, there are nongenomic effects of estrogens that are presumably mediated by membrane receptors. Similar rapid effects of progesterone, testosterone, and aldosterone may also be produced by membrane receptors.

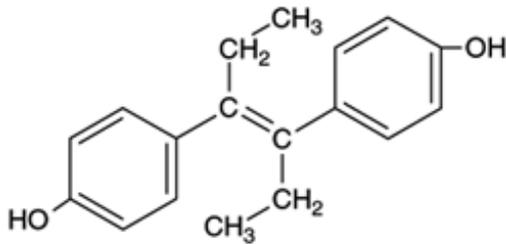

Synthetic Estrogen

The ethinyl derivative of estradiol (Fig 6–15) is a potent estrogen. Unlike naturally occurring estrogens, it is relatively active when given orally because it has an ethinyl group in position 17, which makes it resistant to hepatic metabolism. Naturally occurring hormones have low activity when given orally because the portal venous drainage of the intestine carries them to the liver, where they are largely inactivated before they can reach the general circulation. Some nonsteroidal substances and a few compounds found in plants have estrogenic activity. Plant estrogens rarely affect humans but may cause undesirable effects in farm animals. Diethylstilbestrol (Fig 6–15) and a number of related compounds are strongly estrogenic, possibly because they are converted to steroidlike ring structures in the body.

Synthetic estrogens.

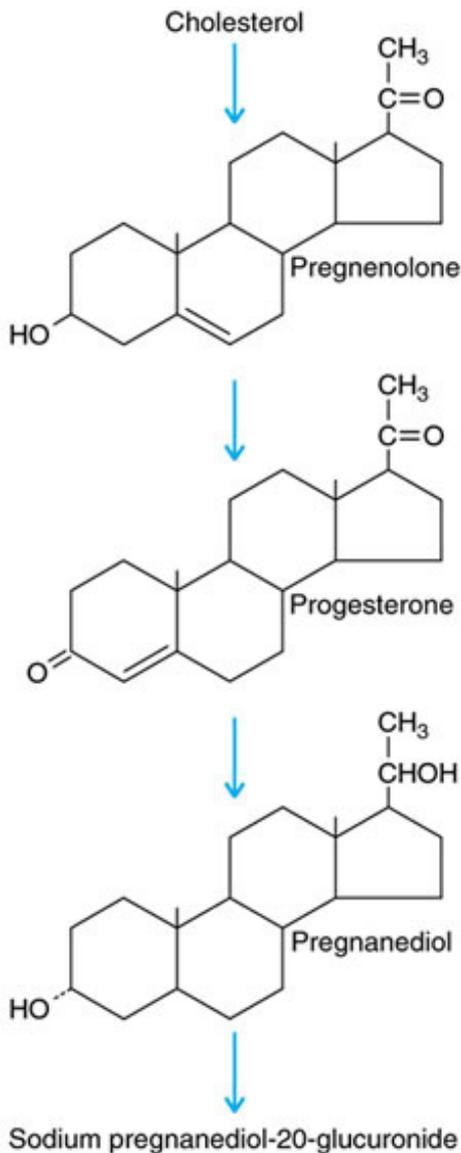

(Reproduced, with permission, from Ganong WF: *Review of Medical Physiology*, 22nd ed. McGraw-Hill, 2005.)

Estradiol reduces the hot flashes and other symptoms of the menopause, and it prevents the development of osteoporosis. It may reduce the initiation and progression of atherosclerosis and the incidence of heart attack. However, it also stimulates the growth of the endometrium and the breast, and it can lead to cancer of the uterus and probably of the breast. Therefore, there has been an active search for "tailor-made" estrogens that have the bone and cardiovascular effects of estradiol but lack its growth-stimulating effects on the uterus and the breast. Two compounds, tamoxifen and raloxifene, show promise in this regard. Neither combats the symptoms of the menopause, but both have the bone-preserving effects of estradiol. They may also have cardioprotective effects but the clinical relevance of these effects has not been established. In addition, tamoxifen does not stimulate the breast, and raloxifene does not stimulate the breast or uterus. The clinical uses of these 2 drugs are discussed elsewhere in this book.

Chemistry, Biosynthesis, & Metabolism of Progesterone

Progesterone (Fig 6–16) is a C_{21} steroid secreted in large amounts by the corpus luteum and the placenta. It is an important intermediate in steroid biosynthesis in all tissues that secrete steroid hormones, and small amounts enter the circulation from the testes and adrenal cortex. The 20α - and 20β -hydroxy derivatives of progesterone are formed in the corpus luteum. About 2% of the progesterone in the circulation is free (Table 6–2), whereas 80% is bound to albumin and 18% is bound to corticosteroid-binding globulin. Progesterone has a short half-life and is converted in the liver to pregnanediol, which is conjugated to glucuronic acid and excreted in the urine (Fig 6–16).

Biosynthesis of progesterone and major pathway for its metabolism. Other metabolites are also formed.

(Reproduced, with permission, from Ganong WF: *Review of Medical Physiology*, 22nd ed. McGraw-Hill, 2005.)

Secretion of Progesterone

The plasma progesterone level in women during the follicular phase of the menstrual cycle is approximately 0.9 ng/mL (3 nmol/L), whereas the level in men is approximately 0.3 ng/mL (1 nmol/L). The difference is due to secretion of small amounts of progesterone by cells in the ovarian follicle. During the luteal phase, the large amounts secreted by the corpus luteum cause ovarian secretion to increase about 20-fold. The result is an increase in plasma progesterone to a peak value of approximately 18 ng/mL (60 nmol/L) (Fig 6–10).

The stimulating effect of LH on progesterone secretion by the corpus luteum is due to activation of adenylyl cyclase and involves a subsequent step that is dependent on protein synthesis.

Actions of Progesterone

The principal target organs of progesterone are the uterus, the breasts, and the brain. Progesterone is responsible for the progestational changes in the endometrium and the cyclic changes in the cervix and vagina described

above. It has antiestrogenic effects on the myometrial cells, decreasing their excitability, their sensitivity to oxytocin, and their spontaneous electrical activity, while increasing their membrane potential. It decreases the number of estrogen receptors in the endometrium and increases the rate of conversion of 17β -estradiol to less active estrogens.

In the breast, progesterone stimulates the development of lobules and alveoli. It induces differentiation of estrogen-prepared ductal tissue and supports the secretory function of the breast during lactation.

The feedback effects of progesterone are complex and are exerted at both the hypothalamic and the pituitary level. Large doses of progesterone inhibit LH secretion and potentiate the inhibitory effects of estrogens, preventing ovulation.

Progesterone is thermogenic and probably is responsible for the rise in basal body temperature at the time of ovulation (Fig 6–10). Progesterone stimulates respiration, and the fact that alveolar P_{CO_2} in women during the luteal phase of the menstrual cycle is lower than that in men is attributed to the action of secreted progesterone. In pregnancy, alveolar P_{CO_2} falls as progesterone secretion rises.

Large doses of progesterone produce natriuresis, probably by blocking the action of aldosterone on the kidney. The hormone does not have a significant anabolic effect.

Mechanism of Action

The effects of progesterone, like those of other steroids, are brought about by an action on DNA to initiate synthesis of new mRNA. The progesterone receptor is bound to a heat shock protein in the absence of the steroid and progesterone binding releases the heat shock protein, exposing the DNA-binding domain of the receptor. The synthetic steroid mifepristone (RU-486) binds to the receptor but does not release the heat shock protein, as it blocks the binding of progesterone. As the maintenance of early pregnancy depends on the stimulatory effect of progesterone on endometrial growth and its inhibition of uterine contractility, mifepristone causes abortion. In some countries, mifepristone combined with a prostaglandin is used to produce elective abortions.

Two isoforms of the progesterone receptor are produced by differential processing from a single gene.

Progesterone receptor A (PR_A) is a truncated form that when activated is capable of inhibiting some of the actions of progesterone receptor B (PR_B). However, the physiologic significance of the existence of the 2 isoforms remains to be determined.

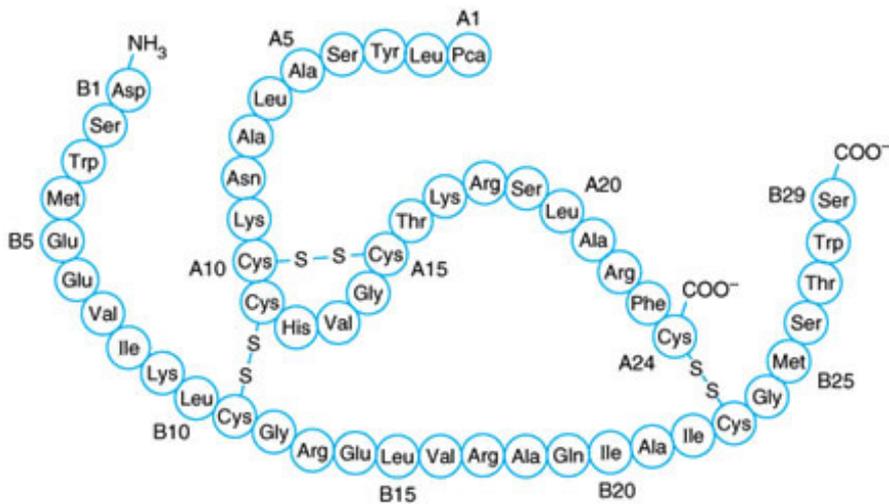

Substances that mimic the action of progesterone are sometimes called progestational agents, gestagens, or progestins. They are used along with synthetic estrogens as oral contraceptive agents.

RELAXIN

Relaxin is a polypeptide hormone that is secreted by the corpus luteum in women and by the prostate in men. During pregnancy, it relaxes the pubic symphysis and other pelvic joints and softens and dilates the uterine cervix during pregnancy. Thus, it facilitates delivery. It also inhibits uterine contractions and may play a role in the development of the mammary glands. In nonpregnant women, relaxin is found in the corpus luteum and the endometrium during the secretory but not the proliferative phase of the menstrual cycle. Its function in nonpregnant women is unknown.

In most species, there is only 1 relaxin gene, but in humans there are 2 genes on chromosome 9 that code for 2 structurally different polypeptides with relaxin activity. However, only 1 of these genes is active in the ovary and the prostate. The structure of the polypeptide produced in these 2 tissues is shown in Fig 6–17.

INHIBINS AND ACTIVINS

Polypeptides called inhibins that inhibit FSH secretion were first isolated from testes but soon were discovered to also be produced by the ovaries. There are 2 inhibins, and they are formed from 3 polypeptide subunits: a glycosylated α subunit with a molecular weight of 18,000, and 2 nonglycosylated β subunits, β_A and β_B , each with a molecular weight of 14,000. The subunits are formed from precursor proteins (Fig 6–18). The α subunit combines with β_A to form a heterodimer and with β_B to form another heterodimer, with the subunits linked by disulfide bonds. Both $\alpha\beta_A$ (inhibin A) and $\alpha\beta_B$ (inhibin B) inhibit FSH secretion by a direct action on the pituitary, although it now appears that inhibin B is the FSH-regulating hormone in adults. Inhibins are produced by Sertoli cells in males and by granulosa cells in females.

Inhibin precursor proteins and the various inhibins and activins that are formed from them. SS, disulfide bonds.
(Reproduced, with permission, from Ganong WF: *Review of Medical Physiology*, 22nd ed. McGraw-Hill, 2005.)

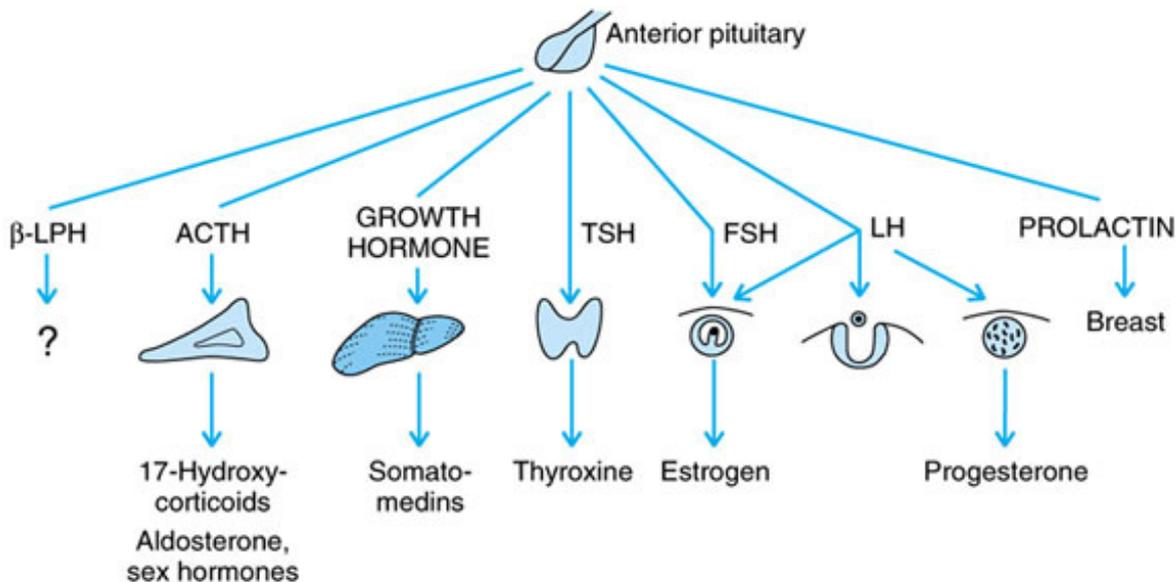

The heterodimer $\beta_A \beta_B$ and the homodimers $\beta_A \beta_A$ and $\beta_B \beta_B$ stimulate rather than inhibit FSH secretion and consequently are called activins. Their function in reproduction is unsettled. However, the inhibins and activins are members of the transforming growth factor- β superfamily of dimeric growth factors that also includes the Mullerian inhibitory substance (MIS) that is important in embryonic development of the gonads. Two activin receptors have been cloned, and both appear to be serine kinases. Inhibins and activins are found not only in the gonads but also in the brain and many other tissues. In the bone marrow, activins are involved in the development of white blood cells. In embryonic life, activins are involved in the formation of mesoderm. All mice in which a targeted deletion of the α -inhibin gene was produced initially grew in a normal fashion but then developed gonadal stromal tumors, so the α -inhibin gene is a tumor suppressor gene.

In plasma, α_2 -macroglobulin binds activins and inhibins. In tissues, activins bind to a family of 4 glycoproteins called follistatins. Binding of the activins inactivates their biologic activity, but the relation of follistatins to inhibins and their physiologic function are unsettled.

PITUITARY HORMONES

Ovarian secretion depends on the action of hormones secreted by the anterior pituitary gland. The anterior pituitary gland secretes 6 established hormones: ACTH, growth hormone, thyroid-stimulating hormone (TSH), FSH, LH, and prolactin (Fig 6–19). It also secretes 1 putative hormone: β -lipotropic hormone (β -LPH).

Figure 6–19.

Anterior pituitary hormones. In women, FSH and LH act in sequence on the ovary to produce growth of the ovarian follicle, which secretes estrogen, then ovulation, followed by formation and maintenance of the corpus luteum, which secretes estrogen and progesterone. In men, FSH and LH control the functions of the testes. Prolactin stimulates lactation. β -LPH, β -lipotropic hormone; ACTH, adrenocorticotropic hormone; TSH, thyroid-stimulating hormone; FSH, follicle-stimulating hormone; LH, luteinizing hormone.

GONADOTROPINS

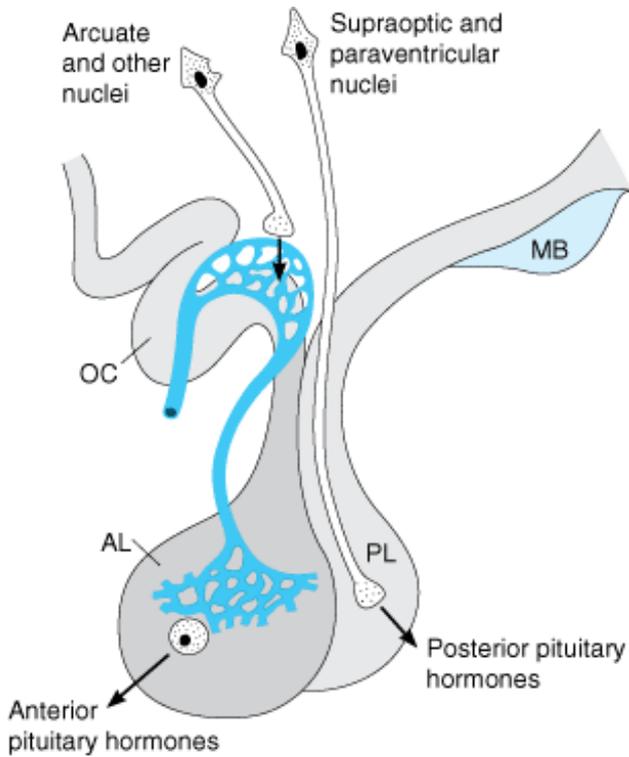

The gonadotropins FSH and LH act in concert to regulate the cyclic secretion of the ovarian hormones. They are glycoproteins made up of α and β subunits. The α subunits have the same amino acid composition as the α subunits in the glycoproteins TSH and human chorionic gonadotropin (hCG); the specificity of these 4 glycoprotein hormones is imparted by the different structures of their β subunits. The carbohydrates in the gonadotropin molecules increase the potency of the hormones by markedly slowing their metabolism. The half-life of human F is about 170 minutes; the half-life of LH is about 60 minutes.

The receptors for FSH and LH are serpentine receptors coupled to adenylyl cyclase through G_s . In addition, each has an extended, glycosylated extracellular domain.

Hypothalamic Hormones

Secretion of the anterior pituitary hormones is regulated by the hypothalamic hypophysiotropic hormones. These substances are produced by neurons and enter the portal hypophysial vessels (Fig 6–20), a special group of blood vessels that transmit substances directly from the hypothalamus to the anterior pituitary gland. The actions of these hormones are summarized in Fig 6–21. The structures of 6 established hypophysiotropic hormones are known (Fig 6–22). No single prolactin-releasing hormone has been isolated and identified. However, several polypeptides that are found in the hypothalamus can increase prolactin secretion, and 1 or more of these may stimulate prolactin secretion under physiologic conditions.

The posterior pituitary differs from the anterior pituitary in that its hormones oxytocin and arginine vasopressin are secreted by neurons directly into the systemic circulation. These hormones are produced in the cell bodies of neurons located in the supraoptic and paraventricular nuclei of the hypothalamus and transported down the axons of these neurons to their endings in the posterior lobe of the pituitary. The hormones are released from the endings into the circulation when action potentials pass down the axons and reach the endings. The structures of the hormones are shown in Fig 6–23.

CONTROL OF OVARIAN FUNCTION

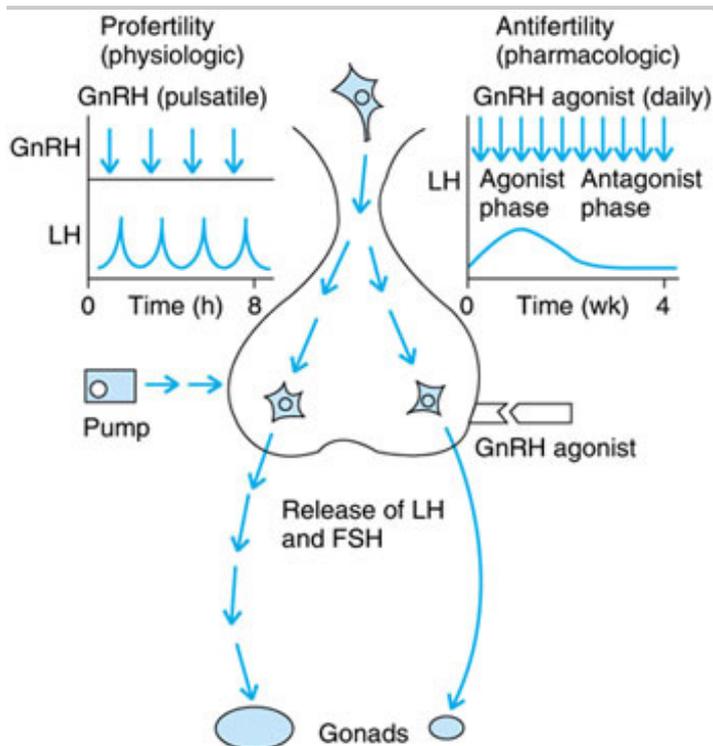

FSH from the pituitary is responsible for early maturation of the ovarian follicles, and FSH and LH together are responsible for final follicle maturation. A burst of LH secretion (Fig 6–10) triggers ovulation and the initial formation of the corpus luteum. There is also a smaller midcycle burst of FSH secretion, the significance of which is uncertain. LH stimulates the secretion of estrogen and progesterone from the corpus luteum.

Hypothalamic Components

The hypothalamus occupies a key role in the control of gonadotropin secretion. Hypothalamic control is exerted by GnRH secreted into the portal hypophysial vessels. GnRH stimulates the secretion of FSH as well as LH, and it is unlikely that there is an additional separate follicle-stimulating hormone–releasing hormone (FRH).

GnRH is normally secreted in episodic bursts (circadian secretion). These bursts are essential for normal secretion of gonadotropins, which are also exerted in an episodic fashion (Fig 6–24). If GnRH is administered by constant infusion, the number of GnRH receptors in the anterior pituitary decreases (downregulation), and LH secretion falls to low levels. However, if GnRH is administered episodically at a rate of 1 pulse per hour, LH secretion is stimulated. This is true even when endogenous GnRH secretion has been prevented by a lesion of the ventral hypothalamus.

Figure 6–24.

Profertility and antifertility actions of GnRH and its agonists. The normal secretion of GnRH is pulsatile, occurring 30- to 60-minute intervals. This mode, which can be mimicked by timed injections, produces circadian peaks of LH and FSH secretion and promotes fertility. If GnRH is administered by continuous infusion or if 1 of its long-acting synthetic agonists is injected, there is initial stimulation of the pituitary receptors. However, this stimulation lasts for only a few days and is followed by receptor downregulation with inhibition of gonadotropin secretion (antifertility effect).

(Reproduced, with permission, from Conn PM, Crowley WF Jr: Gonadotropin-releasing hormone and its analogue

It is now clear not only that episodic secretion of GnRH is a general phenomenon but that fluctuations in the frequency and amplitude of the GnRH bursts are important in generating the other hormonal changes that are responsible for the menstrual cycle. Frequency is increased by estrogens and decreased by progesterone and testosterone. The frequency increases late in the follicular phase of the cycle, culminating in the LH surge. During the secretory phase, the frequency decreases as a result of the action of progesterone, but when estrogen and progesterone secretion decrease at the end of the cycle, frequency once again increases.

At the time of the midcycle LH surge, the sensitivity of the gonadotropes to GnRH is greatly increased because of their exposure to GnRH pulses of the frequency that exist at this time. This self-priming effect of GnRH is important in producing a maximum LH response.

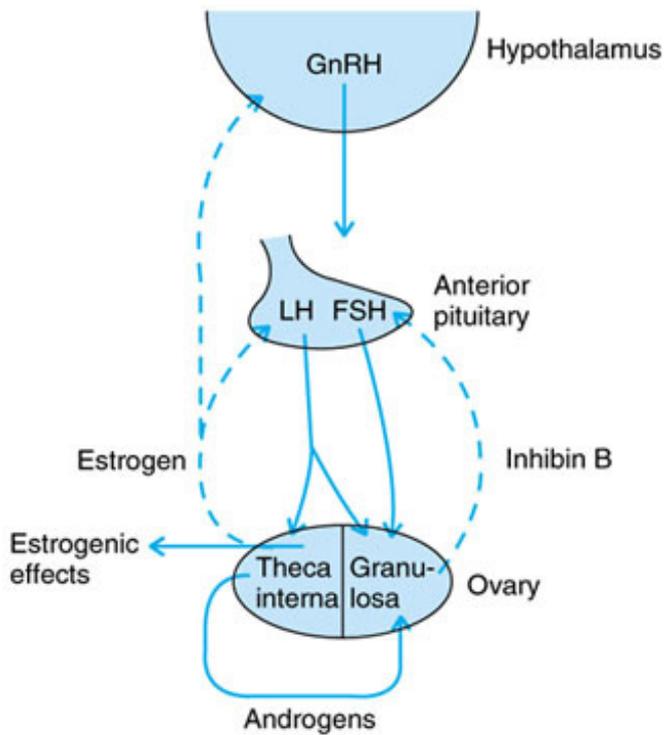

The nature and the exact location of the GnRH pulse generator in the hypothalamus are still unsettled. However, it is known in a general way that norepinephrine and possibly epinephrine in the hypothalamus increase GnRH pulse frequencies. Conversely, opioid peptides such as the enkephalins and β -endorphin reduce the frequency of GnRH pulses.

The downregulation of pituitary receptors and the consequent decrease in LH secretion produced by constantly elevated levels of GnRH has led to the use of long-acting GnRH agonists to inhibit LH secretion in precocious puberty and cancer of the prostate.

Feedback Effects

Changes in plasma levels of LH, FSH, sex steroids, and inhibin B during the menstrual cycle are shown in Fig 6-24 and their feedback relations are diagrammed in Fig 6-25. At the start of the follicular phase, the inhibin B level is low and the FSH level is modestly elevated, fostering follicular growth. LH secretion is held in check by the negative feedback effect of the rising plasma estrogen level. At 36–48 hours before ovulation, the estrogen feedback effect becomes positive, which initiates the burst of LH secretion (LH surge) that produces ovulation. Ovulation occurs about 9 hours after the LH peak. FSH secretion also peaks, despite a small rise in inhibin B level probably because of the strong stimulation of gonadotropes by GnRH. During the luteal phase, secretion of LH and FSH is low because of the elevated levels of estrogen, progesterone, and inhibin B.

Figure 6–25.

Feedback regulation of ovarian function. The cells of the theca interna provide androgens to the granulosa cells, and the thecal cells produce the circulating estrogens, which inhibit the secretion of LH, GnRH, and FSH. Inhibin from the granulosa cells also inhibits FSH secretion. LH regulates thecal cells, whereas the granulosa cells are regulated by both LH and FSH. The dashed arrows indicate inhibition, and the solid arrows indicate stimulation. GnRH, gonadotropin-releasing hormone; LH, luteinizing hormone; FSH, follicle-stimulating hormone.

(Reproduced, with permission, from Ganong WF: *Review of Medical Physiology*, 22nd ed. McGraw-Hill, 2005.)

It should be emphasized that a moderate, constant level of circulating estrogen exerts a negative feedback effect on LH secretion, whereas an elevated estrogen level exerts a positive feedback effect and stimulates LH secretion. It has been demonstrated in monkeys that there is also a minimum time that estrogen levels must be elevated to produce positive feedback. When the circulating estrogen level was increased about 300% for 24 hours, only negative feedback was seen; but when it was increased about 300% for 36 hours or more, a brief decline in secretion was followed by a burst of LH secretion that resembled the midcycle surge. When circulating levels of progesterone were high, the positive feedback effect of estrogen was inhibited. There is evidence in primates that both the negative and the positive feedback effects of estrogen are exerted in the mediobasal hypothalamus, but exactly how negative feedback is switched to positive feedback and then back to negative feedback in the luteal phase remains unknown.

Control of Menstrual Cycle

In an important sense, regression of the corpus luteum (luteolysis) starting 3–4 days before menses is the key to the menstrual cycle. PGF_{2a} appears to be a physiologic luteolysin, but this prostaglandin is only active when endothelial cells producing endothelin-1 (ET-1) are present. Therefore, it appears that at least in some species luteolysis is produced by the combined action of PGF_{2a} and ET-1. In some domestic animals, oxytocin secreted by the corpus luteum appears to exert a local luteolytic effect, possibly by causing the release of prostaglandins. Once luteolysis begins, estrogen and progesterone levels fall, and secretion of FSH and LH increases. A new crop of follicles develops, and then a single dominant follicle matures as a result of the action of FSH and LH. Near

midcycle, there is a rise in estrogen secretion from the follicle. This rise augments the responsiveness of the pituitary to GnRH and triggers a burst of LH secretion. The resulting ovulation is followed by formation of a corpus luteum. There is a drop in estrogen secretion, but progesterone and estrogen levels then rise together, along with inhibin B. The elevated levels inhibit FSH and LH secretion for a while, but luteolysis again occurs and a new cycle starts.

Reflex Ovulation

Female cats, rabbits, mink, and certain other animals have long periods of estrus, or heat, during which they ovulate only after copulation. Such reflex ovulation is brought about by afferent impulses from the genitalia or the eyes, ears, and nose that converge on the ventral hypothalamus and provoke an ovulation-inducing release of LH from the pituitary. In species such as rats, monkeys, and humans, ovulation is a spontaneous periodic phenomenon, but afferent impulses converging on the hypothalamus can also exert effects. Ovulation can be delayed for 24 hours in rats by administering pentobarbital or other neurally active drugs 12 hours before the expected time of follicle rupture. In women, menstrual cycles may be markedly influenced by emotional stimuli.

Contraception

Methods commonly used to prevent conception, along with their failure rates, are listed in Table 6–4.

Contraception is considered in detail in Chapter 36. It is briefly reviewed here because the techniques used are excellent examples of the practical application of the physiologic principles discussed in this chapter.

Data from Vessey M, Lawless M, Yeates D: Efficacy of different contraceptive methods. *Lancet* 1982; 1:841.

Reproduced with permission.

Among the most extensively used contraceptives are estrogens and/or progestins in varying doses and combinations. They interfere with gonadotrophic secretion or, in some cases, inhibit the union of sperms with ova.

Once conception has occurred, abortion can be produced by progesterone antagonists such as mifepristone.

Implantation of foreign bodies in the uterus causes changes in the duration of the sexual cycle in a number of mammalian species. In humans, such foreign bodies do not alter the menstrual cycle, but they act as effective contraceptive devices. Intrauterine implantation of pieces of metal or plastic (intrauterine devices [IUDs]) has been used in programs aimed at controlling population growth. Although their mechanism of action is still unsettled, they seem in general to prevent sperms from fertilizing ova.

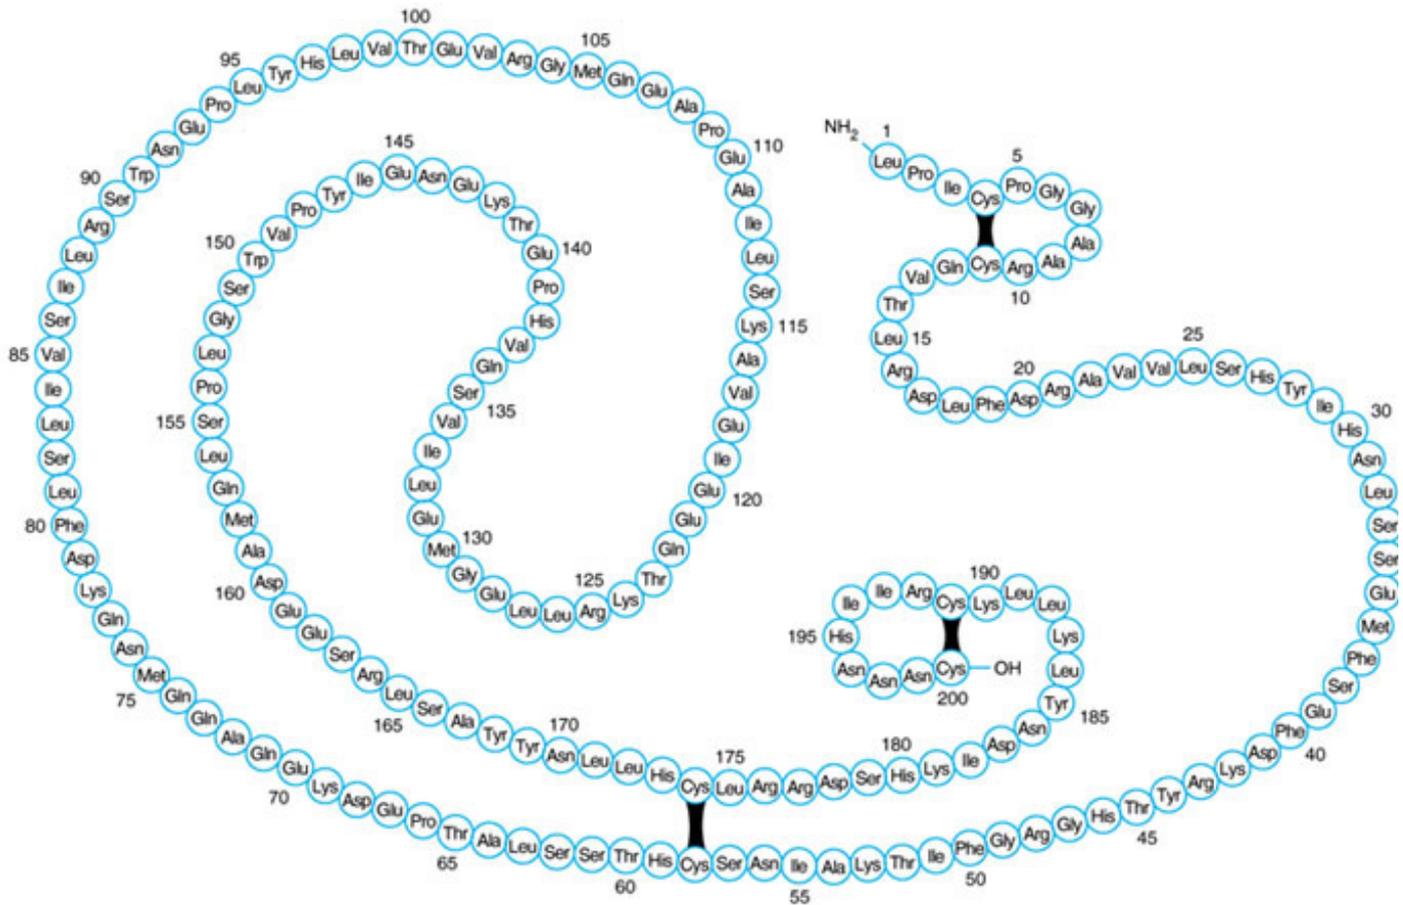

Implants made up primarily of progestins are now being increasingly used in some parts of the world. The implants are inserted under the skin and can prevent pregnancy for up to 5 years. They often produce amenorrhea but otherwise appear to be well tolerated.

PROLACTIN

Chemistry of Prolactin

Prolactin is another anterior pituitary hormone that has important functions in reproduction and pregnancy. The human prolactin molecule contains 199 amino acid residues and 3 disulfide bridges (Fig 6–26) and has considerable structural similarity to human growth hormone and human chorionic somatomammotropin (hCS). The half-life of prolactin, like that of growth hormone, is about 20 minutes. Structurally similar prolactins are secreted by the endometrium and by the placenta.

Structure of human prolactin.

(Reproduced, with permission, from Bondy PK, Rosenberg LE: *Metabolic Control and Disease*, 8th ed. Saunders, 1980.)

Receptors

The human prolactin receptor resembles the growth hormone receptor and is 1 of the superfamily of receptors that includes the growth hormone receptor and receptors for many cytokines and hematopoietic growth factors. It dimerizes and activates the JAK-STAT and other intracellular enzyme cascades.

Actions

Prolactin causes milk secretion from the breast after estrogen and progesterone priming. Its effect on the breast increased production of casein and lactalbumin. However, the action of the hormone is not exerted on the cell nucleus and is prevented by inhibitors of microtubules. Prolactin also inhibits the effects of gonadotropins, possibly by an action at the level of the ovary. Consequently, it is a "natural contraceptive" that spaces pregnancies by preventing ovulation in lactating women. The function of prolactin in normal males is unsettled, but excess prolactin secreted by tumors causes impotence. An action of prolactin that has been used as the basis for bioassay of this hormone is stimulation of the growth and "secretion" of the crop sacs in pigeons and other birds. The pair crop sacs are outpouchings of the esophagus that form, by desquamation of their inner cell layers, a nutritious material ("milk") that the birds feed to their young. However, prolactin, FSH, and LH are now regularly measured by radioimmunoassay.

Regulation of Prolactin Secretion

The normal plasma prolactin concentration is approximately 5 ng/mL in men and 8 ng/mL in women. Secretion is tonically inhibited by the hypothalamus, and section of the pituitary stalk leads to an increase in circulating prolactin. Thus, the effect of the hypothalamic prolactin-inhibiting hormone (PIH) dopamine is greater than the effect of the putative prolactin-releasing hormone. In humans, prolactin secretion is increased by exercise, surgery and psychological stresses, and stimulation of the nipple (Table 6–5). The plasma prolactin level rises during sleep, the rise starting after the onset of sleep and persisting throughout the sleep period. Secretion is increased during pregnancy, reaching a peak at the time of parturition. After delivery, the plasma concentration falls to nonpregnant levels in about 8 days. Suckling produces a prompt increase in secretion, but the magnitude of this rise gradually declines after a woman has been nursing for more than 3 months.

(Modified from Frantz and reproduced, with permission, from Ganong WF: *Review of Medical Physiology*, 22nd ed McGraw-Hill, 2005.)

L -Dopa decreases prolactin secretion by increasing the formation of dopamine, and bromocriptine and other dopamine agonists inhibit secretion because they stimulate dopamine receptors. Chlorpromazine and related drugs that block dopamine receptors increase prolactin secretion. Thyroid-releasing hormone (TRH) stimulates the secretion of prolactin in addition to TSH, and there are additional prolactin-releasing polypeptides in hypothalamic tissue. Estrogens produce a slowly developing increase in prolactin secretion as a result of a direct action on the lactotrophs.

It has now been established that prolactin facilitates the secretion of dopamine in the median eminence. Thus, prolactin acts in the hypothalamus in a negative feedback fashion to inhibit its own secretion.

Hyperprolactinemia

Up to 70% of patients with chromophobe adenomas of the anterior pituitary have elevated plasma prolactin levels. In some instances the elevation may be due to damage to the pituitary stalk, but in most cases the tumor cells are actually secreting the hormone. The hyperprolactinemia may cause galactorrhea, but in many individuals there are no demonstrable abnormalities. Indeed, most women with galactorrhea have normal prolactin levels; definite elevations are found in less than one-third of patients with this condition.

Another interesting observation is that 15–20% of women with secondary amenorrhea have elevated prolactin levels, and when prolactin secretion is reduced, normal menstrual cycles and fertility return. It appears that the prolactin may produce amenorrhea by blocking the action of gonadotropins on the ovaries, but definitive proof of this hypothesis must await further research. The hypogonadism produced by prolactinomas is associated with osteoporosis due to estrogen deficiency.

Hyperprolactinemia in men is associated with impotence and hypogonadism that disappear when prolactin secretion is reduced.

MENOPAUSE

The human ovary gradually becomes unresponsive to gonadotropins with advancing age and its function declines so that sexual cycles and menstruation disappear (menopause). This unresponsiveness is associated with and

probably caused by a decline in the number of primordial follicles (Fig 6–6). The ovaries no longer secrete progesterone and 17 β -estradiol in appreciable quantities. Estrone is formed by aromatization of androstenedione in fat and other tissues, but the amounts are normally small. The uterus and vagina gradually become atrophic. As the negative feedback effect of the estrogens and progesterone is reduced, secretion of FSH and LH is increased and plasma FSH and LH rise to high levels. Old female mice and rats have long periods of diestrus and increased levels of gonadotropin secretion, but a clear-cut "menopause" has apparently not been described in experimental animals.

In women, the menses usually become irregular and cease between the ages of 45 and 55. The average age at onset of the menopause has increased since the turn of the century and is currently about 52 years.

Sensations of warmth spreading from the trunk to the face ("hot flushes," also called hot flashes), night sweats, and various psychic symptoms are common after ovarian function has ceased. Hot flushes are said to occur in 75% of menopausal women and may last as long as 40 years. They are prevented by administration of estrogen. They are not peculiar to the menopause; they also occur in premenopausal women and men whose gonads are removed surgically or destroyed by disease. Their cause is unknown. However, it has been demonstrated that they coincide with surges of LH secretion. LH is secreted in episodic bursts at intervals of 30–60 minutes or more (circadian secretion), and in the absence of gonadal hormones, these bursts are large. Each hot flush begins with the start of a burst. However, LH itself is not responsible for the symptoms, as they can continue after removal of the pituitary. Instead, it appears that some event in the hypothalamus initiates both the release of LH and the episode of flushing. The menopause and the clinical management of patients with menopausal symptoms are discussed in more detail in Chapter 59.

MATERNAL PHYSIOLOGY DURING PREGNANCY: INTRODUCTION

Pregnancy involves a number changes in anatomy, physiology, and biochemistry, which can challenge maternal reserves. A basic knowledge of these adaptations is critical for understanding normal laboratory measurements, knowing the drugs likely to require dose adjustments, and recognizing women who are predisposed to medical complications during pregnancy.

CARDIOVASCULAR SYSTEM

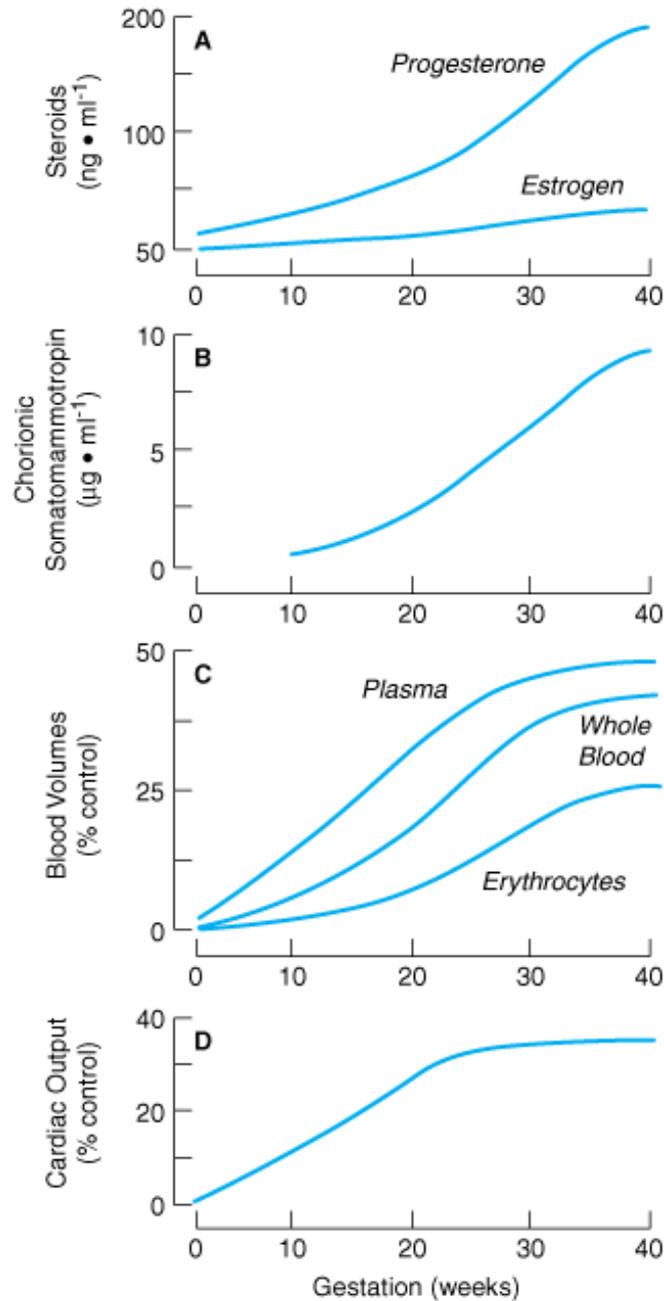

Anatomic Changes

With uterine enlargement and diaphragmatic elevation, the heart rotates on its long axis in a left-upward displacement. As a result of these changes, the apical beat (point of maximum intensity) shifts laterally. Overall, the heart size increases by about 12%, which results from both an increase in myocardial mass and intracardiac volume (approximately 80 mL). Vascular changes include hypertrophy of smooth muscle and a reduction in collagen content.

Blood Volume

Blood volume expansion begins early in the first trimester, increases rapidly in the second trimester, and plateaus at about the 30th week (Fig 7–1). The approximately 50% elevation in plasma volume, which accounts for most of the increment, results from a cascade of effects triggered by pregnancy hormones. For example, increased estrogen production by the placenta stimulates the renin-angiotensin system, which, in turn, leads to higher circulating levels of aldosterone. Aldosterone promotes renal Na⁺ reabsorption and water retention. Progesterone also participates in plasma volume expansion through a poorly understood mechanism; increased venous capacitance is another important factor. Human chorionic somatomammotropin, progesterone, and perhaps other hormones promote erythropoiesis, resulting in the about a 30% increase in red cell mass.

Increases in maternal hormones (A, B), blood volume (C), and cardiac output (D) over gestation. % control represents the increment relative to nonpregnant values.

(Modified from Longo LD: Maternal blood volume and cardiac output during pregnancy: A hypothesis of endocrinologic control. *Am J Physiol* 1983; 245:R720.)

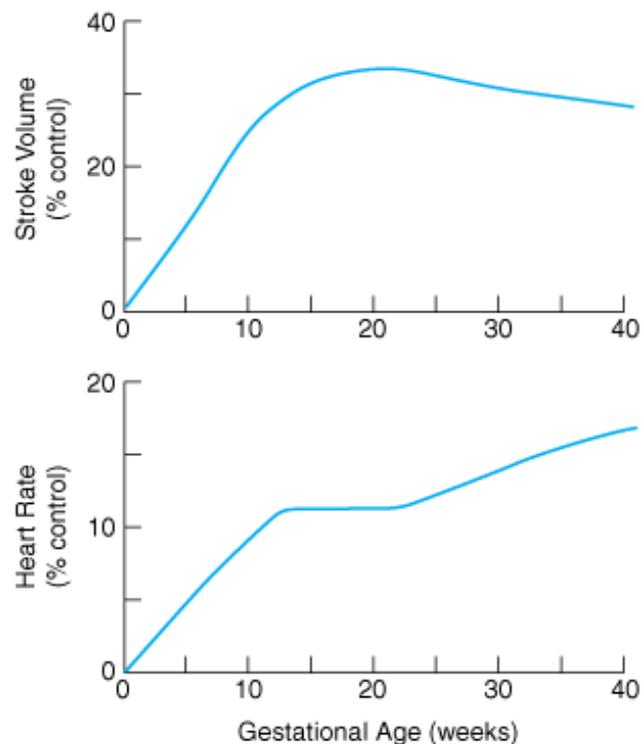

The magnitude of the increase in blood volume varies according to the size of the woman, the number of prior pregnancies, and the number of fetuses she is carrying. This hypervolemia of pregnancy compensates for maternal blood loss at delivery, which averages 500–600 mL for vaginal and 1000 mL for cesarean delivery.

Cardiac Output

Cardiac output increases approximately 40% during pregnancy, with maximum values achieved at 20–24 weeks' gestation. This rise in cardiac output is thought to result from the hormonal changes of pregnancy as well as the arteriovenous-shunt effect of uteroplacental circulation.

Stroke volume increases 25–30% during pregnancy, reaching peak values at 12–24 weeks' gestation (Fig 7–2). Thus, elevations in cardiac output after 20 weeks of gestation depend critically on the rise in heart rate. Maximum cardiac output is associated with a 24% increase in stroke volume and a 15% rise in heart rate. Cardiac output increases in labor in association with painful contractions, which increase venous return and activate the sympathetic nervous system. Cardiac output is further increased, albeit transiently, at delivery.

Figure 7–2.

Increases in maternal stroke volume and heart rate. The % control represents increment relative to measurements in patients who are not pregnant.

(Reproduced, with permission, from Koos BJ: Management of uncorrected, palliated, and repaired cyanotic congenital heart disease in pregnancy. *Prog Ped Cardiol* 2004; 19: 250.)

Stroke volume is sensitive to maternal position. In lateral recumbency, stroke volume remains roughly the same from 20 weeks' gestation until term, but in the supine position stroke volume decreases after 20 weeks and can even fall to nonpregnant levels by 40 weeks' gestation.

The resting maternal heart rate, which progressively increases over the course of gestation, averages at term about 15 beats/min more than the nonpregnant rate (Fig 7–2). Of course, exercise, emotional stress, heat, drugs, and other factors can further increase heart rate.

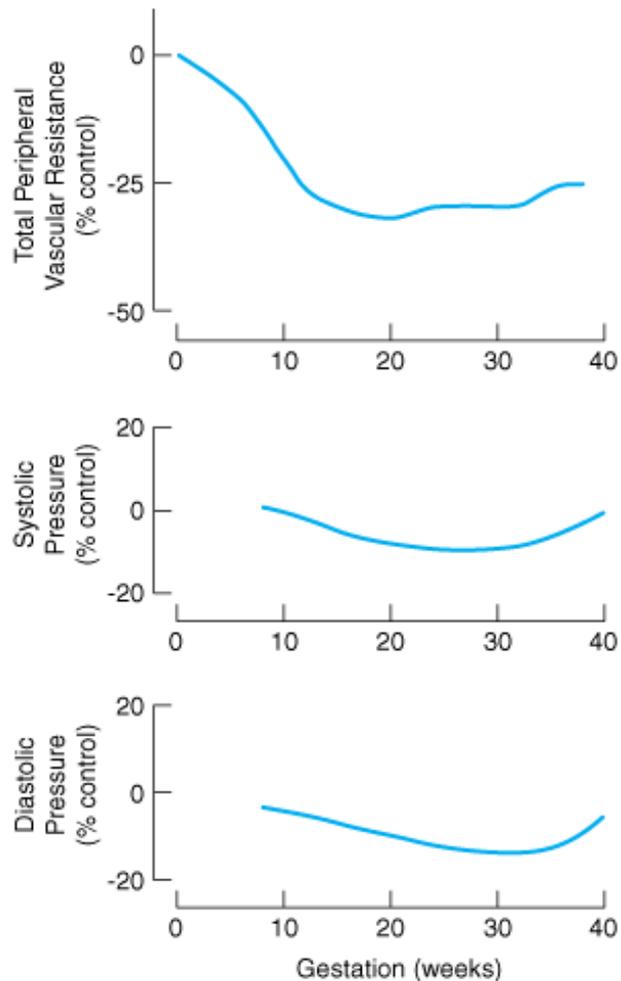

Multiple gestations have even more profound effects on the maternal cardiovascular system. In twin pregnancies, cardiac output is about 20% greater than for singletons, because of greater stroke volume (15%) and heart rate (3.5%). Other differences include greater left ventricular end-diastolic dimensions and muscle mass.

Cardiac output is generally resistant to postural stress. For example, the fall in cardiac output that develops immediately after standing does not occur in the middle of the third trimester, although some reduction can occur earlier in pregnancy. In the third trimester, the supine position can reduce cardiac output and arterial pressure caused by compression of the vena cava by the gravid uterus with an associated reduction in venous return to the heart. About 8% of gravidas will develop supine hypotensive syndrome, characterized by hypotension, bradycardia, and syncope. These women are particularly sensitive to caval compression because of reduced capacitance in venous collaterals. Shifting the gravida to a right or left lateral recumbent position will alleviate caval compression, increase blood return to the heart, and restore cardiac output and arterial pressure.

Blood Pressure

Systemic arterial pressure declines slightly during pregnancy, reaching a nadir at 24–28 weeks of gestation. Pulse pressure widens because the fall is greater for diastolic than for systolic pressures (Fig 7–3). Systolic and diastolic pressures (and mean arterial pressure) increase to prepregnancy levels by about 36 weeks.

Figure 7–3.

Copyright ©2006 by The McGraw-Hill Companies, Inc. All rights reserved.

Changes in maternal peripheral vascular resistance and arterial pressures over gestation. Pressures were measured in the left lateral recumbent position. The % control represents the relative change from nonpregnant values.

(Modified from Thornburg KL et al: Hemodynamic changes in pregnancy. *Semin Perinatol* 2000; 24: 11; Wilson M et al: Blood pressure, the renin-aldosterone system and sex steroids throughout normal pregnancy. *Am J Med* 1980; 68: 97.)

Venous pressure progressively increases in the lower extremities, particularly when the patient is supine, sitting, or standing. The rise in venous pressure, which can cause edema and varicosities, results from compression of the inferior vena cava by the gravid uterus and possibly from the pressure of the fetal presenting part on the common iliac veins. Lying in lateral recumbency minimizes changes in venous pressure. As expected, venous pressure in the lower extremities falls immediately after delivery. Venous pressure in the upper extremities is unchanged by pregnancy.

Peripheral Vascular Resistance

Vascular resistance decreases in the first trimester, reaching a nadir of about 34% below nonpregnancy levels by 14 to 20 weeks of gestation with a slight increase toward term (Fig 7–3). The hormonal changes of pregnancy likely trigger this fall in vascular resistance by enhancing local vasodilators, such as nitric oxide, prostacyclin, and possibly adenosine. Delivery is associated with nearly a 40% fall in peripheral vascular resistance, although mean arterial pressure is generally maintained because of the associated

rise in cardiac output.

Blood Flow Distribution

Blood flow to the uterus increases in a gestational age-dependent manner. Uterine blood flow can be as high as 800 mL/min, which is about 4 times the nonpregnant value. The increased flow during pregnancy results from the relatively low resistance in the uteroplacental circulation.

Renal blood flow increases approximately 400 mL/min above nonpregnant levels, and blood flow to the breasts increases approximately 200 mL/min. Blood flow to the skin also increases, particularly in the hands and feet. The increased skin blood flow helps dissipate heat produced by metabolism in the mother and fetus.

In absolute terms, blood flow increases to the uterus, kidneys, skin, breast, and possibly other maternal organs; the total augmented organ flow reflects virtually the entire increment in maternal cardiac output. However, when expressed as a percentage of cardiac output, blood flow in some of these organs may not be elevated compared to the nonpregnant state.

Strenuous exercise, which diverts blood flow to large muscles, has the potential to decrease uteroplacental perfusion and thus O₂ delivery to the fetus. Women who are already adapted to an exercise routine can generally continue the program in pregnancy; however, pregnant women should discuss their exercise plans with the physician managing the pregnancy.

Heart Murmurs and Rhythm

The physiologic changes of pregnancy alter several clinical findings. For example, systolic ejection murmurs, which result from increased cardiac output and decreased blood viscosity, can be detected in 90% or more gravidas. Thus, caution should be exercised in interpreting systolic murmurs in pregnant women.

The first heart sound may be split, with increased loudness of both portions, and the third heart sound may also be louder. Continuous murmurs or bruits may be heard at the left sternal edge, which arise from the internal thoracic (mammary) artery.

Pregnancy decreases the threshold for reentrant supraventricular tachycardia. Normal pregnancy can also be accompanied by sinus tachycardia, sinus bradycardia, and isolated atrial and ventricular premature contractions.

Electrocardiographic changes can include a 15- to 20-degree shift to the left in the electrical axis. Changes in ventricular repolarization can result in ST segment depression or T-wave flattening. However, pregnancy does not alter the amplitude and duration of the P wave, QRS complex, or T wave.

PULMONARY SYSTEM

Anatomic Changes

Pregnancy alters the circulation of a number of tissues involved in respiration. For example, capillary dilatation leads to engorgement of the nasopharynx, larynx, trachea, and bronchi. Prominent pulmonary vascular markings observed on x-ray are consistent with increased pulmonary blood volume.

As the uterus enlarges, the diaphragm is elevated by as much as 4 cm. The rib cage is displaced upward, increasing the angle of the ribs with the spine. These changes increase the lower thoracic diameter by about 2 cm and the thoracic circumference by up to 6 cm. Elevation of the diaphragm does not impair its function. Abdominal muscles have less tone and activity during pregnancy, causing respiration to be more diaphragm dependent.

Lung Volumes and Capacities

Several lung volumes and capacities are altered by pregnancy (Table 7–1). Dead space volume increases because of relaxation of the musculature of conducting airways. Tidal volume and inspiratory capacity increase. Elevation of the diaphragm is associated with reduction in total lung capacity and functional residual capacity. The latter involves a decrease in both expiratory reserve and residual volumes.

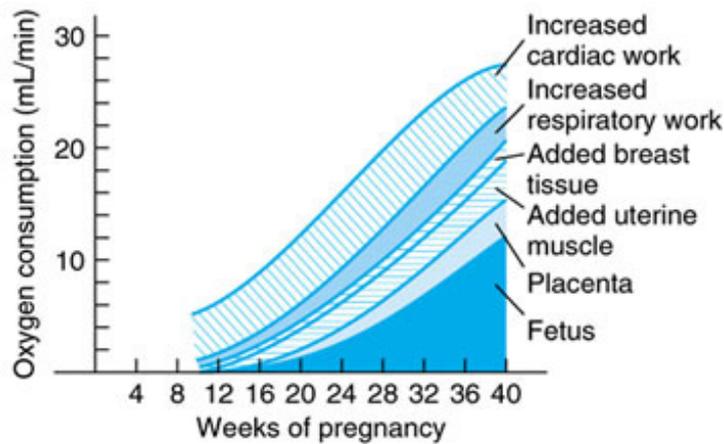

Table 7–1. Effects of Pregnancy on Lung Volumes and Capacities.

	Definition	Change
I. Volumes		
Tidal	Volume inspired and expired with each normal respiratory cycle	↑ 35–50%
Inspiratory reserve	Maximum volume that can be inspired over normal end-tidal inspiration	↓
Expiratory reserve	Maximum volume that can be expired from resting end-tidal expiration	↓ 20%
Residual	Volume remaining in the lungs following maximum expiration	↓ 20%
II. Capacities		
Total lung	Total volume at the end of maximum inspiration	↓ 5%
Vital	Maximum volume expired after maximum inspiration	→
Inspiratory	Maximum volume inspired from end-tidal expiration	↑ 5–10%
Functional	Volume at end-tidal expiration that mixes with tidal air upon inspiration	↓ 20%

Respiration

Pregnancy has little affect on respiratory rate. Thus, the increase in minute ventilation (approximately 50%) results from the rise in tidal volume. This increment in minute ventilation is disproportionately greater than the rise (approximately 20%) in total oxygen consumption in maternal muscle tissues (cardiac, respiratory, uterine, skeletal) and in the products of the fetal genome (placenta, fetus), as shown in Figure 7–4. This hyperventilation, which decreases maternal arterial P_{CO_2} to about 27–32 mm Hg, results in a mild respiratory alkalosis (blood pH of 7.4–7.5). The hyperventilation and hyperdynamic circulation slightly increase arterial P_{O_2} .

Figure 7–4.

All rights reserved.

Components of increased oxygen consumption during pregnancy.

(Reproduced, with permission, from Hytten FE, Leitch I: *The Physiology of Human Pregnancy*. Blackwell, 1964.)

Increased levels of progesterone appear to have a critical role in the hyperventilation of pregnancy, which develops early in the first trimester. As in the luteal phase of the menstrual cycle of nonpregnant women, the increased ventilation appears to be caused by the action of progesterone on central neurons involved in respiratory regulation. The overall respiratory effect appears to be a decrease in the threshold and an increase in the sensitivity of central chemoreflex responses to CO_2 . Maternal hyperventilation may be protective in that it prevents the fetus from being exposed to high CO_2 tensions, which might adversely affect the development of respiratory control and other critical regulatory mechanisms.

Functional measurement of ventilation can also change according to posture and duration of pregnancy. For example, the peak expiratory rate, which declines throughout gestation in the sitting and standing positions, is particularly compromised in the supine position.

RENAL SYSTEM

Anatomic Changes

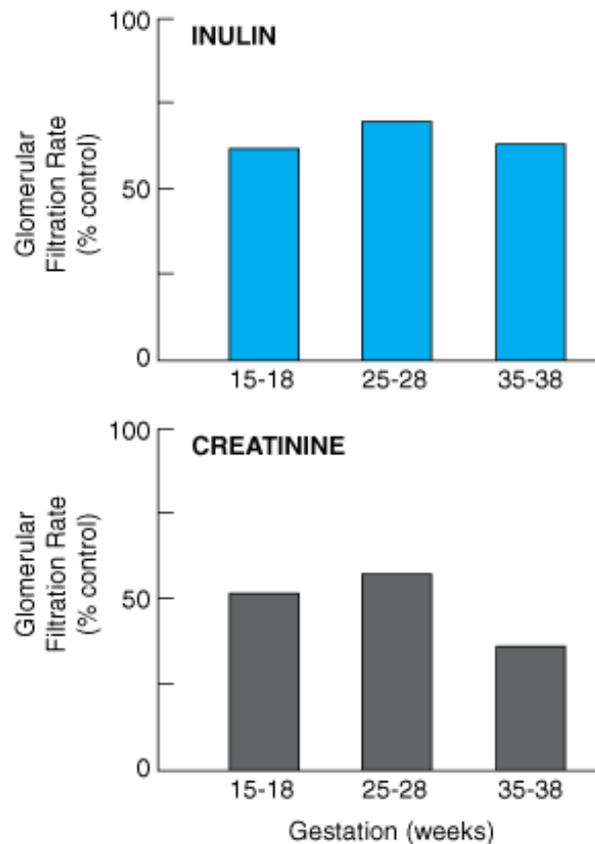

During pregnancy, the length of the kidneys increases by 1–1.5 cm, with a proportional increase in weight. The renal calyces and pelves are dilated in pregnancy, with the volume of the renal pelvis increased up to 6-fold compared to the nonpregnant value of 10 mL. The ureters are dilated above the brim of the bony pelvis, with more prominent effects on the right. The ureters elongate, widen, and become more curved. The entire dilated collecting system may contain up to 200 mL of urine, which predisposes to ascending urinary infections. Urinary tract dilatation disappears in virtually all women by postpartum day 4.

Several factors likely contribute to the hydronephrosis and hydroureter of pregnancy: (1) Pregnancy hormones (eg, progesterone) may cause hypotonia of ureteral smooth muscle. Against this possibility is the observation that high progesterone levels in nonpregnant women do not cause hydroureter. (2) Enlargement of the ovarian vein complex in the infundibulopelvic ligament may compress the ureter at the brim of the bony pelvis. (3) Hyperplasia of smooth muscle in the distal one-third of the ureter may cause reduction in luminal size, leading to dilatation in the upper two-thirds. (4) The sigmoid colon and dextrorotation of the uterus likely reduce compression (and dilatation) of the left ureter relative to the right.

Renal Function

Renal plasma flow increases 50–85% above nonpregnant values during the first half of pregnancy, with a modest decrease in later gestation. The changes in renal plasma flow reflect decreases in renal vascular resistance, which achieves lowest values by the end of the first trimester. Elevated renal perfusion is the principal factor involved in rise in glomerular filtration rate (GFR), which is increased by approximately 25% in the second week after conception. GFR reaches a peak increment of 40–65% by the end of the first trimester and remains high until term (Fig 7–5). The fraction of renal plasma flow that passes through the glomerular membrane (filtration fraction) decreases during the first 20 weeks of gestation, which subsequently rises toward term.

Figure 7–5.

Increases in glomerular filtration over gestation as reflected by changes in inulin and endogenous creatinine clearances. The % control represents relative change from postpartum values.

(Data from Davison JM, Hytten FE: Glomerular filtration during and after pregnancy. *J Obstet Gynaecol Br Commonw* 1974; 81: 558.)

Hormones involved in these changes in renal vascular resistance may include progesterone and relaxin (via upregulation of vascular matrix metalloproteinase-2). Agents elaborated by the endothelium, such as endothelin (ET) (via activation of ET_B receptor subtype) and nitric oxide (via increased cyclic guanosine –3',5'-monophosphate), are likely to be critically involved in the reduction of renal vascular resistance. An additional factor is the increased cardiac output, which permits increased renal perfusion without depriving other organs of blood flow.

Urinary flow and sodium excretion rates in late pregnancy are increased 2-fold in lateral recumbency compared to the supine position. Thus, measurements of urinary function must take into account maternal posture. Collection periods should be at least 12–24 hours to allow for errors caused by the large urinary dead space. However, reasonable estimates of urinary excretion of a particular substance over shorter time periods generally can be calculated by referencing the level to the creatinine concentration in the same sample of urine (substance/creatinine ratio) with the assumption that a pregnant woman excretes 1 g of creatinine per day. Creatinine production (0.7–1.0 g/day) by skeletal muscle is virtually unchanged by pregnancy.

Up to 80% of the glomerular filtrate is reabsorbed by the proximal tubules, a process that is independent of hormonal control. Aldosterone regulates sodium reabsorption in the distal tubules, while arginine vasopressin activity, which regulates free water clearance, determines the ultimate urine concentration. Pregnancy is associated with increased circulating concentrations of aldosterone. Even though the GFR increases dramatically during gestation, the volume of urine excreted per day is unchanged.

Renal clearance of creatinine increases as the GFR rises, with maximum clearances approximately 50% more than nonpregnant levels. The creatinine clearance decreases somewhat after about 30 weeks of gestation. The rise in GFR lowers mean serum creatinine concentrations (pregnant, 0.46 ± 0.13 mg/100 mL; nonpregnant, 0.67 ± 0.14 mg/100 mL) and blood urea nitrogen (pregnant, 8.17 ± 1.5 mg/100 mL; nonpregnant, 13 ± 3 mg/100 mL) concentrations.

Increased GFR with saturation of tubular resorption capacity for filtered glucose can result in glucosuria. In fact, more than 50% of women have glucosuria sometime during pregnancy. Increased urinary glucose levels contribute to increased susceptibility of pregnant women to urinary tract infection.

Urinary protein loss normally does not exceed 300 mg over 24 hours, which is similar to the nonpregnant state. Thus, proteinuria of more than 300 mg over 24 hours suggests a renal disorder.

Renin activity increases early in the first trimester, and continues to rise until term. This enzyme is critically involved in the conversion of angiotensinogen to angiotensin I, which subsequently forms the potent vasoconstrictor angiotensin II. Angiotensin II levels also increase in pregnancy, but the vasoconstriction and hypertension that might be expected do not occur. In fact, normal pregnant women are very resistant to the pressor effects of elevated levels of angiotensin II and other vasopressors; this effect is likely mediated by increased vascular synthesis of nitric oxide and other vasodilators.

Angiotensin II is also a potent stimulus for adrenocortical secretion of aldosterone, which, in conjunction with arginine vasopressin, promotes salt and water retention in pregnancy. The net effect is a decrease in plasma sodium concentrations by approximately 5 mEq/L and a fall in plasma osmolality by nearly 10 mOsm/kg. These effects on electrolyte homeostasis likely involve a resetting of the pituitary osmostat. In pregnancy, the increased pituitary secretion of vasopressin is largely balanced by placental production of vasopressinase. Pregnant women who are unable to sufficiently augment vasopressin secretion can develop a diabetes insipidus–like condition characterized by massive diuresis and profound hyponatremia. Cases have been described with maternal sodium levels reaching 170 mEq/L.

Bladder

As the uterus enlarges, the urinary bladder is displaced upward and flattened in the anteroposterior diameter. One of the earliest symptoms of pregnancy is increased urinary frequency, which may be related to pregnancy hormones. In later gestation, mechanical effects of the enlarged uterus may contribute to the increased frequency. Bladder vascularity increases and muscle tone decreases, which increases bladder capacity up to 1500 mL.

GASTROINTESTINAL SYSTEM

Anatomic Changes

As the uterus grows, the stomach is pushed upward and the large and small bowels extend into more rostralateral regions. The appendix is displaced superiorly in the right flank area. These organs return to their normal positions in the early puerperium.

Oral Cavity

Salivation appears to increase although this may be caused in part by swallowing difficulty associated with nausea. Pregnancy does not predispose to tooth decay or to mobilization of bone calcium.

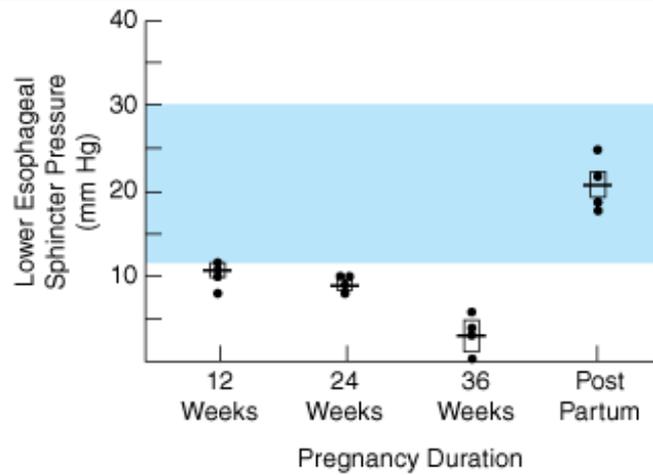

The gums may become hypertrophic and hyperemic; often, they are so spongy and friable that they bleed easily. This may be caused by increased systemic estrogen because similar problems sometimes occur with the use of oral contraceptives.

Esophagus and Stomach

Reflux symptoms (heartburn) affect 30–80% of pregnant women. Gastric production of hydrochloric acid is variable and sometimes exaggerated but more commonly reduced. Pregnancy is associated with greater production of gastrin, which increases stomach volume and acidity of gastric secretions. Gastric production of mucus also may be increased. Esophageal peristalsis is decreased. Most women first report symptoms of reflux in the first trimester (52% vs 24% in the second trimester vs 8.8% in the third trimester), although the symptoms can become more severe with advanced gestation.

The underlying predisposition to reflux in pregnancy is related to hormone-mediated relaxation of the lower esophageal sphincter (Fig 7–6). With advancing gestation, the lower esophageal sphincter has decreased pressure as well as blunted responses to sphincter stimulation. Thus, decreased motility, increased acidity of gastric secretions, and reduced function of the lower esophageal sphincter contribute to the increased gastric reflux. The increased prevalence of gastric reflux and delayed gastric emptying of solid food make the gravida more vulnerable to regurgitation and aspiration with anesthesia. The rate of gastric emptying of solid foods is slowed in pregnancy, but the rate for liquids remains generally the same as in the nonpregnant state.

Figure 7–6.

(Modified from Van Theil DH, Gravalier JS, Joshi SN et al: Heartburn in pregnancy. *Gastroenterology* 1977; 72:666.)

Intestines

Intestinal transit times are decreased in the second and third trimesters (Fig 7-7), whereas first trimester and postpartum transit times are similar. Transit times return to normal within 2 to 4 days postpartum.

Figure 7-7.

Copyright ©2006 by The McGraw-Hill Companies, Inc.

Small-bowel transit times measured by the lactulose hydrogen breath method in a single woman in the third trimester and postpartum. Hydrogen concentrations in maternal breath were determined after administration of a lactulose meal. Hydrogen is released when bacteria in the colon break down lactulose.

(Modified from Wald A, Van Thiel DH, Hoeschstetter L et al: Effect of pregnancy on gastrointestinal transit. *Dig Dis Sci* 1982;27:1015.)

The reduced gastrointestinal motility during pregnancy has been thought to be caused by increased circulating concentrations of progesterone. However, experimental evidence suggests that elevated estrogen concentrations are critically involved through an enhancement of nitric oxide release from the nonadrenergic, noncholinergic nerves that modulate gastrointestinal motility. Other factors may also be involved.

The slow transit time of food through the gastrointestinal tract potentially enhances water absorption, predisposing to constipation. However, diet and cultural expectations may be more important factors in this disorder.

Gallbladder

The emptying of the gallbladder is slowed in pregnancy and often incomplete. When visualized at cesarean delivery, the gallbladder commonly appears dilated and atonic. Bile stasis of pregnancy increases the risk for gallstone formation, although the chemical composition of bile is not appreciably altered.

Liver

Liver morphology does not change in normal pregnancy. Plasma albumin levels are reduced to a greater extent than the slight decrease in plasma globulins. This fall in the albumin/globulin ratio mimics liver disease in nonpregnant individuals. Serum alkaline phosphatase activity can double as the result of alkaline phosphatase isozymes produced by the placenta.

HEMATOLOGIC SYSTEM

Red Blood Cells

The red cell mass expands by about 33%, or by approximately 450 mL of erythrocytes for the average pregnant woman (Fig 7–1). The increase is greater with iron supplementation. The greater increase in plasma volume accounts for the anemia of pregnancy. For example, maternal hemoglobin levels average 10.9 ± 0.8 (SD) g/dL in the second trimester and 12.4 ± 1.0 g/dL at term.

Iron

The enhanced erythropoiesis of pregnancy increases utilization of iron, which can reach 6 to 7 mg per day in the latter half of pregnancy. Many women begin pregnancy in an iron-deficient state, making them vulnerable to iron deficiency anemia. Thus, supplemental iron is commonly given to pregnant women. Because the placenta actively transports iron from the mother to the fetus, the fetus generally is not anemic even when the mother is severely iron deficient.

White Blood Cells

The total blood leukocyte count increases during normal pregnancy from a prepregnancy level of 4,300–4,500/ μ L to 5000–12,000/ μ L in the last trimester, although counts as high as 16,000/ μ L have been observed in the last trimester. Counts in the 20,000–25,000/ μ L range can occur during labor. The cause of the rise in the leukocyte count, which primarily involves the polymorphonuclear forms, has not been established.

Polymorphonuclear leukocyte chemotaxis may be impaired in pregnancy, which appears to be a cell-associated defect. Reduced polymorphonuclear leukocyte adherence has been reported in the third trimester. These observations may predispose pregnant women to infection. Basophil counts decrease slightly as pregnancy advances. Eosinophil counts, although variable, remain largely unchanged.

Platelets

Some studies have reported increased production of platelets (thrombocytopoiesis) during pregnancy that is accompanied by progressive platelet consumption. Platelet counts fall below 150,000/ μ L in 6% of gravidas in the third trimester. This *pregnancy-associated thrombocytopenia*, which appears to be caused by increased peripheral consumption, resolves with delivery and is of no pathologic significance. Levels of prostacyclin (PGI₂), a platelet aggregation inhibitor, and thromboxane A₂, an inducer of platelet aggregation and a vasoconstrictor, increase during pregnancy.

Clotting Factors

Circulating levels of several coagulation factors increase in pregnancy. Fibrinogen (factor I) and factor VIII levels increase markedly, whereas factors VII, IX, X, and XII increase to a lesser extent.

Plasma fibrinogen concentrations begin to increase from nonpregnant levels (1.5–4.5 g/L) during the third month of pregnancy and progressively rise by nearly 2-fold by late pregnancy (4–6.5 g/L). The high estrogen levels of pregnancy may be involved in the increased fibrinogen synthesis by the liver.

Prothrombin (factor II) is only nominally affected by pregnancy. Factor V concentrations are mildly increased. Factor XI decreases slightly toward the end of pregnancy, and factor XIII (fibrin-stabilizing factor) is appreciably reduced, up to 50% at term. The free form of protein S declines in the first and second trimesters and remains low for the rest of gestation.

Fibrinolytic activity is depressed during pregnancy through a poorly understood mechanism. Plasminogen concentrations increase concomitantly with fibrinogen, but there is still a net procoagulant effect of pregnancy.

Coagulation and fibrinolytic systems undergo major alterations during pregnancy. Understanding these physiologic changes is critical for the management of some of the more serious pregnancy disorders, including hemorrhage and thromboembolic disease.

SKIN

Anatomic Changes

Hyperpigmentation is one of the well-recognized skin changes of pregnancy, which is manifested in the linea nigra and melasma, the *mask of pregnancy*. The latter, which is exacerbated by sun exposure, develops in up to 70% of pregnancies and is characterized by an uneven darkening of the skin in the centofacial-malar area. The hyperpigmentation is probably because of the elevated concentrations of melanocyte-stimulating hormone and/or estrogen and progesterone effects on the skin. Similar hyperpigmentation of the face can be seen in nonpregnant women who are taking oral contraceptives.

Striae gravidarum consist of bands or lines of thickened, hyperemic skin. These "stretch marks" begin to appear in the second trimester on the abdomen, breasts, thighs, and buttocks. Decreased collagen adhesiveness and increased ground substance formation are characteristically seen in this skin condition. A genetic predisposition appears to be involved because not every gravida develops these skin changes. Effective treatment (preventive or therapeutic) has yet to be found.

Other common cutaneous changes include spider angiomas, palmar erythema, and cutis marmorata (mottled appearance of skin secondary to vasomotor instability). The development or worsening of varicosities accompanies nearly 40% of pregnancies. Compression of the vena cava by the gravid uterus increases venous pressures in the lower extremities, which dilates veins in the legs, anus (hemorrhoids), and vulva.

The nails and hair also undergo changes. Nails become brittle and can show horizontal grooves (Beau's lines). Thickening of the hair during pregnancy is caused by an increased number of follicles in anagen

(growth) phase, and generalized hirsutism can worsen in women who already have hair that is thick or has a male pattern of distribution. The thickening of the hair ends 1 to 5 months postpartum with the onset of the telogen (resting) phase, which results in excessive shedding and thinning of hair. Normal hair growth returns within 12 months.

METABOLISM

Pregnancy increases nutritional requirements, and several maternal alterations occur to meet this demand. Pregnant women tend to rest more often, which conserves energy and thereby enhances fetal nutrition. The maternal appetite and food intake usually increase, although some have a decreased appetite or experience nausea and vomiting (see Chapter 9). In rare instances, women with pica may crave substances such as clay, cornstarch, soap, or even coal.

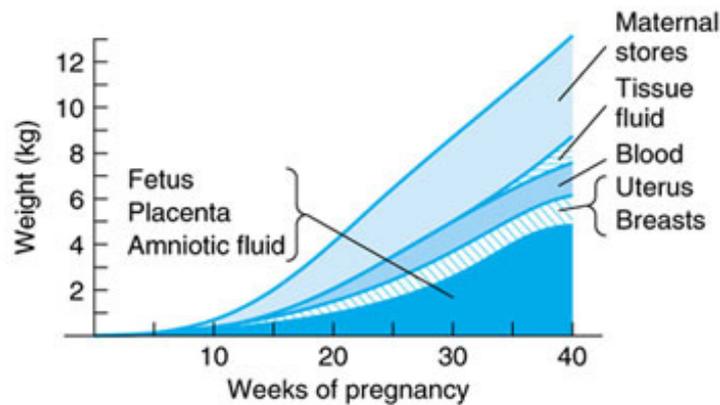

Pregnancy is associated with profound changes in structure and metabolism. The most obvious physical changes are weight gain and altered body shape. Weight gain results not only from the uterus and its contents, but also from increased breast tissue, blood volume, and water volume (about 6.8 L) in the form of extravascular and extracellular fluid (Table 7–2). Deposition of fat and protein and increased cellular water are added to maternal stores. The average weight gain during pregnancy is 12.5 kg (27.5 lb). Distribution of weight gain over gestation is shown in Figure 7–8.

Table 7–2. Estimate of Extracellular and Intracellular Water Added during Pregnancy.

	Total Water (mL)	Extracellular (mL)	Intracellular (mL)
Fetus	2343	1360	983
Placenta	540	260	280
Amniotic fluid	792	792	. . .
Uterus	743	490	253
Mammary glands	304	148	156
Plasma	920	920	. . .
Red cells	163	. . .	163
Extracellular, extravascular water	1195	1195	. . .
Total	7000	5165	1835

Components of weight gain during pregnancy.

(Reproduced, with permission, from Hytten FE, Leitch I: *The Physiology of Human Pregnancy*. Blackwell, 1964.)

Protein accretion accounts for about 1 kg of maternal weight gain, which is evenly divided between the mother (uterine contractile protein, breast glandular tissue, plasma protein, and hemoglobin) and the fetoplacental unit.

Total body fat increases during pregnancy, but the amount varies with the total weight gain. During the second half of pregnancy, plasma lipids increase (plasma cholesterol increases 50%, plasma triglyceride concentration may triple), but triglycerides, cholesterol, and lipoproteins decrease soon after delivery. The ratio of low-density lipoproteins (LDLs) to high-density lipoproteins (HDLs) increases during pregnancy. It has been suggested that most fat is stored centrally during midpregnancy and that as the fetus extracts more nutrition in the latter months, fat storage decreases.

Metabolism of carbohydrates and insulin during pregnancy is discussed in Chapter 18. Pregnancy is associated with insulin resistance, which can lead to hyperglycemia (gestational diabetes) in susceptible women. This metabolic disorder usually disappears after delivery, but may arise later in life as type II diabetes.

Current OB/GYN >Chapter 8. Maternal-Placental-Fetal Unit; Fetal & Early Neonatal Physiology>

MATERNAL-PLACENTAL-FETAL UNIT; FETAL & EARLY NEONATAL PHYSIOLOGY INTRODUCTION

Fetal genetics, physiology, anatomy, and biochemistry can now be studied with ultrasonography, fetoscopy, chorionic sampling, amniocentesis, and fetal cord and scalp blood sampling. Embryology and fetoplacental physiology must be considered when providing direct patient care. Currently, some medical centers measure fetal pulse oximetry, fetal electroencephalograms, and fetal heart rate monitoring to make sure the fetus is not hypoxic or asphyxiated. As the technology improves, we are reaching further into the early perinatal period to determine abnormal physiology and growth.

THE PLACENTA

A placenta may be defined as any intimate apposition or fusion of fetal organs to maternal tissues for physiological support. The basic parenchyma of all placentas is the trophoblast; when this becomes a membrane penetrated by fetal blood, it is called the chorion.

In the evolution of viviparous species, the yolk sac presumably is the most archaic type of placentation, having evolved from the egg-laying ancestors of mammals. In higher mammals, the allantoic sac fuses with the chorion, forming the definitive placenta, which has mesodermal vascular villi. When the trophoblast actually invades the maternal endometrium (pregnancy is largely composed of decidua), a deciduate placenta results. In humans, maternal blood comes into contact with the fetal trophoblast. Thus, the human placenta may be described as a discoid, deciduate, hemochorial chorionic placenta.

DEVELOPMENT OF THE PLACENTA

Soon after ovulation, the endometrium develops its typical secretory pattern under the influence of progesterone from the corpus luteum. The peak of development occurs at about 1 week after ovulation, coinciding with the expected time of implantation of a fertilized ovum.

Pregnancy occurs when healthy spermatozoa in adequate numbers penetrate receptive cervical mucus, ascend through the uterotubal tract, and fertilize a healthy ovum within about 24 hours following ovulation. The spermatozoa that penetrate the favorable mucus travel through the uterine cavity and the uterine tubes at a rate of about 6 mm/min. During this process, an enzymatic change occurs that renders the spermatozoa capable of fertilizing the ovum. This process is called capacitation. The cellular union between the sperm and the egg is referred to as syngamy. The tip of the sperm head (acrosome) penetrates the zona membrane and probably releases a lytic enzyme that facilitates penetration of the zona pellucida surrounding the egg. The sperm head containing all of the paternal genetic material enters the cytoplasm of the ovum, and the zona reaction prevents the entrance of a second sperm. The first cleavage occurs during the next 36 hours. As the conceptus begins to divide and grow, the peristaltic activity of the uterine tube slowly transports it to the uterus, a journey that requires about 3-4 days. Concomitantly, a series of divisions creates a hollow ball, the blastocyst, which then implants within the endometrium. The cells in the wall of the blastocyst are trophoblastic; only a few are destined to become the embryo. This evolutionary process of understanding of conception is critical to the success of artificial reproductive technology, the treatment of infertility, and the emergence of preimplantation genetic diagnoses as acceptable medical procedures.

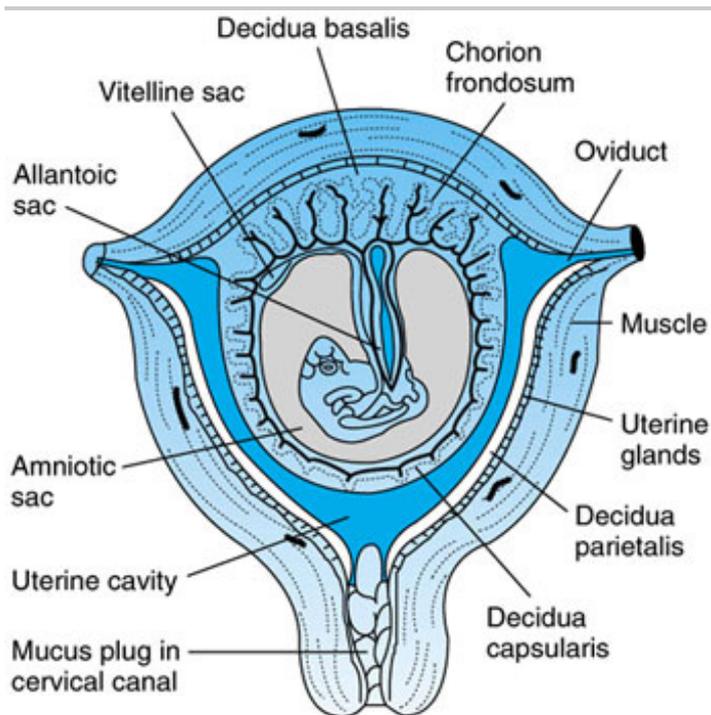

Within a few hours after implantation, the trophoblast invades the endometrium and begins to produce human chorionic gonadotropin (hCG), which is thought to be important in converting the normal corpus luteum into the corpus pregnancy. As the cytotrophoblasts (Langhans' cells) divide and proliferate, they form transitional cells that are ultrastructurally more mature and a likely source of hCG. Next, these transitional cells fuse, lose their individuality, and form the multinucleated syncytiotrophoblast. Mitotic division then ceases. Thus, the syncytial layer becomes part of the invading fetal tissue. Maternal capillaries and venules are tapped by the invading fetal tissue to cause extravasation of maternal blood and the formation of small lakes (lacunae), the forerunners of the intervillous space. These lacunae are filled with maternal blood by reflux from previously tapped veins. An occasional maternal artery then opens, and a sluggish circulation is established (hematotropic phase of the embryo).

The lacunar system is separated by trabeculae, many of which develop buds or extensions. Within these branches the cytotrophoblast forms a mesenchymal core.

The proliferating trophoblast cells then branch to form secondary and tertiary villi. The mesoblast, or central stroma, formed from the original trophoblast, invades these columns to form a supportive structure within which capillaries are formed. The embryonic body stalk (later to become the umbilical cord) invades this stromal core to establish the fetal circulation. If this last step does not occur, the embryo will die. Sensitive tests for hCG suggest that at this stage more embryos die than live.

Where the placenta is attached, the branching villi resemble a leafy tree (the chorion frondosum), whereas the placenta covering the expanding conceptus is smoother (chorion laeve). When the latter is finally pushed against the wall of the uterus, the villi atrophy, leaving the amnion and chorion to form the 2-layered sac of fetal membranes.

Relationships of structures in the uterus at the end of the seventh week of pregnancy.

(Reproduced, with permission, from Benson RC: *Handbook of Obstetrics & Gynecology*, 8th ed. Lange, 1983.)

Around 40 days after conception, the trophoblast has invaded approximately 40–60 spiral arterioles, of which 12 called major arteries. The pulsatile arterial pressure of blood that spurts from each of these major vessels pushes the plate away from the decidua to form 12–15 "tents," or maternal cotyledons. The remaining 24–45 tapped arterioles are crowded between the larger units. As the chorionic plate is pushed away from the base, the anchoring villi pull the maternal basal plate up into septa (columns of fibrous tissue that virtually surround the maternal cotyledons). Thus, at the center of each maternal vascular unit there is 1 artery that terminates in a thin-walled arteriole. There are numerous maternal veins that open through the basal plate at random. The human placenta has no peripheral collecting system. Within each maternal vascular unit is the fetal vascular "tree," with the tertiary free-floating villi (an area for physiologic exchange) acting as thousands of baffles that disperse the maternal bloodstream in many directions. A cross-sectional diagram of the mature placenta is shown in Fig 8–2.

Table 8–1 summarizes the major morphologic-functional correlations that take place during placental development.
Table 8–1. Development of the Human Placenta.¹

6–7
Implantation of blastocyst.

7–8
Trophoblast proliferation and invasion. Cytotrophoblast gives rise to syncytium.

9–11
Lacunar period. Endometrial venules and capillaries tapered. Sluggish circulation of maternal blood.

13–18
Primary and secondary villi form; body stalk and amnion form.

18–21
Tertiary villi, 2–3 mm long, 0.4 mm thick. Mesoblast invades villi, forming a core. Capillaries form in situ and tap vessels, which spread through blastoderm. Fetoplacental circulation established. Sluggish lacunar circulation.

21–40
Chorion frondosum; multiple anchored villi, which form free villi shaped like "inverted trees." Chorionic plate forms

40–50
Cotyledon formation:

(1)
Cavitation. Trophoblast invasion opens 40–60 spiral arterioles. Further invasion stops. spurts of arterial blood form hollows in chorion frondosum. Maternal circulation established.

(2)
Crowning and extension. Cavitation causes concentric orientation of anchoring villi around each arterial spurt, so chorionic plate from basal plate.

(3)
Completion. Main supplying fetal vessels for groups of second-order vessels are pulled from the chorioallantoic membrane to form first-order vessels of fetal cotyledons.

(4)
About 150 rudimentary cotyledons with anchoring villi remain, but without cavitation and crowning ("tent formation"). Low-pressure (5–8 mm Hg) flow of maternal blood around them.

80–225
Continued growth of definitive placenta. Ten to 12 large cotyledons form, with high maternal blood pressures (40–60 mm Hg) in the central intervillous spaces; 40–50 small to medium-sized cotyledons and about 150 rudimentary ones are developed. Chorionic plate pulled up between major cotyledons by anchoring villi to form septa.

225–267 (term)
Cellular proliferation ceases, but cellular hypertrophy continues.

Days After Ovulation	Important Morphologic-Functional Correlations
----------------------	---

¹ Adapted from Reynolds SRM: Formation of fetal cotyledons in the hemichorial placenta. *Am J Obstet Gynecol* 1976;124:1000–1004. (Reproduced, with permission, from Page EW, Villee CA, Villee DB: *Human Reproduction*. Saunders, 1976.)

FUNCTIONS OF THE MATERNAL-PLACENTAL-FETAL UNIT

The placenta is a complex organ of internal secretion, releasing numerous hormones and enzymes into the maternal bloodstream. In addition, it serves as the organ of transport for all fetal nutrients and metabolic products as well as the exchange of oxygen and CO₂. Although fetal in origin, the placenta depends almost entirely on maternal blood for nourishment.

The arterial pressure of maternal blood (60–70 mm Hg) causes it to pulsate toward the chorionic plate into the intervillous space (10–15 mm Hg). Venous blood in the placenta tends to flow along the basal plate and out through the chorionic veins into maternal veins. The pressure gradient within the fetal circulation changes slowly with the mother's posture, movements, and physical stress. The pressure within the placental intervillous space is about 10 mm Hg when the woman is lying down. After a few minutes of standing, this pressure exceeds 30 mm Hg. In comparison, the fetal arterial pressure is 20–40 mm Hg.

Clinically, placental perfusion can be altered by many physiologic changes in the mother or fetus. When a precipitous maternal blood pressure occurs, increased plasma volume improves placental perfusion. Increasing the maternal saline infusion increases the fetal oxygen saturation. An increased rate of rhythmic uterine contractions benefits placental perfusion, but tetanic labor contractions are detrimental to placental and fetal circulation as they do not allow a period in which normal flow resumes to the fetus. An increased fetal heart rate tends to expand the villi during systole, but does not aid in circulatory transfer.

Circulatory Function

UTEROPLACENTAL CIRCULATION

The magnitude of the uteroplacental circulation is difficult to measure in humans. The consensus is that total uterine blood flow near term is 500–700 mL/min. Not all of this blood traverses the intervillous space. It is generally assumed that the uterine blood flow goes to the cotyledons and the rest to the myometrium and endometrium. One may assume that uterine blood flow in the placenta is 400–500 mL/min in a patient near term who is lying quietly on her side and is not in labor.

As the placenta matures, thrombosis decreases the number of arterial openings into the basal plate. At term, the ratio of arteries to veins is 2:1 (approximately the ratio found in other mature organs).

Near their entry into the intervillous spaces, the terminal maternal arterioles lose their elastic reticulum. Because portions of these vessels are lost with the placenta, bleeding from their source can be controlled only by uterine contraction. Thus, uterine atony causes postpartum hemorrhage.

PLASMA VOLUME EXPANSION AND SPIRAL ARTERY CHANGES

Structural alterations occur in the human uterine spiral arteries found in the decidual part of the placental bed. As a consequence of the action of cytotrophoblast on the spiral artery vessel wall, the normal musculoelastic tissue is a mixture of fibrinoid and fibrous tissue. The small spiral arteries are converted to large tortuous channels, creating arteriovenous shunts.

In dogs, when a surgically created arteriovenous shunt is opened, a marked increase in plasma volume, cardiac output, and retention of sodium soon appears. An apparent anemia occurs, as the red blood cell mass is slower to expand. This happens when the shunt is closed. This situation is similar to that of early normal pregnancy, when there is an increase in plasma volume and resulting physiologic anemia as the red blood cell mass slowly expands. Immediately after the closure of the placental shunt, diuresis and natriuresis occur. When the spiral arteries fail to undergo these physiological changes, fetal growth retardation often occurs with preeclampsia. Campbell and colleagues (1983) and more recently Voigt and colleagues (1992) used gated, pulsed Doppler ultrasound to study the uterine arcuate arteries serving the spiral arteries in pregnant women. Among the patients who showed evidence of failure of the spiral arteries to dilate and increase in blood flow, subsequently a high frequency of proteinuric hypertension, poor fetal growth, and fetal hypoxia occurred. Becker (1992) also noted that Doppler ultrasound profiles correlated well with the histologic findings on subsequent examination of the placental bed.

Fleischer and colleagues (1986) reported that normal pregnancy is associated with a uterine artery Doppler velocity ratio of systolic/diastolic ratio of less than 2:6. With a higher ratio and a notch in the waveform, the pregnancy is usually associated with stillbirth, premature birth, intrauterine growth retardation, or preeclampsia.

Wells and coworkers (1984) demonstrated that decidual spiral arteries that have been attacked by the cytotrophoblastic fibrinoid matrix that develops amniotic antigens, apparently to maintain the structural integrity of the vessel wall, are histologic and immunologic explanations for the presence or absence of the marked increase in uterine blood flow and plasma volume expansion seen in human pregnancies.

Goodlin and associates (1984) believed that failure of the spiral arteries to dilate and adequately expand plasma volume led to increased maternal venous reactivity and multiple organ dysfunction. This disorder probably cannot be corrected by medical therapy, but therapy may modify secondary effects. Delivery may be the correct medical decision if the intrauterine

is determined to be irreversibly detrimental to the fetus. The exact primary cause(s) remain unknown, thus extr environment into the neonatal nursery may be justified.

FETOPLACENTAL CIRCULATION

At term, a normal fetus has a total umbilical blood flow of 350–400 mL/min. Thus, the maternoplacental and fetal have a similar order of magnitude.

The villous system is best compared with an inverted tree. The branches pass obliquely downward and outward intervillous spaces. This arrangement probably permits preferential currents or gradients of flow and undoubtedly intervillous fibrin deposition, commonly seen in the mature placenta.

Cotyledons (subdivisions of the placenta) can be identified early in placentation. Although they are separated by septa, some communication occurs via the subchorionic lake in the roof of the intervillous spaces.

Before labor, placental filling occurs whenever the uterus contracts (*Braxton Hicks contractions*). At these times venous exits are closed but the thicker-walled arteries are only slightly narrowed. When the uterus relaxes, blood flows through the maternal veins. Hence, blood is not squeezed out of the placental lake with each contraction, nor does the placental lake in appreciably greater amounts during relaxation.

During the height of an average first-stage contraction, most of the cotyledons are devoid of any flow and the arteries are only partially filled. Thus, intermittently—for periods of up to a minute—maternoplacental flow virtually ceases. It should be evident that any extended prolongation of the contractile phase, as in uterine tetany, could lead to fetal

Maternal Circulation

Aortocaval compression is a common cause of abnormal fetal heart rate during labor. In the third trimester, the gravid uterus obstructs its own blood supply to the level of L3–4 (Poseiro effect) when the mother is supine. This obstruction is completely relieved by turning the patient on her side. Although only about 30% of pregnant women will demonstrate aortocaval compression when supine, women in labor (particularly after epidural anesthesia) should not be maintained in a supine position and should be placed on their left side.

In all supine pregnant women at term, obstruction of the inferior vena cava by uterine pressure is relatively common. Only about 10% have inadequate collateral circulation (intervertebral venous plexus, lumbar venous plexus, abdominal superficial and deep veins, hemorrhoidal plexus, vertebral azygous and portal system) and develop maternal supine hypotension syndrome. This syndrome is characterized by decreased cardiac output, bradycardia, and hypotension, which is obtained when the woman is placed in the lateral position. Most pregnant women near term sleep on their sides and avoid such problems.

Uterine blood flow and placental perfusion values are directly correlated with the pregnancy-related increase in plasma volume. Relative maternal hypovolemia is found in association with many complications of pregnancy, including small-for-gestational age (SGA) fetus, premature labor, and various fetal anomalies.

Endocrine Function

SECRETIONS OF THE MATERNAL-PLACENTAL-FETAL UNIT

The placenta and the maternal-placental-fetal unit produce increasing amounts of steroids late in the first trimester. The importance are the steroids required in fetal development from 7 weeks' gestation through parturition. Immediately after conception and until 12–13 weeks' gestation, the principal source of circulating gestational steroids (progesterone) is the corpus luteum of pregnancy.

After 42 days, the placenta assumes an increasingly important role in the production of several steroid hormones. The production by the embryo occurs even before implantation is detectable in utero. Before implantation, the production of progesterone by the embryo may assist ovum transport.

Once implantation occurs, trophoblastic hCG and other pregnancy-related peptides are secreted. A more sophisticated

fetoplacental steroids is produced during organogenesis and with the development of a functioning hypothalamic-adrenal axis. Adrenohypophyseal basophilic cells first appear at about 8 weeks in the development of the fetus at the presence of significant quantities of adrenocorticotrophic hormone (ACTH). The first adrenal primordial structures appear approximately 4 weeks, and the fetal adrenal cortex develops in concert with the adrenohypophysis.

The fetus and the placenta acting in concert are the principal sources of steroid hormones controlling intrauterine maturation of vital organs, and parturition. The fetal adrenal cortex is much larger than its adult counterpart. From until term, the large inner mass of the fetal adrenal gland (80% of the adrenal tissue) is known as the fetal zone supported by factors unique to the fetal status and regresses rapidly after birth. The outer zone ultimately becomes the postnatal and adult cortex.

The trophoblastic mass increases exponentially through the seventh week, after which time the growth velocity decreases and increases to an asymptote close to term. The fetal zone and placenta exchange steroid precursors to make possible the complement of fetoplacental steroids. Formation and regulation of steroid hormones also take place within the fetus.

In addition to the steroids, another group of placental hormones unique to pregnancy are the polypeptide hormones which has an analogue in the pituitary. These placental protein hormones include hCG and human chorionic somatomammotropin. The existence of placental human chorionic corticotropin also has been suggested.

A summary of the hormones produced by the maternal-placental-fetal unit is shown in Table 8-2.

Table 8-2. Summary of Maternal-Placental-Fetal Endocrine-Paracrine Functions.

Peptides of exclusively placental origin

Human chorionic gonadotropin (hCG)

Human chorionic somatomammotropin (hCS)

Human chorionic corticotropin (hCC)

Pregnancy-associated plasma proteins (PAPP)

PAPP-A

PAPP-B

PAPP-C

PAPP-D (hCS)

Pregnancy-associated β_1 macroglobulin (β_1 PAM)

Pregnancy-associated α_2 macroglobulin (α_2 PAM)

Pregnancy-associated major basic protein (pMBP)

Placental proteins (PP) 1 through 21

Placental membrane proteins (MP) 1 through 7.

MP1 also known as placental alkaline phosphatase (PLAP)

Hypothalamic-like hormone (β -endorphin, ACTH-like)

Steroid of mainly placental origin
Progesterone

Hormones of maternal-placental-fetal origin
Estrone

Estradiol 50% from maternal androgens

Hormone of placental-fetal origin
Estriol

Hormone of corpus luteum of pregnancy
Relaxin

Fetal hormones
Thyroid hormone

Fetal adrenal zone hormones

α -Melanocyte-stimulating hormone

Corticotropin intermediate lobe peptide (CLIP)

Anterior pituitary hormone

Adrenocorticotrophic hormone (ACTH)

Tropic hormones for fetal zone of placenta

β -Endorphin

β -Lipotropin

PLACENTAL SECRETIONS

Human Chorionic Gonadotropin

hCG was the first of the placental protein hormones to be described. Its molecular weight is 36,000–40,000 Da. It is a glycoprotein that has biologic and immunologic similarities to the luteinizing hormone (LH) from the pituitary. Research suggests that hCG is produced by the syncytiotrophoblast of the placenta. hCG is elaborated by all types of trophoblasts, including that of hydatidiform moles, chorioadenoma destruens, and choriocarcinoma. As with all glycoprotein hormones, hCG, like follicle-stimulating hormone [FSH], thyroid-stimulating hormone [TSH], hCG is composed of 2 subunits, alpha and beta. The alpha subunit is common to all glycoproteins, and the beta subunit confers unique specificity to the hormone. The beta subunit is active by itself; only the intact molecule exerts hormonal effects.

Antibodies have been developed to the beta subunit of hCG. This specific reaction allows for differentiation of hCG from LH. hCG is detectable 9 days after the midcycle LH peak, which occurs 8 days after ovulation and only 1 day after fertilization. This measurement is useful because it can detect pregnancy in all patients on day 11 after fertilization. Concentrations rise exponentially until 9–10 weeks' gestation, with a doubling time of 1.3–2 days.

Concentrations peak at 60–90 days' gestation. Afterward, hCG levels decrease to a plateau that is maintained until the end of pregnancy. The half-life of hCG is approximately 32–37 hours, in contrast to that of most protein and steroid hormones, which are measured in minutes. Structural characteristics of the hCG molecule allow it to interact with the human TSH receptor, resulting in activation of the membrane adenylate cyclase that regulates thyroid cell function. The finding of hCG-specific adenylylation in the placenta may mean that hCG provides "order regulation" within the cell of the trophoblast.

Human Chorionic Somatomammotropin

Human chorionic somatomammotropin (hCS) is a protein hormone with immunologic and biologic similarities to growth hormone. It has also been designated human placental lactogen (hPL) and is synthesized in the syncytiotrophoblastic layer of the placenta. It can be found in maternal serum and urine in both normal and molar pregnancies. However, it disappears so rapidly from serum and urine after delivery of the placenta or evacuation of the uterus that it cannot be detected in the serum after the first postpartum day. The somatotrophic activity of hCS is 3%, which is less than that of human growth hormone (hGH). In vitro, hCS stimulates thymidine incorporation into DNA and enhances the action of insulin. It is present in microgram-per-milliliter quantities in early pregnancy, but its concentration increases as pregnancy progresses, with peak levels reached during the last 4 weeks. Prolonged fasting at midgestation and insulin-induced hypoglycemia are reported to raise hCS concentrations. Amniotic instillation of prostaglandin PGF_2 causes a marked increase in hCS levels. hCS may exert its major metabolic effect on the mother to ensure that the nutritional demands of the fetus are met.

It has been suggested that hCS is the "growth hormone" of pregnancy. The in vivo effects of hCS owing to its growth-hormonelike and anti-insulin characteristics result in impaired glucose uptake and stimulation of free fatty acid release, a resultant decrease in insulin effect. The maternal metabolism appears to be directed toward mobilization of maternal fat stores to furnish substrate for the fetus.

Human Chorionic Corticotropin

Human chorionic corticotropin (hCC) is another pituitary-like hormone. The physiologic role of hCC and its regulation are unknown.

Placental Proteins

A number of proteins thought to be specific to the pregnant state have been isolated. The most commonly known pregnancy-associated plasma proteins (PAPPs) designated as PAPP-A, PAPP-B, PAPP-C, and PAPP-D. PAPP-D is the same as hPL (described earlier). All these proteins are produced by the placenta and/or decidua. The physiologic role of these proteins, except for PAPP-D, are at present unclear. Numerous investigators have postulated various functions ranging from fetal "allograft" survival and the regulation of coagulation and complement cascades to the maintenance of the placenta and the regulation of carbohydrate metabolism in pregnancy. A host of other pregnancy-specific and pregnancy-associated proteins have since been isolated. The greatest challenge, however, lies in the identification of their function. Such knowledge

important insights into placental function and hopefully allow us to understand more completely the pregnant state.

FETOPLACENTAL SECRETIONS

The placenta may be an incomplete steroid-producing organ that must rely on precursors reaching it from the fetal and maternal circulations (an integrated maternal-placental-fetal unit). The adult steroid-producing glands can form progesterone and estrogens, but this is not true of the placenta. Estrogen production by the placenta is dependent on precursors from both the fetal and maternal compartments. Placental progesterone formation is accomplished in large part from maternal cholesterol.

In the placenta, cholesterol is converted to pregnenolone and then rapidly and efficiently to progesterone. Progesterone approximates 250 mg/d by the end of pregnancy, at which time circulating levels are on the order of 100–200 ng/ml. To form estrogens, the placenta, which has an active aromatizing capacity, uses circulating androgens obtained from the fetus but also from the mother. The major androgenic precursor is dehydroepiandrosterone sulfate (DHEA-S). This compound comes from the fetal adrenal gland. Because the placenta has an abundance of sulfatase (sulfate-cleaving enzyme), DHEA-S is converted to free unconjugated DHEA when it reaches the placenta, then to androstenedione, testosterone, estrone and 17β -estradiol.

The major estrogen formed in pregnancy is estriol. Ninety percent of the estrogen in the urine of pregnant women is excreted into the urine as sulfate and glucuronide conjugates. Excretion rates increase with advancing gestation from approximately 2 mg/24 h at 16 weeks to 35–40 mg/24 h at term. Estriol is formed during pregnancy by a unique process that demonstrates the interdependence of the fetus, placenta, and mother. DHEA-S is quantitatively the major androgen produced by the fetal adrenal gland, with most of it being produced in the fetal zone. When DHEA-S of the fetus reaches the placenta, estrone and estradiol are formed. However, little of either is converted to estriol by the placenta; some of the DHEA-S undergoes 16α -hydroxylation, primarily in the fetal liver. When the 16α -hydroxydehydroepiandrosterone sulfate (16-OHDHEA-S) reaches the placenta, the placental sulfatase enzyme acts to cleave the sulfate side chain. Unconjugated 16-OHDHEA-S is aromatized to form estriol. The estriol is then secreted into the maternal circulation. When it reaches the maternal liver, it is conjugated to estriol sulfate and estriol glucosiduronate in a mixed conjugate. This conjugate is excreted into the maternal urine.

Circulating progesterone and estriol are thought to be important during pregnancy because they are present in significant amounts. Progesterone may play a role in maintaining the myometrium in a state of relative quiescence during pregnancy. A high local (intrauterine) concentration of progesterone may block cellular immune responses to foreign antigens. Progesterone appears to be essential for maintaining pregnancy in almost all mammals examined. This suggests that progesterone may be instrumental in conferring immunologic privilege to the uterus.

The functional role of estriol in pregnancy is the subject of wide speculation. It appears to be effective in increasing uteroplacental blood flow, as it has a relatively weak estrogenic effect on other organ systems. Indeed, estrogens exert their effect on blood flow via prostaglandin stimulation.

Placental Transport

The placenta has a high rate of metabolism, with consumption of oxygen and glucose occurring at a faster rate than in other tissues. Presumably, this high metabolism requirement is caused by multiple transport and biosynthesis activities.

The primary function of the placenta is the transport of oxygen and nutrients to the fetus and the reverse transport of other catabolites back to the mother. In general, those compounds that are essential for the minute-by-minute survival of the fetus (eg, oxygen, CO_2 , water, sodium) are transported very rapidly by diffusion. Compounds required for the growth of new tissues (eg, amino acids, enzyme cofactors such as vitamins) are transported by an active process. Substances such as certain maternal hormones, which may modify fetal growth and are at the upper limits of admissible molecular size, are transported very slowly, whereas proteins such as IgG immunoglobulins probably reach the fetus by the process of pinocytosis. This process takes place by at least 5 mechanisms: simple diffusion, facilitated diffusion, active transport, pinocytosis, and leakage.

MECHANISMS OF TRANSPORT

Simple Diffusion

Simple diffusion is the method by which gases and other simple molecules cross the placenta. The rate of transport is determined by the chemical gradient, the diffusion constant of the compound in question, and the total area of the placenta available for transfer (Fick's law). The chemical gradient (ie, the differences in concentration in fetal and maternal plasma) is determined by the rates of flow of uteroplacental and umbilical blood. Simple diffusion is also the method of transfer for exogenous compounds such as drugs.

Facilitated Diffusion

The prime example of a substance transported by facilitated diffusion is glucose, the major source of energy for the fetus. The transfer of glucose from mother to fetus occurs more rapidly than can be accounted for by Fick's equation. The transport system operates *with* the chemical gradient (as opposed to active transport, which operates *against* the gradient). The system becomes saturated at high glucose concentrations. In the steady state, the glucose concentration in fetal plasma is about two-thirds that of the maternal concentration, reflecting the rapid rate of fetal utilization. Substances of low molecular weight, minimal electric charge, and high lipid solubility diffuse across the placenta with ease.

Active Transport

When compounds such as the essential amino acids and water-soluble vitamins are found in higher concentrations in fetal plasma than in maternal blood, and when this difference cannot be accounted for by differential protein-binding effects, it is that the placenta concentrates the materials during passage by an active transport system. This has been proved for selected amino acids in human subjects by observing that the natural L forms are transferred with greater rapidity than the unnatural D forms, which are simply optical isomers of identical molecular size. Thus, the selective transport of nutrients is accomplished by enzymatic mechanisms.

Pinocytosis

Electron microscopy has shown pseudopodial projections of the syncytiotrophoblastic layer that reach out to surround small amounts of maternal plasma. These particles are carried across the cell virtually intact to be released on the fetal side, whereupon they promptly gain access to the fetal circulation. Certain other proteins (eg, foreign antigens) may be immunologically rejected. This process may work both to and from the fetus, but the selectivity of the process is determined by the nature of the material. Complex proteins, small amounts of fat, some immunoglobulins, and even viruses may traverse the placenta this way. For the passage of complex proteins, highly selective processes involving special receptors are involved. For example, maternal antibodies of the IgG class are freely transferred, whereas other antibodies are not.

Leakage

Gross breaks in the placental membrane may occur, allowing the passage of intact cells. Despite the fact that the pressure gradient is normally from fetus to mother, tagged red cells and white cells have been found to travel in the maternal circulation. Such breaks probably occur most often during labor or with placental disruption (abruptio placentae, placenta praevia, or placenta percreta), cesarean section, or intrauterine fetal death. It is at these times that fetal red cells can most often be found in the maternal circulation. This is the mechanism by which the mother may become sensitized to fetal red cell antigens, such as the D (Rh) antigen.

PLACENTAL TRANSPORT OF DRUGS

The placental membranes are often referred to as a "barrier" to fetal transfer, but there are few substances (eg, heparin and insulin) that do not cross the membranes at all. A few compounds, such as heparin and insulin, are of sufficiently large molecular weight that minimal transfer occurs. This lack of transfer is almost unique among drugs. Most medications are transferred from maternal to the fetal circulation by simple diffusion, the rate of which is determined by the respective gradients.

These diffusion gradients are influenced in turn by a number of serum factors, including the degree of drug-protein binding (such as sex hormone binding globulin). Because serum albumin concentration is considerably lower during pregnancy, drugs that bind almost exclusively to plasma albumin (eg, warfarin, salicylates) may have relatively higher unbound concentrations in the fetal circulation and, therefore, an effectively higher placental gradient. By contrast, a compound such as carbon monoxide may be bound strongly to the increased total hemoglobin that there will be little left in the plasma for transport.

The placenta also acts as a lipoidal resistance factor to the transfer of water-soluble foreign organic chemicals; chemicals and drugs that are readily soluble in lipids are transferred much more easily across the placental barrier than water-soluble drugs or molecules. Ionized drug molecules are highly water soluble and are therefore poorly transferred across the placenta. Because ionization of chemicals depends in part on their pH-pK relationships, multiple factors determine the "simple diffusion" of drugs across the placenta. *Obviously, drug transfer is not simple, and one must assume that almost any drug will cross the placenta.*

PLACENTAL TRANSFER OF HEAT

The core temperature of the human fetus is only about 0.5 C above that of the maternal blood (core temperature is 0.5 C above that of the amniotic fluid). There is a further temperature gradient of approximately 0.1 C between the fetal surface and the uterine wall. Given these low fetomaternal temperature gradients, it appears that virtually all fetal heat is transferred by umbilical flow through the placenta, as the thermal diffusion capacity of the placental villous surface is considerably greater than that of the fetal body surface.

ANATOMIC DISORDERS OF THE PLACENTA

Observation of structural alterations within the placenta may indicate fetal and maternal disease that otherwise is undetected.

Twin-Twin Transfusion Syndrome

Nearly all monochorionic twin placentas show an anastomosis between the vessels of the 2 umbilical circulations that involve the major branches of the arteries and veins in the placental surface. Artery-to-artery communications are the most common, but the less frequent venovenous anastomosis may also occur. Of great pathologic significance are arteriovenous communications between the 2 circulations. This occurs when there are shared lobules supplied by an arterial branch from one fetus and drained by an umbilical vein branch of the other fetus. Fortunately, one-way communications in a shared lobule may be compensated for by reverse flow through a superficial arterioarterial or venovenous anastomosis that coexist.

Twin-twin transfusion syndrome (TTS) is believed to arise when shared lobules causing blood flow from one twin to the other are not compensated for by the presence of superficial anastomosis or by shared lobules causing flow in the opposite direction. The syndrome occurs in 15–30% of cases of monochorionic placentation and is defined, at birth, in terms of a difference in hemoglobin between the pair of greater than 5 g/dL. The twin receiving the transfusion is plethoric and polycythemic and shows cardiomegaly. The donor twin is pale and anemic and may have organ weights similar to those seen in the malnutrition form of SGA. Criteria for TTS diagnosed in utero differ substantially, but the underlying mechanism is the same.

The exchange of blood flow in multiple gestations is very important, as the death of one may affect the neurologic development of the living either because the shared blood flow allows thrombi to invade the affected twin or because the surviving twin receives blood into the dead twin. Treatment of TTS in utero via fetoscopic laser ablation of the communicating vessels is now feasible.

Placental Infarction

A placental infarct is an area of ischemic necrosis of placental villi resulting from obstruction of blood flow through the spiral arteries as a result of thrombosis. The lesions have a lobular distribution. However, the spiral arteries are not truly end arteries, and if there is adequate flow through the arteries supplying adjacent lobules, sufficient circulation will be maintained to prevent necrosis. Thus, ischemic necrosis of one placental lobule probably indicates not only that the spiral artery supplying that lobule is thrombosed but that flow through adjacent spiral arteries is severely impaired. Placental infarction may be a mechanism allowing the fetus to redistribute blood flow to those placental lobules that are adequately supplied by the remaining circulation. The infarct is usually extensive before the fetus is physiologically impaired.

Chorioangioma of the Placenta

A benign neoplasm composed of fetoplacental capillaries may occur within the placenta. It is grossly visible as a apparently encapsulated mass, variable in size, and occasionally multicentered. Placental hemangioma, or "chorioangioma," is a benign neoplasm composed of fetoplacental capillaries that may occur within the placenta. It is grossly visible as an apparently encapsulated mass, variable in size, and occasionally multicentered. Placental hemangioma, or "chorioangioma," is a benign neoplasm composed of fetoplacental capillaries that may occur within the placenta. It is grossly visible as an apparently encapsulated mass, variable in size, and occasionally multicentered.

be linked with maternal, fetal, and neonatal complications. Many placental tumors are accompanied by hydramnion. Some have been associated with preeclampsia-eclampsia. The developing fetus may be subjected to hypoxia, resulting in low birth weight, because blood within the tumor fails to reach the placental villi (and become oxygenated). The tumor may have an arteriovenous shunt requiring increased fetal cardiac output, with resulting cardiomegaly. Fetal hydrops may occur. Hypoalbuminemia and a microangiopathic type of hemolytic anemia. Neonatal thrombocytopenia has been associated with disseminated intravascular coagulation secondary to the liberation of thromboplastic substances.

Amniotic Bands

Close inspection of the fetal membranes, particularly near the umbilical cord insertion, may reveal band or string segments that are easily lifted above the placental surface. Such amniotic bands appear to be the result of a tear early in pregnancy. They may cause constriction of the developing limbs or other fetal parts. Amputation has been reported as a result. Syndactyly, clubfoot, and fusion deformities of the cranium and face may also be explained on the basis of amniotic bands. Myometrial bands also have been found within the intrauterine cavity but do not appear to exert the same amount of tension on fetal anatomy as do amniotic bands.

Amnion Nodosum

Examination of the fetal surface of the placental peripheral membranes after delivery may disclose small elevated nodules several millimeters in diameter. Microscopic examination of these nodules may reveal areas of ulceration of amnion covered with deposits of celluloid debris probably representing vernix caseosa. These nodules reflect severe oligohydramnios regardless of cause. They frequently occur in association with underlying congenital anomalies of the fetal genital tract. With this information, one is alerted to the possibility that Potter's syndrome or a variant with pulmonary hypoplasia may be present in the infant.

Chronic Intrauterine Infection

Chronic intrauterine infection may have a deleterious effect on organogenesis and interfere with organ development. Infections such as toxoplasmosis, rubella, cytomegalovirus, herpes, and syphilis are seen most frequently. Only in the past few years has chronic inflammation within placental villi been recognized and linked with intrauterine infection. Such inflammation has an incidence of approximately 20% in referral institutions. Usually, no causative organism is found, and the term chronic inflammation of unknown etiology is used. This is an inflammatory lesion that focuses on placental villi. It has a significant correlation with unexplained stillbirth and a considerable association with fetal morbidity and SGA newborns. An increased risk of associated adverse pregnancy outcome is suggested.

The placenta should be sent to the pathology laboratory for examination in the following cases: (1) perinatal death; (2) malformation, edema, or anemia; (3) extremes of amniotic fluid volume; (4) extreme SGA; (5) unexpected severe neonatal asphyxia; (6) preterm birth; (7) multiple gestation; (8) abnormal placenta; and (9) perinatal infection.

Placental Pathology

Any infant born with a complication may benefit from histologic evaluation of the placenta and umbilical cord. Histologic features of a placenta with uteroplacental insufficiency include nonmarginal infarcts, shrunken placental villi, increased intervillous knots, increased perivillous fibrin, and multifocal and diffuse fibrin deposition. Similarly, if the ratio of nucleated red blood cells to leukocytes exceeds 2:3, this indicates fetal hypoxic stress. Chorangiomas are a pathologic change that indicates placental hypoperfusion or low-grade tissue hypoxia.

The presence of meconium and its location can also give insight into the possible time of the presumed insult. Upon gross observation, meconium will stain the placenta and cord after just 3 hours of exposure. Stained infant fingernails indicate meconium exposure for at least 6 hours. Stained vernix equates with exposure of meconium for 15 hours or longer.

Microscopic evaluation also sheds light on the timing of the release of meconium. Meconium-laden macrophages on the surface of the placenta can be seen when meconium has been present for 2–3 hours. When these macrophages are seen within the extraplacental membranes, meconium has been present for at least 6–12 hours.

Lastly, when evaluation of the umbilical cord demonstrates necrobiotic and necrotic arterial media with surrounding laden macrophages, the release of meconium occurred more than 48 hours before delivery.

Abnormalities of Placental Implantation

Normally the placenta selects a location on the endometrium that benefits the growing fetus. However, there are instances when the placental implantation site is not beneficial.

Placenta previa, or the implantation of the placenta over the cervical os, is the most common. The incidence at gestation is about 6% because of the advancement of transvaginal imaging (Taipale et al., 1997). Fortunately, most placenta previa resolve by the time of delivery (reported incidence of 5/1,000 births in Ananth et al., 2001). A placenta previa occurs when the edge of the placenta lies within 2–3 cm of the cervical os; the prevalence ranges from 1% if less accurate abdominal ultrasonogram is used.

Associated consequences of these abnormal placentation sites include increased risk for bleeding, both for the mother and fetus; increased need for cesarean delivery; and possible risk of placenta accreta and increta or percreta, abruptio placentae, and fetal growth restriction. Once the placental edge moves beyond 2–3 cm from the cervical os, these risks are minimized.

Placenta accreta is the most dangerous consequence of placenta previa. It involves abnormal trophoblastic invasion into the decidua basalis. Placenta increta is the term used to describe invasion into the myometrium. Placenta percreta is invasion through the serosa with possible invasion into surrounding tissues such as the bladder. Placenta accreta, increta, or percreta may result in life-threatening postpartum hemorrhage and increased need for immediate hysterectomy.

The risk factors for placenta previa and placenta accreta are similar. Advanced maternal age, increased parity, and prior uterine surgery are common risk factors for both entities. The strongest correlation appears to exist with prior uterine surgery. The prevalence of placenta previa after one prior cesarean delivery reaches 0.65% versus 0.26% in the unscarred uterus. After 4 or more cesarean deliveries the prevalence reaches 10%. Similarly, the frequency of accreta in the presence of placenta previa increases as the number of uterine surgeries increases. In patients with one prior uterine surgery, the frequency of placenta accreta is 1.5%, whereas after 4 or more surgeries the frequency of placenta accreta may be as high as 67%.

Placenta accreta may be suspected with certain ultrasound findings such as loss of the hypoechoic retroplacental zone, thinning or disruption of the hyperechoic uterine serosa-bladder interface or with visualization of an exophytic placenta. In cases of placenta previa, and especially if placenta accreta is suspected, the patient must be counseled that hysterectomy may be needed to control excessive bleeding after delivery. Blood products must be available before delivery of the infant for prompt replacement.

THE UMBILICAL CORD

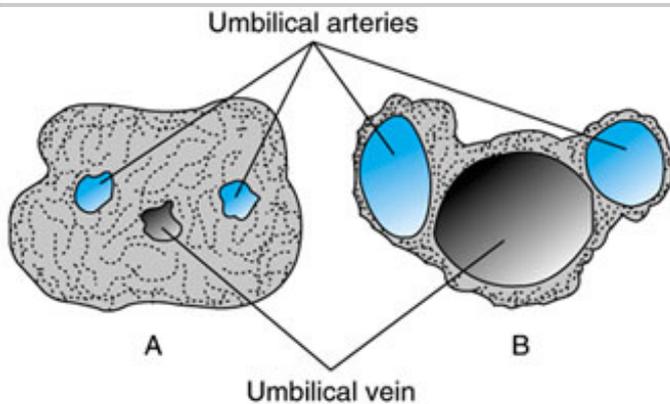

Development

In the early stages, the embryo has a thick embryonic stalk containing 2 umbilical arteries, 1 large umbilical vein, and the primary mesoderm. The arteries carry blood from the embryo to the chorionic villi, and the umbilical vein carries blood from the chorionic villi to the embryo. The umbilical vein and 2 arteries twist around one another.

In the fifth week of gestation, the amnion expands to fill the entire extraembryonic coelom. This process forces the embryo against the embryonic stalk and covers the entire contents with a tube of amniotic ectoderm, forming the umbilical cord. The cord is narrower in diameter than the embryonic stalk and rapidly increases in length. The connective tissue of the cord is called Wharton's jelly and is derived from the primary mesoderm. The umbilical cord can be found in loops around the baby's neck in approximately 23% of normal spontaneous vertex deliveries.

At birth, the mature cord is about 50–60 cm in length and 12 mm in diameter. A long cord is defined as more than 60 cm and a short cord as less than 30 cm. There may be as many as 40 spiral twists in the cord, as well as false knots and kinks. When umbilical blood flow is interrupted at birth, the intra-abdominal sections of the umbilical arteries and vein become fibrous cords. The course of the umbilical vein is discernible in the adult as a fibrous cord from the umbilicus to the liver.

(ligamentum teres) contained within the falciform ligament. The umbilical arteries are retained proximally as the arteries and give off the superior vesicle arteries and the medial umbilical ligaments within the medial umbilical t umbilicus. When the umbilical cord is cut and the end examined at the time of delivery, the vessels ordinarily are 8–3A), but if a segment of cord is fixed while the vessels are distended, the characteristic appearance is as show **Figure 8–3.**

Analysis of the Umbilical Cord in Fetal Abnormalities

A segment of umbilical cord should be kept available as a source of umbilical cord blood for blood gas measurement of delivery. Cord blood gases are a more objective measure of oxygenation than Apgar scores, especially in dark

The umbilical cord has recently become a means of evaluating the fetus in utero. Umbilical cord sampling under guidance has opened new vistas in perinatal physiology, teratology, genetics, and therapeutic endeavors to correct isoimmunization.

ABNORMALITIES OF THE UMBILICAL CORD

Velamentous Insertion

In velamentous insertion, the umbilical vessels divide to course through the membranes before reaching the chorion. Velamentous insertion occurs in about 1% of placentas. When these vessels present themselves ahead of the fetus (velamentous insertion), they may rupture during labor or before to cause fetal exsanguination. When painless vaginal bleeding occurs, it may be tested to determine if it is of fetal origin (Apt test). In practical terms, a high index of suspicion for vasa previa is needed because the time to fetal collapse with bleeding from vasa previa is often too rapid to allow test interpretation.

Short Umbilical Cord

It appears from indirect evidence in the human fetus that the length of the umbilical cord at term is determined of amniotic fluid present during the first and second trimesters and by the mobility of the fetus. If oligohydramnios or bands, or limitation of fetal motion occur for any reason, the umbilical cord will not develop to an average length. Experimental work performed to produce oligohydramnios in pregnant rats at 14–16 days results in significant reduction of umbilical cord length. The length of the umbilical cord does not vary with fetal weight, presentation, or placental size. Simple mechanical factors determine the eventual length of the cord.

Knots in the Umbilical Cord

True knots occur in the cord in 1% of deliveries, leading to a perinatal loss of 6.1% in such cases. False knots are variations with no clinical importance.

Loops of the Umbilical Cord

Twisting of the cord about the fetus may be the reason for excessive cord length. One loop of cord is present about 21% of deliveries, 2 loops in 2.5%, and 3 loops in 0.2%. When 3 loops are present, the cord is usually longer than the study of 1000 consecutive deliveries found 1 or more loops of cord around the neck in approximately 24% of cases. Multiple loops of umbilical cord around the neck caused no fetal morbidity or mortality in that series, but Naeye¹ illustrates that cord entanglement may be an important cause of stillbirth.

Torsion of the Umbilical Cord

Torsion of the cord occurs counterclockwise in most cases. If twisting is extreme, fetal asphyxia may result.

Single Artery

A 2-vessel cord (absence of one umbilical artery) occurs about once in 500 deliveries (6% of twins). The cause is either atresia or atrophy of the missing vessel. The anomaly is more common in blacks than whites but equally frequent in primiparas. In older studies, about 30% of these infants were found to have structural defects. Because many anomalies are detected on ultrasound antenatally, the main clinical question at present is the association of the isolated single umbilical artery (SUA) and fetal anomalies. In this setting the risk of anomalies is much lower, but should still prompt a careful search. There is also a strong association between fetal structural anomalies and placental occlusion or thrombosis. Perinatal examination for such vascular defects should be routine.

THE FETUS

The human fetus is born about 40 weeks after the first day of the last menstrual period (LMP). The gestational age is measured from the first day of the LMP, although obviously conception can not occur until 2 weeks after the beginning of the LMP calculation. The 9.5 calendar months are divided into trimesters for convenient classification of certain obstetric terms. A term fetus is born 9.5 lunar cycles (29.53 days each) after conception, and the postconceptional age in weeks is the stage of development of the embryo.

Because of the error in estimating the date of conception from the LMP, early ultrasound using the crown rump length measurement is widely used in clinical practice to correct and confirm the gestational age.

GROWTH & DEVELOPMENT

During the first 8 weeks, the term embryo is used to denote the developing organism because it is during this time that the major organs are formed (Table 8-3). After the eighth week, the word fetus is proper; this is a period when further organ maturation occurs. The loss of a fetus weighing less than 500 g (about 22 weeks' gestational age) is called abortion. A fetus weighing 500–1000 g (22–28 weeks) is called immature. From 28–36 weeks, it is referred to as a preterm fetus. A term fetus is arbitrarily defined as one that has attained 37 weeks' gestational age. An alternative means of describing fetal weight is widely used in clinical practice: 500–750 g, extremely low birth weight; 750–1500 g, very low birth weight; 1500–2500 g, low birth weight. The growth of the fetus may be conveniently described in units of 4 weeks' gestation beginning with the first day of the LMP:

8 weeks: The embryo is 2.1–2.5 cm long and weighs 1 g, and the head makes up almost half the bulk. The heart can be recognized. Red blood cells are forming in the yolk sac and liver and contain hemoglobin. The kidneys are beginning to form.

16 weeks: The length is 14–17 cm and the weight about 100 g. The sex is discernible. Hemoglobin F is present and hemoglobin A begins.

20 weeks: The weight is about 300 g. Movements may have been perceived by the mother for 2–3 weeks. The fetus is near the level of the umbilicus.

24 weeks: The weight is 600 g. Some fat is beginning to be deposited beneath the wrinkled skin. Viability is reached.

24th week with approximately 50% survival.

28 weeks: The weight is about 1050 g and the length about 37 cm. The lungs are now capable of breathing, but content is low; survival is 90%.

32 weeks: The weight is about 1700 g and the length about 42 cm. If born at this stage, 99% of infants survive.

36 weeks: The weight is about 2500 g and the length about 47 cm. The skin has lost its wrinkled appearance.

40 weeks: The term fetus averages 50 cm in length and 3200–3500 g in weight. The head has a maximal trans (biparietal) diameter of 9.5 cm, and when the neck is well flexed, the diameter from the brow to a point beneath (suboccipitobregmatic) is also 9.5 cm. The average fetus, therefore, requires cervical dilatation of almost 10 cm to descend into the vagina.

Table 8–3. Embryonic and Fetal Growth and Development.

Embryonic stage

1

0.5 mm

0.5 mm

?

Minute clone free in uterus.

Early morula. No organ differentiation.

2

2 mm

2 mm

?

Ovoid vesicle superficially buried in endometrium.

External trophoblast. Flat embryonic disk forming 2 inner vesicles (amnio-ectomesodermal and endodermal).

3

3 mm

3 mm

?

Early dorsal concavity changes to convexity; head, tail folds form; neural grooves close partially.

Optic vesicles appear. Double heart recognized. Fourteen mesodermal somites present.

4

4 mm

4 mm

0.4 g

Head is at right angle to body; limb rudiments obvious, tail prominent.

Vitelline duct only communication between umbilical vesicle and intestines. Initial stage of most organs has begun.

8

3 cm

3.5 cm

2 g

Eyes, ears, nose, mouth recognizable; digits formed, tail almost gone.

Sensory organ development well along. Ossification beginning in occiput, mandible, and humerus (diaphysis). Spiral coil within umbilical cord. Pleural pericardial cavities forming. Gonadal development advanced without differentiation.

Fetal stage

12

8 cm

11.5 cm

19 g

Skin pink, delicate; resembles a human being, but head is disproportionately large.

Brain configuration roughly complete. Internal sex organs now specific. Uterus no longer bicornuate. Blood forms

Upper cervical to lower sacral arches and bodies ossify.

16

13.5 cm

19 cm

100 g

Scalp hair appears. Fetus active. Arm-leg ratio now proportionate. Sex determination possible.

External sex organs grossly formed. Myelination. Heart muscle well developed. Lobulated kidneys in final situatic bowel. Vagina and anus open. Ischium ossified.

20

18.5 cm

22 cm

300 g

Legs lengthen appreciably. Distance from umbilicus to pubis increases.

Sternum ossifies.

24

23 cm

32 cm

600 g

Skin reddish and wrinkled. Slight subcuticular fat. Vernix. Primitive respiratory-like movements.

Os pubis (horizontal ramus) ossifies.

28

27 cm

36 cm

1100 g

Skin less wrinkled; more fat. Nails appear. If delivered may survive with optimal care.

Testes at internal inguinal ring or below. Talus ossifies.

32

31 cm

41 cm

1800 g

Fetal weight increased proportionately more than length.

Middle fourth phalanges ossify.

36

34 cm

46 cm

2200 g

Skin pale, body rounded. Lanugo disappearing. Hair fuzzy or wooly. Ear lobes soft with little cartilage. Umbilicus body. Testes in inguinal canals; scrotum small with few rugae. Few sole creases.

Distal femoral ossification centers present.

40

40 cm

52 cm

3200+ g

Skin smooth and pink. Copious vernix. Moderate to profuse silky hair. Lanugo hair on shoulders and upper back. stiffened by thick cartilage. Nasal and alar cartilages distinguishable. Nails extend over tips of digits. Testes in fu rugous scrotum (or labia majora) well developed. Creases cover sole.

Proximal tibial ossification centers present. Cuboid, tibia (proximal epiphysis) ossify.

Fertilization Age (weeks)	Crown-Rump Length	Crown-Heel Length	Weight	Gross Appearance	Internal Development

FETAL & EARLY NEONATAL PHYSIOLOGY

During the past 2 decades, improved neonatal care has led to increased survival rates for very low–birth-weight those as young as 23–24 weeks. Obviously, an understanding of fetal and early neonatal physiology is critical in management of these babies.

Hematology

The fetal circulation is established at about 25 postconceptional days. At that time, the major sources of red blood islands in the body stalk. By 10 weeks, the liver assumes the major role in erythropoiesis, but the spleen and marrow gradually take over this function. At term, the bone marrow is the source of at least 90% of the red cell erythropoietin is produced in considerable quantities by 32 weeks, but levels fall almost to zero during the first v unless the infant is anemic, in which case the values are higher.

Erythrocytes are the first blood cells produced by the fetus and have a life span of 120 days. The earliest eryth megaloblastic and circulate as nucleated cells. Mean red cell values change as the fetus grows (Table 8–4).

After the first week of life, erythrocyte concentrations begin to decline gradually, reaching zero by 6–12 weeks a hemoglobin concentration decreases to about 10 g/dL and by term to as low as 7–8 g/dL (physiologic anemia newborn).

The synthesis of hemoglobin occurs in the proerythroblast, normoblast, and reticulocyte, but not in the mature Types of fetal hemoglobin present before 12 weeks are Gower I and II and Portland I. There are at least 7 types chains. The synthesis of each chain is under the genetic control of a separate structural gene locus. The complete sequences of the 7 normal globin chains have been determined. A functional hemoglobin molecule is a tetramer globin chains and 4 heme groups. From the eighth week of gestation to term, hemoglobin F is the major hemo fetus, but a small amount of hemoglobin A can also be detected. The ratio of beta to gamma synthesis remains 1:10 during this period and until term (Fig 8–4). Around the time of birth, the ratio changes because of the gradual synthesis of gamma chains and increased synthesis of beta chains (Table 8–5).

Fortuitously, blood in the fetus has a 50% higher hemoglobin concentration than in the adult and a greater oxygen concentration than maternal blood. Even though fetal oxygen tension is less, fetal blood carries an amount of oxygen comparable to

maternal blood. The resistance of hemoglobin F to acid digestion makes it possible to demonstrate hemoglobin F cells in the maternal circulation (Kleihauer-Betke test).

The higher affinity of hemoglobin F for oxygen is accentuated by 2,3-diphosphoglycerate (2,3-DPG), which adult red cells. Fetal and maternal blood have different oxygen saturation curves, mostly because 2,3-DPG competes with oxygen for binding sites on adult cells.

Immunology

There are 3 basic types of leukocytes found in the blood: granulocytes, monocytes, and lymphocytes. The granulocytes are subdivided into 3 types, based on the sustaining characteristics of the acidic plasma granules and function—eosinophilic, basophilic, and neutrophilic granulocytes. A functional difference also exists among the lymphocytes which are divided into 2 broad groups designated as T cells and B cells. The functions of monocytes vary greatly with maturation or with environmental influences; thus, it is not currently possible to divide them into distinct subgroups. These cells are generally regarded as white blood cells, they should be viewed as cell types that merely use the blood as a means of transportation from sites of production to sites of function. Both the sites of production and (for the monocytes) sites of function are extravascular. The fetus presents with relative leukocytosis, the white count being 15,000–20,000/cu mm.

Circulating white cells constitute the first line of defense against pathogenic bacteria, as outlined in Table 8–6. Leukocytes appear in the fetal circulation after 2 months' gestation. The prothymocytes migrate from the fetal liver or bone marrow to the embryonic thymus at approximately 8 weeks' gestation. Soon after, the splenic anlage begins to mature. Both B and T lymphocytes, a major source of the antibodies that constitute the second line of defense against harmful foreign antigens. Antibody-mediated immunity and cell-mediated immunity depend on the activity of small lymphocytes derived from bone marrow precursors. The stem cells, which during the early embryonic stage originate in the yolk sac, in later stages of development in the liver, and in adults in the bone marrow, differentiate to form 2 distinct lymphocyte populations: thymus-derived (T lymphocytes) and the other is bone marrow-derived (B lymphocytes). T lymphocytes are first detected in the thymus after 11 weeks' gestation; they appear in the peripheral blood, spleen, and lymph nodes after 20 weeks, and by 30–32 weeks the fetus has a near-adult number of circulating T lymphocytes.

--	-----------------	------------------

The life span of lymphocytes is not uniform. Recent studies suggest that B- and T-cell populations contain similar long- and short-lived lymphocytes. The T lymphocytes constitute 65–85% of the lymphocytes present in the thoracic duct blood, and lymph nodes. The long-lived lymphocytes represent the major portion (90%) of the thoracic duct cell population. The short-lived lymphocytes are located mainly in the thymus, spleen, and bone marrow. The T cells are effector cells in cell sensitivity reactions and elimination of foreign tissues. They also play an important role in the expression of some immune responses. The T cells can release a variety of nonspecific chemical mediators called lymphokines (eg, transfer factor, mitogenic factor, migration and inhibition factors, and cytotoxic and growth inhibitory factors).

B lymphocytes originate in the bone marrow of most mammals. B cells seem to be more sessile than T cells. B cells are primarily in the perilymphoid organs, lymph nodes, and thymic-independent areas around germinal centers. They are present in very small amounts in the peripheral blood. They seem to be short-lived. B cells differentiate into plasma cells which are ultimately responsible for the synthesis and secretion of all forms of antibody and all circulating immunoglobulins. The average life span of plasma cells is 0.5–2 days.

Immunoglobulins (Ig) are serum globulins with antibody activity as their primary property. The 5 classes of immunoglobulins are designated IgG, IgM, IgA, IgD, and IgE. In the human newborn, plasma cells are absent from the bone marrow and the lamina propria of the ileum and appendix. They appear only 4–6 weeks after birth. However, beginning at 20 weeks' gestation the fetal spleen synthesizes IgG and IgM but not IgA or IgD (Fig 8–5).

Figure 8–5.

Development of IgG levels with age. Relationship of development of normal serum levels of IgG during fetal and neonatal stages, and maternal contribution.

(Modified from Allansmith M et al: The development of immunoglobulin levels in man. *J Pediatr* 1968;72:289.)

IgG is normally produced only in trace amounts prenatally, with its full synthesis beginning 3–4 weeks after birth. It is first found in small amounts in the fetus, primarily in the circulation but not diffused into extravascular spaces. It is produced in lymphocytoid plasma cells and reticular cells of the spleen and lymph nodes. Fetal production of IgG and IgM in comparison with adult production. The fetal spleen synthesizes relatively more IgM than IgG. IgM is the first antibody to enter the circulation after initial immunization and is the predominant class produced by infants in the neonatal period. The plasma level of IgM is about 5% of the normal adult level, with most, if not all, of this antibody being of fetal origin. Within 10 days after birth, the rate of IgM synthesis increases rapidly. IgM, unlike IgG, does not cross the human placenta. The life of IgM is 5 days.

This comparison between IgG and IgM is important in determining possible intrauterine infection. The fetal IgG s

concentration at term equals the maternal concentration because IgG crosses the placenta. IgG constitutes 90% of antibodies in the fetus because of the maternal contribution. IgM is predominantly of fetal origin and, therefore, determine whether fetal infection is present, but there are many false-positive and false-negative results. After birth, the half-life in the newborn circulation is 3–4 weeks. IgE does not cross the placenta, and cord levels are only 10% of maternal levels.

The fetus and newborn are not as well equipped immunologically as the adult to combat infection. The primary cellular and humoral immune responses are immature. T lymphocytes do not respond to specific antigens, and B lymphocytes do not develop into plasma cells. This results in IgG levels that are below maternal levels until late in the third trimester, and complement and proteins which are necessary for opsonization of bacteria, are consistently reduced.

IgA production does not begin until several weeks after birth. Because IgA is produced in response to the antigens of organisms, the newborn is particularly susceptible to intestinal infections.

The response of the fetus to antigens of maternal origin depends on the level of immunologic competence achieved. During the first trimester, for example, rubella virus elicits no response from the embryo, whose tissues are therefore not damaged.

Endocrinology

The thyroid is the first endocrine gland to develop in the fetus. As early as the fourth postconceptional week, the fetus synthesizes thyroxine. The pancreas develops early as an outgrowth of the duodenal endoderm, and as early as the 10th week of gestation, insulin may be extracted from the B cells of the pancreas. Maternal insulin is not transferred to the fetus in physiologic quantities, so the fetus must supply whatever is needed for metabolizing glucose. Insulin is thus the hormone regulating the rate of fetal growth. The beta cells of the normal fetal pancreas respond poorly to hyperglycemia; the stimulus is repeated many times (eg, diabetes in the mother may cause hyperplasia of fetal beta cells so that large quantities of insulin will be produced). This may be why some infants of diabetic mothers grow to an excessive size. There is evidence of hyperinsulinism immediately after birth.

All the tropic hormones synthesized by the anterior pituitary gland are present in the fetus, although the precise role of protein hormones in fetal growth and metabolism is not well understood. ACTH plays a vital role, however, in stimulating the adrenal cortex because the tropic hormones are too large for placental transfer from the mother in significant quantities.

The fetal adrenal cortex consists mainly of a fetal zone that disappears about 6 months after birth. The cortex is an endocrine organ that produces large quantities of steroid hormones. There is evidence that the steadily increasing size of the fetal zone triggers the sequence of events that leads to the initiation of labor. Atrophy of the fetal adrenal gland (as seen in anencephalic fetuses) may result in marked prolongation of pregnancy. The fetal adrenal cortex is larger in preterm fetuses when the cause of labor is unknown, than when the pregnancy is terminated by placental abruption or by elective cesarean labor. The fetal adrenal gland is an important source of catecholamines, which will respond to stress placed on the fetal myocardium. There is a preferential blood flow to the fetal adrenal in acidosis, unlike the adult response to acidosis.

CIRCULATORY FUNCTION IN THE FETUS & NEWBORN

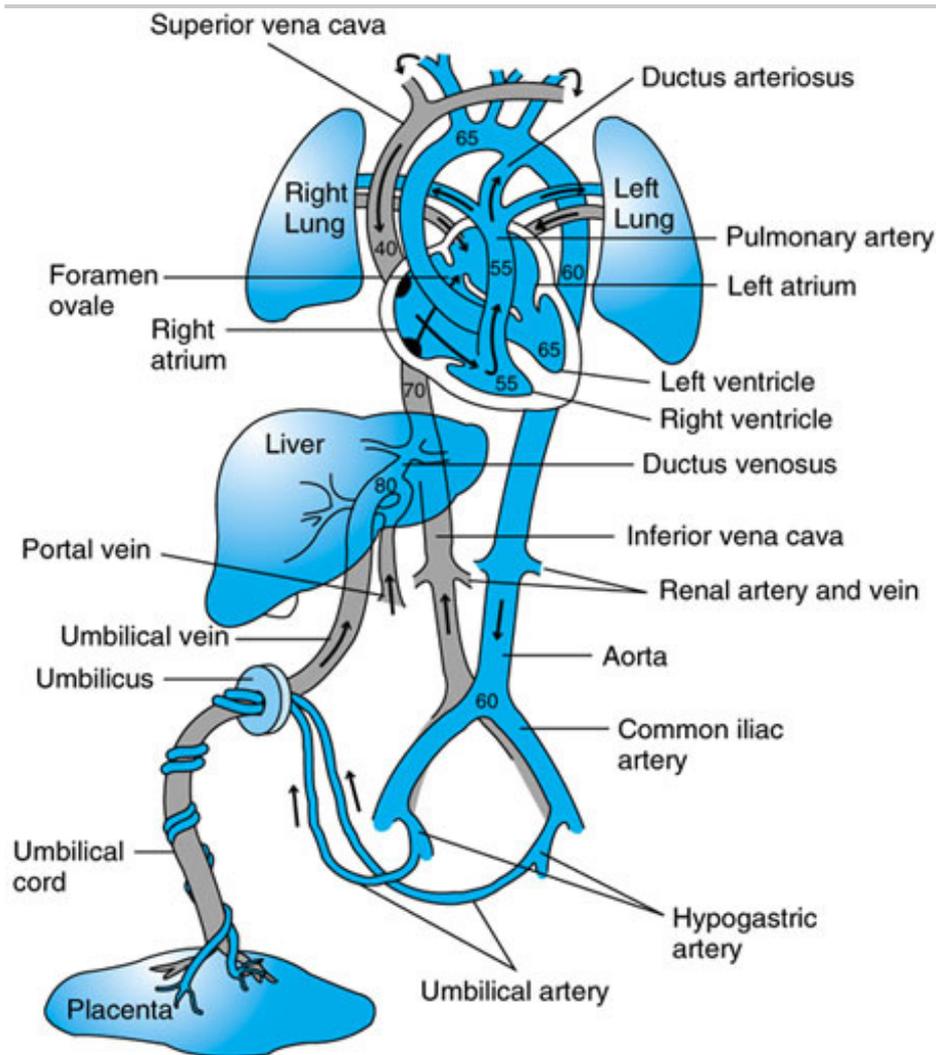

The abrupt transition from intrauterine life to independent existence necessitates circulatory adaptations in the newborn. These include diversion of blood flow through the lungs, closure of the ductus arteriosus and foramen ovale, and obliteration of the ductus venosus and umbilical vessels.

Infant circulation has 3 phases: (1) the intrauterine phase, in which the fetus depends on the placenta; (2) the transitional phase, which begins immediately after delivery with the infant's first breath; and (3) the adult phase, which is normally established during the first few months of life.

Intrauterine Phase

The umbilical vein carries oxygenated blood from the placenta to the fetus (Figs 8–6 and 8–7). In the abdomen,

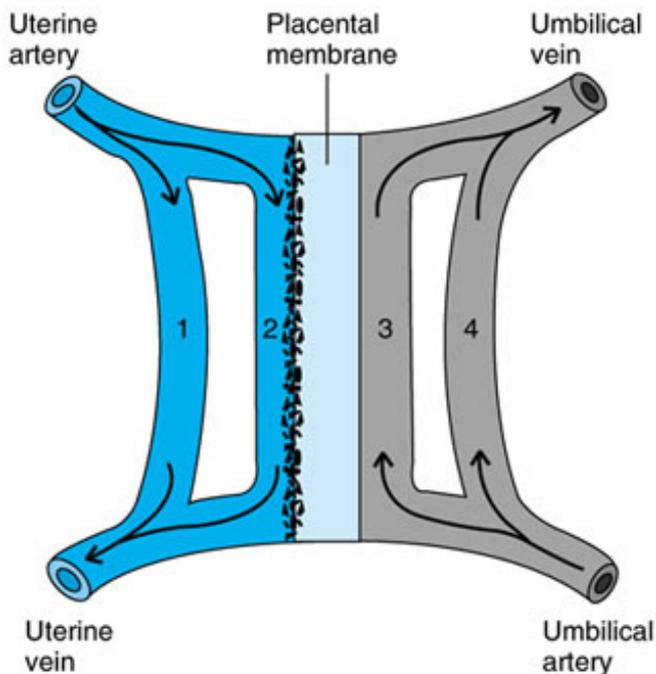

branches and enters the liver; a small branch bypasses the liver as the ductus venosus to enter the inferior vena cava. Figure 8–6.

Almost all the blood from the superior vena cava is directed through the tricuspid valve into the right ventricle, and the pulmonary trunk. Most of this relatively deoxygenated blood then passes directly through the ductus arteriosus to the descending aorta and on to the placenta. Blood from the inferior vena cava, which includes the oxygenated umbilical blood, largely passes directly through the foramen ovale into the left atrium and left ventricle to be ejected into the aorta. The left ventricle ejects about one-third of the combined ventricular output of the fetus. Most of the left ventricular output passes to the fetal head, whereas the right ventricle, with blood of lower oxygen content, ejects mainly into the descending aorta. The aortic oxygen saturation difference is related not only to superior and inferior vena caval flow pattern but also to the flow of the umbilical venous blood as it enters the inferior vena cava. The well-oxygenated blood preferentially perfuses the cerebral and coronary circulations. This system preferentially supplies better-oxygenated blood (saturation 65%) to the brain, whereas the less well-oxygenated (postductal saturation 60%) blood supplies the less vital structures of the abdomen and the lower extremities. Both ventricles pump in parallel, unlike the situation in adults.

The fetal cardiovascular responses to stress represent a complex interplay between state of arousal, changes in hydrogen ion concentration, reflex effects initiated by chemoreceptor or baroreceptor stimulation, and hormonal influences. Superficially, the fetal hypoxemic-asphyxial response is much like the response in an adult when diving into water. It involves selective vasoconstriction and the baroreceptor reflex, a primitive reflex involving changes in heart rate, venous dilatation, and cardiac performance. This reflex is evoked by changes in mean blood pressure and is modulated by oxygen and carbon dioxide gas levels. The ability of some mammals to remain submerged for long periods of time remained a mystery until it was recognized that there is a "heart-brain" preparation through selective vasoconstriction.

In diving mammals, lactic acid is washed out of hypoperfused tissues after relief of the vasoconstriction. The same occurs with the hypoxic fetus, producing a brief period of acidemia after birth or after oxygenation. While selective vasoconstriction provides a "heart-brain" preparation, at the same time it disturbs the flow of oxygenated blood to other essential organs.

A depressed central nervous system often produces a relatively constant heart rate with lack of beat-to-beat variability. This variability is mediated through autonomic stimulation resulting from the push-and-pull nature of the parasympathetic systems. Such central nervous system activity reflects general fetal arousal levels and is decreased when the fetus is immature, asleep, drugged, or asphyxiated. Lack of fetal heart rate variability plus other signs of fetal distress is a ominous sign. The central nervous system and cardiovascular system respond differently to hypoxia according to gestational age.

The umbilical vessels are relatively nonreactive, but the systemic and pulmonary circulations respond, when there is systemic vasoconstriction. The fetal pulmonary circulation receives a small portion (8–10%) of the fetal cardiac output, and does not play a central role in the fetal cardiovascular hypoxia response. Changes in fetal arterial pressure tend to be mediated by fetal umbilical-placental circulation. Likewise, the decrease in fetal cardiac output seen during bradycardia is due to a redistribution of cardiac output to vital organs such as the brain, heart, placenta, and adrenal gland, so that the baroreceptor reflex may not be as effective during fetal life. The response of the fetus to hypoxia is even more complex, with reflex stimulation from the aortic receptors, baroreceptor reflexes, and direct myocardial depression. Fetal tachycardia results from sympathetic nervous stimulation and circulating catecholamines. Because the capacity to respond to these different stimuli varies with gestational age, arousal levels, general health, and the presence of drugs and anesthetics, there are no universal, precise fetal heart rate responses to distress.

When placental transfer of oxygen is inadequate, anaerobic glycolysis leads to the accumulation of excessive lactic acid in the fetus. There is then an associated accumulation of CO₂ and hydrogen ion (H⁺), which results in decreased pH. Although the maternal and fetal H⁺ values maintain a relatively constant gradient, differences in the bicarbonate concentration result in a variation in fetal pH. Thus, determination of fetal scalp or cord blood gases can be useful in assessing fetal well-being. In fetal distress (seriously altered homeostasis), fetal blood levels of prostaglandins, catecholamines, steroids, and pituitary hormones are often elevated (Table 8–7).

	Before Labor	Second Stage of Labor

¹ Population unrelated to cord sample population.

² Related to babies 28–43 weeks with Apgar scores greater than 7 at 1.5 minutes.

When the fetus shows signs of distress during labor, placental transfer can be improved by use of several maneuvers. First, vaginal examination should be performed, and if prolapse of the umbilical cord has occurred, compression of the cord should be relieved immediately by lifting the presenting fetal part off the cord. The second maneuver is to roll the mother on her left side to check for maternal aortocaval compression. Third, it may be helpful to administer oxygen to the mother; this only slightly increases the oxygen content of the uterine arterial blood because the arterial hemoglobin is already saturated. Fourth, discontinuing oxytocin and possibly administering a tocolytic agent may inhibit uterine activity. A fifth maneuver is to rapidly administer 1 L of intravenous fluids to acutely expand the maternal plasma volume; a colloid such as 5% albumin is preferred, but a balanced salt solution is acceptable and usually more readily available.

Blood from the umbilical vein reflects uteroplacental status and is influenced by maternal and placental problems; the umbilical arteries, on the other hand, reflects uteroplacental status plus fetal status. The umbilical artery should be sampled shortly after birth with a needle inserted into the cord or one can use the placenta for both venous and arterial samples (arterial samples run over the veins). Most newborns have umbilical venous and arterial blood gas samples accurately reflecting fetal status. Fetal blood samples are more accurate than Apgar scores in determining fetal status (Pomerance, 2004).

Transition Phase

At birth, 2 events occur that alter the fetal hemodynamics: (1) ligation of the umbilical cord causes an abrupt rise in arterial pressure, and (2) a rise in plasma CO_2 and a fall in blood Po_2 help to initiate regular breathing.

With the first few breaths, the intrathoracic pressure of the newborn remains low (–40 to –50 mm Hg); after distending the airways, however, the pressure rises to the normal adult level (–7 to –8 mm Hg). The initially high vascular resistance in the pulmonary bed is probably reduced by 75–80%. Pressure in the pulmonary artery falls by at least 50%, whereas pressure in the left atrium doubles.

In the fetus, the high resistance of the pulmonary bed causes most of the deoxygenated blood in the pulmonary artery to flow into the descending aorta via the ductus arteriosus. At birth, expansion of the lungs occurs in the newborn, and most of the blood from the right ventricle then enters the lungs via the pulmonary artery. Furthermore, increased systemic arterial pressure reverses the flow of blood through the ductus arteriosus. Neonatal blood flows from the high-pressure aorta to the pulmonary artery.

The increased pressure in the left atrium would normally result in backflow into the right heart through a patent ductus arteriosus. However, the anatomic configuration of the foramen is such that the increased pressure causes closure of the foetal valve-like fold situated in the wall of the left atrium.

The neonatal circulation is complete with closure of the ductus arteriosus and foramen ovale, but adjustments continue for several months, until the adult phase begins.

Adult Phase

The ductus arteriosus usually is obliterated in the early postnatal period, probably by reflex action secondary to

tension and the interaction of prostaglandins. If the ductus remains open, a systolic crescendo murmur that diminishes at diastole ("machinery murmur") is often heard over the second left interspace.

Obliteration of the foramen ovale is usually complete in 6–8 weeks, with fusion of its valve to the left interatrial foramen. The foramen may remain patent in some individuals, however, with few or no symptoms. The obliterated ductus venosus, which carries blood from the vena cava to the vena cava, becomes the ligamentum venosum. The occluded umbilical vein becomes the ligamentum venosum.

The hemodynamics of the normal adult differ from those of the fetus in the following respects: (1) venous and arterial blood mix in the atria; (2) the vena cava carries only deoxygenated blood into the right atrium, where it goes to the right ventricle and then is pumped into the pulmonary arteries and finally to the pulmonary capillary bed; and (3) the systemic veins deliver oxygenated blood to the left heart for distribution to the rest of the body via the aorta.

RESPIRATORY FUNCTION IN THE FETUS & NEWBORN

Gas exchange in the fetus occurs in the placenta. Transfer of gases is proportionate to the difference in partial pressure of gas and surface area and inversely proportionate to membrane thickness. Thus, the placenta can be viewed as a "gas exchange surface in utero."

Until about 12 weeks, placental permeability is low because of the small surface area of the placental "lake" and relative thickness of the trophoblastic membrane. From 12–32 weeks, the membrane thins and the surface area increases. However, placental oxygen utilization makes accurate quantitation of oxygen transfer difficult.

The P_{O_2} of fetal blood is less than that of maternal blood. Although not compatible with extrauterine life, the P_{O_2} for the fetus, as there is a higher concentration of hemoglobin in fetal blood, much of which is hemoglobin F. Hemoglobin F has a much greater affinity for oxygen than adult hemoglobin A, resulting in greater fetal oxygen saturation. However, the ability of the fetus to deliver oxygen to the peripheral tissues seems primarily dependent on a cardiac output that is greater than in the adult.

Both the P_{CO_2} and the CO_2 contents of fetal blood are slightly greater than levels in the mother's blood. As a result, there is a net movement of CO_2 from fetus to mother for elimination.

The central and motor pathways of the fetal respiratory system are active, and respiration at birth is the culmination of these processes. Two main types of fetal breathing movements are recognized. One is a paradoxical irregular sequence, in which the abdominal wall moves outward as the chest wall moves inward. The other is a regular gentle movement, in which the abdominal wall moves outward and inward together. Fetal respiratory activity permits neuromuscular and skeletal muscle development as well as development of the respiratory epithelium. As term approaches, the fetal diaphragm is usually active only during rapid eye movement (REM) sleep. Without such activity, the lungs would be hypoplastic and inadequate for gas exchange. Curiously, the alveolar membrane does excrete chloride into tracheal fluid and perhaps absorbs nutrients from amniotic fluid. Consequently, it has been proposed that, like the fish gill, the fetal alveolar membrane functions as an organ of excretion. In sheep, prolactin acts on both the fetal lung and amniotic membrane in facilitating sodium transport, and this is thought to be a mechanism of control of fetal blood volume.

Hypoxia or maternal cigarette smoking reduces fetal breathing movements, whereas hyperglycemia increases fetal breathing movements. In general, these movements are governed by the same central nervous system patterns that control fetal heart rate and body movements. The greatest clinical accuracy in the biophysical identification of the abnormal fetus is achieved when multiple variables are considered (eg, fetal breathing, general movements, heart rate patterns, and fetal activity in response to stimuli). In both sheep and humans, fetal breathing movements diminish or cease 24–36 hours before the onset of labor. In preterm labor with intact membranes, the presence of fetal breathing movements may indicate that pregnancy is progressing normally, while fetal apnea may indicate early delivery.

The first breath of the newborn normally occurs within the first 10 seconds after delivery. The first breath usually results from a central nervous system reaction to sudden pressure, temperature change, and other external stimuli. A

breath, the slight increase in P_{O_2} may activate chemoreceptors to send impulses to the central nervous system center and then to the respiratory musculature. As a result, a rhythmic but rapid breathing sequence occurs, which is characteristic of the neonatal period. The amniotic fluid usually drains from the respiratory tract or is absorbed. If meconium is present, it may be aspirated; if it is not cleared shortly after birth, it will migrate peripherally as continued respiration is established or partial obstruction of the respiratory tract or chemical pneumonitis may result.

Contrary to popular belief, the fetal lungs are not highly plastic. As development progresses, the ratio of tissue elastin to potential air space decreases. At the same time, the liquid and future air space is enriched with phospholipid surfactants secreted by maturing type 2 sacular alveolar cells. When air breathing begins at birth, dispersion of surfactant-rich liquid in the mature lungs results in formation of stable alveoli. Overall, a mature lung is characterized by relatively low opening pressures, high maximal volume, wide hysteresis, and retained volumes at end deflation or expiration.

With the onset of breathing, pulmonary vascular resistance is reduced and the capillaries fill with blood. Normally, the ductus arteriosus closes and pulmonary circulation is established.

Surfactant-poor lungs do not have the capacity to produce alveolar stability. As a consequence, initial aeration requires a higher opening pressure, achieves a smaller maximal volume, and results in little hysteresis and gas retention during deflation. This is the underlying pathophysiologic mechanism of neonatal respiratory distress syndrome.

GASTROINTESTINAL FUNCTION IN THE FETUS & NEWBORN

The gastrointestinal tract is not truly functional until after birth, because the placenta is the organ of alimentary intake during fetal life. Nevertheless, when contrast medium is injected into the amniotic fluid as early as the fourth month of gestation, it is promptly observed within the stomach and small intestine.

The full development of proteolytic activity does not develop until after birth, but the fetal gastrointestinal tract is capable of absorbing amino acids, glucose, and other soluble nutrients.

Meconium is produced during late pregnancy, but the amount is small. Passage of meconium in utero probably occurs in response to asphyxia, which increases intestinal peristalsis and relaxation of the anal sphincter. Passage of meconium is also increased in frequency as the fetus reaches term and moves beyond term. Meconium is rarely seen in fetuses before 36 weeks. Between 36 and 42 weeks, meconium may be found in 25% of births. After 42 weeks meconium may be seen in 50% of deliveries. In many circumstances, the passage of meconium may simply represent a mature gastrointestinal tract, but it may also be an indicator of an acute hypoxic event.

Intrahepatic erythropoiesis begins during the eighth week in the embryo, and the liver is well developed histologically by midpregnancy. During fetal life, the liver acts as a storage depot for glycogen and iron. Reasonably complete liver function is not achieved until well after the neonatal period has passed. Liver deficiencies at birth are many, including reduced production of fibrinogen and coagulation factors II, VII, IX, XI, and XII.

Vitamin K stored in the liver is deficient at birth because its formation depends on bacteria in the intestine. This deficiency predisposes the newborn to hemorrhage during the first few days of life.

The formation of glucose from amino acids (gluconeogenesis) in the liver and adequate storage of glucose are not fully established in the newborn. Moreover, levels of carbohydrate-regulating hormones such as cortisol, epinephrine, and growth hormone may be initially insufficient. As a consequence, neonatal hypoglycemia is common after stressful stimuli such as hypoxia or malnutrition.

Glucuronidation is limited during the early neonatal period, with the result that bilirubin is not readily conjugated with glucuronic acid. After physiologic hemolysis of excess red blood cells in the first week of life or with pathologic hemolysis in newborns, jaundice occurs. If marked hyperbilirubinemia develops, kernicterus may ensue.

Metabolism of drugs by the liver is poor in the newborn period (eg, sulfonamides and chloramphenicol). Moreover,

inborn errors of metabolism (eg, galactosemia) may be diagnosed soon after birth. Neonatal liver function gradually assuming proper food, freedom from infection, and a favorable environment.

Secretory and absorptive functions are accelerated after delivery. Most digestive enzymes are present, but the gastric juices are neutral at birth, although acidity soon develops. The initial neutrality may briefly delay the growth in the newborn necessary for the formation of vitamin K in the intestine. The newborn can assimilate simple solutions and breast milk immediately after birth but cannot digest cow's milk as well until the second or third day after elimination of meconium. Slow progress of milk through the stomach and upper intestine is usual during the early neonatal period.

Normally, some air enters the stomach during feedings. Pocketing of air in the upper curvature of the stomach in the newborn is lying flat. Hence, turning the infant and "burping" with the infant upright are necessary.

Large bowel peristalsis promptly increases after delivery, and 1–6 stools per day are passed. Absence of stool within 24 hours after birth is indicative of intestinal obstruction or imperforate anus.

RENAL FUNCTION IN THE FETUS & NEWBORN

During uterine growth and development, the placenta serves as the major regulator of fluid and electrolyte balance. Extra-renal mechanisms are unnecessary for fetal growth and development, as demonstrated by the rare neonate born with renal agenesis. The placenta and maternal lungs and kidneys normally maintain fetal fluid and electrolyte balance. When the connection between fetal circulation and the placenta is interrupted during delivery, the kidneys are called on to assume the homeostatic demands of extrauterine life.

The placenta (the major homeostatic organ) receives 40–65% of the fetal cardiac output. Renal blood flow in the fetus is constant when expressed per gram of renal tissue, and renal vascular resistance is maintained at a constant value until birth, renal blood flow increases significantly and renal vascular resistance decreases by about 25%. However, renal blood flow is low and vascular resistance high when compared with adult levels.

The high neonatal vascular resistance may be attributable to increased renal adrenergic activity in the newborn. The neonatal renal vasculature is sensitive to catecholamines, and the kidneys have a high density of high-affinity alpha-adrenergic receptors. At birth, a greater percentage of blood perfuses the deeper cortical nephrons. With maturation, the rise in blood flow to the outer cortical region increases faster than the rise to the inner cortex.

The glomerular filtration rate (GFR) in fetal animals, particularly lambs, increases proportionately with growth (GFR expressed per gram of kidney weight) and rises significantly after birth. Renal blood flow has a similar pattern. Within the first 24 hours of life, measurements of the GFR reflect the status of renal function during intrauterine life; at least a 50% increase is needed for the GFR to adapt to the extrauterine environment. The GFR and renal blood flow follow a similar postnatal course with values more than doubling during the first 2 weeks of life. This is also true in preterm neonates, although at lower levels.

Preterm infants have a negative sodium balance during the first 1–3 weeks of life. The mechanism for sodium loss in premature infants probably involves proximal and distal tubule function. Preterm infants have a lower rate of sodium reabsorption in the proximal tubule than term infants. Newborns also have a limited ability to excrete a salt load when compared with term infants. The functional tubular immaturity of the kidney in newborns is also demonstrated by increased renal excretion of amino acids and by decreased ability to concentrate, dilute, and acidify the urine. A normal serum bicarbonate level in a preterm infant may be as low as 14–16 mmol/L, but this level increases to 21 mmol/L during the first week of life (similar in term newborns). Thus, newborn infants have a limited ability to excrete an acid load as well as a lower capacity to conserve bicarbonate. Preterm infants do not concentrate urine as well as term infants. Most infants do not concentrate urine as adults until 6–12 months of age. Maximal urine osmolality in preterm newborns is 500–600 mOsm/kg water; maximum osmolality is 500–700 mOsm/kg water.

Formation of urine is thought to begin at 9–12 weeks' gestation. By 32 weeks, fetal production of urine approaches that of the term infant, and by term, 28 mL/h. From midgestation, urine is the major component of amniotic fluid. As mentioned before,

amounts of amniotic fluid can provide information on the status of fetal renal function. Oligohydramnios may be renal hypoplasia, dysplasia, or obstructive uropathy. A normal amount of amniotic fluid indicates that there is at least one kidney. Moreover, oligohydramnios is a most clinically useful determinant of hypoxia and asphyxia a Biophysical Profile and the Modified Biophysical Profile. A profound decrease in amniotic fluid may indicate chron decreased urinary output in the stressed state.

Ninety-three percent of all infants, either term or preterm, will void within the first 24 hours of life; 99% will void within 48 hours. Inadequate urine formation by the neonate can be associated with intravascular volume depletion, hypoxia, nephrotic syndrome, tubular necrosis, renal agenesis, bilateral renal arterial or venous thrombosis, or obstructive uropathy. Normal infants may have transient glycosuria or proteinuria and a urine pH of 6.0–7.0.

Ultrasonography allows diagnosis of hydronephrosis prenatally and has stimulated research into therapeutic use of percutaneous urinary aspiration or diversion techniques.

CENTRAL NERVOUS SYSTEM FUNCTION IN THE FETUS & NEWBORN

It has been known for at least a century that the fetus is capable of sustained motor activity well before quicken. At the eighth week of gestation, nearly 95% of responses are contralateral. Ipsilateral responses (torso stimulus) begin to occur with much greater frequency during the ninth week. By 12–13 weeks, local reflexes have almost completely replaced the simple pattern of response. Recent ultrasonographic evaluations have followed motor activity in utero and all confirm a progression from simple whole body movements to complex motor responses. Thus, the sensation of fetal movement is an increasing sensory input to the brainstem.

The cortex begins to develop during the eighth week. The neural maturational events that have been evaluated during transitional periods: (1) a possible consolidation of brainstem influence over motor activity and sensory input near the end of the first trimester, and (2) establishment of the sensory input channel to the neothalamocortical connection around the end of the second trimester. However, it is apparent that the brainstem is only partially developed and functional at term.

The functional development of the human central nervous system is too complex to summarize. Nevertheless, a few correlates must be mentioned. An individual's development neither begins nor ends at birth. Abnormalities in the developing human brain are generally early gestational events induced by genetic factors, teratogens, or infections. Although the major neuronal migrations have formed the cortical plate by 16 weeks' gestation, late migrations from the germinal matrix into the cerebral cortex continue until 5 months postnatally. The external granular layer of the cerebral cortex continues to migrate until age 1 year. Thus, ample opportunity exists for disturbances of these migratory processes during the postnatal period. Moreover, myelination is only rudimentary in the cerebral cortex of term infants. Axons of the pyramidal cells of the motor cortex are myelinated only as far cortically as the cerebral peduncles of the midbrain, as demonstrated by light microscopy, and pyramidal tract axons in the medulla oblongata have only 1 or 2 turns of myelin, as seen by electron microscopy.

Neurologic development not only implies acquisition of perceptual, motor, linguistic, and intellectual skills, but also implies progressive organization of the anatomic and physiologic substrates of those achievements. Formation of the neocortex begins with the embryonic neural plate and terminates with completion of the final myelination cycle in the brainstem (formation of the temporal association bundle at age 32–34 years). It is obvious that there are many things that can interrupt the normal process of neuronal migration, such as a premature infant who suffers a subependymal hemorrhage affecting the radial glial process of a neuron to the surface. The neuron may retract from the cortical surface after its cell origin is destroyed. The neuron is in situ, but the migrating neuron is unable to establish the intended synaptic relations with the cortex. Perhaps the abnormal circuitry of this "incidental finding" at autopsy contributes to the development of an epileptic focus. Another mechanism of prenatal or postnatal cerebral dysgenesis involves toxins that destroy the cytoskeletal elements of glial and neuronal cells (e.g., methylmercury poisoning). Methylmercury chloride abruptly arrests the active movement of migrating neurons in the brain, causes damage to the neural membrane of the growth zone, interferes with DNA synthesis, and ultimately compromises the synthesis of proteins.

Psychiatrists and psychologists have long recognized in utero modifying influences, and Freud stated that "each [fetus] is endowed from the beginning with its own peculiar disposition and tendencies." For example, maternal anxiety level, fetal development, and intrauterine stimuli determine, to a degree, the maturation of nerve cells and structural organization of the developing brain. Maternal emotional stress can have immediate and long-term effects on fetal development, but whether these effects are predictable.

Between 10 and 20 weeks' gestational age, the fetus displays several basic motor patterns that are later integrated into more complex actions. The first jerky patterns of the second trimester become the functional movement patterns that allow the fetus to move about in utero. After midpregnancy, these motor patterns mature in a manner similar to the mature repertoire of movements. Clues to future central nervous system development may be found in the study of these various fetal motor patterns. Progress at various stages seems to indicate subsequent cerebral dysfunction. Real-time ultrasonic examination of fetal motor patterns may lead to improved care in high-risk situations.

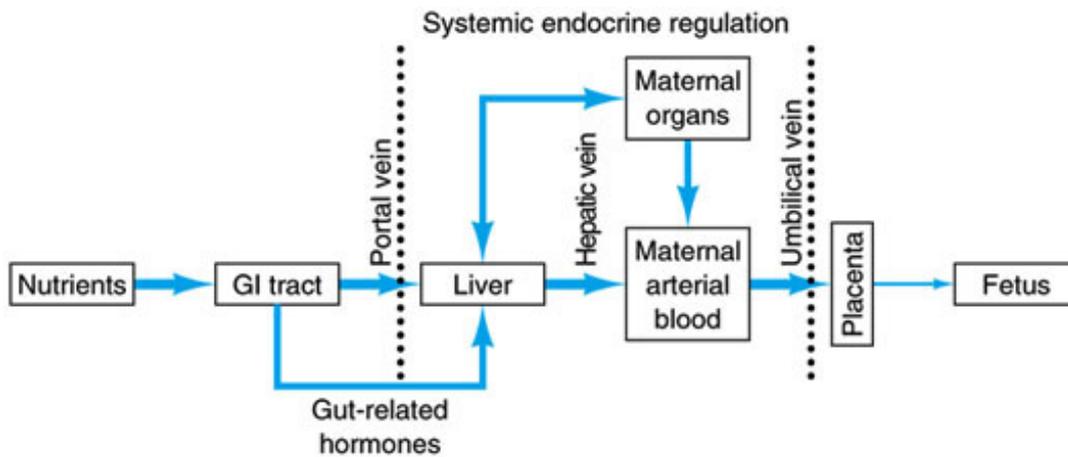

The fetus demonstrates various sleep-wake patterns throughout its development in utero. During most of its early development, electrocortical activity is of low voltage, associated with REMs, slow heart rate, and fetal breathing activity. In the first trimester, high-voltage activity is associated with more-lively activity. Finally, near term, the fetus appears to be awake 30% of the time. These fetal states may be discerned by ultrasonic study of eye movements, which may be altered by maternal anxiety levels. These, in turn, affect fetal heart rate responses to stress.

The term fetus has high endorphin levels that may modify the behavioral state, including heart rate responses. High endorphin levels may be responsible for the primary apnea of the newborn and for the lack of heart rate reactivity in other intrapartum fetuses. The fetus probably suffers pain, as does any other individual, and high endorphin levels may have other effects of stress. The near-term fetus, then, has nearly all the neurologic attributes of the newborn infant.

INTRAUTERINE NUTRITION

Maternal diet among mammals is incredibly varied. For instance, the female black bear hibernates during her pregnancy and she supplies metabolites to her fetus while neither eating nor drinking. In contrast, the pregnant guinea pig eats and drinks. Obviously, forced fasting may have different effects on these different species during pregnancy. As shown in Figure 8-8, maternal and placental modifications of nutrients occur before the nutrients reach the fetus. The mother and the placenta are the first priority in use of these nutrients. Although vitamin B₁₂ accumulates in greater concentrations in fetal blood than in maternal blood, the placental release of most vitamins to the fetus seems to depend on the degree of saturation of the vitamins in the placenta. Because these nutrient-modifying factors differ markedly in different species, it is hazardous to extrapolate from laboratory animals to humans. The human newborn is 16% fat. Normally, the human fetus has a large accumulation of high-calorie fat, which during the last few weeks of gestation represents more than 80% of the fetal caloric accretion. The two components of fetal caloric intake: the building-block, or accretion, component and the growth, or heat production, component. Starvation and protein-turnover studies suggest that the fetus uses calories primarily for maintenance and growth.

Figure 8–8.

Schematic diagram showing the pathway of nutrients in the mother as they are broken down into different concentrations in the maternal portal vein and, finally, the umbilical vein.

(Modified and reproduced, with permission, from Battaglia FC: The comparative physiology of fetal nutrition. *Am J Gynecol* 1984; 148:850.)

In pregnant sheep at term (pregnancy in sheep and humans is comparable in terms of relative fetal/maternal weight), one-third of the maternal glucose is used by the uterus; of this amount, two-thirds is consumed by the uteroplacenta and only one-third by the fetus. In sheep, the placenta rather than the fetus is clearly the primary intrauterine glucose consumer. This large glucose uptake by the placenta is partially explained by its high rate of lactate production. Laboratory studies have shown that when the human fetus is well oxygenated, the umbilical arterial lactate concentration and the umbilical lactate gradient are positive, indicating that lactate is also an important nutrient for the human fetus.

Ammonia is another compound produced in large quantities by the placenta and, like lactate, is released into the maternal circulation. In humans, ketones and free fatty acids play a large role in fetal nutrition. The fetus actively synthesizes lipids in the liver, brain, and lung, which have special requirements for myelin and surfactant. Although fatty acids can cross the placenta, their oxidation does not seem to add much to the total energy economy of the fetus. The fetus uses protein for oxidative metabolism. The metabolism of the human brain is very active during the perinatal period. The brain is an obligatory consumer of glucose. Ketone bodies may partially replace glucose during periods of hypoglycemia and also be a source of carbon for central nervous system lipids and proteins.

The placenta transports more water than any other substance. Because maternal hydrostatic and serum colloid osmotic pressures vary significantly during a normal day, unknown placental mechanisms protect the fetus against rapid fluid shifts which could cause either hydrops or dehydration. It may be that placental water transport is a passive process rather than active solute transfer, as in the intestine.

The most widely recognized fetal hormone known to modify the rate of fetal growth is insulin. Fetuses with an absence of fetal growth hormone, thyroxine, adrenocortical steroids, or sex steroids achieve normal growth. Inasmuch as maternal insulin is not transferred to the fetus in physiologic quantities, the fetal pancreas secretes sufficient insulin for the oxidation of glucose. Under the stimulus of recurring hyperglycemia—as with maternal diabetes mellitus—the B cells of the fetal pancreas may become hyperplastic and secrete larger quantities of insulin.

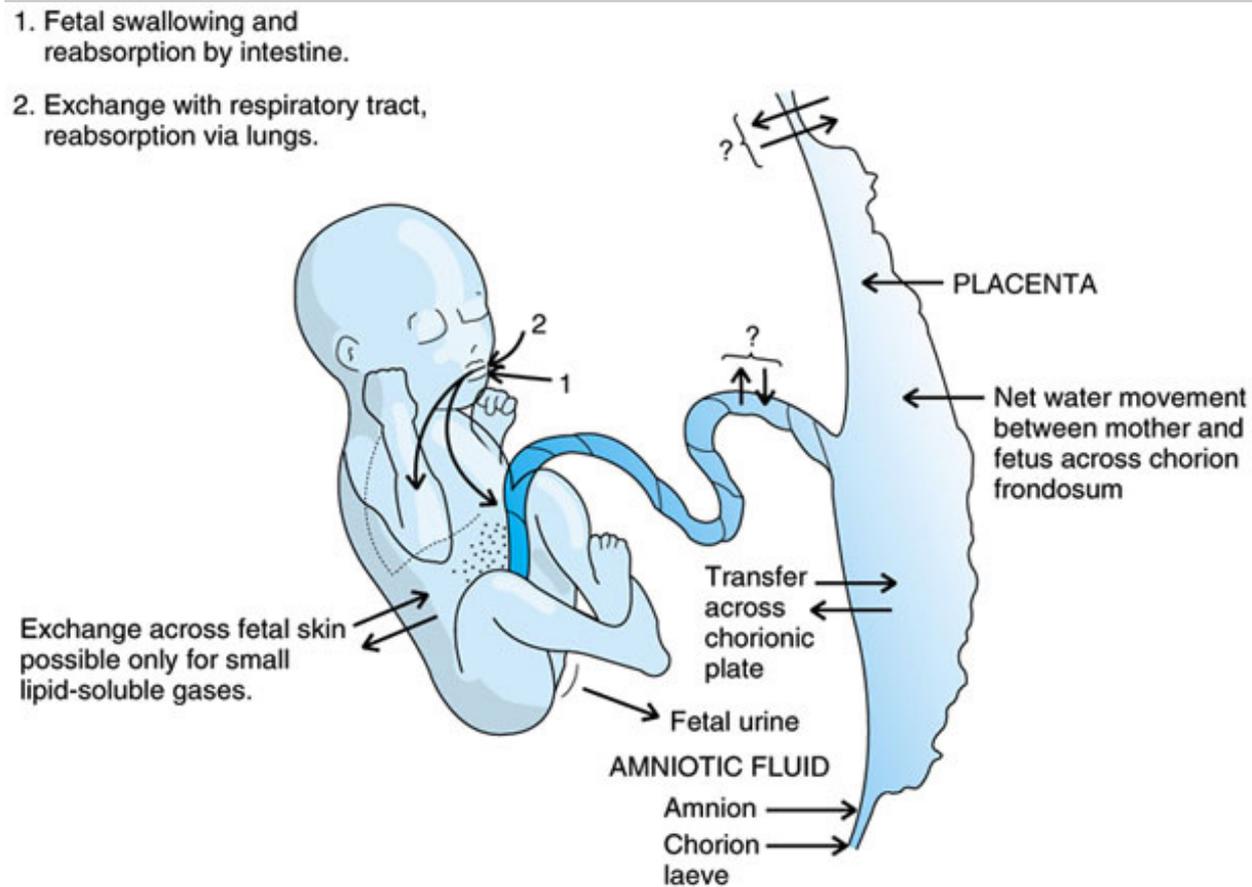

THE AMNIOTIC FLUID

There is a vital need for a nonrestricting intrauterine environment, which develops before the fetus. This environment must be ensured if it is part of the development of the fetus. Every fetus is surrounded by a protective cushion of amniotic fluid, whether the fetus develops inside the mother as a viviparous species or in an egg. In the first half of pregnancy,

volume appears to increase in association with growth of the fetus, and the correlation between fetal weight and very close. The serum osmolality and sodium, urea, and creatinine content of maternal serum and amniotic fluid significantly different. This suggests that amniotic fluid is an ultrafiltrate of maternal serum. Ultrasonographic evidence in the first half of pregnancy reveals that the fetus does empty its bladder during the first half of gestation.

The average volume of amniotic fluid at term is 800 mL, and the sodium concentration is fairly constant. The volume and sodium concentration remain the same despite the fact that a normal fetus will swallow some of the fluid and void in urine, which concentrates sodium. Analysis of amniotic fluid provides unique information about the fetus. In the second half of pregnancy, amniotic fluid appears to maintain the extracellular fluid chemistry of the fetus. In the second half, it reflects the development of renal function and, by virtue of the cells it sheds, the morphologic development of skin membranes. Amniotic fluid has a low specific gravity (1.008) and a pH of 7.2. Pathways of solute and water exchange across amniotic fluid are shown in Fig 8–9.

Figure 8–9.

Solute and water exchange in amniotic fluid.

In the past decade, morphologic chromosomal abnormalities and more than 100 inborn errors of metabolism have been identified. The amniotic fluid collects cells shed from the skin, amnion, and gastrointestinal and genitourinary tract. Fluid obtained by amniocentesis at about 16 weeks, 30–80% of these cells are usually alive. Recent cytotechnology may allow karyotyping from amniotic fluid as early as 11 weeks of gestation. The total number of cells increases with gestation, but the proportion of viable cells does not increase, and at about 24 weeks, only 10–15% of the total cells are viable. The live cells are induced to adhere to the bottom of a tissue culture vessel after 3–4 days in culture and develop either an epithelial or fibroblastic morphology. The cells eventually form a monolayer, and when introduced

suitable culture medium (containing nutrients and supplied with serum) are induced to divide. The dividing cells are arrested in metaphase with colchicine to prevent formation of the mitotic spindle. The advantage of this method is that a number of slides can be prepared, so that specific stain methods can be used and the chromosome preparation can be banded satisfactorily.

There is no simple or accurate method currently available to measure amniotic fluid volume. Oligohydramnios is defined as the presence of some abnormality. Polyhydramnios may occur in normal pregnancy but is also often associated with some abnormality of mother or fetus.

Oligohydramnios may be more objectively determined by identification of the largest pocket of fluid measuring less than 2 cm or the total of 4 quadrants less than 5 cm. However, this definition is associated with many false-positive and false-negative readings.

Oligohydramnios is associated with an SGA fetus, renal tract abnormalities such as renal agenesis, and urinary tract anomalies. The clinical manifestation of oligohydramnios is a direct result of the impairment of urine flow to the amniotic fluid during part of the first half of pregnancy or during the second and third trimesters.

Amniotic fluid inhibits bacterial growth; the phosphate to zinc ratio is a predictor of inhibitory activity. In cases of amniotic fluid infection, "inorganic phosphorus" levels in amniotic fluid are often elevated.

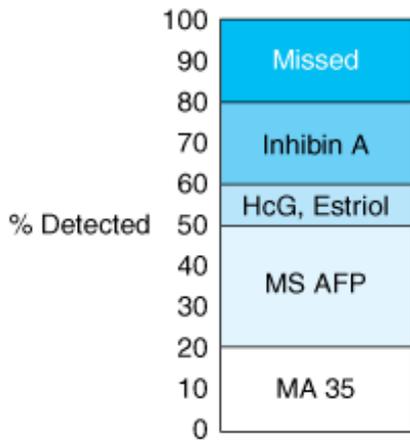

Amniotic Fluid Markers

Alpha-fetoprotein (AFP) is of fetal origin, and concentrations in amniotic fluid and maternal serum are of value in the diagnosis of neural tube defects and other fetal malformations. Fetal serum contains AFP in a concentration 100 times that of maternal serum. High levels of maternal serum AFP are associated with an elevated level of amniotic fluid protein. The subsequent findings of open neural tube defects.

In neural tube defects where there is an open lesion (even when covered with a membrane) in the spinal canal, cerebrospinal fluid passes into the amniotic fluid. A suitable neural marker to determine whether cerebrospinal fluid has entered the amniotic fluid would be a protein of molecular size so large that it would not normally be excreted in the urine. The enzyme acetylcholinesterase has a molecular weight on the order of 300,000. Acetylcholinesterase levels in amniotic fluid appear to be more specific than the AFP test in predicting neural tube defects.

The clinical importance of low levels of AFP in maternal serum has also been recognized. Low levels of AFP in conjunction with low levels of estriol and comparatively high levels of hCG (roughly twice normal for given gestational age) have been shown to be diagnostic for Down syndrome. As an illustration, if one assumes a base rate of diagnostic amniocentesis of 5% (the appropriate proportion of pregnancies occurring beyond age 35), the likelihood of detecting Down syndrome using only maternal serum screening as a risk factor would be only 30%. However, if amniocentesis were to be performed on the basis of age, AFP, and estriol levels, the yield would rise to almost 60%. Down syndrome is the most common congenital cause of severe mental retardation occurring with an incidence of about 1.3 per 1000 live births. Advanced maternal age is the most common consideration in selecting women for diagnostic amniocentesis. This policy derives from the fact that the risk of Down syndrome increases with advancing maternal age. The greatly improved detection rate (Fig 8–10) afforded by combining serum screening with amniocentesis is fast establishing this method as the screening test of choice in many centers throughout the world.

Figure 8–10.

Copyright ©2006 by The McGraw-Hill Companies, Inc.
All rights reserved.

Maternal age 35 (MA 35) identifies about 20% of Down syndrome pregnancies. Low alpha fetoprotein (AFP) brings that number to about 50%. Double or triple screening (for HcG or estriol) raises that number to about 60% of the total and quadruple screening (including inhibin A) brings that number of identified cases to 80%, which is over half of those occurring in women age 35. MS = maternal serum.

Some proteins enter the amniotic fluid by transudation of placental components, but they also enter from other sources including maternal uterine decidua; fetal skin; amnion; chorion; the umbilical cord; amniotic fluid cells; fetal urine; and fetal nasopharyngeal, oral, and lacrimal secretions. It is assumed that the relative contribution of these tissues varies during pregnancy. The major proportion of soluble proteins in amniotic fluid between 10 weeks' gestation and term is (1) of serum type and (2) of maternal origin entering the fluid by diffusing through the chorion. The observed concentration gradient for AFP between fetal serum and amniotic fluid should not be taken to imply that the presence of α -fetoprotein in amniotic fluid is explained largely by permeation. Indeed, the concentration of AFP in fetal urine during the second trimester is comparable with levels of AFP in amniotic fluid at this time.

The amniotic fluid serves a number of important functions besides being a valuable source for analysis of fetal tissue. It cushions the fetus against severe injury; provides a medium in which the fetus can move easily; may be a source of nutrients; and, in early pregnancy, is essential for fetal lung development. The amniotic fluid is continuously exchanged at a rapid rate. Indeed, it is possible, at least on a temporary basis, to increase amniotic fluid volume by rapid expansion of plasma volume with an intravenous infusion of colloid fluid such as 5% albumin. After 34–36 weeks, determining amniotic fluid volume becomes even more complicated because the larger fetus swallows more fluid, upsetting the relationship between fetal size and fluid volume. After 38 weeks, both amniotic fluid and maternal plasma volume decrease. These relationships are even more apparent in postmature pregnancy.

Studies have shown that the fetus near term drinks 400–500 mL of amniotic fluid per day; this is about the same volume of milk consumed by a newborn infant. To maintain a reasonable stability of volume, the fetus must excrete about the same volume of urine into the amniotic fluid each day.

During late pregnancy, the amniotic fluid contains increasing quantities of particulate material, including desquamated fetal origin; lanugo and scalp hairs; vernix caseosa; a few leukocytes; and small quantities of albumin, urates, and inorganic salts. The calcium content of amniotic fluid is low (5.5 mg/dL), but the electrolyte concentration is equivalent to that of maternal plasma. As mentioned previously, meconium is ordinarily absent but is excreted by the fetus in response to vagal activity.

Current OB/GYN >Chapter 9. Normal Pregnancy & Prenatal Care>Normal Pregnancy>

NORMAL PREGNANCY: INTRODUCTION

Pregnancy (gestation) is the maternal condition of having a developing fetus in the body. The human conceptus from fertilization through the eighth week of pregnancy is termed an embryo; from the eighth week until delivery it is a fetus. For obstetric purposes, the duration of pregnancy is based on gestational age: the estimated age the fetus is calculated from the first day of the last (normal) menstrual period (LMP), assuming a 28-day cycle. Gestational age is expressed in completed weeks. This is in contrast to developmental age (fetal age), which is the age of the offspring calculated from the time of implantation.

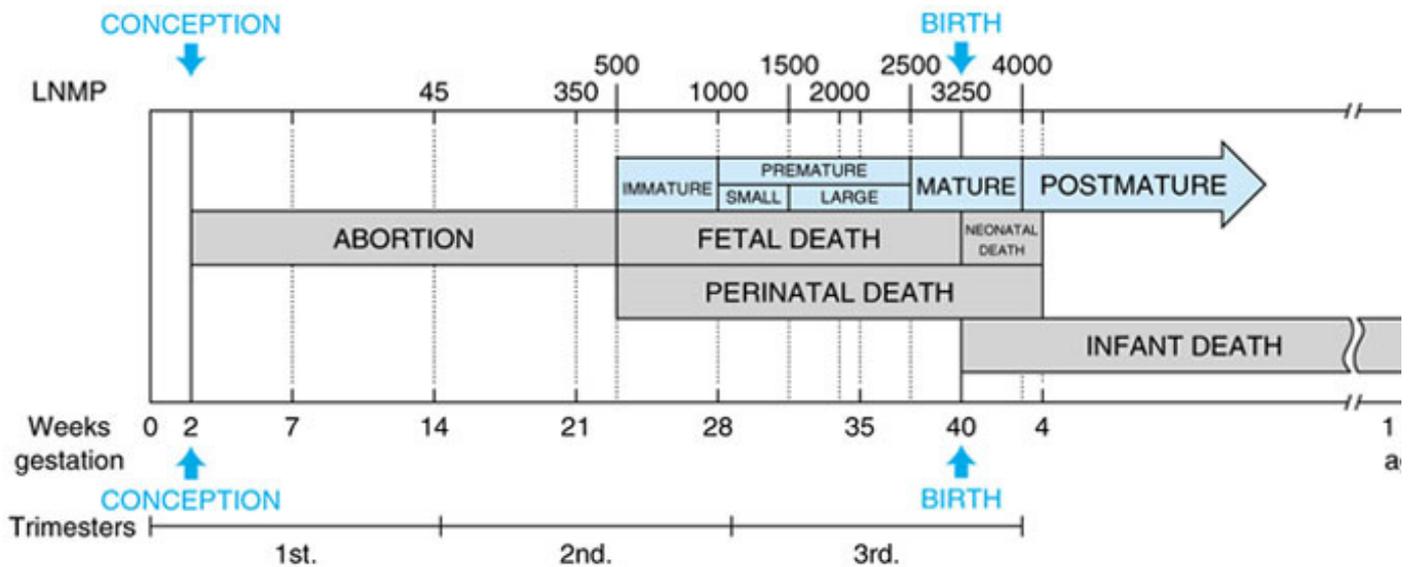

The term gravid means pregnant, and gravidity is the total number of pregnancies (normal or abnormal). Parity is the state of having given birth to an infant or infants weighing 500 g or more, alive or dead. In the absence of known weight, an estimated duration of gestation of 20 completed weeks or more (calculated from the first day of the LMP) may be used. From a practical clinical viewpoint, a fetus is considered viable when it has reached a gestational age of 23–24 weeks and a weight of 500–600 g or more. However, only very rarely will a fetus of 20–23 weeks weighing 500 g or less survive, even with optimal care. With regard to parity, a multiple birth is a single parous experience.

Live Birth

Live birth is the complete expulsion or extraction of a product of conception from the mother, regardless of the duration of pregnancy, which, after such separation, breathes or shows other evidence of life (e.g., beating of the heart, pulsation of the umbilical cord, or definite movements of the involuntary muscles) whether or not the cord has been cut or the placenta detached. An infant is a live-born individual from the moment of birth until the completion of 1 year of life.

In the most recent nomenclature, a preterm infant is defined as one born prior to the 37th week of gestation (259 days). Unfortunately, for purposes of evaluating statistical data, this definition does not specify that there are great differences among fetuses in this group. Therefore, it is useful to preserve the classification by weight or duration of gestation still used by many (Fig 9–1). Using the latter system, an abortion is the expulsion or extraction of all (complete) or any part (incomplete) of the placenta or membranes, without an identifiable fetus with a fetus (alive or dead) weighing less than 500 g. In the absence of known weight, an estimated duration of gestation of under 20 completed weeks (139 days) calculated from the first day of the LMP may be used.

Figure 9–1.

Copyright ©2006 by The McGraw-Hill Companies, Inc.

Graphic display of perinatal nomenclature.

An immature infant weighs 500–1000 g and has completed 20 to less than 28 weeks of gestation. A premature infant is one with a birthweight of 1000–2500 g and a duration of gestation of 28 to less than 37 weeks. A low birthweight infant is any live-born infant weighing 2500 g or less at birth. An undergrown or small-for-gestational-age infant is one who is significantly undersized (< 2 SD) for the period of gestation. A mature infant is a live-born infant who has completed 37 weeks of gestation (and usually weighs more than 2500 g). A postmature infant is one who has completed 42 weeks or more of gestation. The postmaturity syndrome is characterized by prolonged gestation, sometimes an excessive-size fetus (see Large-for-Gestational-Age Pregnancy in Chapter 16), and diminished placental capacity for sufficient exchange, associated with cutaneous and nutritional changes in the newborn infant.

Significantly increased morbidity and mortality rates may be associated with the relative dystocia created by the large fetus. Approximately 10% of newborn infants weigh more than 4000 g and 1.5% of infants weigh in excess of 4500 g. With better nutrition and heavier infants, there has not been a commensurate increase in maternal pelvic dimensions. Excessive fetal size should be suspected in women who have previously delivered a large baby and in those with diabetes mellitus.

Predicting the end of pregnancy constitutes a major problem of perinatal care. The factors that lead to the initiation of labor and the subsequent termination of pregnancy remain unknown. This is the case for both preterm and postterm deliveries. A prolonged pregnancy (postterm) has traditionally been defined as gestation that has advanced 2 weeks past the due date (294 days). Because the perinatal mortality rate increases dramatically as gestation advances past the due date and because the cesarean rate is not increased with induction at 41 weeks it is now common practice to offer induction of labor to all women at 7 days past the due date.

Birth Rate & Fertility Rate

Birth rate is commonly expressed in terms of the number of live births per 1000 population. The fertility rate expressed as the number of live births per 1000 women ages 15–44 years and is thus a more sensitive measure of the reproductive activity of a given population. There were an estimated 4,115,590 live births in the United States in 2004. The birth rate is currently 14.0 per 1000 total population, which is slightly increased compared to its rate of 13.9 in 2002. The general fertility rate is currently 66.3 births per 1000 women aged 15–44. Indeed, the fertility rate appears to have peaked in 1990 at 71.1, after having been 67.1 in 1988.*

* These data are provisional and are from *National Vital Statistics Report* v54 #8, the preeminent source of data concerning births, marriages, divorces, and deaths. It is available on a monthly basis from the National Center for Health Statistics (Centers for Disease Control, Public Health Service), U.S. Department of Health and Human Services.

Neonatal Interval

The neonatal interval is from birth until 28 days of life. During this interval, the infant is referred to as a newborn. The interval may be divided into 3 periods:

Neonatal period I: birth through 23 hours, 59 minutes.

Neonatal period II: 24 hours of life through 6 days, 23 hours, 59 minutes.

Neonatal period III: seventh day of life through 27 days, 23 hours, 59 minutes.

Perinatal Period

The perinatal period is the time from 28 weeks of completed gestation to the first 7 days of life, spanning the fetal and early neonatal interval.

Perinatal Mortality Rates

Jeopardy to life is greatest during the perinatal period than at any subsequent time. Current data indicate that the number of lives lost during the 5-month period from the 20th week of gestation to the 7th day after birth is almost equal to the number lost during the next 40 years of life. One half of these deaths occur *in utero*. In addition, 70% of deaths occurring in the first year of life will occur in the first 28 days of life (the neonatal period). Thus if one adds the neonatal loss rate to the fetal loss rate, it is the period of greatest threat to life for a given interval. There are gender and racial differences in mortality rates; the pertinent data are available through the *Monthly Vital Statistics Report*.

There are many causes of death during the perinatal period. The relative importance of each can only be assessed in the context of overall mortality rates and appraisal of those factors that present the greatest hazard to the fetus and infant.

DIAGNOSIS

The diagnosis of pregnancy is usually made on the basis of a history of amenorrhea and a positive pregnancy test. Nausea and breast tenderness are also often present. It may be crucial to diagnose pregnancy before the first missed menstrual period to prevent exposure of the fetus to hazardous substances (e.g., x-rays, teratogenic drugs), to manage ectopic or nonviable pregnancies, and to provide better health care for the mother.

The manifestations of pregnancy are classified into three groups: presumptive, probable, and positive.

Presumptive Manifestations

SYMPTOMS

Amenorrhea

Cessation of menses is caused by increasing estrogen and progesterone levels produced by the corpus luteum. Thus, amenorrhea is a fairly reliable sign of conception in women with regular menstrual cycles. In women with irregular cycles, amenorrhea is not a reliable sign. Delayed menses may also be caused by other factors such as emotional tension, chronic disease, opioid and dopaminergic medications, endocrine disorders, and certain genitourinary tumors. Spotting caused by bleeding at the implantation site may occur from the time of implantation (about 6 days after fertilization) until 29–35 days after the LMP in many women. Some women have unexplained cyclic bleeding throughout pregnancy.

Nausea and Vomiting

This common symptom occurs in approximately 50% of pregnancies and is most marked at 2–12 weeks' gestation. It is usually most severe in the morning but can occur at any time and may be precipitated by cooking odors and pungent smells. Extreme nausea and vomiting may be a sign of multiple gestation or molar pregnancy. Protracted vomiting associated with dehydration and ketonuria (hyperemesis gravidarum) may require hospitalization and relief of symptoms with antiemetic therapy.

Treatment for uncomplicated nausea consists of light, dry foods, small, frequent meals, and emotional support. Some improvement can be seen with the addition of high-dose vitamin B₆ therapy and the preconceptional use of prenatal vitamins. Antiemetic medications and alternative therapies, such as acupuncture or ginger, are used for women whose symptoms interfere with daily life. The nausea is probably related to rapidly rising serum levels of human chorionic gonadotropin (hCG), although the mechanism is not understood.

Breasts

MASTODYNIA

Mastodynia, or breast tenderness, may range from tingling to frank pain caused by hormonal responses of the mammary ducts and alveolar system. Circulatory increases result in breast engorgement and venous prominence. Similar tenderness may occur just before menses.

ENLARGEMENT OF CIRCUMLACTEAL SEBACEOUS GLANDS OF THE AREOLA (MONTGOMERY'S TUBERCLES)

Enlargement of these glands occurs at 6–8 weeks' gestation and is a result of hormonal stimulation.

COLOSTRUM SECRETION

Colostrum secretion may begin after 16 weeks' gestation.

SECONDARY BREASTS

Secondary breasts may become more prominent both in size and in coloration. These occur along the nipple line. Hypertrophy of axillary breast tissue often causes a symptomatic lump in the axilla.

Quickening

The first perception of fetal movement occurs at 18–20 weeks in primigravidas and at 14–16 weeks in multigravidas. Intestinal peristalsis may be mistaken for fetal movement; therefore, perceived fetal movement alone is not a reliable symptom of pregnancy, although it may be useful in determining the duration of pregnancy.

Urinary Tract

BLADDER IRRITABILITY, FREQUENCY, AND NOCTURIA

These conditions occur because of increased bladder circulation and pressure from the enlarging uterus.

URINARY TRACT INFECTION

Urinary tract infection must always be ruled out because pregnant women are more likely than nonpregnant women to have significant bacteriuria which may be asymptomatic (7% versus 3%). Asymptomatic bacteriuria can also lead to pyelonephritis, which is associated with miscarriage, preterm birth, and intrauterine fetal demise.

SIGNS

Increased Basal Body Temperature

Persistent elevation of basal body temperature over a 3-week period usually indicates pregnancy if temperatures have been carefully charted.

Skin

CHLOASMA

Chloasma, or the mask of pregnancy, is darkening of the skin over the forehead, bridge of the nose, or cheekbones and is most marked in those with dark complexions. It usually occurs after 16 weeks' gestation and is intensified by exposure to sunlight.

LINEA NIGRA

Linea nigra is darkening of the nipples and lower midline of the abdomen from the umbilicus to the pubis.

(darkening of the linea alba). The basis of these changes is stimulation of the melanophores by an increase in melanocyte-stimulating hormone.

STRETCH MARKS

Stretch marks, or striae of the breast and abdomen, are caused by separation of the underlying collagen tissue and appear as irregular scars. This is probably an adrenocorticosteroid response. These marks generally appear later in pregnancy when the skin is under greater tension.

SPIDER TELANGIECTASES

Spider telangiectases are common skin lesions that result from high levels of circulating estrogen. These vascular stellate marks blanch when compressed. Palmar erythema is often an associated sign. Both of these signs are also seen in patients with liver failure.

Probable Manifestations

SYMPTOMS

Symptoms are the same as those discussed under Presumptive Manifestations, above.

SIGNS

Pelvic Organs

Many changes in the pelvic organs are perceivable to the experienced physician, including the following.

CHADWICK'S SIGN

Congestion of the pelvic vasculature causes bluish or purplish discoloration of the vagina and cervix.

LEUKORRHEA

An increase in vaginal discharge consisting of epithelial cells and cervical mucus is due to hormone stimulation. Cervical mucus that has been spread on a glass slide and allowed to dry no longer forms a fernlike pattern but has a granular appearance.

HEGAR'S SIGN

This is widening of the softened area of the isthmus, resulting in compressibility of the isthmus on bimanual examination. This occurs by 6–8 weeks.

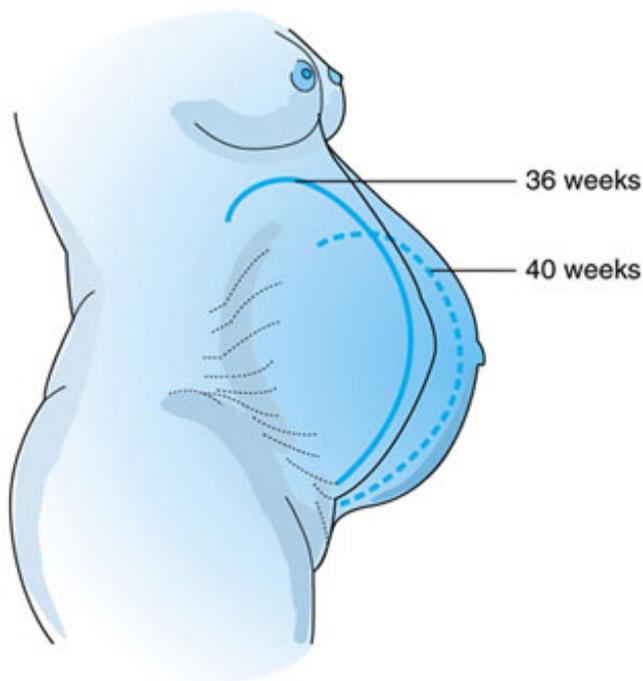

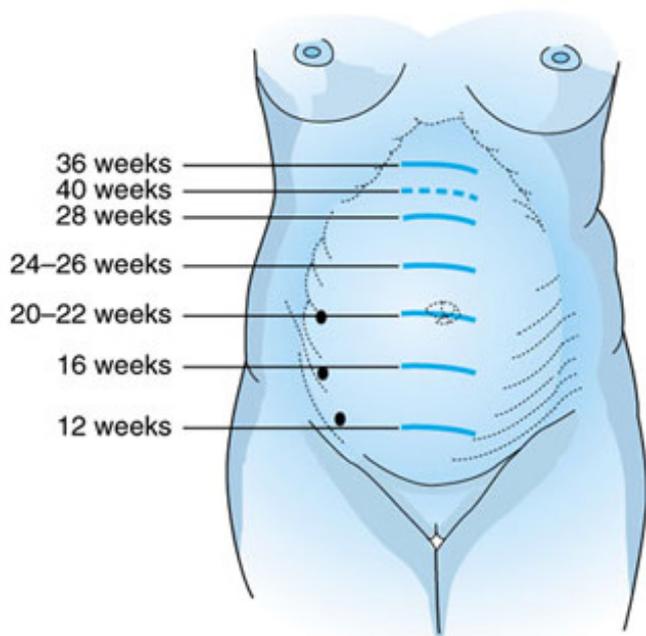

BONES AND LIGAMENTS OF PELVIS

The bony and ligamentous structures of the pelvis also change during pregnancy. There is slight but definite relaxation of the joints. Relaxation is most pronounced at the pubic symphysis, which may separate to an astonishing degree.

Abdominal Enlargement

There is progressive abdominal enlargement from 7–28 weeks. At 16–22 weeks, growth may appear more rapid as the uterus rises out of the pelvis and into the abdomen (Fig 9–2).

Figure 9–2.

All rights reserved.

Height of fundus at various times during pregnancy.

Uterine Contractions

As the uterus enlarges, it becomes globular and often rotates to the right. Painless uterine contractions (Braxton-Hicks contractions) are felt as tightening or pressure. They usually begin at about 28 weeks' gestation and increase in regularity. These contractions usually disappear with walking or exercise, whereas true labor contractions become more intense.

Positive Manifestations

The various signs and symptoms of pregnancy are often reliable, but none is diagnostic. A positive diagnosis mu

be made on objective findings, many of which are not produced until after the first trimester. However, more methods are becoming available to diagnose pregnancy at an early stage.

FETAL HEART TONES (FHTS)

It is possible to detect FHT by hand held Doppler as early as 10 weeks' gestation. The normal fetal heart rate is 120–160 beats per minute. It may be detected by fetoscope by 18–20 weeks' gestation, although this device is rarely used at present.

PALPATION OF FETUS

After 22 weeks, the fetal outline can be palpated through the maternal abdominal wall. Fetal movements may be palpated after 18 weeks. This may be more easily accomplished by a vaginal examination.

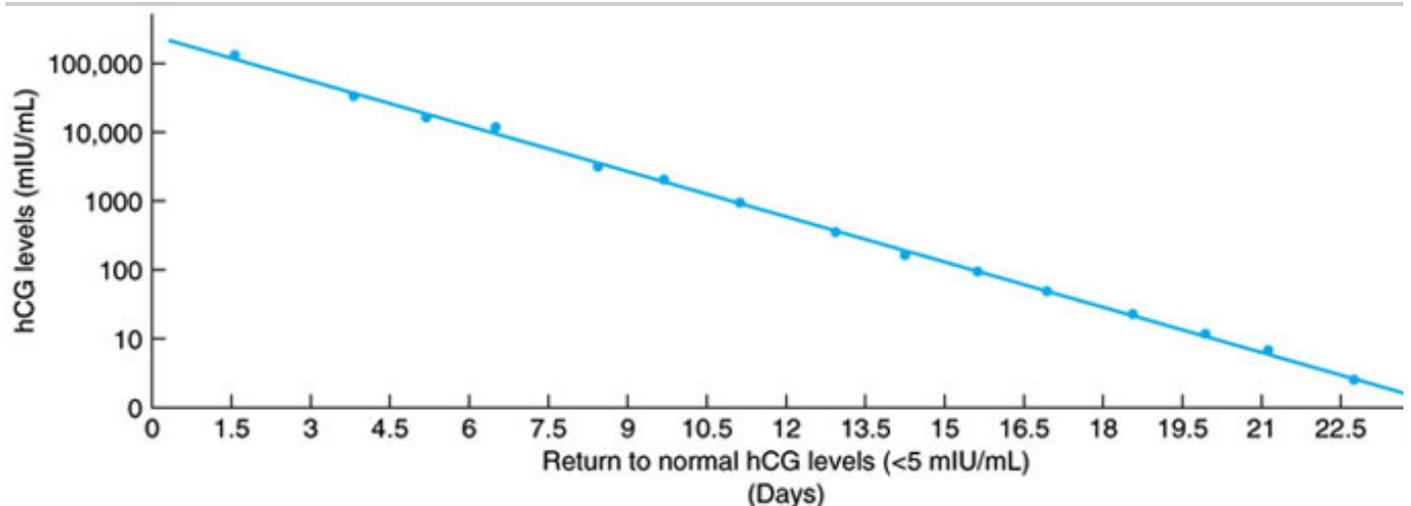

ULTRASOUND EXAMINATION OF FETUS

Sonography is one of the most useful technical aids in diagnosing and monitoring pregnancy. Cardiac activity is discernible at 5–6 weeks, limb buds at 7–8 weeks, and finger and limb movements at 9–10 weeks. At the end of the embryonic period (10 weeks by LMP), the embryo has a human appearance. Fetal well-being can be monitored by ultrasound as the pregnancy progresses.

Pregnancy Tests

Sensitive, early pregnancy tests measure changes in levels of hCG. There is less cross-reaction with luteinizing hormone (LH), follicle stimulating hormone (FSH), and thyrotropin, which all share a common α subunit with hCG when the β subunit of hCG is measured. hCG is produced by the syncytiotrophoblast 8 days after fertilization and may be detected in the maternal serum after implantation occurs, 8–11 days after conception. hCG levels peak at approximately 10–12 weeks of gestation. Levels gradually decrease in the second and third trimesters and increase slightly after 34 weeks. The half-life of hCG is 1.5 days (Fig 9–3). After termination of pregnancy, levels drop exponentially. Normally, serum and urine hCG levels return to nonpregnant values (< 5 mIU/mL) 21–24 days after delivery.

Figure 9–3.

Copyright ©2006 by The McGraw-Hill Companies, Inc.
All rights reserved.

Regression of hCG following delivery, assuming a 1.5-day half-life.

URINE PREGNANCY TEST

This is the most common method used to confirm pregnancy. Using antibodies, the test identifies the β subunit of hCG, minimizing cross-reaction with similarly structured hormones. The test is affordable, reliable and fast (1–5

minutes to obtain results) tool to diagnose pregnancy in the office. The urine pregnancy test is qualitative—positive or negative, based on color change, with the level of hCG detection ranging between 5 and mIU/mL, depending on the kit used.

HOME PREGNANCY TESTS

hCG is detected in a first-voided morning urine sample. A positive test is indicated by a color change or confirmation mark in the test well. Because the accuracy of the home pregnancy test depends on technique and interpretation, it should always be repeated in the office.

SERUM PREGNANCY TEST

hCG can be detected in the serum as early as a week after conception. The serum pregnancy test can be quantitative or qualitative with a threshold as low as 2–4 mIU/mL, depending on the technique used. The serum pregnancy test is a reliable method to diagnose an early pregnancy; it is widely used in the evaluation of threatened abortion, ectopic pregnancy, and other conditions.

CALCULATION OF GESTATIONAL AGE & ESTIMATED DATE OF DELIVERY

After the diagnosis of pregnancy is made, it is imperative to determine the duration of pregnancy and the estimated date of confinement (EDC).

Calculation of Gestational Age

PREGNANCY CALENDAR OR CALCULATOR

Normally, human pregnancy lasts 280 days or 40 weeks (9 calendar months or 10 lunar months) from the last normal menstrual period (LNMP). This may also be calculated as 266 days or 38 weeks from the last ovulation in a normal 28-day cycle. The easiest method of determining gestational age is with a pregnancy calendar or calculator. The estimated date of delivery (EDD) can be determined mathematically using Ngele's rule: subtract months from the month of the LNMP, and add 7 to the first day of the LNMP. Example: With an LNMP of July 14, the EDC is April 21.

CLINICAL PARAMETERS OF GESTATIONAL AGE

Ultrasonography

Ultrasonography is now the most widely used technique for determination of gestational age. Fetal crown to rump length can be measured at 5–13 weeks and is the most accurate means to determine gestational age. Beyond 13 weeks, measurement of fetal biparietal diameter is used in conjunction with the femur length and abdominal circumference to assess gestational age and/or interval fetal growth. Beyond 30 weeks, the accuracy of gestational age assessment by ultrasound is much less.

Ultrasound is used to measure fetal growth parameters, to estimate fetal weight, to assess fetal anatomy, and to measure amniotic fluid volume. Fetal well-being can also be evaluated by measuring biophysical characteristics.

Uterine Size

An early first-trimester examination usually correlates well with the estimated gestational age. The uterus is palpable just at the pubic symphysis at 8 weeks. At 12 weeks, the uterus becomes an abdominal organ and at 16 weeks is usually at the midpoint between the pubic symphysis and the umbilicus. The uterus is palpable at 20 weeks at the umbilicus. Fundal height (determined by measuring the distance in centimeters from the pubic symphysis to the curvature of the fundus) correlates roughly with the estimated gestational age at 26–34 weeks (Fig 9–2). After 36 weeks, the fundal height may decrease as the fetal head descends into the pelvis.

Quickening

The first fetal movement is usually appreciated at 17 weeks in the average multipara and at 18 weeks in the average primipara.

Fetal Heart Tones

FHTs may be heard by fetoscope at 20 weeks, whereas Doppler ultrasound usually detects heart rates by 10 weeks.

DIAGNOSIS OF PREGNANCY AT TERM

A term fetus has reached a stage of development that will allow the best chance for extrauterine survival (37–40 weeks). Whether a fetus has reached this stage can be determined by the methods outlined above for ascertain fetal age and EDD.

At term, a fetus usually weighs more than 2500 g. Depending on maternal factors such as obesity and diabetes, amniotic fluid volume, and genetic and racial factors, the baby may be larger or smaller than expected; therefore the clinician must rely on objective data to determine fetal maturity.

Amniotic Fluid Analysis

The most accurate test of fetal maturity is analysis of amniotic fluid obtained by amniocentesis. This is discussed in Chapter 13.

Ultrasonography

Early ultrasound examination is the most accurate means of determining gestational age and indirectly confirming maturity. Because of the variation in late-pregnancy ultrasound parameters, they are not helpful in confirming maturity.

DIAGNOSIS OF FETAL DEATH

The accepted method of diagnosing pregnancy failure early is ultrasound.

Early in pregnancy, failure to visualize a fetal pole with cardiac activity at the appropriate gestational age suggests fetal death. Serial measurements of serum β -hCG may be helpful when the ultrasound findings are equivocal.

In late pregnancy, the first sign of fetal death is usually absence of fetal movement noted by the mother. This is followed by absence of FHTs. Real-time ultrasonography is virtually 100% accurate in determining the absence of fetal heart motion.

Hypofibrinogenemia may rarely develop 4–5 weeks after fetal death as thromboplastic substances are released from the degenerating products of conception. Coagulation studies should be started 2 weeks after intrauterine death, and delivery should be attempted by 4 weeks or if serum fibrinogen falls below 200 mg/mL. This is only clinically applicable in the case of death of one of twins; otherwise, the singleton demise would be delivered promptly.

PRENATAL CARE: INTRODUCTION

Prenatal care as we know it today is a relatively new development in medicine. It originated in Boston in the first decade of the 20th century. Before that time, the patient who thought she was pregnant may have visited a physician for confirmation but did not visit again until delivery was imminent. The nurses of the Instructive Nurses Association in Boston, thinking they might contribute to the health of pregnant mothers, began making house calls on all mothers registered for delivery at the Boston Lying-In Hospital. These visits were so successful that the principle behind them was gradually accepted by physicians, and our present system of prenatal care, which stresses prevention, evolved.

Pregnancy is a normal physiologic event that is complicated by pathologic processes dangerous to the health of the mother and fetus in only 5–20% of cases. The physician who undertakes care of pregnant patients must be familiar with the normal changes that occur during pregnancy, so that significant abnormalities can be recognized and their effects minimized.

Prenatal care should have as a principal aim the identification and special treatment of the high-risk patient—the

one whose pregnancy, because of some factor in her medical history or an issue that develops during pregnancy is likely to have a poor outcome.

The purpose of prenatal care is to ensure, as much as possible, an uncomplicated pregnancy and the delivery of live, healthy infant. There is evidence that mothers and offspring who receive prenatal care have a lower risk of complications. There is also evidence that the mother's emotional state during pregnancy may have a direct effect on fetal outcome. In one study, it was reported that anxiety in labor is positively correlated with plasma epinephrine levels, which, in turn, seem to result in abnormal fetal heart rate patterns and low Apgar scores. Similarly, another study, which measured anxiety in women in the third trimester, noted that in newborns of anxious women, the 5-minute Apgar score was significantly lower.

Ideally, a woman planning to have a child should have a medical evaluation before she becomes pregnant. This allows the physician to establish by history, physical examination, and laboratory studies the patient's overall fitness for undertaking pregnancy. This is the ideal time to stress the dangers of cigarette smoking, alcohol and drug use, and exposure to teratogens. Instruction on proper diet and exercise habits can also be given. Vitamins especially folic acid, taken 3 months before conception may be beneficial (decreasing the incidence of open neural tube defects). Unfortunately, most patients do not seek preconceptional care, and the initial prenatal visit is scheduled well after pregnancy is under way.

Common reasons why pregnant women may not receive adequate prenatal care are inability to pay for health care, fear of or lack of confidence in health care professionals, lack of self-esteem, delays in suspecting pregnancy or in reporting pregnancy to others, different individual or cultural perceptions of the importance of prenatal care, adverse initial feelings about being pregnant, and religious or cultural prohibitions. These factors should be screened for and addressed.

INITIAL OFFICE VISIT

The purpose of the first visit to the physician is to identify all risk factors involving the mother and fetus. Once identified, high-risk pregnancies require individualized specialized care. The diagnosis of pregnancy is made on the basis of physical signs and symptoms and the results of laboratory tests discussed earlier in this chapter.

History

PRESENT PREGNANCY

The interview should begin with a full discussion of the symptoms. The patient should have time to express her ideas on childbearing and parenting and to discuss the effect of pregnancy on her life situation.

The patient with regular menses may be able to accurately calculate the EDC using the first day of the LMP and Nagele's rule (see above). The EDC may also be determined if the patient knows the probable date of conception.

PREVIOUS PREGNANCY

Outcomes of all prior pregnancies provide important clues to potential problems in the current gestation. The following information should be obtained: length of gestation, birthweight, fetal outcome, length of labor, fetal presentation, type of delivery, and complications (prenatal, during labor, postpartum). If a cesarean section was performed, an operative report details the type of uterine incision and allows the physician to estimate the patient's subsequent risk for uterine scar dehiscence.

MEDICAL HISTORY

Many medical disorders are exacerbated by pregnancy. Many cardiovascular, gastrointestinal, and endocrine disorders require careful evaluation and counseling concerning possible deleterious effects on the mother. A history of previous blood transfusion may suggest the rare possibility of associated hemolytic disease of the newborn because of maternal antibodies from a minor blood group mismatch. Knowledge of drug sensitivities is also important.

A history of maternal infections during pregnancy should be obtained. If possible, current infections should be treated to prevent hazardous fetal effects. Review of the patient's knowledge about avoiding infectious and teratogenic risks (see Chapter 14) is prudent.

The prenatal history should include important social aspects, such as the number of sexual partners, the history of sexually transmitted diseases, and possible contact with intravenous drug users. Human immunodeficiency virus (HIV) testing should be offered to all patients.

SURGICAL HISTORY

Of special importance is a history of previous gynecologic surgery. Prior uterine surgery may necessitate cesarean delivery. A history of multiple induced abortions or midtrimester losses may suggest an incompetent cervix. Patients with previous cesarean deliveries may be candidates for vaginal delivery if they are adequately counseled and meet established guidelines.

FAMILY HISTORY

A family history of diabetes mellitus should alert the physician to possible gestational diabetes, especially if the patient has a history of large or anomalous babies or previous stillbirths. Glucose tolerance testing must be done to determine current endocrine function.

Awareness of familial disorders is also important in pregnancy management. Thus, a brief three-generation pedigree is useful. Antenatal screening tests are available for many hereditary diseases.

A history of twinning is important, because dizygotic twinning (polyovulation) may be a maternally inherited trait.

Physical Examination

GENERAL EXAMINATION

A complete physical examination must be performed on every new patient. In a young, healthy woman, this may be the first complete examination she has ever had.

PELVIC EXAMINATION

The pelvic examination is of special importance to the obstetrician.

Pelvic Soft Tissue

Any pelvic mass should be described accurately and evaluated by ultrasonography.

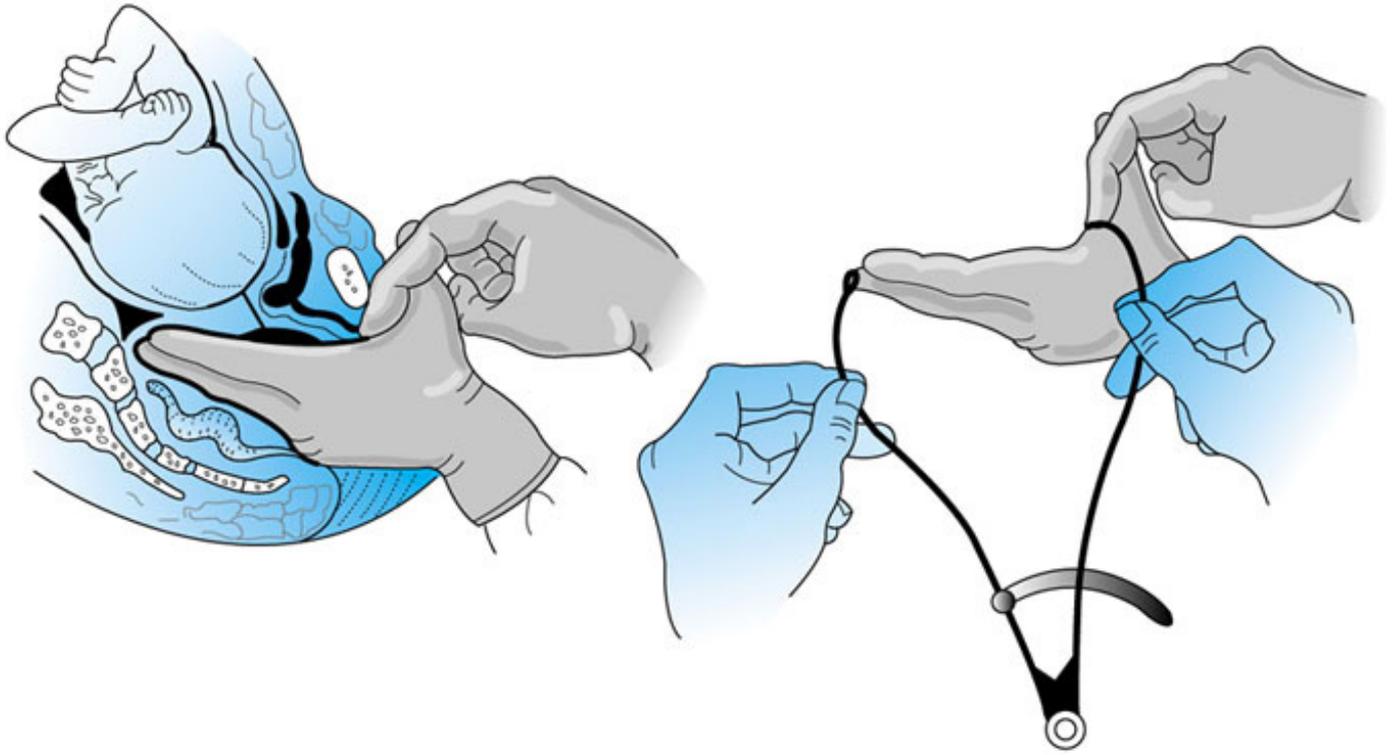

Bony Pelvis

The pelvic configuration should be appraised to determine which patients are more likely to develop cephalopelvic disproportion in labor. Pelvimetry has been largely replaced, however, by clinical trial of the pelvis ("trial of labor").

PELVIC INLET

Although the transverse diameter of the inlet cannot be measured clinically, the anteroposterior diameter or diagonal conjugate usually can be estimated. For this measurement, the middle finger of the examining hand reaches for the promontory of the sacrum, and the tissue between the examiner's index finger and thumb is pushed against the pubic symphysis while the point of pressure is noted (Fig 9–4). The distance between the tip of the examining finger and this point of pressure measures the diagonal conjugate of the inlet. Subtracting 1.5 from the diagonal conjugate gives a satisfactory estimate of the true conjugate (conjugata vera), or the true anterior diameter of the pelvic inlet.

Figure 9–4.

Measurement of the diagonal conjugate (DC) (conjugata diagonalis, CD).

(Reproduced, with permission, from Benson RC: Handbook of Obstetrics & Gynecology, 8th ed. Norwalk, CT: Lange, 1983.)

MIDPELVIS

Precise clinical measurement of the diameter of the midpelvic space is not feasible. With some experience, however, the physician can estimate this distance by noting the prominence and relative closeness of the ischial spines. If the walls of the pelvis seem to converge; if the curve of the sacrum is straightened or shallow; or if the sacrosciatic notches are unusually narrow, doubt about the adequacy of the midpelvis is justified.

PELVIC OUTLET

For clinical purposes, the outlet can be adequately estimated by physical examination. The shape of the outlet can be determined by palpating the pubic rami from the symphysis to the ischial tuberosities and noting the angle of the rami. A subpubic angle of less than 90 degrees suggests inadequacy of the outlet. A prominent or angulated coccyx diminishes the anteroposterior diameter of the pelvic outlet.

On rare occasions, extreme abnormality of the pelvis precludes vaginal delivery. In most cases, below average clinical measurements alert the obstetrician to the possibility of fetopelvic disproportion, and therefore dystocia. However, an adequate trial of labor is usually the final determinant of true adequacy of the bony pelvis.

CERVICAL LENGTH

Assessment should be made by bimanual examination of the cervical length and dilation. Average cervical length 3–4 cm. A nulliparous woman or one who has never given birth vaginally will have a closed os. In women with prior preterm birth, transvaginal ultrasonographic evaluation of cervical length is replacing digital exam; a scan in the midtrimester (18–20 weeks) and further serial examinations can be predictive of preterm delivery.

Laboratory Tests

The following laboratory assessments should be performed as early as possible in pregnancy and some of these

repeated at least once between 24 and 36 weeks' gestation.

BLOOD SCREENING

At the first visit, the following is obtained: hematocrit, hemoglobin, white blood cell count and differential, blood type group, Rh factor, and antibodies to blood group antigens; also needed are a serologic test for syphilis (Venereal Disease Research Laboratory [VDRL] or rapid plasma reagent [RPR] test), rubella, hepatitis B, and HIV. At-risk individuals may need testing for toxoplasmosis. Women with prior gestational diabetes should be given early 1-hour postglucose testing. The glucose level is checked after ingestion of 50 g of glucose. In a woman with no increased risk, this is done at 24–28 weeks' gestation. If the test is abnormal, a 3-hour glucose tolerance test is obtained (fasting glucose level, followed by glucose levels 1, 2, and 3 hours after a 100-g glucose load). Hematocrit should be repeated in the third trimester.

Maternal serum testing for hCG, unconjugated estriol, and α -fetoprotein (AFP) and inhibin (the quad screen) should be offered between 15 and 20 weeks' gestation (ideally at 16–18 weeks) to screen for open neural tube defects and chromosomal abnormalities, primarily trisomies 21 and 18.

To allow earlier detection of certain chromosomal abnormalities, first trimester screening using a combination of maternal serum analytes (pregnancy-associated plasma protein A [PAPP-A] and free β -hCG) and ultrasound measurement of fetal nuchal translucency is becoming more widely available.

GENETICS TESTING

Genetic studies should be offered to women older than age 35 and to those with abnormal pedigrees or other risk factors for inherited diseases. Chorionic villus sampling (CVS) is done at 10–14 weeks' gestation by either a transabdominal or transcervical technique. Amniocentesis is usually offered at 16–20 weeks' gestation. With ultrasound guidance, the complication rate of either of these procedures is well below 1%.

URINE TESTING

Perform urinalysis and screening tests (eg, dipstick nitrite testing) or culture for urinary tract infection. If the bacteria count is over 10^5 /mL on a voided sample or if bacteria are noted on a catheterized specimen, perform antibiotic sensitivity testing. Testing for urinary protein, glucose, and ketones should be done at each prenatal visit. Proteinuria of more than 300 mg/24 h ($\geq 2+$ on standard dipstick testing) may indicate renal dysfunction, and if associated with relative hypertension, the onset or progression of preeclampsia. The presence of glucosuria signifies that the delivery of glucose to the kidneys exceeds renal resorptive capacity. This is not important if blood levels are normal, but elevated blood levels indicate carbohydrate intolerance. During pregnancy, the presence of ketones in the urine usually indicates inadequate intake of carbohydrates but not fetal jeopardy or maternal diabetes. The diet should be evaluated in this case to make certain that carbohydrate intake is adequate.

PAPANICOLAOU SMEAR

Papanicolaou smears are performed unless recent results are available. Some obstetricians routinely screen for gonorrhea and chlamydia; others reserve this for high-risk patients. Microscopic examination of vaginal secretions is performed if indicated.

GROUP B STREPTOCOCCUS

The current recommendations are to perform routine screening for group B streptococcus between 35 and 37 weeks' gestation. The rationale is that if the mother is positive, she should be treated (penicillin is the drug of choice) at the time of admission in labor, thus decreasing the risk of group B streptococcal sepsis in the newborn.

TUBERCULIN SKIN TEST

A tuberculin skin test (purified protein derivative [PPD]) is appropriate for high-risk patients.

SUBSEQUENT VISITS

The standard schedule for prenatal office visits is 0–32 weeks' gestation: once every 4 weeks; 32–36 weeks'

gestation: once every 2 weeks; and 36 weeks' gestation to delivery: once each week. At each visit, weight gain, blood pressure, fundal height, and findings on abdominal examination by Leopold's maneuvers should be recorded. Additionally, FHTs should be documented and urine should be checked for glucose and protein. These findings should be reviewed and compared with those of previous examinations.

MATERNAL WELL-BEING AS A SIGN OF FETAL WELL-BEING

In modern obstetric practice, fetal well-being has been determined mainly by direct monitoring and testing, but it is important not to overlook the status of the mother when determining fetal well-being. Maternal health is obviously crucial to fetal development and must be continuously assessed during pregnancy.

Maternal Height & Weight

Maternal height and prepregnancy weight along with the rate and amount of weight gain during pregnancy are important in fetal development. Women who are underweight or of short stature tend to have smaller babies, and are at risk for low birthweight and preterm delivery. A teenage mother is compromised if her diet is inadequate to meet her own growth requirements and those of her fetus. In such circumstances, women less than 157 cm (5 ft) tall, especially those weighing less than 45 kg (100 lb), should be encouraged to gain at least a minimum of 11–13 kg (25 lb), if not more.

Inadequate progressive weight gain may reflect nutritional deficit, maternal illness, or a hormonal milieu that does not promote proper volume expansion and anabolic state. Often, this is associated with poor fundal growth and a small fetus and placenta, suggesting fetal growth retardation. Weight gain and fundal height should be closely monitored during pregnancy.

Blood Pressure

Blood pressure levels may provide a clue to subtle circulatory compromise. Normally, the mean arterial pressure drops somewhat from prepregnancy or early pregnancy values during the middle trimester. It is important to note this decline so that it does not mask a subsequent rise in blood pressure that may signal the onset of hypertension. In the third trimester, blood pressure recordings taken in the supine position may be higher than those taken in the recumbent or seated position; this also may indicate the onset of hypertension. Normal patients may have a significant drop in blood pressure in the supine position (supine hypotensive syndrome), which is corrected when the patient is in the left lateral position.

Fundal Height

Fundal height should be measured and recorded at each visit after 20 weeks' gestation. Measurements should be made with a centimeter tape (McDonald's technique) from the pubic symphysis to the top of the uterine mass over the curvilinear abdominal surface. Progress is especially important in the third trimester, when fetal growth retardation is most easily determined.

Fetal Heart Tones

FHTs can usually be heard by 10–12 postmenstrual weeks using a hand-held Doppler device. This may be helpful when gestational age is in doubt or in the presence of threatened abortion or other abnormal observations in the late first trimester. Attention should be paid both to rate and rhythm and to any accelerations, decelerations, or irregularities. Significant abnormalities may be further assessed by ultrasonography, fetal echocardiography, or electronic fetal heart rate monitoring, depending on gestational age.

Edema

At each prenatal visit, abnormal or potentially abnormal findings should be noted, and a careful record should be made of any unusual events that have occurred since the last visit. Transient episodes of general edema or swelling should be noted. Lower-extremity edema in late pregnancy is a natural consequence of hydrostatic

changes in lower body circulation.

Edema of the upper body (eg, face and hands), especially in association with relative or absolute increases in blood pressure, may be the first sign of preeclampsia. A moderate rise in blood pressure without excessive fluid retention may suggest a predisposition to chronic hypertension.

Fetal Size & Position

Manual assessment of fetal size and position is always indicated after about 26 weeks' gestation. The fetus may assume a number of positions before late gestation, but persistence of an abnormal lie into late pregnancy suggests abnormal placentation, uterine anomalies, or other problems that should be investigated by ultrasound. If an abnormal lie persists, consider external version after 37 weeks' gestation. Suspected abnormal fetal size should also be investigated; a difference between gestational age and fetal heart size by 2 cm or more should prompt consideration of ultrasound evaluation.

PREPARATION FOR LABOR

As term approaches, the patient must be instructed on the physiologic changes associated with labor. She is usually admitted to the hospital when contractions occur at 5- to 10-minute intervals. She should be told to seek medical advice for any of the following danger signals: (a) rupture of membranes, (b) vaginal bleeding, (c) decreased fetal movement, (d) evidence of preeclampsia (eg, marked swelling of the hands and face, blurring of vision, headache, epigastric pain, convulsions), (e) chills or fever, (f) severe or unusual abdominal or back pain, (g) any other severe medical problems.

NUTRITION IN PREGNANCY

The mother's nutrition from the moment of conception is an important factor in the development of the infant's metabolic pathways and future well-being. The pregnant woman should be encouraged to eat a balanced diet and should be made aware of special needs for iron, folic acid, calcium, and zinc.

The average woman weighing 58 kg (127 lb) has a normal dietary intake of 2300 kcal/d. An additional 300 kcal/d is needed during pregnancy and an additional 500 kcal/d is needed during breastfeeding (Table 9–1). Consumption of fewer calories could result in inadequate intake of essential nutrients.

Table 9–1. Recommended Daily Dietary Allowances for Nonpregnant, Pregnant, and Lactating Women.

Nonpregnant Women (years)				Pregnant Women	Lactating Women
15–18	19–24	25–50	50+		

WEIGHT GAIN

The American College of Obstetricians and Gynecologists along with the Institute of Medicine (IOM) recommend weight gain of 11.5–16 kg (25–35 lb) during singleton pregnancy. Underweight women may need to gain more, whereas obese women should gain only 7–11.5 kg (15–25 lb). Heavier women and those with excessive weight gain during pregnancy are likely to have macrosomic infants. Inadequate weight gain is associated with small-for-gestational age (SGA) infant.

The fetus accounts for about one-third of the normal weight gain (3500 g); the placenta, amniotic fluid, and uterus for 650–900 g; interstitial fluid and blood volume for 1200–1800 g each; and breast enlargement for 400 g. The remaining 1640 g or more is largely maternal fat.

NUTRITIONAL REQUIREMENTS

PROTEIN

Protein needs in the second half of pregnancy are 1 g/kg plus 20 g/d (approximately 80 g/d for the average woman). Protein intake is essential for embryonic development.

CALCIUM

Calcium intake should be increased to 1.5 g/d in the later months and during lactation. If calcium intake is inadequate, fetal needs will be met through demineralization of the maternal skeleton. Maternal calcium stores may be further drained during lactation.

IRON

To avoid iron-deficiency anemia, the IOM recommends supplementing the diet of every pregnant woman with 30 mg/d of elemental iron during the second and third trimester. If iron-deficiency anemia is diagnosed, the therapeutic doses of elemental iron prescribed range between 60 and 120 mg/d.

VITAMINS AND MINERALS

Vitamin and mineral preparations are commonly given but should not be substituted for adequate food intake. Folic acid has been shown to effectively reduce the risk of neural tube defects (NTDs). A daily 4-mg dose is recommended for patients who have had a previous pregnancy affected by NTDs. It should begin more than 1 month prior to pregnancy (preferably 3 months) and continued through the first 6–12 weeks of pregnancy. Studies show this amount reduces the risk of recurrence by 70%. For all other women, a daily intake of at least 0.4 mg taken before conception and through the first 6 weeks of pregnancy is recommended. Patients with insulin-dependent diabetes mellitus and those with seizure disorders treated by valproic acid and carbamazepine are also at greater risk for neural tube defects and these women should ingest at least 1 mg/d of folic acid. Vitamin B₁₂ supplements are also desirable for vegetarian patients and those with known megaloblastic anemia.

Salt Restriction

Moderate amounts of foods containing sodium are not harmful during normal pregnancy. In fact, sodium

restriction may be potentially dangerous. There is no evidence that rapid weight gain in preeclampsia can be controlled with sodium restriction.

COMMON COMPLAINTS DURING PREGNANCY

Most of the minor complaints during pregnancy can be minimized with patient education and prompt treatment.

Ptyalism

Excessive salivation (sialism, ptyalism) is an infrequent but troublesome complaint of pregnant women. The cause is unknown but it is strongly associated with severe nausea and vomiting of pregnancy.

Pica

Pica (cissa) is the ingestion of substances that have no value as food or are unwholesome. Common examples are clay and laundry starch. Pica is harmful because it interferes with good nutrition by substituting nonnutritious but for nutritionally important foods. The necessity for good nutrition must be explained to these patients.

Frequency of Urination

Urinary frequency is a common complaint throughout pregnancy. Vascular engorgement of the pelvis and hormonal changes are responsible for altered bladder function. Late in pregnancy, when pressure on the bladder by the enlarging uterus and the fetal presenting part decreases bladder capacity, urination becomes even more frequent.

Dysuria or hematuria may be signs that infection has developed; diagnostic and therapeutic measures are needed.

Sexually Transmitted Diseases (STDs)

SYPHILIS

Syphilis screening tests such as the VDRL slide test and the RPR tests are sensitive, but not specific, for syphilis infection and may remain positive even after disease treatment. They are used to screen for syphilis infections secondary to their cost-effectiveness. Treponemal antibody tests are used to confirm syphilis infection in patient with a positive VDRL or RPR. Penicillin remains the treatment of choice in pregnancy, secondary to its ability to cross the placenta and treat the fetus, with treatment protocols correlating with disease severity. Erythromycin and ceftriaxone are treatment alternatives for the pregnant patient, but because of treatment failures, penicillin desensitization is recommended. Monthly serologic tests are followed to assess treatment response.

CHLAMYDIA

The most effective screening consists of DNA probe analysis for this infection. Treatment usually consists of 7 days of erythromycin or one dose of azithromycin in the pregnant woman. Amoxicillin is used for patients with intolerance to erythromycin base or ethylsuccinate.

GONORRHEA

Gonorrhea is best detected by cervical culture or DNA probe. Because many strains are penicillin-resistant, ceftriaxone is the drug of choice. Amoxicillin is used for nonresistant strains and spectinomycin is recommended for the penicillin-allergic patient.

HERPES SIMPLEX VIRUS

Tissue culture is the best confirmation of herpes infection. Topical acyclovir may improve symptoms. Oral acyclovir may be used for recurrent outbreaks and should be considered after 36 weeks for prophylaxis against outbreaks at the time of delivery. Cultures are recommended when a lesion is suspected. If no lesions are found, vaginal delivery is safe. Cesarean delivery is the route of choice for patients with active lesions at the time of delivery or with prodromal symptoms at the time of delivery secondary to the high rate of morbidity and mortality associated with neonatal herpes infection.

HIV

The standard approach to HIV testing in prenatal care includes testing via ELISA (enzyme-linked immunosorbent assay) followed by confirmatory Western blot or immunofluorescence assay (IFA) for ELISA positive specimens. The Centers for Disease Control and Prevention (CDC) recommends that women who have not had prenatal HIV testing be offered rapid HIV testing at delivery to initiate prophylaxis of neonate in the event that the mother is HIV seropositive. The goal of prenatal care for HIV-positive pregnant women focuses on appropriately treating maternal disease and minimizing vertical transmission of HIV, which correlates with the concentration of virus in maternal plasma (viral load). Management of an HIV-infected pregnant woman involves serial measurements of viral load and CD4 T-cell count. The pharmacotherapy varies, but usually consists of regimen of highly active antiretroviral therapy (HAART) and intrapartum infusion of azidothymidine (AZT). Cesarean delivery is recommended only for patients with high viral load (> 1000 copies/mL); otherwise mode of delivery is dictated by obstetric indications.

Other Infections

TRICHOMONIASIS

Trichomonas vaginalis can be found in 20–30% of pregnant patients, but only 5–10% complain of leukorrhea or irritation. This flagellated, pear-shaped, motile organism can be seen under magnification when the vaginal discharge is diluted with warm normal saline solution and examined microscopically. Suspect trichomoniasis when the discharge is fetid, foamy, or greenish, or when there are reddish ("strawberry") petechiae on the mucous membranes of the cervix or vagina.

Treatment is discussed in Chapter 41.

CANDIDIASIS

Candida albicans can be cultured from the vagina in many pregnant women, but symptoms occur in less than 50%. When symptoms do occur, they consist of severe vaginal burning and itching and a profuse, caseous, white discharge. Marked inflammation of the vagina and introitus may be noted. The symptoms are likely to be aggravated by intercourse, and the male partner not infrequently develops mild irritation of the penis. Topical miconazole nitrate or nystatin suppositories are the preferred treatment during pregnancy. Oral fluconazole should be avoided for the uncomplicated vaginal infection. The infection often flares up during pregnancy, in which case retreatment is necessary.

BACTERIAL VAGINOSIS (BV)

This is a change in the vaginal bacterial milieu characterized by a diminution in lactobacilli and overgrowth of other species. The pH is decreased. The presence of BV is associated with a 2-fold increased risk of preterm birth in general. Many authorities advocate screening for BV and treating it in women at high risk for preterm birth.

Varicose Veins

Varicosities may develop in the legs or in the vulva. A family history of varicosities is often present. Pressure by the enlarging uterus on the venous return from the legs is a major factor in the development of varicosities. The physician should warn the patient early in pregnancy of the need for elastic stockings and elevation of the legs if varices develop. Specific therapy (injection or surgical correction) usually is contraindicated during pregnancy. Superficial varicosities may rarely signal deeper venous disease. These patients should be examined carefully for signs of deep vein thrombosis.

Joint Pain, Backache, & Pelvic Pressure

Although the main bony components of the pelvis consist of 3 separate bones, the symphyseal and sacroiliac articulations permit practically no motion in the nonpregnant state. In pregnancy, however, endocrine relaxation of these joints permits some movement. The pregnant patient may develop an unstable pelvis, which produces pain. A tight girdle or a belt worn about the hips, together with frequent bed rest, may relieve the pain; however, hospitalization is sometimes necessary.

Improvement in posture often relieves backache. The increasingly protuberant abdomen causes the patient to throw her shoulders back to maintain her balance; this causes her to thrust her head forward to remain erect. Thus, she increases the curvature of both the lumbar spine and the cervicothoracic spine. A maternity girdle to support the abdominal protuberance and shoes with 2-inch heels, which tend to keep the shoulders forward, may reduce the lumbar lordosis and thus relieve backache. Local heat and back rubs may relax the muscles and ease discomfort. Exercises to strengthen the back are most rewarding.

Leg Cramps

The cause of leg cramps in pregnancy is unknown but may be the result of a reduced level of diffusible serum calcium or elevation of serum phosphorus. Treatment for this includes curtailment of phosphate intake (less milk and nutritional supplements containing calcium phosphate) and an increase of calcium intake (without phosphorus) in the form of calcium carbonate or calcium lactate tablets. Alternatively, a randomized trial showed that magnesium citrate, 300 mg/d, reduces leg cramps. Symptomatic treatment consists of leg massage, gentle flexing of the feet, and local heat. Tell the patient to avoid pointing toes when she stretches her legs (eg, on awakening in the morning) as this triggers a gastrocnemius cramp. She should also practice "leading with the heel" in walking.

Breast Soreness

Physiologic breast engorgement may cause discomfort, especially during early and late pregnancy. A well-fitting brassiere worn 24 hours a day affords relief. Ice bags are temporarily effective. Hormone therapy is of no value.

Discomfort in the Hands

Acrodysesthesia of the hands consists of periodic numbness and tingling of the fingers (the feet are never involved). It affects at least 5% of pregnant women. In some cases it is thought to be a brachial plexus traction syndrome caused by drooping of the shoulders during pregnancy; carpal tunnel syndrome is a common cause of similar symptom complex. The discomfort is most common at night and early in the morning. It may progress to partial anesthesia and impairment of manual proprioception. The condition is apparently not serious, but it may persist after delivery as a consequence of lifting and carrying the baby.

Other Common Complaints

See Chapters 7 and 25 for discussions of other common complaints during pregnancy, including abdominal pain, nausea and vomiting, syncope and faintness, heartburn, constipation, hemorrhoids, genital tract complications, headache, and carpal tunnel syndrome.

DRUGS, CIGARETTE SMOKING, & ALCOHOL DURING PREGNANCY

Drugs

Teratogenicity has been established for only a few drugs. The U.S. Food and Drug Administration (FDA) propose a classification system for drugs in pregnancy and lactation that uses available data to address relative safety of administering medications to pregnant women. The physician should have good reason for prescribing any drug early in pregnancy, or indeed during the last half of the menstrual cycle, when any fertile, sexually active woman might become pregnant.

Little is known about the effects of marijuana on the fetus, but major deleterious consequences have not been reported. Heroin and methadone, on the other hand, are associated with major problems in the neonate, especially potentially fatal withdrawal symptoms.

Cigarette Smoking

An increased incidence of low-birth-weight infants has been ascribed to heavy cigarette smoking by pregnant women. Smoking during pregnancy is associated with increased risk of intrauterine growth restriction, placenta

placenta accreta, preterm birth, low birth weight, and perinatal mortality. Pregnant women should be encouraged not to smoke, and can be offered pharmaceutical agents to assist with smoking cessation. If cessation is not possible, reducing the number of cigarettes smoked per day is encouraged.

Alcoholic Beverages

In the past, it was thought that moderate ingestion of alcohol caused no deleterious effects on the uterus or fetus despite the easy passage of alcohol across the placenta. Instances of newborns showing alcoholic withdrawal symptoms have been reported, but usually these infants were born to chronic alcoholics who drank heavily during pregnancy. However, the precise level of alcohol consumption during pregnancy that causes adverse fetal effects has not been established. Moreover, the chronic alcoholic may suffer from malnutrition, to the extent that the craving for alcohol exceeds the desire for food.

A fetal alcohol syndrome (FAS) following maternal ethanol ingestion has been described, with an incidence varying from 1 in 1500 to 1 in 600 live births. The rate of reported cases identified among newborns in the United States during 1979–1992 increased approximately 4-fold. The major features include growth retardation, characteristic facial dysmorphism (including microcephaly and microphthalmia), central nervous system deficiencies, and other abnormalities.

There is no exact dose–response relationship between the amount of alcohol consumed during the prenatal period and the extent of damage caused by alcohol in the infant. Infants whose mothers consume alcohol during pregnancy can have fetal alcohol effects (FAEs), alcohol-related birth defects (ARBDs), FAS, or be normal. The term *fetal alcohol spectrum disorder* has been coined to describe the broad range of adverse sequelae in alcohol-exposed offspring.

Pregnant women should be encouraged to avoid alcohol intake completely during pregnancy. If this is not possible, the intake should be reduced to a minimum.

OTHER MATTERS OF CONCERN DURING PREGNANCY

Intercourse

There has always been a suspicion that intercourse may be responsible for early abortion. Few adverse consequences can be attributed directly to intercourse during pregnancy. Naturally, if cramps or spotting follow coitus, it should be proscribed for the time being. Coitus late in pregnancy may initiate labor, perhaps because of an orgasm that causes a uterine contraction reflex. Pelvic rest should be considered for patients who have had a previous premature delivery or are currently experiencing uterine bleeding.

Bathing

Bath water does not enter the vagina. Even swimming is not contraindicated during normal pregnancy. Diving should be avoided because of possible trauma. A woman in the last trimester of pregnancy may have impaired balance. For this reason, she should be cautioned about slipping and falling in the tub or shower.

Douching

Douching, which is seldom necessary, may be harmful during pregnancy.

Dental Care

There may be generalized gum hypertrophy and bleeding during pregnancy. Interdental papillae (epulis) may also form in the upper gingivae, and these rarely resorb and must be excised. Normal dental procedures under local anesthesia (ie, drilling and filling) may be carried out at any time during gestation. Lengthy procedures should be postponed until the second trimester. Antibiotics are given for dental abscesses and in cases of rheumatic heart disease and mitral valve prolapse. Periodontal disease has been associated with an increased risk of preterm birth but there have been no trials of treatment during pregnancy.

Immunization

Killed virus, toxoid, or recombinant vaccines may be safely administered during pregnancy, and patients should be vaccinated appropriately for both maternal and fetal benefit. The American College of Obstetricians and Gynecologists recommends that all women who are pregnant in the second or third trimester during the flu season (October to March) should receive the influenza vaccination. Diphtheria and tetanus toxoid may be administered during pregnancy if a woman has not received a booster in 10 years, or if no primary series had been received. The hepatitis B vaccine series and killed polio vaccine may be given during pregnancy to women at risk. Live, attenuated vaccines, including those for varicella, measles, mumps, polio, and rubella, should be given 3 months prior to pregnancy or immediately postpartum. These vaccines are contraindicated in pregnancy secondary to the potential of fetal infection. Viral shedding occurs in children receiving vaccination, but they do not transmit the virus; consequently, vaccination may be safely given to the children of pregnant women. Secondary prophylaxis with specific immune globulin is recommended for pregnant women exposed to measles, hepatitis A, hepatitis B, tetanus, chickenpox, or rabies.

Clothing

Loose-fitting conventional clothing often suffices until late in pregnancy, although maternity garments may be used as desired. A well-fitted brassiere is essential. A maternity girdle is rarely prescribed except for the relief of back pain or for abdominal weakness. Panty girdles and garters should be avoided because they interfere with circulation in the legs. Well-fitted shoes with heels of medium height are best in pregnancy.

Exercise

Exercise in moderation is acceptable during pregnancy, but the patient should also rest an hour or two during the day. Those activities with high risk of falling or for abdominal trauma (eg, horseback riding, downhill skiing) and undue physical stress should be avoided. Aerobic and exercise classes have to be designed for pregnancy. Target heart rates are adjusted for age and weight, and routines are aimed to protect joints and promote flexibility.

Employment

Women who have sedentary jobs may continue to work throughout the pregnancy. Employment that requires physical exertion calls for a careful evaluation by the obstetrician and an occupational medical practitioner. It is unwise to adopt rigid policies regarding work during pregnancy—each patient has a different level of capability, level of prepregnancy conditioning, exercise tolerance, and physique.

Substantial physical effort increases maternal oxygen consumption and places an increased demand on cardiac reserve that may result in decreased uterine blood flow. There are no studies as yet that prove this theory beyond doubt, but a conservative approach to the problem is recommended.

Travel

Travel (by automobile, train, or plane) does not adversely affect a pregnancy, but separation from the physician may be of concern. For this reason, instruct patients with a history of spontaneous abortion and those who have experienced vaginal bleeding in the course of the present pregnancy to avoid travel to distant places.

Current OB/GYN >Chapter 10. The Course & Conduct of Normal Labor & Delivery>

THE COURSE & CONDUCT OF NORMAL LABOR & DELIVERY: INTRODUCTION

Labor is a sequence of uterine contractions that results in effacement and dilatation of the cervix and voluntary bearing-down efforts leading to the expulsion per vagina of the products of conception. Delivery is the mode of expulsion of the fetus and placenta. Labor and delivery is a normal physiologic process that most women experience without complications. The goal of the management of this process is to foster a safe birth for mother and their newborns. Additionally, the staff should attempt to make the patient and her support person(s) feel welcome, comfortable, and informed throughout the labor and delivery process. Physical contact between the newborn and the parents in the delivery room should be encouraged. Every effort should be made to foster family interaction and to support the desire of the family to be together. The role of the obstetrician/midwife and the labor and delivery staff is to anticipate and manage complications that may occur that could harm the mother or the fetus. When a decision is made to intervene, it must be considered carefully, because each intervention carries both potential benefits and potential risks. The best management in the majority of cases may be close observation and, when necessary, cautious intervention.

PHYSIOLOGIC PREPARATION FOR LABOR

Prior to the onset of true labor, several preparatory physiologic changes commonly occur. The settling of the fetal head into the brim of the pelvis, known as lightening, usually occurs 2 or more weeks before labor in first pregnancies. In women who have had a previous delivery, lightening often does not occur until early labor. Clinically, the mother may notice a flattening of the upper abdomen and increased pressure in the pelvis. This descent of the fetus is often accompanied by a decrease in discomfort associated with crowding of the abdominal organs under the diaphragm (eg, heartburn, shortness of breath), and an increase in pelvic discomfort and frequency of urination.

During the last 4–8 weeks of pregnancy irregular, generally painless uterine contractions occur with slowly increasing frequency. These contractions, known as Braxton Hicks contractions, may occur more frequently, sometimes every 10–20 minutes, and with greater intensity during the last weeks of pregnancy. When these contractions occur early in the third trimester, they must be distinguished from true preterm labor. Later, they are a common cause of "false labor," which is distinguished by the lack of cervical change in response to the contractions.

During the course of several days to several weeks before the onset of true labor, the cervix begins to soften, efface, and dilate. In many cases, when labor starts, the cervix is already dilated 1–3 cm in diameter. This is usually more pronounced in the multiparous patient, the cervix being relatively more firm and closed in nulliparous women. With cervical effacement, the mucus plug within the cervical canal may be released. When this occurs, the onset of labor is sometimes marked by the passage of a small amount of blood-tinged mucus from the vagina known as bloody show.

In true labor, the woman is usually aware of her contractions during the first stage. The intensity of pain depends on the fetal/pelvic relationships, the quality and strength of uterine contractions, and the emotional and physical

status of the patient. Few women experience no discomfort during the first stage of labor. Some women describe slight low back pain that radiates around to the lower abdomen. Each contraction starts with a gradual build-up in intensity, and dissipation of discomfort promptly follows the climax. Normally, the contraction will be at its height well before discomfort is reported. Dilatation of the lower birth canal and distention of the perineum during the second stage of labor will almost always cause discomfort.

CHARACTERISTICS OF NORMAL LABOR

Normal labor is a continuous process that has been divided into three stages for purposes of study, with the first stage further subdivided into two phases, the latent phase and the active phase. The first stage of labor is the interval between the onset of labor and full cervical dilatation. The second stage is the interval between full cervical dilatation and delivery of the infant. The third stage of labor is the period between the delivery of the infant and the delivery of the placenta.

In his classic studies of labor in 1967, Friedman presented data describing the process of spontaneous labor over time. The duration of the first stage of labor in primipara patients is noted to range from 6–18 hours, while in multiparous patients the range is reported to be 2–10 hours. The lower limit of normal for the rate of cervical dilatation during the active phase is 1.2 cm per hour in first pregnancies and 1.5 cm per hour in subsequent pregnancies. The duration of the second stage in the primipara is 30 minutes to 3 hours, and is 5–30 minutes for multiparas. For both, the duration of the third stage was reported to be 0–30 minutes for all pregnancies. These data, while extremely helpful as guidelines, should not be used as strict deadlines that trigger interventions if not met. Even if a numerical (statistical) approach is used to define "abnormal," the cutoff figure would not be the average range, but the 5th percentile numbers (eg, 25.8 hours for the first stage of labor in a primipara). The course that is more appropriate is to consider the overall clinical presentation and use the progress of labor to estimate the likelihood that successful vaginal delivery will occur.

Evaluation of Labor Progress

The first stage of labor is evaluated by the rate of change of cervical effacement, cervical dilatation, and descent of the fetal head. The frequency and duration of uterine contractions alone is not an adequate measure of labor progress. The second stage of labor begins after full cervical dilatation. The progress of this stage is measured by the descent, flexion, and rotation of the presenting part.

CLINICAL MANAGEMENT OF NORMAL LABOR

Women most likely to have a normal labor and delivery have had adequate prenatal care without significant maternal or fetal complications and are at 36 weeks' gestation or beyond. Whenever a pregnant woman is evaluated for labor, the following factors should be assessed and recorded:

- Time of onset and frequency of contractions, status of membranes, any history of bleeding, and any fetal movement.
- History of allergies, use of medication, and time, amount, and content of last oral intake.
- Prenatal records with special attention to prenatal laboratory results that impact intrapartum and immediate postpartum management (eg, human immunodeficiency virus [HIV] and hepatitis B status).
- Maternal vital signs, urinary protein and glucose, and uterine contraction pattern.
- Fetal heart rate, presentation, and clinical estimated fetal weight.
- Status of the membranes, cervical dilatation and effacement (unless contraindicated, eg, by placenta previa), and station of the presenting part.

If no complications are detected during the initial assessment and the patient is found to be in prodromal labor, admission for labor and delivery may be deferred. When a patient is admitted, a hematocrit or hemoglobin

measurement should be obtained and a blood clot should be obtained in the event that a cross-match is needed. A blood group, Rh type, and antibody screen should also be done.

The First Stage of Labor

In the first stage of normal labor, the pregnant woman may be allowed to ambulate or sit in a comfortable chair as desired. When the patient is lying in bed, the supine position should be discouraged. Patients in active labor should avoid ingestion of anything except sips of clear liquids, ice chips, or preparations for moistening the mouth and lips. When significant amounts of fluids and calories are required because of long labor, they should be given intravenously.

Maternal pulse and blood pressure should be recorded at least every 2–4 hours in normal labor, and more frequently if indicated. Maternal fluid balance (ie, urine output and intravenous and oral intake) should be monitored and both dehydration and fluid overload should be avoided.

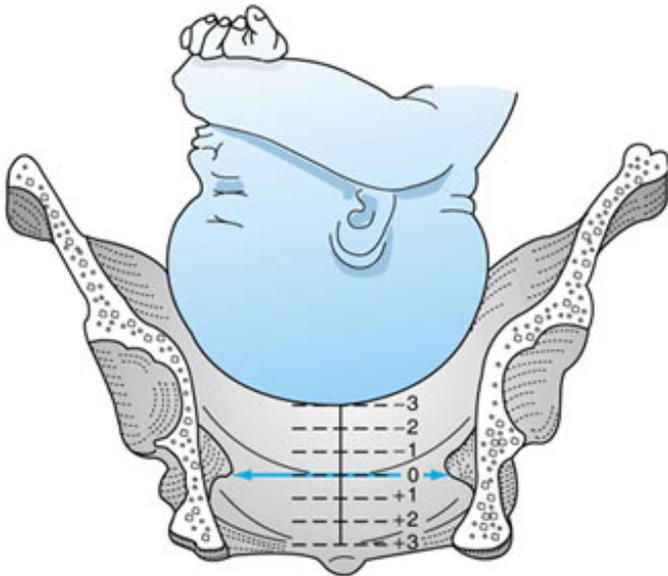

Management of discomfort and pain during labor and delivery is a necessary part of good obstetric practice. A patient's request is sufficient justification for providing pain relief during labor. Specific analgesic and anesthetic techniques are discussed in Chapter 29. Some patients tolerate the pain of labor by using techniques learned in childbirth preparation programs. Common methods of preparation include Lamaze, Bradley, Read, hypnotherapy and prenatal yoga. While specific techniques vary, these classes usually teach relief of pain through the application of principles of education, emotional support, touch, relaxation, paced breathing, and mental focus. The staff at the bedside should be knowledgeable about these pain-management techniques and should be supportive of the patient's decision to use them. When such methods fail to provide adequate pain relief, some patients will ask for medical assistance and such requests should be respected. Indeed, the use of appropriate medical analgesic techniques should be explained to the patient and her labor partner and their use encouraged where medically indicated.

Reassurance of fetal well-being is sought through fetal monitoring. In patients with no significant obstetric risk factors, the fetal heart rate should be auscultated or the electronic monitor tracing should be evaluated at least every 30 minutes in the active phase of the first stage of labor, and at least every 15 minutes in the second stage of labor. In patients with obstetric risk factors, the fetal heart rate should be evaluated every 15 minutes during the active phase of the first stage of labor, and at least every 5 minutes during the second stage.

Uterine contractions should be monitored by palpation every 30 minutes to assess their frequency, duration, and intensity. For at-risk pregnancies, uterine contractions should be monitored continuously along with the fetal heart rate. This can be achieved by using either an external tocodynamometer or an internal pressure catheter in the amniotic cavity. The latter method is particularly useful when abnormal progression of labor is suspected or when the patient requires oxytocin for augmentation of labor.

The progress of labor is monitored by examination of the cervix. During the latent phase, especially when the membranes are ruptured, vaginal examinations should be done sparingly to decrease the risk of an intrauterine infection. In the active phase the cervix should be assessed approximately every 2 hours. The cervical effacement and dilatation, and the station and position of the fetal head should be recorded (Fig 10–1). Additional examinations to determine if full dilation has occurred may be required if the patient reports the urge to push, or to search for prolapse of the umbilical cord or perform fetal scalp stimulation if a significant fetal heart rate deceleration is detected.

Stations of the fetal head.

(Reproduced, with permission, from Benson RC: Handbook of Obstetrics & Gynecology, 8th ed. Lange, 1983.)

The therapeutic rupture of fetal membranes (amniotomy) has been largely discredited as a means of induction when used alone. Moreover, artificial rupture of the membranes increases the risk of chorioamnionitis and the need for antibiotics (especially if labor is prolonged), as well as the risk of cord prolapse if the presenting part is not engaged. Amniotomy may, however, provide information on the volume of amniotic fluid and the presence of meconium. In addition, rupture of the membranes may cause an increase in uterine contractility. Amniotomy should not be performed routinely. It should be used when internal fetal or uterine monitoring is required, and may be helpful when enhancement of uterine contractility in the active phase of labor is indicated. Care should be taken to palpate for the umbilical cord and to avoid dislodging the fetal head. The fetal heart rate should be recorded before, during, and immediately after the procedure.

Second Stage of Labor

At the beginning of the second stage of labor the mother usually feels a desire to bear down with each contraction. This abdominal pressure, together with the force of the uterine contractions, expels the fetus. During the second stage of labor the descent of the fetal head is measured to assess the progress of labor. The descent of the fetus is evaluated by measuring the relationship of the bony portion of the fetal head to the level of the maternal ischial spines (station) (Fig 10–1). When the bony portion of the fetal head is at the level of the ischial spines, the station is "0." The ACOG (American College of Obstetricians and Gynecologists)-endorsed method for describing station is to estimate the number of centimeters from the ischial spines, but some practitioners find it useful to refer to station in estimated thirds of the maternal pelvis. An approximate correlation of these two methods would be: 2 cm = +1, 4 cm = +2, and 6 cm = +3.

The second stage generally takes from 30 minutes to 3 hours in primigravid women and from 5–30 minutes in multigravid women. The median duration is 50 minutes in a primipara and 20 minutes in a multipara. These times may vary depending on the pushing efforts of the mother, the quality of the uterine contractions, and the type of analgesia.

Mechanism of Labor

The mechanism of labor in the vertex position consists of engagement of the presenting part, flexion, descent,

internal rotation, extension, external rotation, and expulsion (Table 10–1). The progress of labor is dictated by the pelvic dimensions and configuration, the size of the fetus, and the strength of the contractions. In essence, delivery proceeds along the line of least resistance, that is, by adaptation of the smallest achievable diameters of the presenting part to the most favorable dimensions and contours of the birth canal.

Table 10–1. Mechanisms of Labor: Vertex Presentation.

Generally occurs in late pregnancy or at onset of labor. Mode of entry into superior strait depends on pelvic configuration.

Good flexion is noted in most cases. Flexion aids engagement and descent. (Extension occurs in brow and face presentations.)

Depends on pelvic architecture and cephalopelvic relationships. Descent is usually slowly progressive.

Takes place during descent. After engagement, vertex usually rotates to the transverse. It must next rotate to the anterior or posterior to pass the ischial spines, whereupon, when the vertex reaches the perineum, rotation from a posterior to an anterior position generally follows.

Follows distention of the perineum by the vertex. Head concomitantly stems beneath the symphysis. Extension is complete with delivery of the head.

Following delivery, head normally rotates to the position it originally occupied at engagement. Next, the shoulders descend (in a path similar to that traced by the head). They rotate anteroposteriorly for delivery. Then the head swings back to its position at birth. The body of the baby is then delivered.

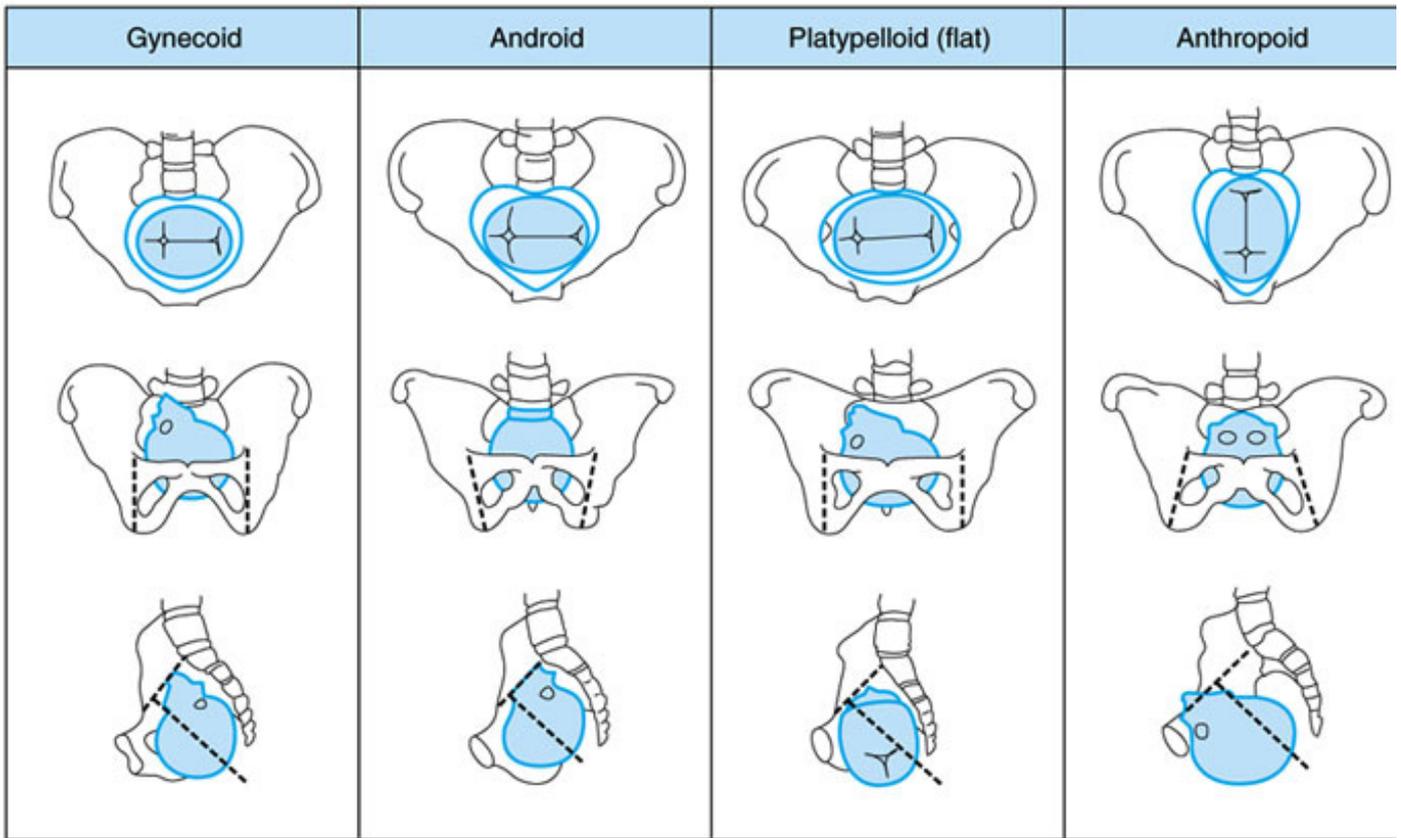

Engagement	Flexion	Descent	Internal Rotation	Extension	External Rotation (Restitution)
------------	---------	---------	-------------------	-----------	---------------------------------

The sequence of events in vertex presentation is as follows:

ENGAGEMENT

This usually occurs late in pregnancy in the primigravida, commonly in the last 2 weeks. In the multiparous patient, engagement usually occurs with the onset of labor. The head enters the superior strait in the occiput transverse position in 70% of women with a gynecoid pelvis (Figs 10–2 and 10–3).

Left occipitoanterior engagement.

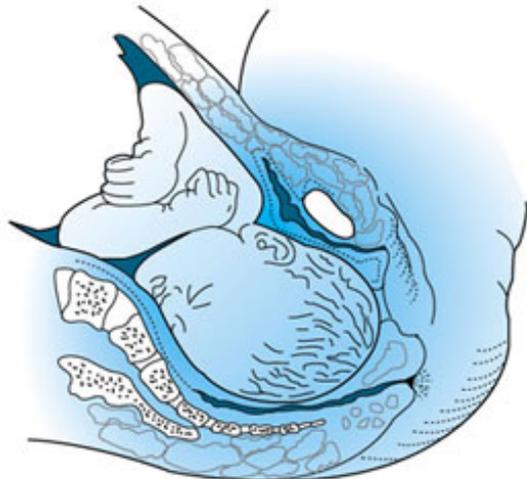

FLEXION

In most cases, flexion is essential for both engagement and descent. This will vary, of course, if the head is small in relation to the pelvis or if the pelvis is unusually large. When the head is improperly fixed—or if there is significant narrowing of the pelvic strait (as in the platypelloid type of pelvis)—there may be some degree of deflexion if not actual extension. Such is the case with a brow (deflexion) or face (extension) presentation.

DESCENT

Descent is gradually progressive and is affected by the forces of labor and thinning of the lower uterine segment. Other factors also play a part (eg, pelvic configuration and the size and position of the presenting part). The greater the pelvic resistance or the poorer the contractions, the slower the descent. Descent continues progressively until the fetus is delivered; the other movements are superimposed on it (Fig 10–4).

Figure 10–4.

Descent in left occipitoanterior position.

INTERNAL ROTATION

With the descent of the head into the midpelvis, rotation occurs so that the sagittal suture occupies the anteroposterior diameter of the pelvis. Internal rotation normally begins with the presenting part at the level of the ischial spines. The levator ani muscles form a V-shaped sling that tends to rotate the vertex anteriorly. In cases of occipitoanterior vertex, the head has to rotate 45 degrees, and in occipitoposterior vertex, 135 degrees to pass beneath the pubic arch (Fig 10–5).

Figure 10–5.

Anterior rotation of head.

EXTENSION

Because the vaginal outlet is directed upward and forward, extension must occur before the head can pass through it. As the head continues its descent, there is a bulging of the perineum followed by crowning. Crowning occurs when the largest diameter of the fetal head is encircled by the vulvar ring (Fig 10–6). At this time, spontaneous delivery is imminent and careful management by the practitioner with controlled efforts of the mother will minimize perineal trauma. Routine episiotomy is unnecessary, and is associated with increased maternal blood loss, increased risk of disruption of the anal sphincter (third-degree extension) and rectal mucos (fourth-degree extension), as well as delay in the patient's resumption of sexual activity. Further extension follows extrusion of the head beyond the introitus. Once the head is delivered, the airway is cleared of blood and amniotic fluid using a bulb suction device. The oral cavity is cleared initially, followed by clearing of the nares.

Extension of the head.

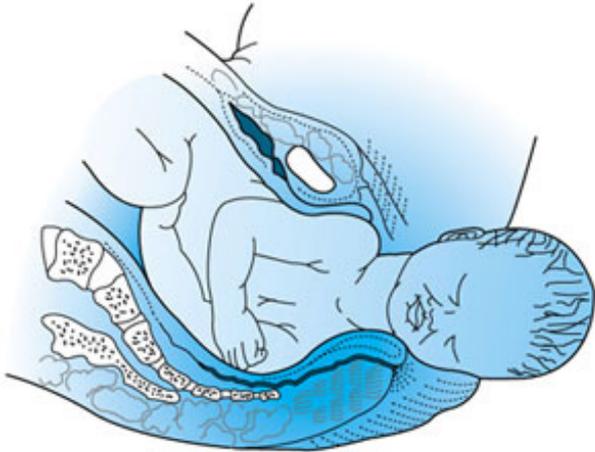

After the airway is cleared, an index finger is used to check whether the umbilical cord encircles the neck. If so,

the cord can usually be slipped over the infant's head. If the cord is too tight, it can be cut between two clamps.

EXTERNAL ROTATION

External rotation (restitution) follows delivery of the head when it rotates to the position it occupied at engagement. Following this, the shoulders descend in a path similar to that traced by the head. The anterior shoulder rotates internally about 45 degrees to come under the pubic arch for delivery (Fig 10–7). As this occurs the head swings back to its position at birth. Delivery of the anterior shoulder is aided by gentle downward traction on the externally rotated head (Fig 10–8). The posterior shoulder is then delivered by gentle upward traction on the head (Fig 10–9). The brachial plexus may be injured if excessive force is used. Following these maneuvers, the body, legs, and feet are delivered with gentle traction on the shoulders.

Delivery of posterior shoulder.

After delivery, blood will be infused from the placenta into the newborn if the baby is held below the mother's introitus. Delayed cord clamping can result in neonatal hyperbilirubinemia as additional blood is transferred to the newborn infant. Generally, a vigorous newborn can be delivered directly from the introitus to the abdomen and waiting arms of a healthy, alert mother. Placing the child skin to skin (abdomen to abdomen) results in optimum warmth for the newborn. Then the cord, which has been doubly clamped may then be cut between the clamps, either the practitioner, the mother, or her partner.

Third Stage of Labor

Immediately after the baby is delivered, the cervix and vagina should be inspected for actively bleeding lacerations and surgical repair should be performed as needed. Repair of vaginal lacerations should be performed using absorbable suture material, either 2-0 or 3-0. The inspection and repair of the cervix, vagina, and perineum is often easier prior to the separation of the placenta before uterine bleeding obscures visualization.

Separation of the placenta generally occurs within 2–10 minutes of the end of the second stage, but it may take 30 minutes or more to spontaneously separate. Signs of placental separation are: (a) a fresh show of blood from vagina, (b) the umbilical cord lengthens outside the vagina, (c) the fundus of the uterus rises up, and (d) the uterus becomes firm and globular. When these signs appear, it is safe to place traction on the cord. The gentle traction, with or without counterpressure between the symphysis and fundus to prevent descent of the uterus, allows delivery of the placenta.

After the delivery of the placenta, attention is turned to prevention of excessive postpartum bleeding. Uterine contractions which reduce this bleeding may be enhanced with uterine massage and/or the infusion of a dilute solution of oxytocin. The placenta should be examined to ensure complete removal and to detect placental abnormalities.

Puerperium

The puerperium consists of the period following the delivery of the baby and placenta to approximately 6 weeks postpartum. The immediate postpartum period (within the first hour of delivery) is a critical time for both maternal and neonatal physiologic and emotional adjustment. During that hour, the maternal blood pressure, pulse rate, and uterine blood loss must be monitored closely. It is during this time that most postpartum hemorrhage usually occurs, largely as a result of uterine relaxation, retained placental fragments, or unrepaired lacerations. Occult bleeding (eg, vaginal wall hematoma formation) may manifest as increasing pelvic pain.

At the same time, maternal bonding to the newborn is evolving, and ideally breastfeeding is initiated. Early initiation of breastfeeding is beneficial to the health of both the mother and the newborn. Both benefit because babies are extremely alert and programmed to latch onto the breast during this period. Mother–infant pairs that begin breastfeeding early are most able to continue breastfeeding for longer periods of time. For the mother, nursing accelerates the involution of the uterus, thereby reducing blood loss by increasing uterine contractions. For the newborn, there are important immunologic advantages. For example, various maternal antibodies are present in breast milk, which provide the newborn with passive immunity against certain infections. Also immunoglobulin (Ig) A, a secretory immunoglobulin present in significant amounts in breast milk, protects the infant's gut by preventing attachment of harmful bacteria to cells of the gut mucosal surface. It is also believed that maternal lymphocytes pass through the infant's gut wall and initiate immunologic processes that are not yet fully understood. In addition to the immunologic benefits, breast milk is the ideal nutritional source for the newborn. Moreover it is inexpensive and is usually in good supply. Given all the advantages (the above is only a partial list of the benefits), encouraging successful breastfeeding is an important health goal.

Induction and Augmentation of Labor

Induction of labor is the process of initiating labor by artificial means; augmentation is the artificial stimulation of labor that has begun spontaneously. Labor induction should be performed only after appropriate assessment of the mother and fetus. Additionally, the risks, benefits, and alternatives to induction in each case must be evaluated and explained to the patient. In the absence of medical indications for induction, fetal maturity must be confirmed by either exact pregnancy dating, first trimester ultrasound measurements, and/or amniotic fluid analysis. Evaluation of the cervical status in terms of effacement and softening is important in predicting success of induction and is highly recommended before any elective induction (Table 10–2). Generally, induction should be done in response to specific indications.

Elective induction of labor may be performed safely when pelvic score is 9 or more.

INDICATIONS

The following are common indications for induction of labor:

Maternal

Preeclampsia, diabetes mellitus, heart disease, and history of fast labors.

Fetal/Maternal

Prolonged pregnancy, Rh incompatibility, fetal abnormality, chorioamnionitis, premature rupture of membranes, placental insufficiency, suspected intrauterine growth restriction.

CONTRAINDICATIONS

Absolute contraindications to induction of labor include contracted pelvis; placenta previa; uterine scar because of previous classical cesarean section, myomectomy entering the endometrium, hysterotomy, or unification surgery; and transverse lie.

Labor induction should be carried out with caution in the following situations: breech presentation, oligohydramnios, multiple gestation, grand multiparity, previous cesarean section with transverse scar, prematurity, suspected fetal macrosomia.

Complications of Induction of Labor

FOR THE MOTHER

In many cases, induction of labor exposes the mother to more distress and discomfort than judicious delay and subsequent vaginal or cesarean delivery. The following hazards must be kept in mind: (a) failure of induction wi

increased risk of cesarean delivery; (b) uterine inertia and prolonged labor; (c) tumultuous labor and tetanic contractions of the uterus, causing premature separation of the placenta, rupture of the uterus, and laceration of the cervix; (d) intrauterine infection; and (e) postpartum hemorrhage.

FOR THE FETUS

An induced delivery exposes the infant to the risk of prematurity if the estimated date of conception has been inaccurately calculated. Precipitous delivery may result in physical injury. Prolapse of the cord may follow amniotomy. Injudicious administration of oxytocin or inadequate observation during induction could lead to fetal heart rate abnormalities or delivery of a baby with poor Apgar scores.

Methods of Cervical Ripening

Cervical ripening prior to induction of labor could facilitate the onset and progression of labor and increase the chance of vaginal delivery, particularly in primigravid patients.

PROSTAGLANDIN

Two forms of prostaglandins are commonly used for cervical ripening prior to induction at term: misoprostol (PGE₁) and dinoprostone (PGE₂). Although only dinoprostone, commercially available as prostaglandin gel, is currently Food and Drug Administration (FDA)-approved for this use, off-label use of misoprostol for cervical ripening is widely practiced. Indeed, although both misoprostol and dinoprostone applied locally intravaginally can provide significant improvement in the Bishop score, a meta-analysis of randomized, controlled trials focusing on cervical ripening and induction of labor found the time to delivery was shorter and the rate of cesarean delivery was lower in the misoprostol group.

Dinoprostone comes prepackaged in a single-dose syringe containing 0.5 mg of PGE₂ in 2.5 mL of a viscous gel with colloidal silicon dioxide in triacetin. The syringe is attached to a soft-plastic catheter for intracervical administration, and the catheter is shielded to help prevent application above the internal cervical os. Misoprostol is manufactured in 100-µg unscored and 200-µg scored tablets that can be administered orally, vaginally, and rectally. PGE₂ should not be used in patients with a history of asthma, glaucoma, or myocardial infarction. Unexplained vaginal bleeding, chorioamnionitis, ruptured membranes, and previous cesarean section are relative contraindications to the use of prostaglandins for cervical ripening.

For cervical ripening and induction at term, misoprostol is given vaginally at a dose of 25 µg every 4–6 hours. With dinoprostone, usually 12 hours should be allowed for cervical ripening, after which oxytocin induction should be started. PGE₁ and PGE₂ have similar side-effect and risk profiles, including fetal heart rate deceleration, fetal distress, emergency cesarean section, uterine hypertonicity, nausea, vomiting, fever, and peripartum infection. However, a current literature review does not indicate any significant differences in reported side effects between control and treatment groups with prostaglandin cervical ripening.

RELAXIN

Relaxin is a polypeptide hormone that is produced in the human corpus luteum, decidua, and chorion. Purified protein relaxin, 2 mg in tylose gel, given vaginally or intracervically is noted to induce cervical ripening in 80% of cases and labor in about one-third of patients over a 12-hour period.

BALLOON CATHETER

A Foley catheter with a 25- to 50-mL balloon is passed into the endocervix above the internal os using tissue forceps. The balloon is then inflated with sterile saline, and the catheter is withdrawn gently to the level of internal cervical os. This method should induce cervical ripening over 8–12 hours. The cervix will be dilated 2–3 cm when the balloon falls out, which will make amniotomy possible, but effacement may be unchanged.

HYGROSCOPIC DILATORS

Laminaria tents are made from desiccated stems of the cold-water seaweed *Laminaria digitata* or *L. japonica*. When placed in the endocervix for 6–12 hours, the laminaria increases in diameter 3- to 4-fold by extracting

water from cervical tissues, gradually swelling and expanding the cervical canal. Synthetic dilators like lamicel, a polyvinyl alcohol polymer sponge impregnated with 450 mg of magnesium sulfate, and dilapan, which is made from a stable nontoxic hydrophilic polymer of polyacrylonitrile, are also noted to be highly effective in mechanical cervical dilation.

Induction of Labor

OXYTOCIN

Intravenous administration of a very dilute solution of oxytocin is the most effective medical means of inducing labor. Oxytocin exaggerates the inherent rhythmic pattern of uterine motility, which often becomes clinically evident during the last trimester and increases as term is approached.

The dosage must be individualized. The administration of oxytocin is determined with a biologic assay: the smallest possible effective dose must be determined for each patient and then used to initiate and maintain labor. Constant observation by qualified attendants is required when this method is used.

In most cases it is sufficient to add 1 mL of oxytocin (10 units oxytocin to 1 L of 5% dextrose in water [1 mU/mL]). One acceptable oxytocin infusion regimen is to begin induction or augmentation at 1 mU/min, preferably with an infusion pump or other accurate delivery system, and increase oxytocin in 2-mU increments at 15-minute intervals.

When contractions of 50–60 mm Hg (per the internal monitor pressure) or lasting 40–60 seconds (per the external monitor) occur at 2.5- to 4-minute intervals, the oxytocin dose should be increased no further. Oxytocin infusion is discontinued whenever hyperstimulation or fetal distress is identified, but can be restarted when reassuring fetal heart rate and uterine activity patterns are restored.

AMNIOTOMY

Early and variable decelerations of the fetal heart rate are noted to be relatively common with amniotomy. Nonetheless, amniotomy may be an effective way to induce labor in carefully selected cases with high Bishop scores. Release of amniotic fluid shortens the muscle bundles of the myometrium; the strength and duration of the contractions are thereby increased and a more rapid contraction sequence follows. The membranes should be ruptured with an amniohook. Make no effort to strip the membranes, and do not displace the head upward to drain off amniotic fluid. Because amniotomy has not been proven effective in augmenting labor uniformly, it is recommended that the active phase of labor be entered prior to performing amniotomy for augmentation. Amniotomy in selected cases, while slightly increasing the risk of infectious morbidity, could shorten the course of labor without increasing or reducing the incidence of operative delivery.

Current OB/GYN > Chapter 11. Essentials of Normal Newborn Assessment and Care >

ESSENTIALS OF NORMAL NEWBORN ASSESSMENT AND CARE: INTRODUCTION

A full-term newborn is a baby born at 37 weeks' or more gestation. Term newborns are evaluated in the delivery room immediately following birth to assure that they do not require respiratory or circulatory support, have no birth-related trauma or congenital anomalies requiring immediate intervention and are transitioning as expected to extrauterine life. Approximately 97% of newborns are healthy and are transferred to the normal newborn nursery after birth. In the nursery, newborns receive a thorough evaluation to determine maturity, evaluate growth and development and identify those with signs of acute illness or underlying congenital disease.

DELIVERY ROOM MANAGEMENT

At every delivery there should be at least one person whose primary responsibility is attending to the newborn. Although approximately 90% of the time no resuscitation will be required, the attendant must be able to recognize signs of distress in a newborn and carry out a skilled resuscitation.

After the umbilical cord is cut, newborns should be placed in a warm environment. They may be placed on the mother's chest, skin-to-skin, or they may be brought to a radiant warmer. Early skin-to-skin contact increases the likelihood and duration of breastfeeding, decreases infant crying, and positively impacts early signs of bonding, and is therefore encouraged when possible. However, it should only be done when the newborn is vigorous and there are no risk factors that increase the likelihood that resuscitation will be required. The infant is dried with prewarmed towels to prevent heat loss and the airway is positioned and cleared to ensure patency. The airway is cleared by suctioning the mouth and nares with a bulb syringe or a suction catheter connected to mechanical suction. If the newborn is well-appearing and not at increased risk, the airway can be cleared simply by wiping the mouth and nose with a towel.

During this initial postpartum period the newborn's respiratory effort, heart rate, color, and activity are evaluated to determine the need for intervention. If drying and suctioning do not provide adequate stimulus, it is appropriate to flick the soles or rub the back to stimulate breathing. It is important to note the presence of meconium in the amniotic fluid or on the newborn's skin. All newborns born with meconium-stained amniotic fluid should have the oropharynx suctioned by the obstetrician upon delivery of the head. If a newborn is in distress or has depressed respiratory effort and there is evidence that meconium was passed in utero, the appropriate intervention is to intubate and suction the trachea before stimulating the baby in any way. Meconium can block the airway, preventing the newborn lungs from filling with oxygen, a vital step in normal transitioning. An active, crying, well-appearing newborn does not require endotracheal intubation, regardless of the presence of meconium staining or the thickness of the meconium.

If the newborn remains apneic despite drying, suctioning, and stimulation, or if there are signs of distress such as grunting, central cyanosis, or bradycardia, resuscitation should quickly be initiated. The initial step in neonatal resuscitation is to provide positive pressure ventilation (PPV) and the decision to initiate

PPV should ideally be made within the first 30 seconds after birth.

THE ASSIGNMENT OF APGAR SCORES

The Apgar score was introduced by Virginia Apgar in 1952 to quantitatively evaluate the newborn's condition after birth (Table 11–1). Scores between 0 and 2 in each of 5 different categories are assigned at 1 and 5 minutes of life. The score reflects the cardiorespiratory and neurologic status at those time points. If the score is less than 7 at 5 minutes, scores should be assigned every 5 minutes until the baby has a score of 7 or greater or has reached 20 minutes of life. The Apgar score is not what determines the need for resuscitation. Although scores are based on the same elements used to evaluate the newborn's status, the assessment of the need for intervention with PPV should already have been made by the time the 1-minute Apgar score is assigned. Studies do not show a correlation between a low 1-minute Apgar score and outcome. However, the change between the scores at 1 and 5 minutes is a meaningful measure of the effectiveness of the resuscitation efforts and a 5-minute score of 0–3 is associated with increased mortality in both preterm and full-term infants. It is important to know that factors such as prematurity, maternal medications and congenital disease can adversely impact scores.

Table 11–1. Apgar Scoring.

Signs	Points Scored		
	0	1	2
Heartbeats per minute	Absent	Slow (< 100)	Over 100
Respiratory effort	Absent	Slow, irregular	Good, crying
Muscle tone	Limp	Some flexion of extremities	Active motion
Reflex irritability	No response	Grimace	Cry or cough
Color	Blue or pale	Body pink, extremities blue	Completely pink

THE IMPORTANCE OF THE PRENATAL AND INTRAPARTUM HISTORY

Knowledge of the prenatal and intrapartum history is essential for adequate care of the newborn. The history should be reviewed before delivery (if possible) as it may alter care in the immediate postpartum period. For example, information about the use of certain anesthetic drugs during labor and delivery alerts those attending the delivery to the possibility of newborn respiratory depression and allows them to anticipate a role for the use of naloxone in the resuscitation. Other important pieces of information are the presence of chronic disease in the mother (such as diabetes mellitus, Grave's disease, or systemic lupus erythematosus), maternal illicit or prescription drug use, prenatal ultrasound findings, maternal screening laboratory test results, and the presence of risk factors for neonatal infection. All of these will impact how the newborn is monitored during the nursery admission and in the first few weeks of life, and adequate care is not possible without them.

INITIAL EXAM

Although a complete and detailed physical exam is delayed until the newborn is admitted to the nursery and has had time to transition to extrauterine life, a brief examination should be done shortly after delivery to rule out any problems that require immediate attention.

Airway

The airway should be evaluated for patency. A suction catheter may be passed through each naris if needed to remove secretions from the nasopharynx or if there is concern about the possibility of choanal

atresia, but is not necessary if adequate clearance of secretions is achieved with a bulb syringe and the newborn is breathing comfortably. Although a suction catheter is an effective means of removing secretions, it should be used cautiously as it can induce bradycardia and cause trauma and edema to the mucous membranes.

Chest

The chest should be examined to determine the adequacy of the respiratory effort. One should assess chest wall movement, respiratory rate and breathing pattern and look for signs of distress such as retractions. Crackles are often audible initially, but should clear over time as fetal lung fluid is being resorbed and the lungs inflate with air. Decreased breath sounds may result from pneumothorax, atelectasis, and consolidation as a result of pneumonia or effusions. The presence of asymmetric breath sounds should be noted as they may alert the examiner to the presence of an intrathoracic mass. Heart rate and rhythm should be evaluated and the presence or absence of a murmur noted. The heart rate should be greater than 100 beats per minute.

Abdomen

The abdomen should be soft and nondistended. A distended, firm abdomen may indicate a bowel obstruction, pneumoperitoneum, or intra-abdominal mass. A scaphoid abdomen, when accompanied by respiratory distress, should raise the examiner's suspicion of a diaphragmatic hernia. The umbilical stump should be examined and the number of blood vessels noted. A single umbilical artery may be a clue to the presence of other anomalies, renal anomalies in particular.

Skin

The skin color should be evaluated. Although acrocyanosis, bluish discoloration of the hands and feet, may be seen in well newborns, central cyanosis of the trunk is not normal for longer than a few seconds after birth and is a sign that the newborn is not receiving sufficient oxygen. Cyanosis and pallor can result from a wide variety of causes such as sepsis, anemia, respiratory insufficiency with or without abnormally elevated cardiac vascular resistance, congenital heart disease, and hypoxic-ischemic injury with cardiac dysfunction; the pre- and intrapartum history is often useful in determining the etiology. A cyanotic infant with a normal heart rate and respiratory effort may be given free-flow 100% oxygen by face mask or tubing held close to the nose and should be observed for improvement in skin coloring. If the skin does not become pink, the patient may require positive pressure ventilation to achieve improved oxygenation.

Genitalia

It is important to closely evaluate the genitalia prior to pronouncing the sex of the newborn. If there is ambiguity of the genitalia the situation must be explained to the parents and a full evaluation, including karyotyping and consultation with a pediatric endocrinologist and urologist, should be done prior to gender assignment.

General

Alertness, activity, tone and movement of the extremities should be noted. The face and extremities should be evaluated for evidence of congenital anomalies or birth trauma. The most common birth-related injuries are nerve injuries (facial and brachial nerve palsies) and fractures (primarily clavicular). Unilateral peripheral facial nerve palsy should be suspected when the newborn has normal movement of the forehead, but difficulty closing the eye and flattening of the nasolabial folds on the affected side and an asymmetric facial expression with crying (the unaffected side will go down). Peripheral facial nerve injury is thought to result from compression of the nerve against the sacrum during delivery and is not associated with the use of forceps in delivery. The risk of brachial plexus injury is increased when there is

shoulder dystocia or the baby is large for gestational age (LGA). Erb's palsy (C5-C6 injury) manifests as an inability to externally rotate or abduct the shoulder; the affected arm is held adducted and internally rotated and is extended and pronated at the elbow ("waiter-tip" position). If the C5-T1 nerve roots are all affected, the function of the hand will be affected as well.

CARE AND OBSERVATION IN THE FIRST FEW HOURS OF LIFE

A single 1 mg intramuscular injection of vitamin K is recommended for all newborns to prevent bleeding as a result of vitamin K deficiency. Vitamin K prophylaxis has been standard of care since 1961, when it was first recommended by the American Academy of Pediatrics (AAP). Standard newborn care also includes applying either 0.5% erythromycin ointment, 1% silver nitrate solution, or 1% tetracycline ointment to the infant's eyes shortly after birth to prevent infectious neonatal conjunctivitis.

The well newborn may remain with the mother after birth and attempt an initial feed. There should be continued intermittent assessment to assure that there is no cardiorespiratory distress, temperature instability, altered level of activity, or other signs of distress. It is important that caregivers are aware that babies that require resuscitation after birth are at increased risk of difficulties with transitioning and must be monitored closely.

NEWBORN NURSERY CARE

Vital Signs

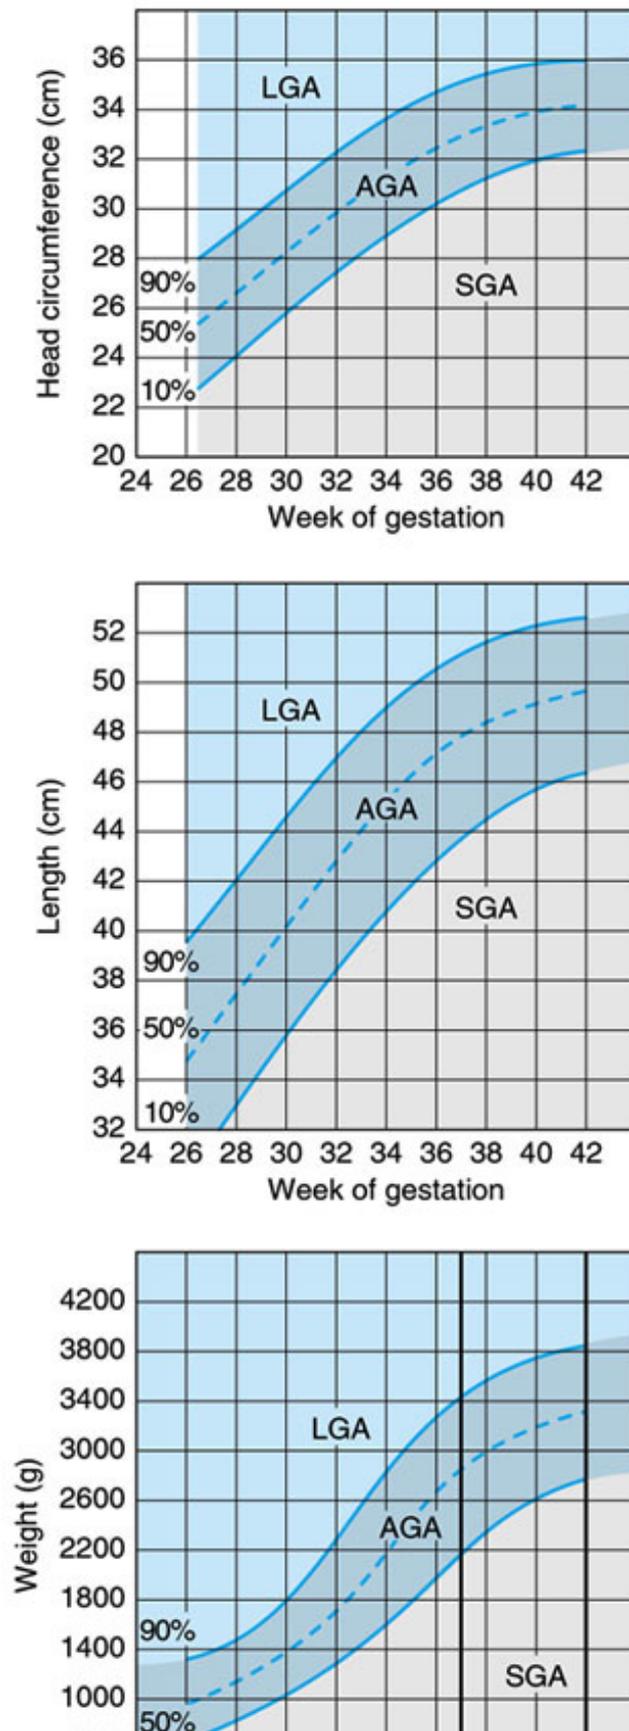

Vital signs should be recorded by the nursing staff for all newborns admitted to the nursery. Body temperature is typically measured in the axilla. Fever, defined as a temperature greater than 38.0° Celsius, is often caused by excessive environmental heat or overbundling when it occurs shortly after birth. Hypothermia may result if newborns are left in the delivery room unbundled and off the radiant warmer. A newborn with hypothermia or hyperthermia whose temperature fails to normalize in response to appropriate environmental measures should be evaluated for possible sepsis and central nervous system pathology.

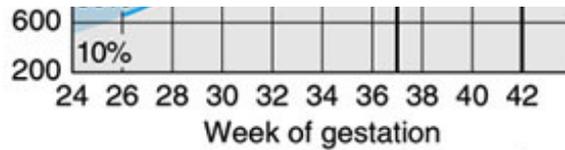

A normal respiratory rate for a newborn is typically between 40 and 60 breaths per minute. A normal heart rate for a newborn is generally 100–160 bpm, but varies considerably with sleep and activity level. If measured, pulse oximetry should be > 95% in the term baby. Blood pressure varies with gestation and birth weight. There is still debate about what constitutes an abnormal blood pressure in a neonate, but hypotension in the first 12–24 hours of life is typically defined as a mean blood pressure less than the gestational age. Hypertension in the full-term newborn is defined as a systolic blood pressure greater than 90 mm Hg and diastolic blood pressure greater than 60 mm Hg and a mean blood pressure > 70 mm Hg. Blood pressures should be measured in all 4 extremities if there is any suspicion of cardiac disease. Coarctation of the aorta is characterized by elevated blood pressure in the upper extremities and decreased pressure in the lower extremities.

Growth and Development

Weight, length, and head circumference should be measured and plotted on curves to assess intrauterine growth (Fig 11–1). Newborns that are small for gestational age (SGA), historically defined as less than the 10th percentile on the growth curve, may warrant evaluation for congenital infections, chromosomal syndromes or other causes if there is no identifiable cause for the growth retardation, such as multiple pregnancy or preeclampsia or other evidence of placental insufficiency. Infants that are SGA or large for gestational age (LGA) should be treated similarly to the infants of diabetic mothers, and should be monitored for hypoglycemia in the first few hours of life.

Figure 11-1.

Preterm | Term | Postterm

Classification of newborns based on gestational age plotted against head circumference, length, and weight. AGA, appropriate for gestational age; LGA, large for gestational age; SGA, small for gestational age.

Although gestational age is usually estimated prior to delivery by prenatal ultrasounds (preferably early on in the pregnancy) or the mother's last menstrual period, information is sometimes unavailable or inaccurate and maturity should be reassessed postnatally. There are measures, such as Ballard's modified version of the Dubowitz exam (Table 11–2), which incorporate multiple elements of the physical exam and may be useful at 12–24 hours of life to help determine gestational age.

Table 11–2. Newborn Maturity Rating and Classification.

	0	1	2	3	4	5
Neuromuscular maturity						
Posture						
Square window (wrist)	90°	60°	45°	30°	0°	
Arm recoil	180°		100°–180°	90°–100°	< 90°	
Popliteal angle	180°	160°	130°	110°	90°	< 90°
Scarf sign						
Heel to ear						
Physical maturity						
Skin	Gelatinous, red, transparent	Smooth, pink; visible veins	Superficial peeling and/or rash; few veins	Cracking, pale area; rare veins	Parchment, deep cracking; no vessels	Leathery, cracked, wrinkled
Lanugo	None	Abundant	Thinning	Bald areas	Mostly bald	

	0	1	2	3	4	5
Plantar creases	No crease	Faint red marks	Anterior transverse crease only	Creases anterior two-thirds	Creases cover entire sole	
Breast	Barely perceptible	Flat areola; no bud	Stippled areola; bud, 1–2 mm	Raised areola; bud, 3–4 mm	Full areola; bud, 5–10 mm	
Ear	Pinna flat; stays folded	Slightly curved pinna; soft; slow recoil	Well-curved pinna; soft; ready recoil	Formed and firm; instant recoil	Thick cartilage; ear stiff	
Genitalia (male)	Scrotum empty; no rugae		Testes descending; few rugae	Testes down; good rugae	Testes pendulous; deep rugae	
Genitalia (female)	Prominent clitoris and labia minora		Majora and minora equally prominent	Majora large; minora small	Clitoris and minora completely covered	

The following information should be recorded: Birth date and Apgar score at 1 and 5 minutes. Two separate examinations should be made within the first 24 hours to determine the estimated gestational age according to maturity rating. Each examination and the age of the infant at each examination should be noted.

Score	5	10	15	20	25	30	35	40	45	50
Weeks	26	28	30	32	34	36	38	40	42	44

Maturity rating:

Physical Exam

A physician should perform a complete physical exam of the newborn within the first 24 hours of life.

SKIN

As on the initial brief examination, the color of the skin should be evaluated and the presence of cyanosis, pallor, or jaundice noted. The healthy newborn should be pink. Postterm infants often have dry, cracked skin. Clinical jaundice is rare in the first 24 hours of life and should trigger an evaluation. Plethora, often seen in infants of diabetic mothers, may indicate significant polycythemia. Practice varies, but most neonatologists consider a hematocrit greater than 70% in an asymptomatic newborn and 65% in a symptomatic newborn grounds for a partial exchange transfusion. Symptoms of hyperviscosity include hypoxia, hypoglycemia, increased work of breathing, and seizures. Neurologic sequelae can be serious.

Petechiae are often present over the face and upper torso, particularly when a nuchal cord is present. When present below the nipple line, petechiae should raise concern about the possibility of sepsis or platelet dysfunction. Bruising occurs frequently, especially with breech presentation, but should be noted as it may lead to excessive hemolysis and hyperbilirubinemia when extensive. Mongolian spots are dark purple-blue hyperpigmented areas usually over the back and buttocks that look like bruising, but are clusters of melanocytes deep within the dermis. They are present in a majority of black and Asian newborns and fade over time. Dermal sinuses, dimples, and cysts should be noted; they may indicate

underlying defects or pose a risk for infection.

The most common newborn rash is erythema toxicum, which presents at 24–48 hours of life in almost half of all newborns as erythematous papular-pustular lesions that tend to spare the palms and soles. Other frequently seen benign rashes include milia, small white papules typically around the nares, and transient neonatal pustular melanosis, small vesicles or pustules present at birth that leave pigmented macules surrounded by scale when they disappear.

Hemangiomas and vascular malformations may be present at birth. Hemangiomas are benign tumors of vascular endothelium and are often not present at birth, but may be noted soon after. They eventually involute without therapy, but only after an initial period of growth, usually of 6–12 months. If present near the eyes or airways they may require early intervention to prevent visual or airway compromise. In contrast, vascular malformations such as port-wine stains and salmon patches are always present at birth. Developmental anomalies composed of one or more types of vessels typically grow as the child grows and do not resolve spontaneously.

HEAD, FACE, AND NECK

The head should be evaluated for any asymmetry. The sutures lines may be open or slightly overriding, but premature fusion requires intervention as it presents a constraint to brain growth. The anterior fontanelle should be soft, not tense or bulging, when the newborn is calm. It is typically 1–4 cm in size, and may be enlarged with hypothyroidism or increased intracranial pressure. The posterior fontanelle is typically <1 cm and may not be palpable.

Scalp edema (caput succedaneum) can most easily be differentiated from a cephalohematoma (a localized collection of blood under the dura mater) by noting whether or not the swelling crosses suture lines; cephalohematoma is typically confined by suture lines. A cephalohematoma should raise awareness of the possible development of hyperbilirubinemia as the collection of blood is broken down and resorbed. Skull fractures can occur and the skull should be palpated carefully.

The face should be evaluated for dysmorphic features, malformations, and asymmetries. Micrognathia may cause significant airway compromise in the neonate and is associated with various syndromes. The palate should be palpated to ensure that it is not high-arched or clefted. A naris is patent if there is air movement through it (demonstrated by holding cotton in front of it) when the mouth and other naris are closed. Subconjunctival hemorrhages are a common finding as a result of the birth process. An absent red reflex should prompt an immediate ophthalmologic evaluation to rule out a congenital cataract, retinoblastoma, or glaucoma. Pupils should be equal and reactive. Abnormalities of the positioning or formation of the eyes, nose, or ears may suggest specific syndromes or chromosomal defects. Although preauricular tags and pits have been associated with renal malformations, there is no current evidence to suggest that their presence, when an isolated finding, is sufficient to warrant a renal ultrasound. The neck should be examined for masses, cysts, and webbing. The clavicles should be palpated for crepitus, swelling, and tenderness, which would suggest an underlying fracture. Although not usually detected until several weeks of age, torticollis may occur as a result of ischemia within, or hemorrhage into, the sternocleidomastoid muscle at birth. It manifests as a head tilt with or without a fibrous mass palpable in the muscle. Surgery is rarely necessary; the overwhelming majority of cases are managed with a home stretching regimen or physical therapy.

CHEST

The chest should be evaluated for deformities such as widely spaced or accessory nipples and pectus excavatum. Breast buds may be present in both sexes and are normal, a product of exposure to circulating maternal hormones in utero.

The respiratory effort and rate should be evaluated, looking for signs of respiratory distress. Early on, tachypnea may be the only sign of pathologic processes as varied as pneumonia, amniotic fluid and/or meconium aspiration syndrome, sepsis, or congenital heart disease (CHD). Breath sounds are auscultated, paying attention to the quality of the breath sounds, the air entry, and any asymmetry that is present across the lung fields. Asymmetry of the breath sounds may indicate an area of consolidation from atelectasis or infection, a pneumothorax, effusion, or mass. Upper airway sounds, such as congestion or stridor, are often mistaken for abnormal breath sounds on exam. The listener can usually distinguish noises of upper airway origin from those of intrathoracic origin by listening for the presence of the sounds over the patient's neck. Respiratory distress or an abnormal lung exam should be evaluated with a chest radiograph. In an emergency situation where a pneumothorax is suspected, a transilluminator may be used. Transillumination is increased over the side of a pneumothorax, but it is sometimes difficult to assess accurately and should be confirmed by chest radiograph when possible prior to needle aspiration or chest tube placement.

A hyperdynamic precordium may indicate underlying heart disease with volume overload to one or both ventricles. The heart is auscultated to evaluate the heart rate and rhythm and characterize the heart sounds. A split-second heart sound can assure the examiner that both the aortic and pulmonary valves are present. A murmur should be described by where it is heard, what it sounds like, if it occurs in systole or diastole, and how loud it is. Murmurs are often audible in the newborn and are frequently innocent. Innocent murmurs are often attributed to a closing ductus arteriosus or foramen ovale, but the most commonly heard innocent murmur in the neonate is produced by peripheral pulmonic stenosis (PPS). PPS murmurs occur during systole and are best heard over the back or axillae.

Murmurs may or may not be present in newborns with CHD. Ventricular septal defects, the most common form of CHD, have a characteristic harsh, systolic murmur associated with them. However, the pressures in the newborn pulmonary system are still high (roughly equal to systemic pressures) and thus there is usually no flow gradient across a large ventricular defect to produce a murmur in the first few days of life. Complex CHD typically presents as cyanosis, tachypnea, or shock, and will rarely present as an asymptomatic murmur. Signs may develop quickly with closure of the ductus arteriosus if the lesion has ductal-dependent pulmonary or systemic flow. The initial steps in evaluating a stable patient for suspected CHD include 4-extremity blood pressure measurements, measurement of pre- and postductal saturations, electrocardiogram, chest radiography, and a hyperoxia test. The diagnosis of CHD is usually established by echocardiogram.

ABDOMEN

The examiner should listen for bowel sounds and palpate the abdomen for masses, organomegaly, or abnormal musculature. The liver is easily palpable in the newborn and the inferior edge is usually 1–2 cm below the right costal margin. It is often possible to palpate the kidneys and spleen. Absence of the abdominal musculature may be associated with significant urinary tract abnormalities. The umbilical stump should be assessed for redness or induration to suggest infection. Umbilical hernias are common and typically require no intervention in infancy. Omphalocele and gastroschisis are major abdominal wall defects and require emergent surgical evaluation. Omphalocele is a > 4-cm midline abdominal wall defect. Bowel, and often liver, herniate through the defect, and the umbilicus is typically on the anterior aspect of the omphalocele. Unless ruptured, an omphalocele is covered by a membrane, unlike a gastroschisis. The defect in gastroschisis is typically to the right of the umbilicus on the abdominal wall. The entire bowel may be externalized, but the liver typically remains internal. Bowel atresias may be present in gastroschisis. Omphalocele is more frequently associated with other congenital anomalies whereas gastroschisis occurs more commonly in intrauterine growth restriction (IUGR) and with young maternal age.

GENITALIA

The penile length and clitoral size should be inspected to rule out ambiguous genitalia. The labia majora should cover the labia minora and clitoris in a term female. White mucouslike discharge from the vagina is often present and is physiologic.

The scrotum should be evaluated for hernias or masses and descent of the testicles. Transillumination of the scrotum will help to distinguish a hydrocele from an inguinal hernia. The position of the urethral meatus is important to note, as the presence of hypospadias should preclude routine circumcision so as to allow for optimal surgical correction of the hypospadias.

ANUS

The rectum should be evaluated for patency and position. An anteriorly displaced rectum may be associated with a rectogenital fistula.

MUSCULOSKELETAL SYSTEM

The extremities, spine, and hips are examined for signs of fracture, malformation, or deformation. Range of motion of the joints is assessed. Arthrogyrosis, contractures of the joints, may be seen with neuromuscular disease or oligohydramnios as a result of decreased or limited movement in utero. Abnormalities of the extremities, such as polydactyly or syndactyly, are seen in different chromosomal abnormalities and syndromes, and may help in making the diagnosis. Particular attention should be paid to the examination of the hips (despite the fact that a dislocation may not be detectable in the first weeks of life) because developmental dysplasia of the hip (DDH) can cause permanent damage if left undetected throughout the first year of life. Either the Barlow or Ortolani test may be used to determine whether a dislocation is present. The Barlow test involves positioning the patient on the back, bringing the knees together at midline, and then pushing down and out on the upper inner thighs. The Ortolani test involves pushing downward on the femurs while abducting the hips. With both maneuvers the dislocation is detected as a clunk as the femoral head is dislocated from the acetabulum (posteriorly with the Barlow, laterally with the Ortolani). Asymmetry of the gluteal folds and skin creases of the legs is another clue to the presence of DDH.

NEUROLOGIC SYSTEM

Observing the activity level, alertness and positioning of the newborn provides a tremendous amount of information about the overall state of health. A healthy, full-term newborn at rest should lie with the extremities flexed. Decreased tone may be a sign of neuromuscular or systemic illness such as sepsis. There should be spontaneous intermittent movement of all 4 limbs and the baby should be alert during at least portions of the examination. Pupil size and symmetry should be noted. Primitive reflexes such as the Moro, grasp, suck, and tonic neck reflex should all be present at birth. To elicit the Moro reflex, the newborn is supported with a hand under the back and then rapidly dropped a few centimeters back toward the examination bed. The full Moro reflex consists of extension and then flexion and adduction of the arms ("embrace"), opening of the eyes, and a cry. Reflexes are elicited by tapping a finger over the appropriate tendon. Significant clonus may be a sign of central nervous system injury. A sacral dimple or tuft of hair over the sacral spine may indicate spina bifida occulta and should be evaluated with a spinal ultrasound; if the findings of the ultrasound are equivocal, a magnetic resonance imaging (MRI) scan should be done at approximately 3 months of age.

FEEDING

The benefits of breastfeeding on everything from the strength of the immune system to developmental outcomes and IQ have been well documented. The caloric value of human milk is clearly superior to formula and it is the most easily digested form of infant nutrition. Mothers should be counseled prenatally about the benefits of breastfeeding and encouraged by their obstetric caregivers to consider breastfeeding. Contraindications to breastfeeding include human immunodeficiency virus (HIV) infection, active tuberculosis infection and the use of certain medications. Maternal hepatitis C virus (HCV) infection is not a contraindication to breastfeeding. Transmission of HCV via breastmilk is not documented in the absence of coexisting maternal infection with HIV. Nevertheless, infected mothers should be informed that transmission via breastmilk is theoretically possible.

Breastfeeding may be difficult and frustrating for new mothers. It is important that the newborn nursery staff work to provide mothers with the support and knowledge they need to make breastfeeding a positive experience. It is also important that mothers of newborns who require bottle supplementation (such as a dehydrated, jaundiced infant) are reassured that their efforts at breastfeeding will not be derailed by exposure to the bottle during a limited, medically necessary period, and that breastfeeding can still ultimately succeed.

Regardless of the overwhelming literature to support the value of breastmilk, many mothers in the United States choose to bottle-feed their children. Selection of the formula given to the newborn is often based on what formula is available in the nursery or by the mother's preference. Standard-term infant formula contains iron supplementation and provides 20 kcal/oz. No one formula is better than another for healthy term infants. Mothers with a family history of lactose intolerance sometimes request soy formula and standard soy formula will provide adequate nutrition for growth and development. Formulas such as Alimentum and Nutramigen are available for infants with more significant protein allergy. Premature infant formulas contain 24 kcal/oz and provide higher amounts of protein, medium-chain triglycerides, and vitamins and minerals (such as calcium and phosphorous) than standard formulas. The AAP currently recommends formula for the first year of life.

VOIDING AND STOOLING

Voiding should be monitored closely in the nursery. Changes in the baby's weight and the frequency of urination can be used to assess the hydration status and adequacy of intake in a breastfeeding baby. The time of the first void of urine and stool should be documented. Failure to void in the first 24 hours of life should prompt an evaluation for renal function and hydration status. Failure to pass stool in the first 48 hours of life should prompt an evaluation for possible bowel obstruction; 94% of normal term newborns will pass meconium in the first 24 hours of life. Obstruction can result from conditions such as bowel atresia or stenosis, Hirschsprung disease, and meconium ileus.

NEWBORN SCREENING AND PROPHYLAXIS

The initial newborn exam may be normal despite the presence of serious occult illness. Signs of complex congenital heart disease, sepsis, gastrointestinal obstruction, significant jaundice, inborn errors of metabolism, and other illnesses may not be present until the second or third day of life at the earliest: shortly before, and at times after, the baby's discharge. Screening is done in the hopes of detecting disease before a patient becomes symptomatic. Screening is usually reserved for processes that have a worse prognosis if not detected early and for which we have effective therapy. The maternal medical history, the obstetric and perinatal history, and state laws determine what screening is done on any given baby.

Standard newborn screening tests screen for the following:

1. Phenylketonuria by Guthrie test for phenylalanine level.
2. Congenital hypothyroidism by thyroid function testing.
3. Congenital syphilis by either rapid plasma reagent (RPR) or Venereal Disease Research Laboratory (VDRL) test (whichever test was performed on the mother).
4. ABO incompatibility using infant blood type and direct Coombs' test (standard if mother has O blood type, done at many institutions for all newborns).
5. Hearing loss (evaluated by auditory brainstem response or otoacoustic emissions).

In most states, standard screening also includes testing for sickle cell anemia, galactosemia, congenital adrenal hyperplasia and a small number of less common diseases. Some states are now doing expanded newborn screens by tandem mass spectrometry, a method that can screen for a large number of metabolic diseases from a single blood sample.

Additional targeted screening often includes evaluation for infection, illicit drug exposure, hyperbilirubinemia and hypoglycemia when there are risk factors that increase the yield of the testing. A history of rupture of amniotic membranes for greater than 18 hours prior to delivery, maternal intrapartum fever, chorioamnionitis and a positive maternal group B streptococcus culture without adequate treatment prior to delivery are all risk factors for newborn sepsis. A history of any of these risk factors warrants a screening evaluation of the asymptomatic newborn for laboratory evidence of infection. Screening is routinely done for hypoglycemia in infants of diabetic mothers as well as for SGA and LGA babies. At many institutions, infants of diabetic mothers are screened for polycythemia as well.

Information about maternal hepatitis B, HIV, herpes simplex virus (HSV), chlamydia, and syphilis status is essential to newborn care. Adequate prophylaxis for hepatitis B can prevent transmission in 95% of infants born to hepatitis B surface antigen-positive (HBsAg+) mothers. A baby born to a mother who is HBsAg+ should receive the hepatitis B vaccine and hepatitis B immune globulin (HBIG) within the first 12 hours of life in order to prevent hepatitis B virus (HBV) transmission. If the mother's status is unknown, the newborn should receive the vaccine within 12 hours of birth and every effort should be made to determine the mother's status. If the baby weighs more than 2 kg, HBIG can be given as late as 7 days of life if maternal status is positive or still unknown and still provide effective postexposure prophylaxis. However, a baby who weighs <2 kg at birth should receive HBIG by 12 hours of postnatal life to receive adequate prophylaxis. Appropriate screening and treatment for infants born to mothers with a history of infection with HIV, chlamydia, HSV, or syphilis are detailed in the AAP's *Red Book*.

CIRCUMCISION

Routine circumcision is not currently recommended by the AAP. Although there is evidence that supports some medical benefits of circumcision (such as decreased incidence of urinary tract infections during infancy, sexually transmitted disease, and penile cancer), the data is insufficient for the AAP to recommend the procedure for all newborn males given concerns about the impossibility of informed consent in an infant and evidence of the pain and stress caused by the procedure. Parents should be provided with unbiased information about the procedure and the decision to proceed should be left to them. If circumcision is performed, analgesia, either topical or by nerve block, should be given.

DISCHARGE PLANNING

The physician should complete another thorough examination on the day of discharge to reevaluate the overall health of the newborn. Anticipatory guidance should be given to parents to help them care for their newborns and recognize signs of illness and distress. Safety issues, such as the use of car seats, should be addressed. Parents should be alerted to problems such as fever, lethargy, and poor feeding that should prompt them to see a physician. They should be taught about expected newborn behavior, adequate feeding, monitoring of voiding and stooling, and umbilical cord care.

Anticipatory guidance is particularly important now that hospital stays after delivery are often only 36–48 hours. Criteria for newborn discharge at less than 48 hours of life are outlined in a 2004 AAP policy statement. Newborns discharged before 48 hours of life must be examined by a health care professional within 48 hours of the discharge. The plan for the newborn's first visit to the physician and any necessary follow-up laboratory testing or nursing visits to the home should be clearly established at the time of discharge and parents should be able to demonstrate skill and comfort with feeding and tending to the baby's basic needs.

Current OB/GYN > Chapter 12. The Normal Puerperium >

THE NORMAL PUERPERIUM: INTRODUCTION

The puerperium, or postpartum period, generally lasts 6–12 weeks and is the period of adjustment after delivery when the anatomic and physiologic changes of pregnancy are reversed, and the body returns to the normal nonpregnant state. The postpartum period has been arbitrarily divided into the immediate puerperium—the first 24 hours after parturition—when acute postanesthetic or postdelivery complications may occur; the early puerperium, which extends until the first week postpartum; and the remote puerperium, which includes the period of time required for involution of the genital organs and return of menses, usually by 6 weeks in nonlactating women, and the return of normal cardiovascular and psychological function, which may require months.

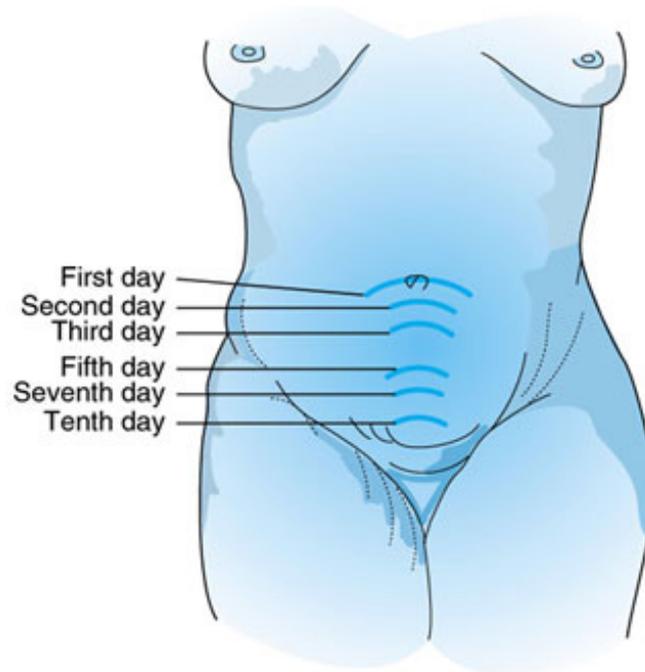

ANATOMIC & PHYSIOLOGIC CHANGES DURING THE PUERPERIUM

Uterine Involution

The uterus increases markedly in size and weight during pregnancy (about 10 times the nonpregnant weight, reaching a crude weight of 1000 g) but involutes rapidly after delivery to the nonpregnant weight of 50 to 100 g. The gross anatomic and histologic characteristics of this process have been studied through autopsy, hysterectomy, and endometrial specimens. In addition, the decrease in size of the uterus and cervix has been demonstrated by magnetic resonance imaging, sonography, and computed tomography.

Immediately following delivery, the uterus weighs about 1 kg, and its size approximates that of a 20-week pregnancy (at the level of the umbilicus). At the end of the first postpartum week, it normally will have decreased to the size of a 12-week gestation and is just palpable at the symphysis pubis (Fig 12–1). Ultrasonography can be used to measure length and width of the uterine cavity. During the first week, there is a 31% decrease in uterine area; during the second and third weeks, a 48% decrease; and subsequently, an 18% decrease. The observed changes in uterine area are mainly due to changes in uterine length, as the transverse diameter remains relatively constant during the puerperium.

Figure 12–1.

Involucional changes in the height of the fundus and the size of the uterus during the first 10 days postpartum.

Myometrial contractions or afterpains assist in involution. These contractions occur during the first 2–3 days of the puerperium and produce more discomfort in multiparas than in primiparas. Such pains are accentuated during nursing as a result of oxytocin release from the posterior pituitary. During the first 12 hours postpartum, uterine contractions are regular, strong, and coordinated (Fig 12–2). The intensity, frequency, and regularity of contractions decrease after the first postpartum day as involutional changes proceed. Uterine involution is nearly complete by 6 weeks, at which time the organ weighs less than 100 g. The increase in the amount of connective tissue and elastin in the myometrium and blood vessels and the increase in numbers of cells are permanent to some degree, so the uterus is slightly larger following pregnancy.

Figure 12–2.

Uterine activity during the immediate puerperium (left) and at 20 hours postpartum (right).

Changes in the Placental Implantation Site

Following delivery of the placenta, there is immediate contraction of the placental site to a size less than half the diameter of the original placenta. This contraction, as well as arterial smooth muscle contractions, leads to hemostasis. Involution occurs by means of the extension and downgrowth of marginal endometrium and by endometrial regeneration from the glands and stroma in the decidua basalis.

By day 16, placental site, endometrial, and superficial myometrial infiltrates of granulocytes and mononuclear cells are seen. Regeneration of endometrial glands and endometrial stroma has also begun. Endometrial regeneration at the placental site is not complete until 6 weeks postpartum. In the disorder termed subinvolution of the placental site, complete obliteration of the vessels in the placental site fails to occur. Patients with this condition have persistent lochia and are subject to brisk hemorrhagic episodes. This condition usually can be treated with uterotonics. In the rare event uterine curettage is performed, partly obliterated hyalinized vessels can be seen on the histologic specimen.

Normal postpartum discharge begins as lochia rubra, containing blood, shreds of tissue, and decidua. The amount of discharge rapidly tapers and changes to a reddish-brown color over the next 3–4 days. It is termed lochia serosa when it becomes serous to mucopurulent, paler, and often malodorous. During the second or third postpartum week, the lochia becomes thicker, mucoid, and yellowish-white (lochia alba), coincident with a predominance of leukocytes and degenerated decidual cells. Typically during the fifth or sixth week postpartum, the lochial secretions cease as healing nears completion.

Changes in the Cervix, Vagina, & Muscular Walls of the Pelvic Organs

The cervix gradually closes during the puerperium; at the end of the first week, it is little more than 1 cm dilated. The external os is converted into a transverse slit, thus distinguishing the parous woman who delivered vaginally from the nulliparous woman or from one who delivered by cesarean section. Colposcopic examination soon after delivery may reveal ulceration, ecchymosis, and laceration. Complete healing and reepithelialization occur 6–12 weeks later. Stromal edema and round cell infiltration and the endocervical glandular hyperplasia of pregnancy may persist for up to 3 months. Cervical lacerations heal in most uncomplicated cases, but the continuity of the cervix may not be restored, so the site of the tear may remain as a scarred notch.

After vaginal delivery, the overdistended and smooth-walled vagina gradually returns to its antepartum condition by about the third week. Thickening of the mucosa, cervical mucus production, and other estrogenic changes may be delayed in a lactating woman. The torn hymen heals in the form of fibrosed nodules of mucosa, the *carunculae myrtiformes*.

Two weeks after delivery, the fallopian tube reflects a hypoestrogenic state marked by atrophy of the epithelium. Fallopian tubes removed between postpartum days 5 and 15 demonstrate acute inflammatory changes that have not been correlated with subsequent puerperal fever or salpingitis. Normal changes in the pelvis after uncomplicated term vaginal delivery include widening of the symphysis and sacroiliac joints and occasionally gas in these joints. Gas is often seen by ultrasonography in the endometrial cavity after uncomplicated vaginal delivery and does not necessarily indicate the presence of endometritis.

Ovulation occurs as early as 27 days after delivery, with a mean time of 70–75 days in nonlactating women and 6 months in lactating women. In lactating women the duration of anovulation ultimately depends on the frequency of breastfeeding, duration of each feed, and proportion of supplementary feeds. Ovulation suppression is due to high prolactin levels, which remain elevated until approximately 3 weeks after delivery in nonlactating women and 6 weeks in lactating women. However, estrogen levels fall immediately after delivery in all mothers and remain suppressed in lactating mothers. Menstruation returns as soon as 7 weeks in 70% and by 12 weeks in all nonlactating mothers, and as late as 36 months in 70% of breastfeeding mothers.

The voluntary muscles of the pelvic floor and the pelvic supports gradually regain their tone during the puerperium. Tearing or overstretching of the musculature or fascia at the time of delivery predisposes to genital hernias. Overdistention of the abdominal wall during pregnancy may result in rupture of the elastic fibers of the cutis, persistent striae, and diastasis of the rectus muscles. Involution of the abdominal musculature may require 6–7 weeks, and vigorous exercise is not recommended until after that time.

Urinary System

In the immediate postpartum period, the bladder mucosa is edematous as a result of labor and delivery. In addition, bladder capacity is increased. Overdistention and incomplete emptying of the bladder with the presence of residual urine are therefore common problems. The diminished postpartum bladder function appears to be unaffected by infant weight and episiotomy but perhaps is transiently diminished by epidural anesthesia and prolonged labor. Nearly 50% of patients have a mild proteinuria for 1–2 days after delivery. Ultrasonographic examination demonstrates resolution of collecting system dilatation by 6 weeks postpartum in most women. Urinary stasis, however, may persist in more than 50% of women at 12 weeks postpartum. The incidence of urinary tract infection is generally higher in women with persistent dilatation. Significant renal enlargement may persist for many weeks postpartum.

Pregnancy is accompanied by an estimated increase of about 50% in the glomerular filtration rate. These

values return to normal or less than normal during the eighth week of the puerperium. Endogenous creatinine clearance similarly returns to normal by 8 weeks. Renal plasma flow, which increased during pregnancy by 25% in the first trimester, falls in the third trimester and continues to fall to below normal levels for up to 24 months. Normal levels return slowly over 50–60 weeks. The glucosuria induced by pregnancy disappears. The blood urea nitrogen rises during the puerperium; at the end of the first week postpartum, values of 20 mg/dL are reached, compared with 15 mg/dL in the late third trimester.

Fluid Balance & Electrolytes

An average decrease in maternal weight of 10–13 lb occurs intrapartum and immediately postpartum due to the loss of amniotic fluid and blood as well as delivery of the infant and placenta. The average patient may lose an additional 4 kg (9 lb) during the puerperium and over the next 6 months as a result of excretion of the fluids and electrolytes accumulated during pregnancy. Contrary to widespread belief, breastfeeding has minimal effects on hastening weight loss postpartum.

There is an average net fluid loss of at least 2 L during the first week postpartum and an additional loss of approximately 1.5 L during the next 5 weeks. The water loss in the first week postpartum represents a loss of extracellular fluid. A negative balance must be expected of slightly more than 100 mEq of chloride per kilogram of body weight lost in the early puerperium. This negative balance probably is attributable to the discharge of maternal extracellular fluid. The puerperal losses of salt and water are generally larger in women with preeclampsia–eclampsia.

The changes occurring in serum electrolytes during the puerperium indicate a general increase in the numbers of cations and anions compared with antepartum values. Although total exchangeable sodium decreases during the puerperium, the relative decrease in body water exceeds the sodium loss. The diminished aldosterone antagonism due to falling plasma progesterone concentrations may partially explain the rapid rise in serum sodium. Cellular breakdown due to tissue involution may contribute to the rise in plasma potassium concentration noted postpartum. The mean increase in cations, chiefly sodium, amounts to 4.7 mEq/L, with an equal increase in anions. Consequently, the plasma osmolality rises by 7 mOsm/L at the end of the first week postpartum. In keeping with the chloride shift, there is a tendency for the serum chloride concentration to decrease slightly postpartum as serum bicarbonate concentration increases.

Metabolic & Chemical Changes

Total fatty acids and nonesterified fatty acids return to nonpregnant levels on about the second day of the puerperium. Both cholesterol and triglyceride concentrations decrease significantly within 24 hours after delivery, and this change is reflected in all lipoprotein fractions. Plasma triglycerides continue to fall and approach nonpregnant values 6–7 weeks postpartum. By comparison, the decrease in plasma cholesterol levels is slower; low-density lipoprotein (LDL) cholesterol remains above nonpregnant levels for at least 7 weeks postpartum. Lactation does not influence lipid levels, but, in contrast to pregnancy, the postpartum hyperlipidemia is sensitive to dietary manipulation.

During the early puerperium, blood glucose concentrations (both fasting and postprandial) tend to fall below the values seen during pregnancy and delivery. This fall is most marked on the second and third postpartum days. Accordingly, the insulin requirements of diabetic patients are lower. Reliable indications of the insulin sensitivity and the blood glucose concentrations characteristic of the nonpregnant state can be demonstrated only after the first week postpartum. Thus, a glucose tolerance test performed in the early puerperium may be interpreted erroneously if nonpuerperal standards are applied to the results.

The concentration of free plasma amino acids increases postpartum. Normal nonpregnant values are regained rapidly on the second or third postpartum day and are presumably a result of reduced utilization

and an elevation in the renal threshold.

Cardiovascular Changes

BLOOD COAGULATION

The production of both prostacyclin (prostaglandin I₂ [PGI₂]), an inhibitor of platelet aggregation, and thromboxane A₂, an inducer of platelet aggregation and a vasoconstrictor, is increased during pregnancy and the puerperium. Possibly, the balance between thromboxane A₂ and PGI₂ is shifted to the side of thromboxane A₂ dominance during the puerperium because platelet reactivity is increased at this time. Rapid and dramatic changes in the coagulation and fibrinolytic systems occur after delivery (Table 12–1). A decrease in the fibrinogen concentration begins to decrease during labor and reaches its lowest point during the first day postpartum. Thereafter, rising plasma fibrinogen levels reach prelabor values by the third or fifth day of the puerperium. This secondary peak in fibrinogen activity is maintained until the second postpartum week, after which the level of activity slowly returns to normal nonpregnant levels during the following 7–10 days. A similar pattern occurs with respect to factor VIII and plasminogen. Circulating levels of antithrombin III are decreased in the third trimester of pregnancy. Patients with a congenital deficiency of antithrombin III (an endogenous inhibitor of factor X) have recurrent venous thromboembolic disease, and a low level of this factor has been associated with a hypercoagulable state.

Table 12–1. Changes in Blood Coagulation and Fibrinolysis during the Puerperium.

	Time Postpartum				
	1 Hour	1 Day	3–5 Days	1st Week	2nd Week
Platelet count	↓	↑	↑↑	↑↑	↑
Platelet adhesiveness	↑	↑↑	↑↑↑	↑	0
Fibrinogen	↓	↓	↑	0	↓
Factor V		↑	↑↑	↑	0
Factor VIII	↓	↓	↑	↑	↓
Factors II, VII, X		↓	↓	↓↓	↓↓
Plasminogen	↓	↓↓	0	↓	↓
Plasminogen activator	↑↑↑	↑↑	0		
Fibrinolytic activity	↑	↑↑	↑↑	↑	
Fibrin split products	↑	↑↑	↑↑		

The arrows indicate the direction and relative magnitude of change compared with the late third trimester or antepartum values. Zero indicates a return to antepartum but not necessarily nonpregnant values.

Prepared from data from Manning FA et al: Am J Obstet Gynecol 1971;110:900, Bonnar J et al: Br Med J 1970;2:200; Ygg J: Am J Obstet Gynecol 1969;104:2; and Shaper AG et al: J Obstet Gynaecol Br Commonw 1968;75:433.

The fibrinolytic activity of maternal plasma is greatly reduced during the last months of pregnancy but increases rapidly after delivery. In the first few hours postpartum, an increase in tissue plasminogen activator (t-PA) develops, together with a slight prolongation of the thrombin time, a decrease in plasminogen activator inhibitors, and a significant increase in fibrin split products. Protein C is an important coagulation inhibitor that requires the nonenzymatic cofactor protein S (which exists as a free

protein and as a complex) for its activity. The level of protein S, both total and free, increases on the first day after delivery and gradually returns to normal levels after the first week postpartum.

According to current concepts, the fibrinolytic system is in dynamic equilibrium with the factors that promote coagulation. Thus, after delivery, the increased plasma fibrinolytic activity coupled with the consumption of several clotting factors suggests a large deposition of fibrin in the placental bed. Because of the continued release of fibrin breakdown products from the placental site, the concentration of fibrin split products continues to rise even after spontaneous plasma fibrinolytic activity decreases. Increased levels of soluble fibrin monomer complexes are observed during the early puerperium compared with levels at 3 months postpartum.

The increased concentration of clotting factors normally seen during pregnancy can be viewed as teleologically important in providing a reserve to compensate for the rapid consumption of these factors during delivery and in promoting hemostasis after parturition. Nonetheless, extensive activation of clotting factors, together with immobility, sepsis, or trauma during delivery, may set the stage for later thromboembolic complications (see Chapter 26). The secondary increase in fibrinogen, factor VIII, or platelets (which remain well above nonpregnant values in the first week postpartum) also predisposes to thrombosis during the puerperium. The abrupt return of normal fibrinolytic activity after delivery may be a protective mechanism to combat this hazard. A small percentage of puerperal women who show a diminished ability to activate the fibrinolytic system appears to be at high risk for the development of postpartum thromboembolic complications.

BLOOD VOLUME CHANGES

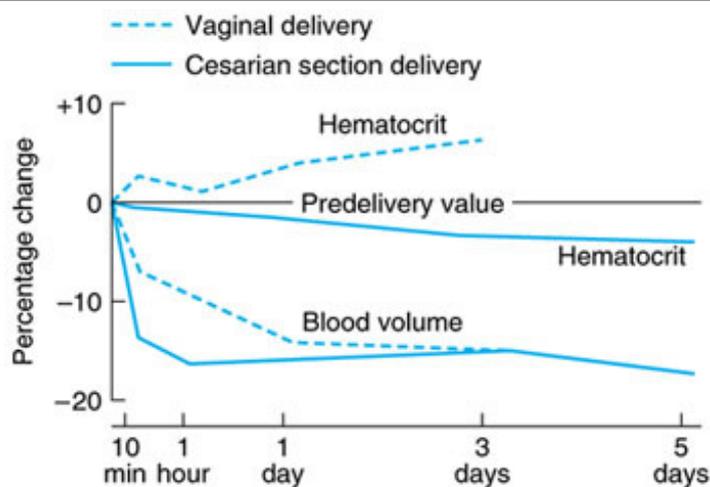

The total blood volume normally decreases from the antepartum value of 5–6 L to the nonpregnant value of 4 L by the third week after delivery. One-third of this reduction occurs during delivery and soon afterward, and a similar amount is lost by the end of the first postpartum week. Additional variation occurs with lactation. The hypervolemia of pregnancy may be viewed as a protective mechanism that allows most women to tolerate considerable loss of blood during parturition. The quantity of blood lost during delivery generally determines the blood volume and hematocrit during the puerperium. Normal vaginal delivery of a single fetus entails an average blood loss of about 400 mL, whereas cesarean section leads to a blood loss of nearly 1 L. If total hysterectomy is performed in addition to cesarean section delivery, the mean blood loss increases to approximately 1500 mL. Delivery of twins and triplets entails blood losses similar to those of operative delivery, but a compensatory increase in maternal plasma volume and red blood cell mass is observed during multiple pregnancy.

Dramatic and rapid readjustments occur in the maternal vasculature after delivery so that the response to blood loss during the early puerperium is different from that occurring in the nonpregnant woman. Delivery leads to obliteration of the low-resistance uteroplacental circulation and results in a 10–15% reduction in the size of the maternal vascular bed. Loss of placental endocrine function also removes a stimulus to vasodilatation.

A declining blood volume with a rise in hematocrit is usually seen 3–7 days after vaginal delivery (Fig 12–3). In contrast, serial studies of patients after cesarean section indicate a more rapid decline in blood volume and hematocrit and a tendency for the hematocrit to stabilize or even decline in the early puerperium. Hemoconcentration occurs if the loss of red cells is less than the reduction in vascular capacity. Hemodilution takes place in patients who lose 20% or more of their circulating blood volume at delivery. In patients with preeclampsia–eclampsia, resolution of peripheral vasoconstriction and mobilization of excess extracellular fluid may lead to significant expansion of vascular volume by the third postpartum day. Plasma atrial natriuretic peptide levels nearly double during the first days postpartum in response to atrial stretch caused by blood volume expansion and may have relevance for postpartum

natriuresis and diuresis. Occasionally, a patient sustains minimal blood loss at delivery. In such a patient, marked hemoconcentration may occur in the puerperium, especially if there has been a preexisting polycythemia or a considerable increase in the red cell mass during pregnancy.

Postpartum changes in hematocrit and blood volume in patients delivered vaginally and by cesarean section. Values are expressed as the percentage change from the predelivery hematocrit or blood volume.

(Based upon data from Ueland K et al: Maternal cardiovascular dynamics. 1. Cesarean section under subarachnoid block anesthesia. *Am J Obstet Gynecol* 1968;100:42; and Ueland K, Hansen J: Maternal cardiovascular dynamics. 3. Labor and delivery under local and caudal analgesia. *Am J Obstet Gynecol* 1969;103:8.)

HEMATOPOIESIS

The red cell mass increases by about 30% during pregnancy, whereas the average red cell loss at delivery is approximately 14%. Thus, the mean postpartum red cell mass level should be about 15% above nonpregnant values. The sudden loss of blood at delivery, however, leads to a rapid and short-lived reticulocytosis (with a peak on the fourth postpartum day) and moderately elevated erythropoietin levels during the first week postpartum.

The bone marrow in pregnancy and in the early puerperium is hyperactive and capable of delivering a large number of young cells to the peripheral blood. Prolactin may play a minor role in bone marrow stimulation.

A striking leukocytosis occurs during labor and extends into the early puerperium. In the immediate puerperium, the white blood cell count may be as high as 25,000/mL, with an increased percentage of granulocytes. The stimulus for this leukocytosis is not known, but it probably represents a release of sequestered cells in response to the stress of labor.

The serum iron level is decreased and the plasma iron turnover is increased between the third and fifth days of the puerperium. Normal values are regained by the second week postpartum. The shorter duration of ferrokinetic changes in puerperal women compared with the duration of changes in nonpregnant women who have had phlebotomy is due to the increased erythroid marrow activity and the circulatory changes described above.

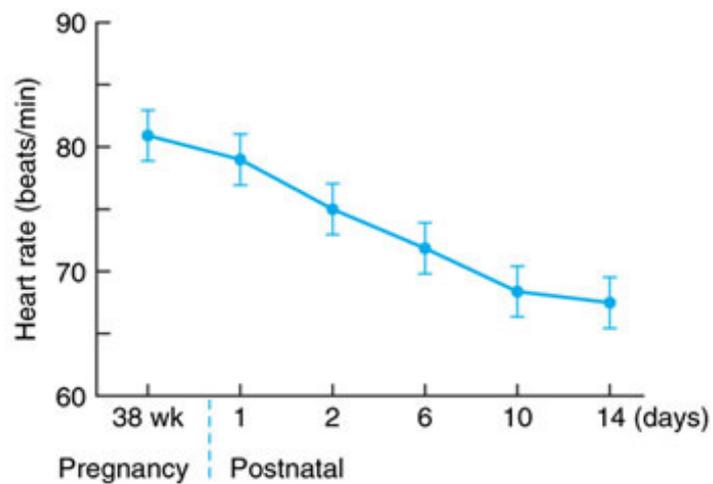

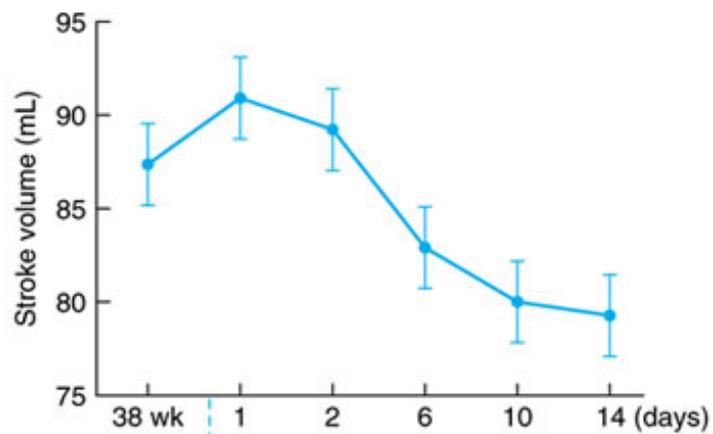

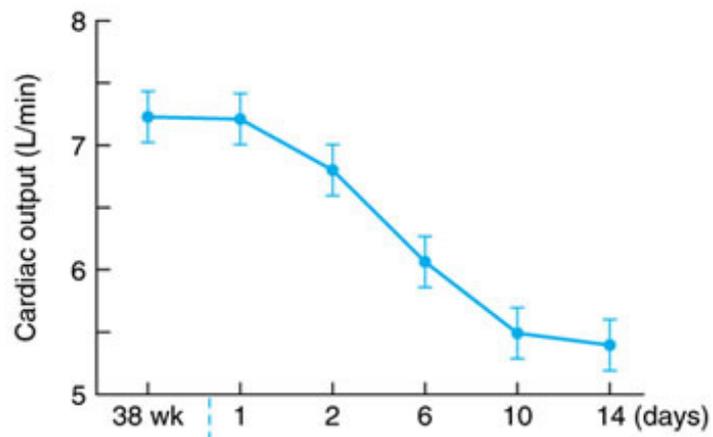

Most women who sustain an average blood loss at delivery and who received iron supplementation during pregnancy show a relative erythrocytosis during the second week postpartum. Because there is no evidence of increased red cell destruction during the puerperium, any red cells gained during pregnancy will disappear gradually according to their normal life span. A moderate excess of red blood cells after delivery, therefore, may lead to an increase in iron stores. Iron supplementation is not necessary for normal postpartum women if the hematocrit or hemoglobin concentration 5–7 days after delivery is equal to or greater than a normal predelivery value. In the late puerperium, there is a gradual decrease in the red cell mass to nonpregnant levels as the rate of erythropoiesis returns to normal.

HEMODYNAMIC CHANGES

The hemodynamic adjustments in the puerperium depend largely on the conduct of labor and delivery, eg, maternal position, method of delivery, mode of anesthesia or analgesia, and blood loss. Cardiac output increases progressively during labor in patients who have received only local anesthesia. The increase in cardiac output peaks immediately after delivery, at which time it is approximately 80% above the prelabor value. During a uterine contraction there is a rise in central venous pressure, arterial pressure, and stroke volume—and, in the absence of pain and anxiety, a reflex decrease in the pulse rate. These changes are magnified in the supine position. Only minimal changes occur in the lateral recumbent position because of unimpaired venous return and absence of aortoiliac compression by the contracting uterus (Poseiro effect). Epidural anesthesia modifies the progressive rise in cardiac output during labor and reduces the absolute increase observed immediately after delivery, probably by limiting pain and anxiety.

Although major hemodynamic readjustments occur during the period immediately following delivery, there is a return to nonpregnant conditions in the early puerperium. A trend for normal women to increase their blood pressure slightly in the first 5 days postpartum reflects an increased uterine vascular resistance and a temporary surplus in plasma volume. A small percentage will have diastolic blood pressures of 100 mm Hg. Cardiac output (measured by Doppler and cross-sectional echocardiography) declines 28% within 2 weeks postpartum from peak values observed at 38 weeks' gestation. This change is associated with a 20% reduction in stroke volume and a smaller decrease in myocardial contractility indices. Postpartum resolution of pregnancy-induced ventricular hypertrophy takes longer than the functional postpartum changes (Fig 12–4). In fact, limited data support a slow return of cardiac hemodynamics to prepregnancy levels over a 1-year period. There are no hemodynamic differences between lactating and nonlactating mothers.

Respiratory Changes

The pulmonary functions that change most rapidly are those influenced by alterations in abdominal contents and thoracic cage capacity. Lung volume changes in the puerperium are compared with those occurring during pregnancy in Figure 12–5. The residual volume increases, but the vital capacity and inspiratory capacities decrease. The maximum breathing capacity is also reduced after delivery. An increase in resting ventilation and oxygen consumption and a less efficient response to exercise may persist during the early postpartum weeks. Comparisons of aerobic capacity prior to pregnancy and again postpartum indicate that lack of activity and weight gain contribute to a generalized detraining effect 4–8 weeks postpartum.

Alterations in lung volumes during pregnancy and 1 week and 6 months postpartum.

(Modified, with permission, from Cugell DW et al: Pulmonary function in pregnancy. *Am Rev Tuberc* 1953;67:568.)

Changes in acid–base status generally parallel changes in respiratory function. The state of pregnancy is characterized by respiratory alkalosis and compensated metabolic acidosis, whereas labor represents a transitional period. A significant hypocapnia (< 30 mm Hg), a rise in blood lactate, and a fall in pH are

first noted at the end of the first stage of labor and extend into the puerperium. Within a few days, a rise toward the normal nonpregnant values of P_{CO_2} (35–40 mm Hg) occurs. Progesterone influences the rate of ventilation by means of a central effect, and rapidly decreasing levels of this hormone are largely responsible for the increased P_{CO_2} seen in the first week postpartum. An increase in base excess and plasma bicarbonate accompanies the relative postpartum hypercapnia. A gradual increase in pH and base excess occurs until normal levels are reached at about 3 weeks postpartum.

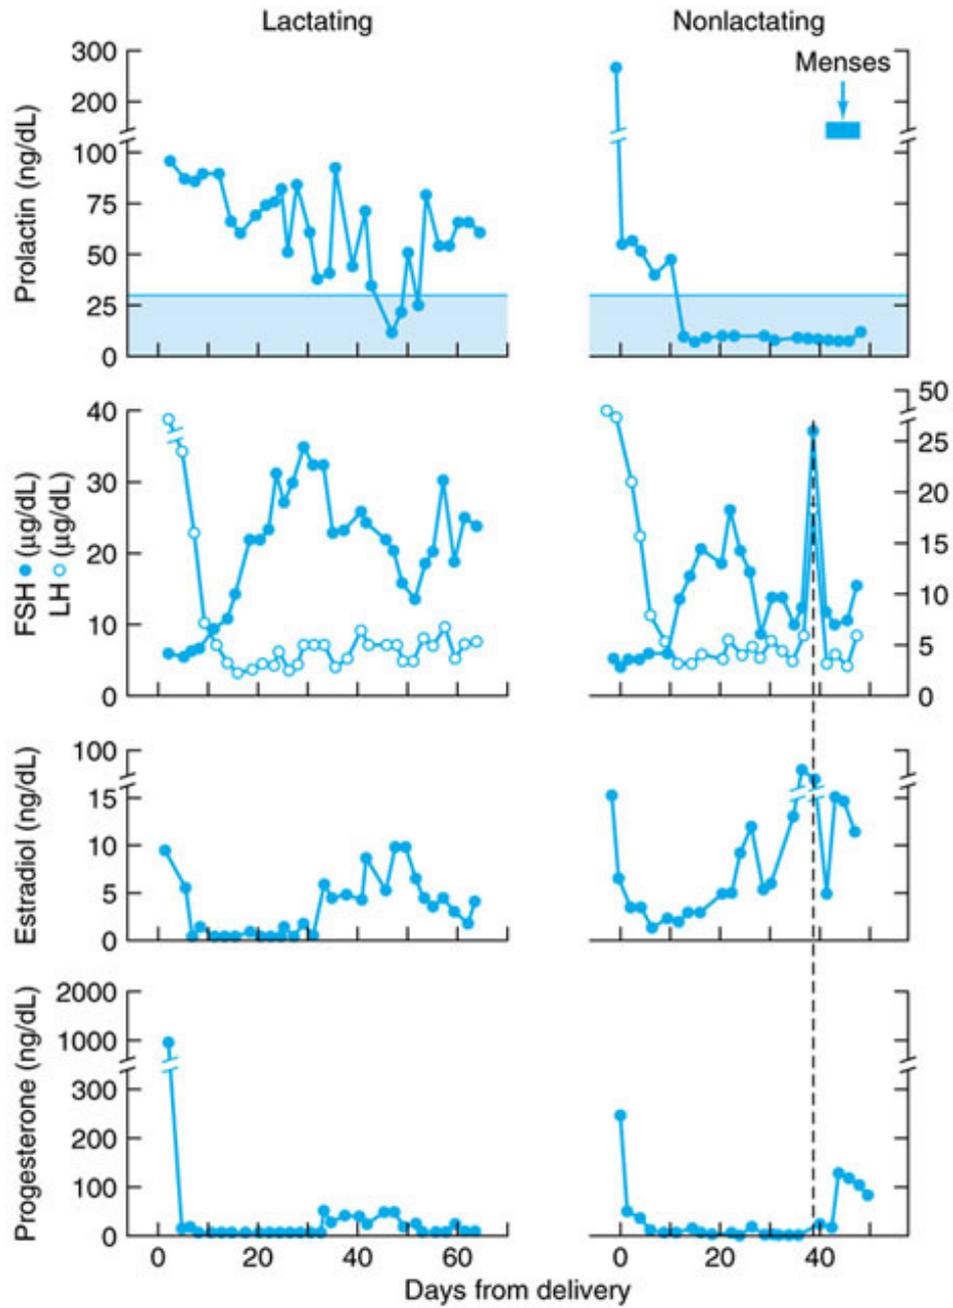

The resting arterial P_{O_2} and oxygen saturation during pregnancy are higher than those in nonpregnant women. During labor, the oxygen saturation may be depressed, especially in the supine position, probably as a result of a decrease in cardiac output and a relative increase in the amount of intrapulmonary shunting. However, a rise in the arterial oxygen saturation to 95% is noted during the first postpartum day. An apparent oxygen debt incurred during labor extends into the immediate puerperium and appears to depend on the length and severity of the second stage of labor. Many investigators have commented on the continued elevation of the basal metabolic rate for a period of 7–14 days following delivery. The increased resting oxygen consumption in the early puerperium has been attributed to mild anemia, lactation, and psychologic factors.

Pituitary–Ovarian Relationships

The plasma levels of placental hormones decline rapidly following delivery. Human placental lactogen has a half-life of 20 minutes and reaches undetectable levels in maternal plasma during the first day after delivery. Human chorionic gonadotropin (hCG) has a mean half-life of about 9 hours. The concentration of hCG in maternal plasma falls below 1000 mU/mL within 48–96 hours postpartum and falls below 100 mU/mL by the seventh day. Follicular phase levels of immunoreactive luteinizing hormone (LH)-hCG are reached during the second postpartum week. Highly specific and sensitive radioimmunoassays for the subunit of hCG indicate virtual disappearance of hCG from maternal plasma between the 11th and 16th days following normal delivery. The regressive pattern of hCG activity is slower after first-trimester abortion than it is after term delivery and even more prolonged in patients who have undergone suction curettage for molar pregnancy.

Within 3 hours after removal of the placenta, the plasma concentration of 17β -estradiol falls to 10% of the antepartum value. The lowest levels are reached by the seventh postpartum day (Fig 12–6). Plasma estrogens do not reach follicular phase levels (> 50 pg/mL) until 19–21 days postpartum in nonlactating women. The return to normal plasma levels of estrogens is delayed in lactating women. Lactating women who resume spontaneous menses achieve follicular phase estradiol levels (> 50 pg/mL) during the first 60–80 days postpartum. Lactating amenorrheic persons are markedly hypoestrogenic (plasma estradiol < 10 pg/mL) during the first 180 days postpartum. The onset of breast engorgement on days 3–4 of the puerperium coincides with a significant fall in estrogen levels and supports the view that high estrogen levels suppress lactation.

Serum concentrations of prolactin, FSH, LH, estradiol, and progesterone in a lactating and nonlactating woman during the puerperium. The hatched bars for the prolactin data represent the normal nongravid range. To convert the FSH and LH to milli-international units per milliliter, divide the FSH values by 2 and multiply the LH values by 4.5. FSH, follicle-stimulating hormone; LH, luteinizing hormone.

(Reproduced, with permission, from Reyes FI, Winter JS, Faiman C: Pituitary-ovarian interrelationships during the puerperium. *Am J Obstet Gynecol* 1972; 114:589.)

The metabolic clearance rate of progesterone is high, and, as with estradiol, the half-life is calculated in

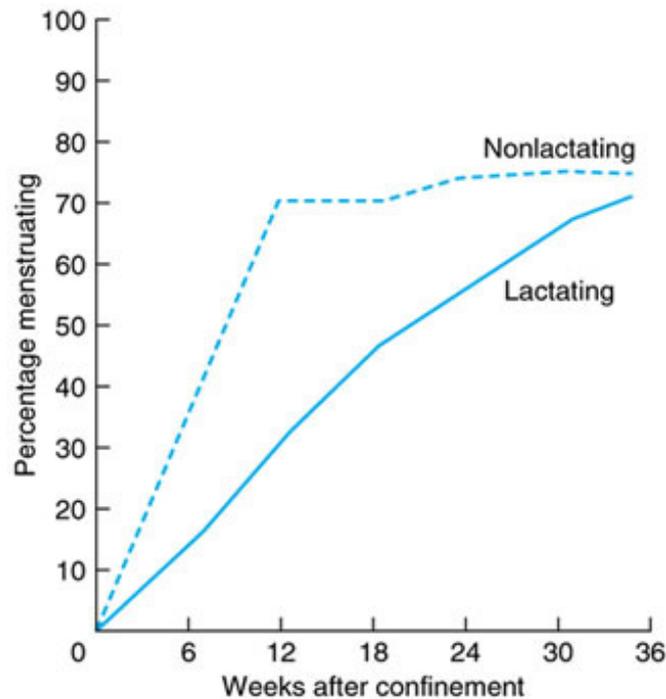

minutes. By the third day of the puerperium, the plasma progesterone concentrations are below luteal phase levels (< 1 ng/mL).

Prolactin levels in maternal blood rise throughout pregnancy to reach concentrations of 200 ng/mL or more. After delivery, prolactin declines in erratic fashion over a period of 2 weeks to the nongravid range in nonlactating women (Fig 12–6). In women who are breastfeeding, basal concentrations of prolactin remain above the nongravid range and increase dramatically in response to suckling. As lactation progresses, the amount of prolactin released with each suckling episode declines. If breastfeeding occurs only 1–3 times each day, serum prolactin levels return to normal basal values within 6 months postpartum; if suckling takes place more than 6 times each day, high basal concentrations of prolactin will persist for more than 1 year. The diurnal rhythm of peripheral prolactin concentrations (a daytime nadir followed by a nighttime peak) is abolished during late pregnancy but is re-established within 1 week postpartum in non-nursing women.

Serum follicle-stimulating hormone (FSH) and LH concentrations are very low in all women during the first 10–12 days postpartum, whether or not they lactate. The levels increase over the following days and reach follicular phase concentrations during the third week postpartum (Fig 12–6). At this time, marked LH pulse amplification occurs during sleep but disappears as normal ovulatory cycles are established. In this respect, the transition from postpartum amenorrhea to cyclic ovulation is reminiscent of puberty, when gonadotropin secretion increases during sleep. There is a preferential release of FSH over LH postpartum during spontaneous recovery or after stimulation by exogenous gonadotropin-releasing hormone (GnRH). In the early puerperium, the pituitary is relatively refractory to GnRH, but 4–8 weeks postpartum the response to GnRH is exaggerated. The low levels of FSH and LH postpartum are most likely related to insufficient endogenous GnRH secretion during pregnancy and the early puerperium, resulting in depletion of pituitary gonadotropin stores. The high estrogen and progesterone milieu of late pregnancy is associated with increased endogenous opioid activity, which may be responsible for suppression of GnRH activity in the puerperium. Resumption of FSH and LH secretion can be accelerated by administering a long-acting GnRH agonist during the first 10 days postpartum.

The frequency with which menstruation is re-established in the puerperium in lactating and nonlactating women is shown in Figure 12–7. The first menses after delivery usually follows an anovulatory cycle or one associated with inadequate corpus luteum function. The ovary may be somewhat refractory to exogenous gonadotropin stimulation during the puerperium in both lactating and nonlactating women. When prolactin is suppressed with bromocriptine, postpartum ovarian refractoriness to gonadotropin stimulation persists, suggesting that hyperprolactinemia plays only a partial role in the diminished gonadal response. Lactation is characterized by an increased sensitivity to the negative feedback effects and a decreased sensitivity to the positive feedback effects of estrogens on gonadotropin secretion.

Figure 12–7.

Frequency at which menstruation is re-established in the puerperium in lactating and nonlactating multiparous women.

(Adapted, with permission, from Sherman A: *Reproductive Physiology of the Post-partum Period*. Livingstone, 1966.)

Because ovarian activity normally resumes upon weaning, either the suckling stimulus itself or the raised level of prolactin is responsible for suppression of pulsatile gonadotropin secretion. Hyperprolactinemia may not entirely account for the inhibition of gonadotropin secretion during lactation, as bromocriptine treatment abolishes the hyperprolactinemia of suckling but not the inhibition of gonadotropin secretion. Sensory inputs associated with suckling (if sufficiently intense), as well as oxytocin and endogenous opioids that are released during suckling, may affect the hypothalamic control of gonadotropin secretion, possibly by inhibiting the pulsatile secretion of GnRH. It appears that by 8 weeks after delivery, while ovarian activity still remains suppressed in fully breastfeeding women, pulsatile secretion of LH has resumed at a low and variable frequency in most women. However, the presence or absence of GnRH or LH pulses at 8 weeks does not predict the time of resumption of ovarian activity.

The time of appearance of the first ovulation is variable, but it is delayed by breastfeeding. Approximately 10–15% of non-nursing mothers ovulate by the time of the 6-week postpartum examination, and approximately 30% ovulate within 90 days postpartum. An abnormally short luteal phase is noted in 35% of first ovulatory cycles. The earliest reported time of ovulation as determined by endometrial biopsy is 33 days postpartum. Patients who have had a first-trimester abortion or ectopic pregnancy generally ovulate sooner after termination of pregnancy (as early as 14 days) than do women who deliver at term. Moreover, the majority of these women do ovulate before the first episode of postabortal bleeding—in contrast to women who have had a term pregnancy.

Endometrial biopsies in lactating women do not show a secretory pattern before the seventh postpartum week. Provided that nursing is in progress and that menstruation has not returned, ovulation before the tenth week postpartum is rare. In well-nourished women who breastfed for an extended period of time, less than 20% had ovulated by 6 months postpartum. Much of the variability in the resumption of menstruation and ovulation observed in lactating women may be due to individual differences in the strength of the suckling stimulus and to partial weaning (formula supplementation). This emphasizes the fact that suckling is not a reliable form of birth control. Because the period of lactational infertility is relatively short in Western societies, some form of contraception must be used if pregnancy is to be prevented. Among women who have unprotected intercourse only during lactational amenorrhea but adopt other contraceptive measures when they resume menstruation, only 2% will become pregnant during the first 6 months of amenorrhea. In underdeveloped countries, lactational amenorrhea and infertility may persist for 1–2 years owing to frequent suckling and poor maternal nutrition. When maternal dietary intake is improved, menstruation resumes at least 6 months earlier.

Other Endocrine Changes

Progressive enlargement of the pituitary gland occurs during pregnancy, with a 30–100% increase in weight achieved at term. Magnetic resonance imaging shows a linear gain in pituitary gland height of about 0.08 mm/wk during pregnancy. An additional increase in size occurs during the first week postpartum. Beyond the first week postpartum, however, the pituitary gland returns rapidly to its normal size in both lactating and nonlactating women.

The physiologic hypertrophy of the pituitary gland is associated with an increase in the number of pituitary lactotroph cells at the expense of the somatotrophic cell types. Thus, growth hormone secretion is depressed during the second half of pregnancy and the early puerperium. Because levels of circulating insulinlike growth factor (IGF)-1 increase throughout pregnancy, a placental growth hormone has been postulated and recently identified. Maternal levels of IGF-1 correlate highly with this distinct placental growth hormone variant but not with placental lactogen during pregnancy and in the immediate puerperium.

Late pregnancy and the early puerperium are also characterized by pituitary somatotroph hyporesponsiveness to growth hormone-releasing hormone and to insulin stimulation. Whatever the inhibitory mechanism may be (possibly increased somatostatin secretion), it persists during the early postpartum period.

The rapid disappearance of placental lactogen and the low levels of growth hormone after delivery lead to a relative deficiency of anti-insulin factors in the early puerperium. It is not surprising, therefore, that low fasting plasma glucose levels are noted at this time and that the insulin requirements of diabetic patients usually drop after delivery. Glucose tolerance tests performed in women with gestational diabetes demonstrate that only 30% have abnormal test results 3–5 days after delivery and 20% have abnormal glucose tolerance at 6 weeks postpartum. When the relative hyperinsulinism and hypoglycemia of pregnancy return to the nonpregnant range at 6–8 weeks postpartum, a paradoxical decline in fasting glucagon levels is found. Because the early puerperium represents a transitional period in carbohydrate metabolism, the results of glucose tolerance tests may be difficult to interpret.

Evaluation of thyroid function is also difficult in the period immediately after birth because of rapid fluctuations in many indices. Characteristically, the plasma thyroxine level and other indices of thyroid function are highest at delivery and in the first 12 hours thereafter. A decrease to antepartum values is seen on the third or fourth day after delivery. Reduced available estrogens postpartum lead to a subsequent decrease in circulating thyroxine-binding globulin and a gradual diminution in bound thyroid hormones in serum. Serum concentrations of thyroid-stimulating hormone (TSH) are not significantly

different postpartum from those of the pregnant or nonpregnant state. Administration of thyroid-releasing hormone (TRH) in the puerperium results in a normal increase in both TSH and prolactin, and the response is similar in lactating and nonlactating patients. Because pregnancy is associated with some immunosuppressive effects, hyperthyroidism or hypothyroidism may recur postpartum in autoimmune thyroid disease. Failure of lactation and prolonged disability may be the result of hypothyroidism postpartum. In Sheehan's syndrome of pituitary infarction, postpartum cachexia and myxedema are seen secondary to anterior hypophyseal insufficiency.

Maternal concentrations of total and unbound (free) plasma cortisol, adrenocorticotrophic hormone (ACTH), immunoreactive corticotropin-releasing hormone (CRH), and β -endorphin rise progressively during pregnancy and increase further during labor. Plasma 17-hydroxycorticosteroid levels increase from a concentration of 4–14 $\mu\text{g}/\text{dL}$ at 40 weeks' gestation. A 2- to 3-fold increase is seen during labor. ACTH, CRH, and β -endorphin decrease rapidly after delivery and return to nonpregnant levels within 24 hours. Prelabor cortisol values are regained on the first day postpartum, but a return to normal, nonpregnant cortisol and 17-hydroxycorticosteroid levels is not reached until the end of the first week postpartum.

Much of the rise in total cortisol (but not in the unbound fraction) can be explained by the parallel increase in corticosteroid-binding globulin (CBG) during pregnancy. Displacement of cortisol from CBG by high concentrations of progesterone cannot account for the increased free cortisol levels because saliva progesterone levels (a measure of the unbound hormone) do not fluctuate, whereas a normal diurnal rhythm of saliva cortisol is maintained during pregnancy and postpartum. An extrapituitary source of ACTH, a progesterone-modulated decrease in the hypothalamic–pituitary sensitivity to glucocorticoid feedback inhibition, and an extrahypothalamic (eg, placental) source of CRH have been suggested as explanations for elevated plasma ACTH levels and the inability of dexamethasone to completely suppress ACTH in pregnant women.

In the third trimester, the placenta produces large amounts of CRH, which is released into the maternal circulation and may contribute to the hypercortisolemia of pregnancy. Present evidence suggests that it stimulates the maternal pituitary to produce ACTH while desensitizing the pituitary to further acute stimulation with CRH. Maternal hypothalamic control of ACTH production is retained (perhaps mediated by vasopressin secretion); this permits a normal response to stress and a persistent diurnal rhythm.

Overall, it is most likely that under the influence of rising estrogens and progesterone, there is a resetting of the hypothalamic–pituitary sensitivity to cortisol feedback during pregnancy, which persists for several days postpartum. Several studies have suggested a relationship between peripartum alterations in maternal levels of cortisol and β -endorphin and the development of postnatal mood disturbances.

The excretion of urinary 17-ketosteroids is elevated in late pregnancy as a result of an increase in androgenic precursors from the fetoplacental unit and the ovary. An additional increase of 50% in excretion occurs during labor. Excretion of 17-ketosteroids returns to antepartum levels on the first day after delivery and to the nonpregnant range by the end of the first week. The mean levels of testosterone during the third trimester of pregnancy range from 3 to 7 times the mean values for nonpregnant women. The elevated levels of testosterone decrease after parturition parallel with the gradual fall in sex hormone-binding globulin (SHBG). Androstenedione, which is poorly bound to SHBG, falls rapidly to nonpregnant values by the third day postpartum. Conversely, the postpartum plasma concentration of dehydroepiandrosterone sulfate (DHEAS) remains lower than that of nonpregnant women, because its metabolic clearance rate continues to be elevated in the early puerperium. Persistently elevated levels of 17-ketosteroids or androgens during the puerperium are an indication for investigation of ovarian abnormalities. Plasma renin and angiotensin II levels fall during the first 2 hours postpartum to levels

within the normal nonpregnant range. This suggests that an extrarenal source of renin has been lost with the expulsion of the fetus and placenta.

There is little direct information about the puerperal changes in numerous other hormones, including aldosterone, parathyroid hormone, and calcitonin. More research should be done on these important endocrine relationships in the puerperium.

CONDUCT AND MANAGEMENT OF THE PUERPERIUM

Most patients will benefit from 2–4 days of hospitalization after delivery. Only 3% of women with a vaginal delivery and 9% of women having a cesarean section have a childbirth-related complication requiring prolonged postpartum hospitalization or readmission. Although a significant amount of symptomatic morbidity may exist postpartum (painful perineum, breastfeeding difficulties, urinary infections, urinary and fecal incontinence, and headache), most women can return home safely 2 days after normal vaginal delivery if proper education and instructions are given, if confidence exists with infant care and feeding, and if adequate support exists at home. Earlier discharge is acceptable in select mothers and infants who have had uncomplicated labors and deliveries. Discharge criteria should be met and follow-up care provided. Optimal care includes home nursing visits through the fourth postpartum day. Disadvantages of early discharge are the increased risks of rehospitalization of some neonates for hyperbilirubinemia and neonatal infection (eg, from group B streptococci).

Activities & Rest

The policy of early ambulation after delivery benefits the patient. Early ambulation provides a sense of well-being, hastens involution of the uterus, improves uterine drainage, and lessens the incidence of postpartum thrombophlebitis. If the delivery has been uncomplicated, the patient may be out of bed as soon as tolerated. Early ambulation does not mean immediate return to normal activity or work. Commonly mothers complain of lethargy and fatigue. Therefore, rest is essential after delivery, and the demands on the mother should be limited to allow for adequate relaxation and adjustment to her new responsibilities. It is helpful to set aside a few hours each day for rest periods. Many mothers do not sleep well for several nights after delivery, and it is surprising how much of the day is occupied with the care of the newborn.

In uncomplicated deliveries, more vigorous activity, climbing stairs, lifting of heavy objects, riding in or driving a car, and performing muscle toning exercises may be resumed without delay. Specific recommendations should be individualized. Current American College of Obstetricians and Gynecologists committee opinions support gradual resumption of exercise routines as soon as medically and physically safe, as detraining may have occurred during pregnancy. No known maternal complications are associated with resumption of exercise, even in women who choose to resume an exercise routine within days. Exercise postpartum does not compromise lactation or neonatal weight gain. It may be beneficial in decreasing anxiety levels and decreasing the incidence of postpartum depression.

Sexual Activity during the Postpartum Period

Establishment of normal prepregnancy sexual response patterns is delayed after delivery. However, it is safe to resume sexual activity when the woman's perineum is comfortable and bleeding is diminished. Although the median time for resumption of intercourse after delivery is 6 weeks and the normal sexual response returns at 12 weeks, sexual desire and activity vary tremendously among women. Most women report low or absent sexual desire during the early puerperium and ascribe this to fatigue, weakness, pain on intromission, irritative vaginal discharge, or fear of injury. Nearly 50% report a return of sexual desire within 2–3 weeks postpartum. In spite of minimal desire in a substantial proportion of women, nearly all resume sexual intercourse by 6–8 weeks after delivery. Roughly 20% of women have no desire

for sexual activity at 3 months from delivery, and an additional 21% lose the desire completely or develop an aversion. The variation in desire depends on the site and state of perineal or vaginal healing, return of libido, and vaginal atrophy resulting from breastfeeding. Lactating women, however, generally report higher sexual interest than do bottle-feeding mothers.

Sexual counseling is indicated before the mother is discharged from the hospital. A discussion of the normal fluctuations of sexual interest during the puerperium is appropriate, as are suggestions for noncoital sexual options that enhance the expression of mutual pleasure and affection. The importance of sleep and rest and of the partner's emotional and physical support are emphasized. If milk ejection during sexual relations is a concern, nursing the baby prior to sexual intimacy can help. Sexual relations can generally be resumed by the third week postpartum, if desired. A water-soluble lubricant or vaginal estrogen cream is especially helpful in lactating amenorrheic mothers in whom vaginal atrophy occurs, usually because of low circulating estrogen levels. Patients should be informed that roughly 50% of women engaging in sexual intercourse by 6 weeks will experience dyspareunia, which may last for 1 year. Dyspareunia also occurs in women with cesarean sections and in women using oral contraceptives who are not breastfeeding.

Diet

A regular diet is permissible as soon as the patient regains her appetite and is free from the effects of analgesics and anesthetics. Protein foods, fruits, vegetables, milk products, and a high fluid intake are recommended, especially for nursing mothers. However, even lactating women probably require no more than 2600–2800 kcal/d. It may be advisable to continue the daily vitamin–mineral supplement during the early puerperium. Following cesarean section, there is no evidence to support compromise of safety or comfort from the introduction of solid food early and allowing the patient to decide when to eat postoperatively. In fact, early feeding as tolerated by the patient has been shown to be safe and to facilitate a more rapid return to normal diet and bowel function.

Care of the Bladder

Most women empty the bladder during labor or have been catheterized at delivery. Even so, serious bladder distention may develop within 12 hours. A long and difficult labor or a forceps delivery may traumatize the base of the bladder and interfere with normal voiding. In some cases, overdistention of the bladder may be related to pain or spinal anesthesia. The marked polyuria noted for the first few days postpartum causes the bladder to fill in a relatively short time. Hence, obstetric patients require catheterization more frequently than most surgical patients. The patient should be catheterized every 6 hours after delivery if she is unable to void or empty her bladder completely. Intermittent catheterization is preferable to an indwelling catheter because the incidence of urinary tract infection is lower. However, if the bladder fills to more than 1000 mL, 1–2 days of decompression by a retention catheter usually is required to establish voiding without significant residual urine.

The incidence of true asymptomatic bacteriuria is approximately 5% in the early puerperium. Postpartum patients with a history of previous urinary tract infection, conduction anesthesia, and catheterization during delivery and operative delivery should have a bacterial culture of a midstream urine specimen. In cases of confirmed bacteriuria, antibiotic treatment should be given; otherwise, bacteriuria will persist in nearly 30% of patients. Three days of therapy is sufficient and avoids prolonged antibiotic exposure to the lactating mother.

Bowel Function

Pregnancy itself is associated with increased gastric emptying, but gastrointestinal motility is commonly delayed after labor and delivery. The mild ileus that follows delivery, together with perineal discomfort

and postpartum fluid loss by other routes, predisposes to constipation during the puerperium. Obstruction of the colon by a retroverted uterus is a rare complication during the puerperium. If an enema was given before delivery, the patient is unlikely to have a bowel movement for 1–2 days after childbirth. Milk of magnesia, 15–20 mL orally on the evening of the second postpartum day, usually stimulates a bowel movement by the next morning. If not, a rectal suppository, such as bisacodyl or a small tap water or oil retention enema, may be given. Less bowel stimulation will be needed if the diet contains sufficient roughage. Stool softeners, such as dioctyl sodium sulfosuccinate, may ease the discomfort of early bowel movements. Hemorrhoidal discomfort is a common complaint postpartum and usually responds to conservative treatment with compresses, suppositories containing corticosteroids, local anesthetic sprays or emollients, and sitz baths. Surgical treatment of hemorrhoids postpartum is rarely necessary unless thrombosis is extensive.

Operative vaginal delivery and lacerations involving the anal sphincter increase a woman's risk for anal incontinence. However, 5% of pregnant women overall have some degree of anal incontinence at 3 months postpartum. Complaints of fecal incontinence are often delayed because of embarrassment. Most cases are transient; however, cases persisting beyond 6 months require investigation and probable treatment.

Bathing

As soon as the patient is ambulatory, she may take a shower. Sitz or tub baths probably are safe if performed in a clean environment, because bath water will not gain access to the vagina unless it is directly introduced. Most patients prefer showers to tub baths because of the profuse flow of lochia immediately postpartum. However, sitz baths may be beneficial for perineal pain relief. Vaginal douching is contraindicated in the early puerperium. Tampons may be used whenever the patient is comfortable. However, use should be limited to daylight hours to prevent long hours of use or inadvertent tampon loss.

Care of the Perineum

Postpartum perineal care, even in the patient with an uncomplicated and satisfactorily repaired episiotomy or laceration, usually requires no more than routine cleansing with a bath or shower and analgesia.

Immediately after delivery, cold compresses (usually ice) applied to the perineum decrease traumatic edema and discomfort. The perineal area should be gently cleansed with plain soap at least once or twice per day and after voiding or defecation. If the perineum is kept clean, healing should occur rapidly. Cold or iced sitz baths, rather than hot sitz baths, may provide additional perineal pain relief for some patients. The patient should be put in a lukewarm tub to which ice cubes are added for 20–30 minutes. The cold promotes pain relief by decreasing the excitability of nerve endings, decreased nerve conduction, and local vasoconstriction, which reduces edema, inhibits hematoma formation, and decreases muscle irritability and spasm. Episiotomy pain is easily controlled with nonsteroidal anti-inflammatory agents, which appear to be superior to acetaminophen or propoxyphene.

An episiotomy or repaired lacerations should be inspected daily. A patient with mediolateral episiotomy, a third- or fourth-degree laceration or extension, or extensive bruising or edema may experience severe perineal pain. In the case of persistent or unusual pain, a vaginal and/or rectal examination should be performed to identify a hematoma, perineal infection, or potentially fatal conditions, such as angioedema, necrotizing fasciitis, or perineal cellulitis. Episiotomy wounds rarely become infected, which is remarkable considering the difficulty of preventing contamination of the perineal area. In the event of sepsis, local heat and irrigation should cause the infection to subside. Appropriate antibiotics may be indicated if an

immediate response to these measures is not observed. In rare instances, the wound should be opened widely and sutures removed for adequate drainage.

Uterotonic Agents

Prophylactic administration of oxytocin after the second stage of labor and/or after placental delivery is beneficial in preventing postpartum hemorrhage and the need for therapeutic uterotonics. The routine use of ergot preparations or prostaglandins may be as effective as oxytocin but has significantly more side effects. There appear to be no data supporting the prophylactic use of oxytocic agents beyond the immediate puerperium. These agents should be limited to patients with specific indications, such as postpartum hemorrhage or uterine atony.

Emotional Reactions

Several basic emotional responses occur in almost every woman who has given birth to a normal baby. A woman's first emotion is usually one of extreme relief, followed by a sense of happiness and gratitude that the new baby has arrived safely. A regular pattern of behavior occurs in the human mother immediately after birth of the infant. Touching, holding, and grooming of the infant under normal conditions rapidly strengthen maternal ties of affection. However, not all mothers react in this way, and some may even feel detached from the new baby. These reactions range from the common, physiologic, relatively mild and transient "maternity blues," which affect some 50–70% of postpartum women, to more severe reactions including depression and rare puerperal psychosis.

Postpartum blues or maternity blues occurs in up to 70% of postpartum women and appear to be a normal psychological adjustment or response. It is generally characterized by tearfulness, anxiety, irritation, and restlessness. This symptomatology can be quite diverse and may include depression, feelings of inadequacy, elation, mood swings, confusion, difficulty concentrating, headache, forgetfulness, insomnia, depersonalization, and negative feelings toward the baby. These transient symptoms usually occur within the first few days after delivery and cease by postpartum day 10, although bouts of weeping may occur for weeks after delivery. The blues are self-limiting, but the distress can be diminished by physical comfort and reassurance. Evidence suggests that rooming-in during the hospital stay reduces maternal anxiety and results in more successful breastfeeding.

Prematurity or illness of the newborn delays early intimate maternal–infant contact and may have an adverse effect on the rapid and complete development of normal mothering responses. Stressful factors during the puerperium (eg, marital infidelity or loss of friends as a result of the necessary confinement and preoccupation with the new baby) may leave the mother feeling unsupported and may interfere with the formation of a maternal bond with the infant.

When a baby dies or is born with a congenital defect, the obstetrician should tell the mother and father about the problem together, if possible. The baby's normal, healthy features and potential for improvement should be emphasized, and positive statements should be made about the present availability of corrective treatment and the promises of ongoing research. In the event of a perinatal loss, parents should be assisted in the grieving process. They should be encouraged to see and touch the baby at birth or later, even if maceration or anomalies are present. Mementos such as footprints, locks of hair, or a photograph can be a solace to the parents after the infant has been buried. During the puerperium, the obstetrician has an important opportunity to help the mother whose infant has died work through her period of mourning or discouragement and to assess abnormal reactions of grief that suggest a need for psychiatric assistance. Pathologic grief is characterized by the inability to work through the sense of loss within 3–4 months, with subsequent feelings of low self-esteem.

Postpartum Immunization

PREVENTION OF RH ISOIMMUNIZATION

The postpartum injection of Rh₀ (D) immunoglobulin* will prevent sensitization in the Rh-negative woman who has had fetal-to-maternal transfusion of Rh-positive fetal red cells. The risk of maternal sensitization rises with the volume of fetal transplacental hemorrhage. The usual amount of fetal blood that enters the maternal circulation is less than 0.5 mL. The usual dose of 300 µg of Rh₀ (D) immunoglobulin is in excess of the dose generally required, because 25 mg of RhoGAM per milliliter of fetal red cells is sufficient to prevent maternal immunization. If neonatal anemia or other clinical symptoms suggest the occurrence of a large transplacental hemorrhage, the amount of fetal blood in the maternal circulation can be estimated by the Kleihauer-Betke smear and the amounts of RhoGAM to be administered adjusted accordingly. A dose of 10 mL per estimated milliliter of whole fetal blood should be administered. An alternative to the acid elution smear is the Du test, which will detect 20 mL or more of Rh-positive fetal blood in the maternal circulation.

Rh₀ (D) immunoglobulin is administered after abortion without qualifications or after delivery to women who meet all of the following criteria: (1) The mother must be Rh₀ (D)-negative without Rh antibodies; (2) the baby must be Rh₀ (D)- or Du-positive; and (3) the cord blood must be Coombs-negative. If these criteria are met, a 1:1000 dilution of Rh₀ (D) immunoglobulin is cross-matched to the mother's red cells to ensure compatibility, and 1 mL (300 µg) is given intramuscularly to the mother within 72 hours after delivery. If the 72-hour interval has been exceeded, it is advisable to give the immunoglobulin rather than withhold it because it may still protect against sensitization 14–28 days after delivery, and the time required to mount a response varies among cases. The 72-hour time limit for administration of Rh immune globulin was a study limitation in a study in which patients in prison were allowed to be visited only every 3 days; thus, the use of Rh immunoglobulin past the 3-day interval was never studied. Rh₀ (D) immunoglobulin should also be given after delivery or abortion when serologic tests of maternal sensitization to the Rh factor are questionable.

The average risk of maternal sensitization after abortion is approximately half the risk incurred by full-term pregnancy and delivery; the latter has been estimated at 11%. Even though mothers have received Rh₀ (D) immunoglobulin, they should be screened with each subsequent pregnancy because postpartum prophylaxis failures still exist. Failures are related to inadequate Rh₀ (D) immunoglobulin administration postpartum, an undetected very low titer in the previous pregnancy, and inexcusable oversights. Routine use of postpartum screening protocols to identify excess fetomaternal hemorrhage and strict adherence to recommended protocols for the management of unsensitized Rh-negative women will prevent most of these postpartum sensitizations.

*Trade names include Gamulin Rh, HypRho-D, and RhoGAM.

RUBELLA VACCINATION

A significant number of women of childbearing age have never had rubella. When tested by the hemagglutination inhibition method, 10–20% of women are seronegative (titer of 1:8 or less). Women who are susceptible to rubella can be vaccinated safely and effectively with a live attenuated rubella virus vaccine (RA 27/3 strain) during the immediate puerperium. It is more immunogenic than earlier forms of the vaccine and is available in monovalent, bivalent (measles-rubella [MR]), and trivalent (measles-mumps-rubella [MMR]) forms. Seroconversion occurs in approximately 95% of women vaccinated postpartum. The puerperium is an ideal time for vaccination because there is no risk of inadvertently vaccinating a pregnant woman. Breastfeeding mothers are not excluded from immunization. There is concern, however, that 75% of such women may shed rubella virus in the breast milk, and a persistent rubella carrier state with periodic viral reactivation may rarely occur in the child. The neonate's exposure to the virus in breast milk is not associated with an alteration of responses to subsequent immunization.

Women who receive rubella vaccinations are not contagious and cannot transmit infection to other susceptible children or adults. In addition, the serologic response against rubella is satisfactory when given concomitantly with other immunoglobulins such as Rh-immunoglobulin. However, blood transfusions can prevent the success of rubella vaccination if it is performed soon after the transfusion.

Vaccinated patients should be informed that transient side effects can result from rubella vaccination. Mild symptoms such as low-grade fever and malaise may occur in less than 25% of patients, arthralgias and rash in less than 10%, and, rarely, overt arthritis may develop. Among adult women there is a 10–15% incidence of acute polyarthritis following immunization. Although the Centers for Disease Control and Prevention (CDC) registry of approximately 400 women receiving rubella vaccination within 3 months of conception reports no cases of congenital rubella, the recommendation that secure contraception be used for 3 months after vaccination remains. Rubella virus was, however, isolated from some women who received the vaccination during early pregnancy and elected to terminate. The theoretical maximum theoretical risk of congenital rubella resulting from vaccination during early pregnancy is 1–2%.

Contraception & Sterilization

The immediate puerperium has long been recognized as a convenient time for the discussion of family planning, although these discussions ideally should begin during prenatal care. Pregnancy prevention and birth control decisions should be made prior to discharge with a qualified nurse, physician, or physician's assistant, or with the aid of educational tools. Anovulation infertility lasts only 5 weeks in nonlactating women and greater than 8 weeks in fully lactating women. The lactational pregnancy rate is approximately 1% at 1 year postpartum.

Tubal sterilization is the most common method of contraception used in the United States. It is the procedure of choice for women desiring permanent sterilization. It can be performed easily at the time of cesarean section, 24–48 hours after an uncomplicated vaginal delivery, or immediately postpartum in uncomplicated patients with a labor epidural in place, without prolonging hospitalization or significantly increasing morbidity. Sterilization is not recommended in young women of low parity or when the neonatal outcome is in doubt and survival of the infant is not assured. Postponing tubal sterilization 6–8 weeks postpartum is desirable for many couples, as it allows time to ensure that the infant is healthy, to fully understand the implications of permanent sterilization, and, according to the United States Collaborative Review on Sterilization, to decrease feelings of guilt and regret.

Appropriate counseling regarding risks of failure, permanence of the procedure, the medical risks, and the potential psychosocial reactions to the procedure should be discussed with the patient. Patient ambivalence at the last minute is not unusual, in which case it is advisable to defer the procedure until after the puerperium. The 10-year failure rate of postpartum sterilization is less than 1%, with rate variations dependent on the type of sterilization procedure performed. The risks of postpartum or interval tubal ligation are infrequent, and deaths from the procedure occur in 2–12 per 100,000 cases. Long-term complications, such as the posttubal syndrome (irregular menses and increased menstrual pain) have been reported in some 10–15% of women; however, well-controlled prospective studies have failed to confirm that these symptoms occur more frequently with sterilization than in controls. A major anesthetic should be initiated only after careful evaluation by the anesthesia service because the parturient may have an increased risk of regurgitation and aspiration of gastric contents. Postpartum laparoscopic sterilization has not gained popularity because of increased pelvic vascularity, the large size of the uterus, and the risk of visceral injury.

Natural family planning as contraception may begin after normal menses resumes. Breastfeeding with no supplementation will provide 98% contraceptive protection for up to 6 months. When menses returns, natural family planning may begin. This method, which has pregnancy rates comparable to barrier

methods, utilizes detection of the periovulation period by evaluating cervical mucous changes and/or basal body temperature changes. These techniques are often misrepresented by providers who have limited understanding of their use and success in pregnancy prevention.

Use of spermicides, a condom, or both may be prescribed until the postpartum examination; these methods carry a failure rate of 1.6–21 per 100 woman-years. Fitting of a diaphragm is not practical until involution of the reproductive organs has taken place and may be more difficult in lactating women with vaginal dryness. It should always be used in conjunction with a spermicidal lubricant containing nonoxynol-9. The failure rate for the diaphragm varies from 2.4–19.6 per 100 woman-years, with the lowest failure rates (comparable to the intrauterine device [IUD]) occurring in women who are older, motivated, experienced, or familiar with the technique.

In patients who are not breastfeeding, combination oral contraceptive agents can be taken as early as 2–3 weeks postpartum. These agents should not be given sooner than this period in view of the hypercoagulable state postpartum. The combined estrogen–progestin preparations, which contain 35 µg or less of estrogen and varying amounts of progestin, are associated with pregnancy rates of less than 0.5 per 100 woman-years. In addition, these low-estrogen compounds used in nonsmokers have fewer cardiovascular complications. Lactating women should be given progestin-only oral contraceptives (norethindrone 0.35 mg/d) because they do not suppress lactation and may enhance it.

Intramuscular injection of a long-acting progestin such as depot medroxyprogesterone acetate (Depo-Provera®), 150 mg given every 3 months, provides effective contraception (> 99% contraceptive efficacy) for the lactating woman without provoking maternal thromboembolism or decreasing milk yield. However, concerns related to prolonged amenorrhea, the inconvenience of unpredictable and irregular bleeding, as well as reversible bone density reduction and lipid metabolism changes, limit the usefulness of this method.

Levonorgestrel implants placed after establishment of lactation (immediately postpartum or by 6 weeks) provide acceptable contraception with no effect on lactation or infant growth. They have gained little favor, probably because of irregular bleeding, high cost, and difficulty in insertion and removal.

Insertion of an IUD (copper-containing TCu 380 Ag® and ParaGard T380A®, progesterone-releasing Progestasert®, or levonorgestrel-releasing Mirena®) is highly effective in preventing pregnancy (< 2–3 pregnancies per 100 woman-years) and is not considered an abortifacient. Ideally, an IUD should be placed at the first postpartum visit; however, it may be placed as early as immediately postpartum. In this latter case, the incidence of expulsion is high. The main side effects include syncope from vagal response to insertion, pelvic infection (relative risk 1.7–9.3), uterine perforation (0–8 per 1000), and abnormal uterine bleeding. The risk of ectopic pregnancy is higher among women using Progestasert compared to women not using contraception. The risk of uterine perforation during IUD insertion is higher in lactating women, probably because of the accelerated rate of uterine involution. However, the risk of expulsion is not increased. Uterine perforation is highest when insertion is performed in the first 1–8 weeks following delivery.

Discharge Examination & Instructions

Before the patient's hospital discharge, the breasts and abdomen should be examined. The degree of uterine involution and tenderness should be noted. The calves and thighs should be palpated to rule out thrombophlebitis. The characteristics of the lochia are important and should be observed. The episiotomy wound should be inspected to see whether it is healing satisfactorily. A blood sample should be obtained for hematocrit or hemoglobin determination. Unless the patient has an unusual pelvic complaint, there is little need to perform a vaginal examination. The obstetrician should be certain that the patient is voiding

normally, has normal bowel function, and is physically able to assume her new responsibilities at home.

The patient will require some advice on what she is allowed to do when she arrives home. Hygiene is essentially the same as practiced in the hospital, with a premium on cleanliness. Upon discharge from the hospital, the patient should be instructed to rest for at least 2 hours during the day, and her usual household activities should be curtailed. Activities, exercise, and return to work will be individualized. Accepted disability following delivery is 6 weeks. Various forms of social support are critical for mothers, especially those employed outside the home: available, high-quality day care; parental leave for both mothers and fathers; and support provided by the workplace such as flexible hours, the opportunity to breastfeed, on-site day care, and care for sick children. The patient who has had frequent prenatal visits to her obstetrician may feel cut off from the doctor during the interval between discharge and the first postpartum visit. She will feel reassured in this period if she receives thoughtful advice on what she is allowed to do and what she can expect when she arrives home. She should be instructed to take her temperature at home twice daily and to notify the physician or nurse in the event of fever, vaginal bleeding, or back pain. At the time of discharge, the patient should be informed that she will note persistent but decreasing amounts of vaginal lochia for about 3 weeks and possibly for a short period during the fourth or fifth week after delivery.

Postpartum Examination

At the postpartum visit—4–6 weeks after discharge from hospital—the patient's weight and blood pressure should be recorded. Most patients retain about 60% of any weight in excess of 11 kg (24 lb) that was gained during pregnancy. A suitable diet may be prescribed if the patient has not returned to her approximate prepregnancy weight. If the patient was anemic upon discharge from the hospital or has been bleeding during the puerperium, a complete blood count should be determined. Persistence of uterine bleeding demands investigation and definitive treatment.

The breasts should be examined, and the adequacy of support, abnormalities of the nipples or lactation, and the presence of any masses should be noted. The patient should be instructed concerning self-examination of the breasts. A complete rectovaginal evaluation is required.

Nursing mothers may show a hypoestrogenic condition of the vaginal epithelium. Prescription of a vaginal estrogen cream to be applied at bedtime should relieve local dryness and coital discomfort without the side effects of systemic estrogen therapy. The cervix should be inspected and a Papanicolaou (Pap) smear obtained. Women whose prenatal smears are normal are still at risk for an abnormal Pap smear at their postpartum visit.

The episiotomy incision and repaired lacerations must be examined and the adequacy of pelvic and perineal support noted. Bimanual examination of the uterus and adnexa is indicated. At the time of the postpartum examination, most patients have some degree of retrodisplacement of the uterus, but this may soon correct itself.

Asymptomatic retroposition of the uterus is not regarded as an abnormal condition. If pain, abnormal bleeding, or other symptoms are present, a vaginal pessary may be inserted as a trial procedure to encourage anteversion of the fundus. However, pessary support for long periods of time is not recommended. In the absence of pelvic disease, uterine retrodisplacement rarely, if ever, requires surgical correction. If marked uterine descensus is noted or if the patient develops stress incontinence, symptomatic cystocele, or rectocele, surgical correction should be considered if childbearing has been completed. Hysterectomy or vaginal repair is best postponed for at least 3 months after delivery to allow maximal restoration of the pelvic supporting structures.

The patient may resume full activity or employment if her course to this point has been uneventful. Once

again, the patient should be advised regarding family planning and contraceptive practices. The postnatal visit is an important opportunity to consider general disorders such as backache and depression and to discuss infant feeding and immunization. The rapport established between the obstetrician and the patient during the prenatal and postpartum periods provides a unique opportunity to establish a preventive health program in subsequent years.

PHYSIOLOGY

The mammary glands are modified exocrine glands that undergo dramatic anatomic and physiologic changes during pregnancy and in the immediate puerperium. Their role is to provide nourishment for the newborn and to transfer antibodies from mother to infant.

During the first half of pregnancy, proliferation of alveolar epithelial cells, formation of new ducts, and development of lobular architecture occur. Later in pregnancy, proliferation declines, and the epithelium differentiates for secretory activity. At the end of gestation, each breast will have gained approximately 400 g. Factors contributing to increase in mammary size include hypertrophy of blood vessels, myoepithelial cells, and connective tissue; deposition of fat; and retention of water and electrolytes. Blood flow is almost double that of the nonpregnant state.

The mammary gland has been called the mirror of the endocrine system, because lactation depends on a delicate balance of several hormones. An intact hypothalamic–pituitary axis is essential to the initiation and maintenance of lactation. Lactation can be divided into 3 stages: (1) mammogenesis, or mammary growth and development; (2) lactogenesis, or initiation of milk secretion; and (3) galactopoiesis, or maintenance of established milk secretion (Table 12–2). Estrogen is responsible for the growth of ductular tissue and alveolar budding, whereas progesterone is required for optimal maturation of the alveolar glands. Glandular stem cells undergo differentiation into secretory and myoepithelial cells under the influence of prolactin, growth hormone, insulin, cortisol, and an epithelial growth factor. Although alveolar secretory cells actively synthesize milk fat and proteins from midpregnancy onward, only small amounts are released into the lumen. However, lactation is possible if pregnancy is interrupted during the second trimester.

Table 12–2. Multihormonal Interaction in Mammary Growth and Lactation.

Mammogenesis	Lactogenesis	Galactopoiesis
Estrogens	Prolactin	↓Gonadal hormones
Progesterone	↓Estrogens	Suckling (oxytocin, prolactin)
Prolactin	↓Progesterone	Growth hormone
Growth hormone	↓hPL(?)	Glucocorticoids
Glucocorticoids	Glucocorticoids	Insulin
Epithelial growth factor	Insulin	Thyroxine and parathyroid hormone

Arrows signify that lower than normal levels of the hormone are necessary for the effect to occur.

Prolactin is an necessary hormone for milk production, but lactogenesis also requires a low-estrogen environment. Although prolactin levels continue to rise as pregnancy advances, placental sex steroids block prolactin-induced secretory activity of the glandular epithelium. It appears that sex steroids and prolactin are synergistic in mammogenesis but antagonistic in galactopoiesis. Therefore, lactation is not initiated until plasma estrogens, progesterone, and human placental lactogen (hPL) levels fall after delivery. Progesterone inhibits the biosynthesis of lactose and α -lactalbumin; estrogens directly

antagonize the lactogenic effect of prolactin on the mammary gland by inhibiting α -lactalbumin production. hPL may also exert a prolactin-antagonist effect through competitive binding to alveolar prolactin receptors.

The maintenance of established milk secretion requires periodic suckling and the actual emptying of ducts and alveoli. Growth hormone, cortisol, thyroxine, and insulin exert a permissive effect. Prolactin is required for galactopoiesis, but high basal levels are not mandatory, because prolactin concentrations in the nursing mother decline gradually during the late puerperium and approach that of the nonpregnant state. However, if a woman does not suckle her baby, her serum prolactin concentration will return to nonpregnant values within 2–3 weeks. If the mother suckles twins simultaneously, the prolactin response is about double that when 1 baby is fed at a time, illustrating an apparent synergism between the number of nipples stimulated and the frequency of suckling. The mechanism by which suckling stimulates prolactin release probably involves the inhibition of dopamine, which is thought to be the hypothalamic prolactin-inhibiting factor.

Nipple stimulation by suckling or other physical stimuli evokes a reflex release of oxytocin from the neurohypophysis. Because retrograde blood flow can be demonstrated within the pituitary stalk, oxytocin may reach the adenohypophysis in very high concentrations and affect pituitary release of prolactin independently of any effect on dopamine. The release of oxytocin is mediated by afferent fibers of the fourth to sixth intercostal nerves via the dorsal roots of the spinal cord to the midbrain.

The paraventricular and supraoptic neurons of the hypothalamus make up the final afferent pathway of the milk ejection reflex. The central nervous system can modulate the release of oxytocin by either stimulating or inhibiting the hypothalamus to increase or decrease prolactin-inhibiting factor (dopamine) and thus the release of oxytocin from the posterior pituitary. Thus, positive senses related to nursing, crying of an infant, positive attitudes in pregnancy and toward breastfeeding can improve milk yield and the ultimate success of breastfeeding. Likewise, the expectation of nursing is sufficient to release oxytocin prior to milk let-down but is not effective in releasing prolactin in the absence of suckling. Contrarily, negative stimuli, such as pain, stress, fear, anxiety, insecurity, or negative attitudes, may inhibit the let-down reflex. Oxytocin levels may rise during orgasm, and sexual stimuli may trigger milk ejection.

SYNTHESIS OF HUMAN MILK

Prolactin ultimately promotes milk production by inducing the synthesis of mRNAs for the production of milk enzymes and milk proteins at the membrane of mammary epithelial cells (alveolar cells). Milk synthesis and secretion are then initiated via four major transcellular and paracellular pathways. The substrates for milk production are primarily derived from the maternal gut or produced in the maternal liver. The availability of these substrates is aided by a 20–40% increased blood flow to the mammary gland, gastrointestinal tract, and liver, as well as increased cardiac output during breastfeeding. The principal carbohydrate in human milk is lactose. Glucose metabolism is a key function in human milk production, because lactose is derived from glucose and galactose; the latter originates from glucose-6-phosphate. A specific protein, α -lactalbumin, catalyzes lactose synthesis. This rate-limiting enzyme is inhibited by gonadal hormones during pregnancy. Prolactin and insulin, which enhance the uptake of glucose by mammary cells, also stimulate the formation of triglycerides. Fat synthesis takes place in the endoplasmic reticulum. Most proteins are synthesized *de novo* in the secretory cells from essential and nonessential plasma amino acids. The formation of milk protein and mammary enzymes is induced by prolactin and enhanced by cortisol and insulin.

Mature human milk contains 7% carbohydrate as lactose, 3–5% fat, 0.9% protein, and 0.2% mineral constituents expressed as ash. Its energy content is 60–75 kcal/dL. About 25% of the total nitrogen of

human milk represents nonprotein compounds, eg, urea, uric acid, creatinine, and free amino acids. The principal proteins of human milk are casein, α -lactalbumin, lactoferrin, immunoglobulin (Ig) A, lysozyme, and albumin. Milk also contains a variety of enzymes that may contribute to the infant's digestion of breast milk, eg, amylase, catalase, peroxidase, lipase, xanthine oxidase, and alkaline and acid phosphatase. The fatty acid composition of human milk is rich in palmitic and oleic acids and varies somewhat with the diet. The major ions and mineral constituents of human milk are Na^+ , K^+ , Ca^{2+} , Mg^{2+} , Cl^- , phosphorus, sulfate, and citrate. Calcium concentrations vary from 25–35 mg/dL and phosphorus concentrations from 13–16 mg/dL. Iron, copper, zinc, and trace metal contents vary considerably. All the vitamins except vitamin K are found in human milk in nutritionally adequate amounts. The composition of breast milk is not greatly affected by race, age, parity, normal diet variations, moderate postpartum dieting, weight loss, or aerobic exercise. Volume and caloric density may be reduced in extreme scenarios, such as developing countries where starvation or daily caloric intake is less than 1600 kcal/d. In addition, milk composition does not differ between the 2 breasts unless 1 breast is infected. However, the volume and concentration of constituents varies during the day. The volume per feed increases in the late afternoon and evening. Nitrogen peaks in the late afternoon. Fat concentrations peak in the morning and are lowest at night. Lactose levels remain fairly constant.

Colostrum, the premilk secretion, is a yellowish alkaline secretion that may be present in the last months of pregnancy and for the first 2–3 days after delivery. It has a higher specific gravity (1.040–1.060); a higher protein, vitamin A, immunoglobulin, and sodium and chloride content; and a lower carbohydrate, potassium, and fat content than mature breast milk. Colostrum has a normal laxative action and is an ideal natural starter food.

Ions and water pass the membrane of the alveolar cell in both directions. Human milk differs from the milk of many other species by having a lower concentration of monovalent ions and a higher concentration of lactose. The aqueous phase of milk is isosmotic with plasma; thus, the higher the lactose, the lower the ion concentration. The ratio of potassium/sodium is 3:1 in both milk and mammary intracellular fluid. Because milk contains about 87% water and lactose is the major osmotically active solute, it follows that milk yield is largely determined by lactose production.

IMMUNOLOGIC SIGNIFICANCE OF HUMAN MILK

The neonate's secretory immune system and cellular responses are immature. In particular, the IgM and IgA responses are poor and cellular immunity is impaired for several months. Maternal transfer of immunoglobulins through breast milk provides support for the infant's developing immune system and thereby enhances neonatal defense against infection. All classes of immunoglobulins are found in milk, but IgA constitutes 90% of immunoglobulins in human colostrum and milk. The output of immunoglobulins by the breast is maximal in the first week of life and declines thereafter as the production of milk-specific proteins increases. Lacteal antibodies against enteric bacteria and their antigenic products are largely of the IgA class. IgG and IgA lacteal antibodies provide short-term systemic and long-term enteric humoral immunity to the breastfed neonate. IgA antipoliomyelitis virus activity present in breastfed infants indicates that at least some transfer of milk antibodies into serum does occur. However, maternal lacteal antibodies are absorbed systemically by human infants for only a very short time after birth. Long-term protection against pathogenic enteric bacteria is provided by the adsorption of lacteal IgA to the intestinal mucosa. In addition to providing passive immunity, there is evidence that lacteal immunoglobulins can modulate the immunocompetence of the neonate, but the exact mechanisms have not been described. For instance, the secretion of IgA into the saliva of breastfed infants is enhanced in comparison with bottle-fed controls.

Breast milk is highly anti-infective, containing more than 4000 cells/mm³, the majority of which are

leukocytes. The total cell count is even higher in colostrum. In human milk, the leukocytes are predominantly mononuclear cells and macrophages. Both T and B lymphocytes are present. During maternal infection, antigen-specific lymphocytes can migrate to the breast mucosa or produce immunoglobulins, both of which are key in the fight against infection. Fully functional immunoglobulins are present, primarily as IgA, IgG, and IgM. Polymeric secretory IgA is easily transported across the mucous membrane of the breast, blocking the mucosal receptors of infectious agents.

Elements in breast milk other than immunoglobulins and cells have prophylactic value against infections. The marked difference between the intestinal flora of breastfed and bottle-fed infants is due to a dialyzable nitrogen-containing carbohydrate (bifidus factor) that supports the growth of *Lactobacillus bifidus* in breastfed infants. The stool of bottle-fed infants is more alkaline and contains predominantly coliform organisms and *Bacteroides* spp. *L. bifidus* inhibits the growth of *Shigella* spp, *Escherichia coli*, and yeast. Human milk also contains a nonspecific antimicrobial factor, lysozyme (a thermostable, acid-stable enzyme that cleaves the peptidoglycans of bacteria), and a "resistance factor," which protect the infant against staphylococcal infection. Lactoferrin, an iron chelator, exerts a strong bacteriostatic effect on staphylococci and *E. coli* by depriving the organisms of iron. Both C3 and C4 components of complement and antitoxins for neutralizing *Vibrio cholerae* are found in human milk. Unsaturated vitamin B₁₂-binding protein in milk renders the vitamin unavailable for utilization by *E. coli* and *Bacteroides*. Finally, interferon in milk may provide yet another nonspecific anti-infection factor.

Human milk may also have prophylactic value in childhood food allergies. During the neonatal period, permeability of the small intestine to macromolecules is increased. Secretory IgA in colostrum and breast milk reduces the absorption of foreign macromolecules until the endogenous IgA secretory capacity of the newborn intestinal lamina propria and lymph nodes develops at 2–3 months of age. Protein of cow's milk can be highly allergenic in the infant predisposed by heredity. The introduction of cow's milk-free formulas has considerably reduced the incidence of milk allergy. Thus, comparative studies on the incidence of allergy, bacterial and viral infections, severe diarrhea, necrotizing enterocolitis, tuberculosis, and neonatal meningitis in breastfed and bottle-fed infants support the concept that breast milk fulfills a protective function.

ADVANTAGES & DISADVANTAGES OF BREASTFEEDING

For the Mother

ADVANTAGES

Breastfeeding is convenient, economical, and emotionally satisfying to most women. It helps to contract the uterus and accelerates the process of uterine involution in the postpartum period, including decreased maternal blood loss. It promotes mother–infant bonding and self-confidence and improves maternal tolerance to stress through an oxytocin-associated antifight/fight response. Maternal gastrointestinal motility and absorption are enhanced. Ovulatory cycles are delayed with nonsupplemented breastfeeding. According to epidemiologic studies, breastfeeding may help to protect against premenopausal cancer and ovarian cancer.

DISADVANTAGES

Regular nursing restricts activities and may be perceived by some mothers as an inconvenience. Twins can be nursed successfully, but few women are prepared for the first weeks of almost continual feeding. Cesarean section may necessitate modifications of early breastfeeding routines. Difficulties such as nipple tenderness and mastitis may develop. Compared with nonlactating women, breastfeeding women have a significant decrease (mean 6.5%) in bone mineral content at 6 months postpartum, but there is "catch-up" remineralization after weaning.

Breastfeeding by a hypoparathyroid mother is undesirable, because adequate calcium supplementation to replace losses in breast milk is difficult in these patients. Furthermore, large amounts of 25-hydroxyvitamin D₃ appear in the milk of mothers receiving therapy for hypoparathyroidism. There are few absolute contraindications to breastfeeding (see Disadvantages and Contraindications for the Infant).

Many women with breast implants breastfeed successfully, but reduction mammoplasty involving nipple autotransplantation severs the lactiferous ducts and precludes nursing. Several situations may arise in which a case-by-case assessment will be needed to determine the impact of breastfeeding: environmental exposures, hepatitis C, illicit drugs, metabolic disorders, use of pharmaceutical drugs, and tobacco and alcohol consumption.

For the Infant

ADVANTAGES

Breast milk is digestible, of ideal composition, available at the right temperature and the right time, and free of bacterial contamination. Infants of breastfed mothers have a decreased incidence of all of the following: diarrhea, lower respiratory tract infection, otitis media, pneumonia, urinary tract infections, necrotizing enterocolitis, invasive bacterial infection, and sudden infant death. Breastfed infants may have a decreased risk of developing insulin-dependent diabetes, Crohn's disease, ulcerative colitis, lymphoma, and allergic diseases later in life. Breastfed infants are less likely to become obese as neonates and adolescents. Suckling promotes infant–mother bonding. Cognitive development and intelligence may be improved.

DISADVANTAGES AND CONTRAINDICATIONS

Absolute contraindications to breastfeeding are use of street drugs or excess alcohol; human T-cell leukemia virus type 1; breast cancer; active herpes simplex infection of the breast; active pulmonary tuberculosis in the mother; galactosemia in the infant; and maternal intake of cancer chemotherapeutic agents or certain other drugs. Table 12–3 lists some of the medications that are contraindicated during breastfeeding. Additional medications are not recommended during breastfeeding. Therefore, specific precautions for individual medications should be reviewed when prescribing drugs to lactating women. Human immunodeficiency virus (HIV) infection in the United States is also a contraindication to breastfeeding. Breastfeeding has been recognized as a mode of HIV transmission. Breastfeeding might pose an additional risk (about 15%) for an infant above that already present at birth because the mother had HIV. The risk of HIV transmission through breast milk is substantially higher among women who become infected during the postpartum lactation period. Most mothers in developed countries who know of their seropositivity choose not to breastfeed; in underdeveloped countries where lactation is critical to infant survival, HIV-infected mothers may choose to breastfeed their infants.

Table 12–3. Medications Contraindicated during Breastfeeding.

Medication	Reason
Bromocriptine	Suppresses lactation; may be hazardous to the mother
Cocaine	Cocaine intoxication
Cyclophosphamide	Possible immune suppression; unknown effect on growth or association with carcinogenesis; neutropenia
Cyclosporine	Possible immune suppression; unknown effect on growth or association with carcinogenesis
Doxorubicin ¹	Possible immune suppression; unknown effect on growth or association with carcinogenesis
Ergotamine	Vomiting, diarrhea, convulsions (at doses used in migraine medications)
Lithium	One third to one half of therapeutic blood concentration in infants
Methotrexate	Possible immune suppression; unknown effect on growth or association with carcinogenesis; neutropenia
Phencyclidine	Potent hallucinogen
Phenindione	Anticoagulant; increased prothrombin and partial thromboplastin time in one infant; not used in United States
Radioactive iodine and other radiolabeled elements	Contraindications to breastfeeding for various periods

¹Medication is concentrated in human milk.

American Academy of Pediatrics, American College of Obstetricians and Gynecologists. Guidelines for perinatal care, 4th ed. Elk Grove Village, Illinois: AAP; Washington, DC: ACOG, 1997.

Breastfeeding does not protect against the deleterious effects of congenital hypothyroidism. The milk of a nursing mother with cystic fibrosis is high in sodium and places the infant at risk for hypernatremia. A woman with clinically infectious varicella should be isolated from the infant and should neither breastfeed nor bottle-feed. Once the infant has received varicella zoster immune globulin and there are no skin lesions on the mother's breast, she may provide expressed milk for her infant. A small number of otherwise healthy breastfed infants develop unconjugated hyperbilirubinemia (sometimes exceeding 20 mg/dL) during the first few weeks of life because of the higher-than-normal glucuronyl transferase inhibitory activity of the breast milk. The inhibitor may be a pregnanediol, although increased milk lipase activity and free fatty acids are likely the critical factors.

Breastfeeding is not usually possible for weak, ill, or very premature infants or for infants with cleft palate, choanal atresia, or phenylketonuria. It is common practice in many nurseries to feed premature infants human milk collected fresh from their mothers or processed from donors. The effects of processing and storage on the persistence of viral agents are not well studied. Cytomegalovirus transmission through breast milk has been documented and may pose a significant hazard for preterm infants. It is recommended that seronegative preterm infants receive milk from seronegative donors only. Because maternal antibodies are present in breast milk, an otherwise healthy term infant may do better if breastfed.

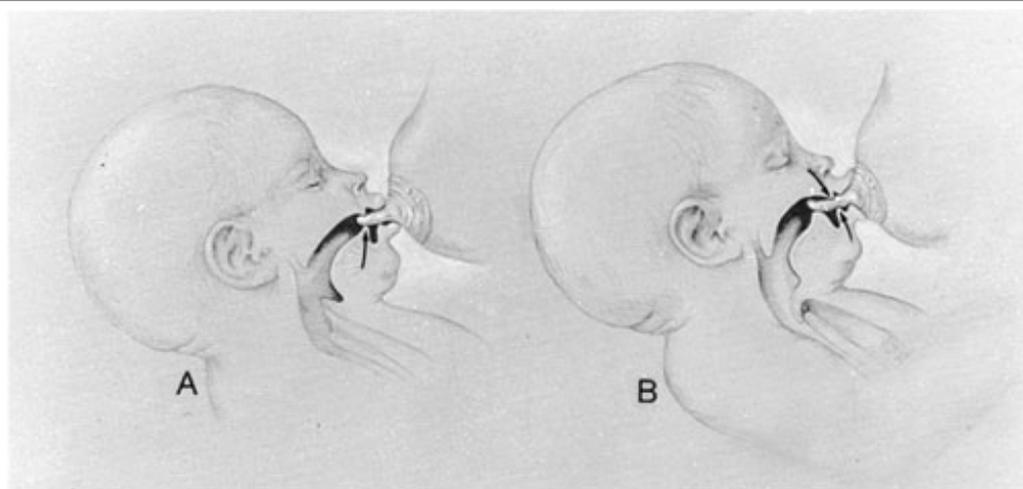

PRINCIPLES & TECHNIQUES OF BREASTFEEDING

In the absence of anatomic or medical complications, the timing of the first feeding and the frequency and duration of subsequent feedings largely determine the outcome of breastfeeding. Infants and mothers who are able to initiate breastfeeding within 1–2 hours of delivery are more successful than those whose initial interactions are delayed for several hours. Lactation is established most successfully if the baby remains with the mother and she can feed on demand for adequate intervals throughout the first 24-hour period. The initial feeding should last 5 minutes at each breast in order to condition the let-down reflex. At first, the frequency of feedings may be very irregular (8–10 times per day), but after 1–2 weeks a fairly regular 4- to 6-hour pattern will emerge.

When the milk "comes in" abruptly on the third or fourth postpartum day, there is an initial period of discomfort caused by vascular engorgement and edema of the breasts. The baby does not nurse so much by developing intermittent negative pressure as by a rhythmic grasping of the areola; the infant "works" the milk into its mouth. Little force is required in nursing because the breast reservoirs can be emptied and refilled without suction. Nursing mothers notice a sensation of drawing and tightening within the breast at the beginning of suckling after the initial breast engorgement disappears. They are thus conscious of the milk ejection reflex, which may even cause milk to spurt or run out.

Some women expend a great deal of emotion on the subject of breastfeeding, and a few are almost overwhelmed by fear of being unable to care for their babies in this way. If attendants are sympathetic and patient, however, a woman who wants to nurse usually can do so. Attendants must be certain that the baby "latches" on (actually over) the nipple and the areola so as to feed properly without causing pain for the mother (Fig 12–8).

Figure 12–8.

Mechanism of suckling in the neonate. A: Tongue moves forward to draw nipple in as glottis still permits breathing. B: Tongue moves along nipple, pressing it against the palate with the glottis closed. Ductules under the areola are compressed, and milk flow begins. The cheeks fill the mouth and provide negative pressure.

The baby should nurse at both breasts at each feeding, because overfilling of the breasts is the main deterrent to the maintenance of milk secretion. Nursing at only 1 breast at each feeding inhibits the reflex that is provoked simultaneously in both breasts. Thus, nursing at alternate breasts from 1 feeding to the next may increase discomfort due to engorgement and reduce milk output. It is helpful for the

mother to be taught to empty the breasts after each feeding; a sleepy baby may not have accomplished this. The use of supplementary formula or other food during the first 6–8 weeks of breastfeeding can interfere with lactation and should be avoided except when absolutely necessary. The introduction of an artificial nipple, which requires a different sucking mechanism, will weaken the sucking reflex required for breastfeeding. Some groups, such as the La Leche League, recommend that other fluids be given by spoon or dropper rather than by bottle.

In preparing to nurse, the mother should (1) wash her hands with soap and water, (2) clean her nipples and breasts with water, and (3) assume a comfortable position, preferably in a rocking or upright chair with the infant and mother chest-to-chest. If the mother is unable to sit up to nurse her baby because of painful perineal sutures, she may feel more comfortable lying on her side. An alternative position is the football hold. A woman with large pendulous breasts may find it difficult to manage both the breasts and the baby. If the baby lies on a pillow, the mother will have both hands free to guide the nipple.

Each baby nurses differently; however, the following procedure is generally successful:

1. Allow the normal newborn to nurse at each breast on demand or approximately every 3–4 hours, for 5 minutes per breast per feeding the first day. Over the next few days, gradually increase feeding time to initiate the let-down reflex, but do not exceed 10–15 minutes per breast. Suckling for longer than 15 minutes may cause maceration and cracking of the nipples and thus lead to mastitis.
2. Stimulating the cheek or lateral angle of the baby's mouth should precipitate a reflex turn to the nipple and opening of the mouth. The infant is brought firmly to the breast, and the nipple and areola are placed into the mouth as far as the nipple–areola line. Slight negative pressure holds the teat in place, and milk is obtained with a peristaltic motion of the tongue. Compressing the periareolar area and expressing a small amount of colostrum or milk for the baby to taste may stimulate the baby to nurse.
3. Try to keep the baby awake by moving or patting, but do not snap its feet, work its jaw, push its head, or press its cheeks.
4. Before removing the infant from the breast, gently open its mouth by lifting the outer border of the upper lip to break the suction.

After nursing, gently wipe the nipples with water and dry them.

MILK YIELD

The prodigious energy requirements for lactation are met by mobilization of elements from maternal tissues and from dietary intake. Physiologic fat stores laid down during pregnancy are mobilized during lactation, and the return to prepregnancy weight and figure is promoted. A variety of studies suggest that a lactating woman should increase her normal daily food intake by 600 kcal/d, but intakes of 2000–2300 calories are sufficient for lactating women. The recommended daily dietary increases for lactation are 20 g of protein; a 20% increase in all vitamins and minerals except folic acid, which should be increased by 50%; and a 33% increase in calcium, phosphorus, and magnesium. There is no evidence that increasing fluid intake will increase milk volume. Fluid restriction also has little effect because urine output will diminish in preference to milk output.

With nursing, average milk production on the second postpartum day is about 120 mL. The amount increases to about 180 mL on the third postpartum day and to as much as 240 mL on the fourth day. In time, milk production reaches about 300 mL/d.

A good rule of thumb for the calculation of milk production for a given day in the week after delivery is to multiply the number of the postpartum day by 60. This gives the approximate number of milliliters of milk secreted in that 24-hour period.

If all goes well, sustained production of milk will be achieved by most patients after 10–14 days. A yield of 120–180 mL per feeding is common by the end of the second week. When free secretion has been established, marked increases are possible; a wet nurse can often suckle 3 babies successfully for weeks.

Early diminution of milk production often is due to failure to empty the breasts because of weak efforts by the baby or ineffectual nursing procedures; emotional problems, such as aversion to nursing; or medical complications, such as mastitis, debilitating systemic disease, or Sheehan's syndrome. Late diminution of milk production results from too generous complementary feedings of formula, emotional or other illness, and pregnancy.

Adequate rest is essential for successful lactation. Sometimes it is difficult to ensure an adequate milk yield if the mother is working outside the home. If it is not possible to rearrange the nursing schedule to fit the work schedule or vice versa, it may be necessary to empty the breasts manually or by pump. Milk output can be estimated by weighing the infant before and after feeding. If there has been a bowel movement during feeding, the baby should be weighed before the diaper is changed.

It may be necessary to substitute bottle-feeding for breastfeeding if the mother's supply continues to be inadequate (less than 50% of the infant's needs) after 3 weeks of effort, if nipple or breast lesions are severe enough to prevent pumping, or if the mother is either pregnant or severely (physically or mentally) ill. Nourishment from the inadequately lactating breast can be augmented with the Lact-Aide Nursing Trainer, a device that provides a supplemental source of milk via a plastic capillary tube placed beside the breast and suckled simultaneously with the nipple. Disposable plastic bags serve as reservoirs, and the supplemental milk is warmed by hanging the bag next to the mother. The Lact-Aide supplementer has also been used to help nurse premature infants and to re-establish lactation after untimely weaning due to illness. The long-term success of breastfeeding is increased by a structured home support system of postnatal visits by allied health personnel or experienced volunteers.

DISORDERS OF LACTATION

Painful Nipples

Tenderness of the nipples, a common symptom during the first days of breastfeeding, generally begins when the baby starts to suck. As soon as milk begins to flow, nipple sensitivity usually subsides. If maternal tissues are unusually tender, dry heat may help between feedings. Nipple shields should be used only as a last resort because they interfere with normal sucking. Glass or plastic shields with rubber nursing nipples are preferable to shields made entirely of rubber.

Nipple fissures cause severe pain and prevent normal let-down of milk. Local infection around the fissure can lead to mastitis. The application of vitamin A and D ointment or hydrous lanolin, which do not have to be removed, is often effective. To speed healing, the following steps are recommended. Apply dry heat for 20 minutes 4 times per day with a 60-watt bulb held 18 inches away from the nipple. Conduct prefeeding manual expression. Begin nursing on the side opposite the fissure with the other breast exposed to air to allow the initial let-down to occur atraumatically. Apply expressed breast milk to nipples and let it dry in between feedings. If necessary, use a nipple shield while nursing, and take ibuprofen or acetaminophen with or without codeine just after nursing. On rare occasions, it may be necessary to stop nursing temporarily on the affected side and to empty the breast either manually or by gentle pumping.

A cause of chronic severe sore nipples without remarkable physical findings is candidal infection. Prompt relief is provided by topical nystatin cream. Thrush or candidal diaper rash or maternal candidal vaginitis must be treated as well.

Engorgement

Engorgement of the breasts occurs in the first week postpartum and is due to vascular congestion and accumulation of milk. Vascularity and swelling increase on the second day after delivery; the areola or breast may become engorged. Prepartum breast massage and around-the-clock demand feedings help to prevent engorgement in these patients. When the areola is engorged, the nipple is occluded and proper grasping of the areola by the infant is not possible. With moderately severe engorgement, the breasts become firm and warm, and the lobules may be palpable as tender, irregular masses. Considerable discomfort and often a slight fever can be expected.

Mild cases may be relieved by acetaminophen or other analgesics, cool compresses, and partial expression of the milk before nursing. In severe cases, the patient should empty the breasts manually or with an electric pump.

Mastitis

Mastitis occurs most frequently in primiparous nursing patients and usually is caused by coagulase-positive *Staphylococcus aureus*. High fever should never be ascribed to simple breast engorgement alone. Inflammation of the breast seldom begins before the fifth day postpartum. Most frequently, symptoms of a painful erythematous lobule in an outer quadrant of the breast are noted during the second or third week of the puerperium. Inflammation may occur with weaning when the flow of milk is disrupted, or the nursing mother may acquire the infection during her hospital stay and then transmit it to the infant. Demonstration of antibody-coated bacteria in the milk indicates the presence of infectious mastitis. Many infants harbor an infection and, in turn, infect the mother's breast during nursing. Neonatal streptococcal infection should be suspected if mastitis is recurrent or bilateral.

Infection may be limited to the subareolar region but more frequently involves an obstructed lactiferous duct and the surrounding breast parenchyma. If cellulitis is not properly treated, a breast abscess may develop. When only mastitis is present, it is best to prevent milk stasis by continuing breastfeeding or by using a breast pump. Apply local heat, provide a well-fitted brassiere, and institute appropriate antibiotic treatment. Cephalosporins, methicillin sodium, and dicloxacillin sodium are the antibiotics of choice to combat penicillinase-producing bacteria.

Pitting edema over the inflamed area and some degree of fluctuation are evidence of abscess formation. It is necessary to incise and open loculated areas and provide wide drainage. Unlike the case with mastitis, continuing breastfeeding is not recommended in the presence of a breast abscess.

Miscellaneous Complications

A galactocele, or milk-retention cyst, is caused by blockage of a milk duct. It usually will resolve with warm compresses and continuation of breastfeeding. Sometimes the infant will reject 1 or both breasts. Strong foods such as beans, cabbage, turnips, broccoli, onions, garlic, and rhubarb may cause aversion to milk or neonatal colic. A common cause of nursing problems is maternal fatigue.

INHIBITION & SUPPRESSION OF LACTATION

Despite a recent upsurge in breastfeeding in Western countries, many women will not or cannot breastfeed, and others will fail in the attempt. Lactation inhibition is desirable in the event of fetal or neonatal death as well.

The oldest and simplest method of suppressing lactation is to stop nursing, to avoid nipple stimulation, to refrain from expressing or pumping the milk, and to wear a supportive bra. Analgesics are also helpful. Patients will complain of breast engorgement (45%), pain (45%), and leaking breasts (55%). Although the breasts will become considerably engorged and the patient may experience discomfort, the collection of milk in the duct system will suppress its production, and resorption will occur. After approximately 2–3 days, engorgement will begin to recede, and the patient will be comfortable again. Medical suppression of lactation with estrogens or bromocriptine is no longer recommended.

Current OB/GYN > Chapter 13. Methods of Assessment for Pregnancy at Risk >

ESSENTIALS OF DIAGNOSIS

- A careful history to reveal specific risk factors.
- A maternal physical examination organized to identify or exclude risk factors.
- Routine maternal laboratory screening for common disorders.
- Special maternal laboratory evaluations for disorders suggested by any evaluative process.
- Comprehensive fetal assessment by an assortment of techniques over the entire course of the pregnancy.

OVERVIEW

High-risk pregnancy is broadly defined as one in which the mother, fetus, or newborn is, or may possibly be, at increased risk of morbidity or mortality before, during, or after delivery. Factors that may lead to this increased risk include maternal health, obstetric abnormalities, and fetal disease. Table 13–1 provides an overview of some major categories that comprise a high-risk pregnancy.

Table 13–1. Risk Factors Related to Specific Pregnancy Problems.

Preterm labor

- Age below 16 or over 35 years
- Low socioeconomic status
- Maternal weight below 50 kg (110 lb)
- Poor nutrition
- Previous preterm birth
- Incomplete cervix
- Uterine anomalies
- Smoking
- Drug addiction and alcohol abuse
- Pyelonephritis, pneumonia
- Multiple gestation
- Anemia

Abnormal fetal presentation

Preterm rupture of membranes

Placental abnormalities

Infection

Polyhydramnios

Diabetes mellitus

Multiple gestation

Fetal congenital abnormalities

Isoimmunization (Rh or ABO)

Nonimmune hydrops

Abnormal fetal presentation

Intrauterine growth restriction (IUGR)

Multiple gestation

Poor nutrition

Maternal cyanotic heart disease

Chronic hypertension

Pregnancy-induced hypertension

Recurrent antepartum hemorrhage

Smoking

Maternal diabetes with vasculopathy

Fetal infections

Fetal cardiovascular anomalies

Drug addiction and alcohol abuse

Fetal congenital anomalies

Hemoglobinopathies

Oligohydramnios

Renal agenesis (Potter's syndrome)

Prolonged rupture of membranes

Intrauterine growth restriction

Intrauterine fetal demise

Postterm pregnancy

Anencephaly

Placental sulfatase deficiency

Perinatal hypoxia, acidosis

Placental insufficiency

Chromosomal abnormalities

Maternal age 35 years or more at delivery

Balanced translocation (maternal and paternal)

The purpose of this chapter is to outline basic and essential aspects of diagnostic modalities available for determination of pregnancies at risk that can be used in practice in a rational manner.

The incidence of high-risk pregnancy varies according to the criteria used to define it. A great many factors are involved, and the effects of any given factor differ from patient to patient. Outcomes can include mortality of the mother and/or the fetus/neonate. Leading causes of maternal death include thromboembolic disease, hypertensive disease, hemorrhage, infection, and ectopic pregnancy. The leading causes of infant mortality (death from birth to 1 year of age) are congenital malformations and prematurity-related conditions. Although there is legal variation by jurisdiction in the United States, a perinatal death is one that occurs at any time after 22 weeks' gestation (or above 500 g if gestational age is not known) through 28 days after delivery. The perinatal mortality rate is the sum of fetal (stillbirths) and neonatal deaths. Preterm birth is the leading cause of perinatal morbidity and neonatal mortality.

In assessing pregnancies to determine risk, several key concepts may offer tremendous insight. Human reproduction is a complex social, biochemical, and physiologic process that is not as successful as once thought. Approximately half of all conceptions are lost before pregnancy is even recognized. Another 15–20% are lost in the first trimester. Of this latter group, more than half have abnormal karyotypes and defy current methodologies for prevention of loss. However, many other causes of reproductive loss are amenable to diagnosis and treatment. In this chapter we discuss the indications and justifications for antepartum care and intrapartum management.

Preconceptional Care

Preconceptional evaluation and counseling of women of reproductive age has gained increasing acceptance as an important component of women's health. Care given in family planning and gynecology centers provides an opportunity that is rarely seen in the prenatal visits. This valuable opportunity to maximize maternal and fetal health benefits before conception should be taken advantage of. Issues of potential consequence to a pregnancy, such as medical problems, lifestyle (including substance abuse, weight, and exercise), or genetic issues should be investigated and interventions devised prior to pregnancy. Specific recommendations include folic acid for the prevention of fetal neural tube defects (0.4 mg/d), strict blood sugar control in diabetic women, and general management of any medical problems in the mother.

PRENATAL PERIOD

Initial Screening

The initial prenatal visit is important in evaluation and assessment of risk during the pregnancy and should take place as early in the pregnancy as possible, preferably in the first trimester. Information of vital importance includes maternal medical and obstetric history, physical examination, and key laboratory findings.

MATERNAL AGE

Extremes of maternal age increase risks of maternal or fetal morbidity and mortality. Adolescents are at increased risk for preeclampsia–eclampsia, intrauterine growth restriction (IUGR), and maternal malnutrition.

Women 35 years of age or older at the time of delivery are at higher risk for pregnancy-induced hypertension, diabetes, and obesity, as well as other medical conditions. Chromosomal abnormalities are also more common in infants born to older women. An increased risk of cesarean section, preeclampsia, and placenta previa is noted in women with advanced maternal age.

MODALITY OF CONCEPTION

It is important to differentiate spontaneous pregnancy from that resulting from assisted reproductive technologies (ART). Use of ART increases the risks of multiple gestation, preterm delivery, and low birth weight.

PAST MEDICAL HISTORY

Many medical disorders can complicate the pregnancy course for the mother and thus the fetus. It is important that these diseases and their severity be addressed before conception if possible. During pregnancy the patient may require aggressive management and additional visits and testing to follow the course of the disease, in addition to possible consultation or management of a high-risk specialist. Table 13–2 lists the most important disorders that may complicate pregnancy.

Table 13–2. Some Diseases and Disorders Complicating Pregnancy.

Chronic hypertension
Renal disease
Diabetes mellitus
Heart disease
Previous endocrine ablation (eg, thyroidectomy)
Maternal cancer
Sickle cell trait and disease
Substance use or abuse
Pulmonary disease (eg, tuberculosis, sarcoidosis, asthma)
Thyroid disorders
Gastrointestinal and liver disease
Epilepsy

Blood disorders (eg, anemia, coagulopathy)

Others, including previous pelvic injury or disease producing pelvic deformity, connective tissue disorders, mental retardation, psychiatric disease

FAMILY HISTORY

A detailed family history is helpful in determining any increased risk of heritable disease states (eg, Tay-Sachs, cystic fibrosis, sickle cell disease) that may affect the mother or fetus during the pregnancy or the fetus following delivery.

ETHNIC BACKGROUND

Population screening for certain inheritable genetic diseases is not cost effective because of the relative rarity of those genes in the general population. However, many genetic diseases affect certain ethnicities in disproportionate amounts, allowing cost-effective screening of those particular groups. Table 13–3 lists several common inheritable genetic diseases for which screening is possible. It includes the group at risk as well as the method of screening.

Table 13–3. Common Inheritable Genetic Diseases.

Disease	Population at Increased Risk	Method of Testing
Alpha thalassemia	Chinese, Southeast Asian, African	CBC Hemoglobin electrophoresis
Beta thalassemia	Chinese, Southeast Asians, Mediterraneans, Pakistanis, Bangladeshis, Middle Easterners, African	CBC Hemoglobin electrophoresis
Bloom's syndrome	Ashkenazi Jews	Mutation analysis
Canavan's disease	Ashkenazi Jews	Mutation analysis
Cystic fibrosis	North American Caucasians of European ancestry, Ashkenazi Jews	Mutation analysis
Familial dysautonomia	Ashkenazi Jews	Mutation analysis
Fanconi's anemia	Ashkenazi Jews	Mutation analysis
Gaucher's disease	Ashkenazi Jews	Mutation analysis
Niemann-Pick disease	Ashkenazi Jews	Mutation analysis
Sickle cell disease and other structural hemoglobinopathies	African-Americans, Africans, Hispanics, Mediterranean, Middle Easterners, Caribbean Indians	CBC Hemoglobin electrophoresis
Tay-Sachs	Ashkenazi Jews, French Canadians, Cajuns	Enzyme and mutation analysis

PAST OBSTETRIC HISTORY

Recurrent Abortion

A diagnosis of recurrent abortion can be made after 3 or more consecutive spontaneous losses of a

previable fetus. Recurrent abortion is best investigated before another pregnancy occurs. If the patient is currently pregnant, however, as much of the work-up as possible should be performed.

- Karyotype of abortus specimen
- Parental karyotype
- Survey for cervical and uterine anomalies
- Connective tissue disease work-up
- Screening for hormonal abnormalities (ie, hypothyroidism)
- Acquired and inherited thrombophilias
- Infectious disease evaluation of the genital tract

Previous Stillbirth or Neonatal Death

A history of previous stillbirth or neonatal death should trigger an immediate investigation as to the conditions or circumstances surrounding the event. If the demise was the result of a nonrecurring event, such as cord prolapse or traumatic injury, then the present pregnancy has a risk approaching a background risk. However, stillbirth or neonatal death may suggest a cytogenetic abnormality, structural malformation syndrome, fetomaternal hemorrhage, or thrombophilia (fetal or maternal), requiring a work-up similar to that just listed.

Previous Preterm Delivery

A history of preterm birth confers an increased risk of early delivery in subsequent pregnancies. Furthermore, the risk of a subsequent preterm birth increases as the number of prior preterm births increases, and the risk decreases with each birth that is not preterm. The recurrence risk also rises as the gestational age of the previous preterm delivery decreases. Despite intense investigation, the incidence of preterm delivery has slightly increased in the United States, due in large measure to medical intervention producing indicated preterm deliveries. Eighty-five percent of preterm deliveries occur between 32 and 36 weeks, and they carry minimal fetal or neonatal morbidity. The remaining 15% of preterm deliveries, however, account for nearly all of the perinatal morbidity and mortality. Common causes of perinatal morbidity in premature infants include respiratory distress syndrome, intraventricular hemorrhage, bronchopulmonary dysplasia, necrotizing enterocolitis, sepsis, apnea, retinopathy of prematurity, and hyperbilirubinemia. Preterm deliveries can be divided into 2 types: spontaneous and indicated, with indicated preterm deliveries caused by medical or obstetric disorders that place the mother and/or fetus at risk. The clinical risk factors most often associated with spontaneous preterm birth include history of previous preterm birth, genital tract infection, nonwhite race, multiple gestation, bleeding in the second trimester, and low prepregnancy weight. Recent multicenter trials have shown that progesterone in the form of 17 α -hydroxyprogesterone, given as weekly injections of 250 mg beginning in the second trimester, can decrease the risk of preterm delivery in patients with a history of prior spontaneous preterm delivery.

Rh Isoimmunization or ABO Incompatibility

All pregnant patients should undergo an antibody screen at the first prenatal visit. Those patients who are RhD-negative with no evidence of anti-D alloimmunization should receive Rh_o (D) immunoglobulin (RhoGAM) 300 μ g at 28 weeks of gestation. In patients who are Rh sensitized, the patient can be followed by maternal titers and/or amniocentesis for fetal blood typing, followed by either serial amniocentesis for Δ OD₄₅₀ or serial middle cerebral artery velocity measurements, as well as fetal blood sampling via cordocentesis.

Previous Preeclampsia–Eclampsia

Previous preeclampsia–eclampsia increases the risk for hypertension in the current pregnancy, especially if underlying chronic hypertension or renal disease is present.

Previous Infant with Genetic Disorder or Congenital Anomaly

A woman with a previous history of a fetus with a chromosomal abnormality is a frequent indication of cytogenetic testing, although this may be preceded by first- or second-trimester screening and anatomy ultrasound (US). The rate of recurrence depends on the abnormality.

Teratogen Exposure

A teratogen is any substance, agent, or environmental factor that has an adverse effect on the developing fetus. Whereas malformations caused by teratogen exposure are relatively rare, knowledge of exposure can aid in the diagnosis and management.

DRUGS

Alcohol, antiseizure medications (phenytoin, valproic acid, etc), lithium, mercury, thalidomide, diethylstilbestrol (DES), warfarin (Coumadin), isotretinoin, etc.

INFECTIOUS AGENTS

Cytomegalovirus, *Listeria*, rubella, toxoplasmosis, varicella, *Mycoplasma*, etc.

RADIATION

It is believed that medical diagnostic radiation delivering less than 0.05 Gy (5 rad) to the fetus has no teratogenic risk.

Physical Examination

Physical examination is important not only during the initial visit but also throughout the pregnancy. Vital sign abnormalities can lead to the diagnosis of many key obstetric complications. Fever, defined as a temperature of 100.4°F or greater, can be a sign of chorioamnionitis. Signs or symptoms of chorioamnionitis should be assessed, and, if chorioamnionitis is suspected, amniocentesis for microscopy and culture should be considered. Depending on clinical correlation, delivery may be necessary. Maternal tachycardia can be a sign of infection, anemia, or both. Isolated mild tachycardia (> 100 bpm) should be evaluated and followed up, as should maternal tachyarrhythmias. Maternal heart rate is noted to increase normally in pregnancy, however. The normal pattern of maternal blood pressure readings is a decrease from baseline during the first trimester, reaching its nadir in the second trimester, and slightly rising in the third trimester, although not as high as the baseline levels. Repeated blood pressure readings of 140/90 mm Hg taken 6 hours apart should be considered evidence of pregnancy-induced hypertension. Increases in systolic and diastolic blood pressure, although no longer a part of the definition, may also be an indication of development of pregnancy-induced hypertension. The rest of the physical examination should be performed during the initial visit and focused examination during each visit. Fundal height measurements and fetal heart tone checks should also be performed.

Urinalysis

At the first prenatal visit, a clean-catch urine culture and sensitivity should be performed. Any growth should be treated with the appropriate antibiotics. At all subsequent visits, urine dipstick testing to screen for protein, glucose, leukocyte esterase, blood, or any combination of markers is useful in identifying patients with a change in baseline urinary composition.

Screening Tests

Screening tests during the initial visit include testing for rubella, rapid plasma reagin, hepatitis B, blood type, human immunodeficiency virus, gonorrhea, and *Chlamydia*, and Pap smear.

ANTEPARTUM MANAGEMENT

Genetic Testing

FIRST-TRIMESTER SCREENING

Nuchal translucency, measured between 11(0/7) and 13(6/7) weeks, combined with free β -human chorionic gonadotropin (β -hCG) and pregnancy-associated plasma protein-A levels, has been found to have 87.0% sensitivity for detection of trisomy 21 with a 5% false positive rate. In the absence of chromosomal abnormalities, an increased nuchal translucency is associated with an increased risk of structural cardiac abnormalities and skeletal dysplasias, etc. Further US findings in the first trimester, including absence of nasal bone and abnormal ductus venosus Doppler findings, may further improve the detection rate for aneuploidy but require a high level of sonographic skill.

Maternal Serum Analyte Testing

Frequently known as the "triple screen," this test includes maternal serum α -fetoprotein (MSAFP), β -hCG, and estriol. In some institutions, only the MSAFP is used, whereas in other institutions a fourth test for inhibin is included, making it a "quad test." The usefulness of this screen is its ability to identify pregnancies at increased risk for open neural tube defects, as well as for certain chromosomal abnormalities, especially trisomy 21 (70% sensitivity for Down syndrome detection). This test is effective at 15–22 weeks' gestation and therefore can identify an at-risk pregnancy in time to pursue more definitive diagnosis, if desired. It is important to note, however, that the triple screen is not a definitive test, and that many positive screens have yielded normal fetuses and many abnormal fetuses have had normal screens.

Syndromic Testing

Screening for sickle cell disease should be offered to individuals of African and African American descent and those from the Mediterranean basin, the Middle East, and India. Hemoglobin electrophoresis is the definitive test to determine the carrier status of sickle cell disease.

The decision on who to offer cystic fibrosis testing to remains controversial, as the sensitivity of the testing depends on the ethnicity of the parents, with the highest pick-up rate in those with the highest risk—Caucasian and Ashkenazi Jewish descent. Current guidelines recommend offering testing to all groups but counseling lower-risk groups of the limitations of the testing.

The current standard of care is to offer carrier testing for Tay-Sachs disease and Canavan's disease to those of Ashkenazi Jewish descent.

Preterm Labor Detection

Many patients present throughout pregnancy with signs and symptoms of preterm labor, specifically uterine contractions. Although the cost of missing true preterm labor is high, many patients are not in true labor, and the financial cost of aggressive management of these patients is also high. Two screening tests have aided in the management of these patients: cervical length measurement and fetal fibronectin. A preterm birth is very unlikely (97–99%) when the cervical length is 30 mm (before 34–35 weeks) or when the fetal fibronectin is negative (within 14 days).

Diabetes Screening/Gestational Diabetes

Although recent consensus groups have recommended screening for gestational diabetes based on risk factors, many studies have shown this to be inadequate for detecting patients with gestational screening versus universal screening.

Routine screening consists of performing a glucose challenge test between 24 and 28 weeks. The test consists of a 50-g oral glucose load with a plasma glucose level drawn exactly 1 hour after. If the value is 140 mg/dL or over, a more specific glucose tolerance test (GTT) should be performed (the cutoff may be

lowered to 130 mg/dL to improve sensitivity). The GTT involves obtaining a fasting plasma glucose level, giving a 100-g oral glucose load, then drawing plasma levels at 1 hour, 2 hours, and 3 hours after the glucose load. A test is considered positive for gestational diabetes if 2 of the 4 values are elevated. The thresholds proposed by Carpenter and Coustan are currently favored (fasting > 95 mg/dL, 1 hour > 180 mg/dL, 2 hour > 155 mg/dL, 3 hour > 140 mg/dL).

Group B Streptococcus

Group B streptococcus (GBS) asymptomatically colonizes between 10% and 30% of pregnant women, but perinatal transmission can result in a severe and potentially fatal neonatal infection. Recent changes to the protocol for GBS testing emphasize the importance of culture screening and treatment over risk factor–based screening. For this reason, patients should be screened with a rectovaginal culture at 35–37 weeks. If the culture is positive, patients should be treated with intrapartum antibiotics. Intrapartum antibiotic prophylaxis has been shown to decrease the risk of perinatal GBS transmission. If the culture result is unknown, patients should be treated if in preterm labor, with rupture of membranes greater than or equal to 18 hours, or maternal fever greater than 100.4°F during labor. All patients with GBS bacteriuria during the pregnancy or previous neonate with GBS sepsis should be treated with intrapartum antibiotics.

FETAL ASSESSMENT

Performed during all trimesters, the techniques used are diverse, and the information obtained varies according to the quality of imaging, depth of investigation, and gestational age of pregnancy.

Ultrasound

US has evolved continuously over the last 30 years, with better equipment produced each year. Real-time sonography allows a 2-dimensional (2-D) image to demonstrate fetal anatomy, as well as characteristics such as fetal weight, movement, volume of amniotic fluid, and structural anomalies such as myomas or placenta previa that may affect the pregnancy. Three-dimensional sonography allows volume to be ascertained, creating a 3-D–appearing image on the 2-D screen, which assists in identifying certain anatomic anomalies. Most recently, 4-D machines have been developed, which produce a 3-D image in real time. As the machines become more technically advanced and the computers that run them become faster, the images obtained will continue to improve and push the boundaries of sonographic prenatal diagnosis.

Diagnostic ultrasonography is widely used in the assessment of the pregnancy and the fetus. However, it is not the standard of care, nor is it recommended by the American College of Obstetricians and Gynecologists (ACOG) for every pregnancy. The indications for ultrasonography are multiple and diverse, and the type and timing of the examination varies depending on the information being sought.

A standard US examination should provide information such as fetal number, presentation, documentation of fetal viability, assessment of gestational age, amniotic fluid volume, placental location, fetal biometry, and an anatomic survey. A limited US examination is a goal-directed search for a suspected problem or finding. A limited US can be used for guidance during procedures such as amniocentesis or external cephalic version, assessment of fetal well-being, or documentation of presentation or placental location intrapartum. A specialized US examination is performed when an anomaly is suspected based on history, biochemical abnormalities, or results of either the limited or standard scan. Other specialized examinations include fetal Doppler, biophysical profile (BPP), fetal echocardiogram, or additional biometric studies.

US evaluation of fetal anatomy may detect major structural anomalies. Gross malformations such as anencephaly and hydrocephaly are commonly diagnosed and rarely missed; however, more subtle

anomalies such as facial clefts, diaphragmatic hernias, and neural tube defects are more commonly reported to have been missed by US. The basic fetal anatomy survey should include visualization of the cerebral ventricles, 4-chamber view of the heart, and examination of the spine, stomach, urinary bladder, umbilical cord insertion site, and renal region. Any indication of an anomaly should be followed by a more comprehensive sonogram. Typically, the fetal anatomic survey is performed at 17–20 weeks; however, there is controversy regarding the potential benefits of an earlier sonogram at 14–16 weeks using the transvaginal probe. The earlier scan allows earlier detection of anomalies that are almost always present by the second trimester, as well as allowing greater detailed viewing of the fetal anatomy by using the higher-resolution vaginal transducers.

Aneuploidy Screening

Multiple sonographic findings associated with markers for aneuploidy have been identified. The presence of single or multiple markers adjusts the patient's age-related risk of aneuploidy based on the particular markers present. Such sonographic findings include, but are not limited to:

- Echogenic intracardiac focus
- Choroid plexus cysts
- Pyelectasis
- Echogenic bowel
- Short femur
- Hypomineralization of the fifth digit of the fetal hand

Amniocentesis

Amniocentesis is now almost always performed under the guidance of ultrasonography. A needle is inserted transcutaneously through the abdominal wall into the amniotic cavity, and fluid is removed. There are many uses for this amniotic fluid. In the early second trimester, these include AFP evaluation for neural tube defect assessment and the most common indication of cytogenetic analysis. In this case, amniocentesis is often performed between 15 and 20 weeks' gestation, and fetal cells from the amniotic fluid are obtained. Risks associated with the procedure are considered to be very low, with the risk of abortion as a result of amniocentesis considered to be between 1 in 200 to 1 in 450 amniocenteses.

Amniocentesis also provides a useful tool later in pregnancy, at low risk, for diagnosis of intra-amniotic inflammation and infection as a risk factor for preterm labor and adverse outcome, as well as documentation of fetal lung maturity.

Chorionic Villus Sampling

Chorionic villus sampling (CVS) is an alternative to amniocentesis. It is performed between 10 and 12 weeks' gestation and can be performed either transcervically or transabdominally. CVS is also performed under sonographic guidance, with the passing of a sterile catheter or needle into the placental site. Chorionic villi are aspirated and undergo cytogenetic analysis. The benefit of CVS over amniocentesis is its availability earlier in pregnancy; however, the rate of abortion is higher—as high as 1%. One disadvantage of CVS is that, unlike amniocentesis, it does not allow diagnosis of neural tube defects.

Fetal Blood Sampling

Also referred to as cordocentesis or percutaneous umbilical blood sampling (PUBS), fetal blood sampling is an option for chromosomal or metabolic analysis of the fetus. Benefits of the procedure include a rapid result turnaround and the ability to perform the procedure in the second and third trimesters.

Intravascular access to the fetus is useful for assessment and treatment of certain fetal conditions such as Rh sensitization and alloimmune thrombocytopenia. However, there is a higher risk of fetal death compared to the other methods. Fetal loss rates are approximately 2% but can vary depending on the fetal condition involved.

ANTEPARTUM FETAL TESTING

Fetal Movement Assessment

A decrease in maternal perception of fetal movement can precede fetal death, sometimes by several days. Perception of 10 distinct movements in a period of up to 2 hours is considered reassuring; if less, patients are often advised to undergo further testing.

Nonstress Test

Fetal movements associated with accelerations of fetal heart rate (FHR) provide reassurance that the fetus is not acidotic or neurologically depressed. A reactive and therefore reassuring nonstress test (NST) is defined as 2 or more FHR accelerations, at least 15 bpm above the baseline and lasting at least 15 seconds within a 20-minute period. Vibroacoustic stimulation can elicit FHR accelerations that can reduce overall testing time without compromising detection of an acidotic fetus. In the case of a nonreassuring NST, further evaluation or delivery depend on the clinical context. In a patient at term, delivery is warranted. Pregnancy remote from term poses a more challenging dilemma to the clinician. If resuscitative efforts are not successful in restoring reactivity to the NST, ancillary tests or testing techniques may prove useful in avoiding a premature iatrogenic delivery for nonreassuring FHR patterns, as the false-positive rate may be as high as 50–60%.

Biophysical Profile

The BPP is composed of 5 components: NST, fetal breathing movements (30 seconds or more in 30 minutes), fetal movement (3 or more in 30 minutes), fetal tone (extension/flexion of an extremity), and amniotic fluid volume (vertical pocket of 2 cm or more). Each component is worth 2 points; a score of 8 or 10 is normal, 6 is equivocal, and 4 or less is abnormal.

Modified Biophysical Profile

Modified BPP combines NST, a short-term indicator of fetal acid–base status, with amniotic fluid index (AFI), a long-term indicator of placental function. AFI is measured by dividing the uterus into 4 equal quadrants and measuring the largest vertical pocket in each quadrant; the results are then summed and expressed in millimeters. The modified BPP has become a primary mode of antepartum fetal surveillance; a nonreactive NST or an AFI less than 50 mm (oligohydramnios) requires further intervention.

Contraction Stress Test

The contraction stress test (CST) is based on the response of HFR to uterine contractions, with the premise that fetal oxygenation will be worsened. This results in late decelerations in an already suboptimally oxygenated fetus. The test requires 3 contractions in 10 minutes, a positive or abnormal test when late decelerations occur with more than half of the contractions, suspicious with any late decelerations, and negative with no late decelerations. Contraindications to CST include any contraindications to labor, such as placenta previa or prior classic cesarian section. This test is now rarely used.

Growth Ultrasound

Growth US studies, performed every 3–4 weeks, are useful for assessment of fetuses that may be at risk for growth restriction secondary to medical conditions of pregnancy or fetal abnormalities.

Doppler Studies

Fetal Doppler studies initially were used to assess the placenta by evaluation of umbilical artery outflow. They have since evolved to a more comprehensive multivessel evaluation of fetal status. Doppler studies can be used to assess a compromised fetus (particularly the growth-restricted fetus) and may function as a diagnostic tool that alerts the clinician to the need for further intervention, including BPP, continuous fetal monitoring, or possibly delivery.

Fetal Maturity Tests

INDICATIONS FOR ASSESSING FETAL LUNG MATURITY

ACOG has recommended that fetal pulmonary maturity should be confirmed before elective delivery at less than 39 weeks' gestation unless fetal maturity can be inferred from any of these criteria: fetal heart tones have been documented for 20 weeks by nonelectronic fetoscope or for 30 weeks by Doppler; 36 weeks have elapsed since a serum or urine hCG-based pregnancy test was reported to be positive; US measurement of crown-rump length at 6–11 weeks of gestation or measurements at 12–20 weeks support a gestational age equal to or greater than 39 weeks.

Lecithin/Sphingomyelin Ratio

The lecithin/sphingomyelin (L/S) ratio for assessment of fetal pulmonary maturity was first introduced by Gluck and colleagues in 1971. The test depends upon outward flow of pulmonary secretions from the lungs into the amniotic fluid, thereby changing the phospholipid composition of the latter and permitting measurement of the L/S ratio in a sample of amniotic fluid. In the absence of complications, the ratio of these 2 components reaches 2.0 at about 35 weeks. The presence of blood or meconium may interfere with test interpretation.

Phosphatidylglycerol

Phosphatidylglycerol (PG) is a minor constituent of surfactant. It begins to increase appreciably in amniotic fluid several weeks after the rise in lecithin. Its presence is more indicative of fetal lung maturity because PG enhances the spread of phospholipids on the alveoli. However, it is not commonly used at present because of a high false-negative rate.

Fluorescence Polarization

The fluorescence polarization test, currently the most widely used test, uses polarized light to quantitate the competitive binding of a probe to both albumin and surfactant in amniotic fluid; thus, it is a true direct measurement of surfactant concentration. It reflects the ratio of surfactant to albumin and is measured by an automatic analyzer, such as the TDx-FLM. An elevated ratio has been correlated with the presence of fetal lung maturity; the threshold for maturity is 55 mg of surfactant per gram of albumin.

Table 13–4 lists all fetal maturity tests available, discriminating levels, and specific characteristics of the tests.

Table 13–4. Fetal Maturity Tests.

Test	Positive Discriminating Value	Positive Predictive Value	Relative Cost	Pros and Cons
L/S ratio	> 2.0	95–100%	High	Large laboratory variation
PG	"Present"	95–100%	High	Not affected by blood, meconium; can use vaginal pooled sample
FSI	> 47	95%	Low	Affected by blood, meconium silicone tubes
TDx-FLM	> 55	96–100%	Moderate	Minimal inter/intra-assay variability; simple test
Optical density	OD 0.15	98%	Low	Simple technique
Lamellar body counts	30–40,000	97–98%	Low	Still investigational

INTRAPARTUM MANAGEMENT

Fetal Heart Rate Monitoring

Use of electronic fetal monitoring (EFM) has been increasing over the last several decades, up to 85% in 2002. No randomized controlled trials have compared the benefits of EFM versus no form of monitoring during labor. Randomized clinical trials comparing EFM with intermittent auscultation showed an increase in cesarian section rate, cesarian section rate for fetal distress, and operative vaginal delivery rate, with no reduction in overall perinatal mortality but possibly a decrease in perinatal mortality from fetal hypoxia. Given these findings, ACOG has stated that either EFM or intermittent auscultation is acceptable, given that guidelines for intermittent auscultation are met. Intermittent auscultation may not be acceptable in high-risk patients, however.

Despite its widespread use, EFM suffers from poor interobserver and intraobserver reliability, uncertain efficacy, and a high false-positive rate. To improve consistency, the National Institute of Child Health and Human Development (NICHD) Planning Workshop proposed definitions for intrapartum FHR tracing.

Fetal Heart Rate

The baseline is the mean FHR rounded to increments of 5 bpm, at least 2 minutes in any 10-minute segment. Normal baseline is between 110 and 160 bpm. Baseline FHR below 110 is defined as *bradycardia*, above 160 is defined as *tachycardia*. Either bradycardia (particularly when the new baseline is below 80 bpm) or tachycardia (particularly when associated with a decrease in variability or repetitive late or severe variable decelerations) suggests a nonreassuring fetal status. *Accelerations* (at 32 weeks or greater) are defined as elevations above the baseline of 15 bpm lasting 15 seconds or longer; less than 32 weeks it is defined by elevations of 10 bpm lasting at least 10 seconds. Two or more accelerations in a 20-minute interval are reassuring; this defines reactivity in an NST. *Variability* is defined by fluctuations in the FHR of 2 cycles per minute or greater and can range from absent to marked. Decelerations are categorized as early, late, and variable. *Early decelerations* generally mirror contractions in timing and shape and are generally not ominous, often representing head compression. *Late decelerations* are smooth falls in the FHR beginning after the contraction has started and ending after the contraction has ended. They are associated with fetal hypoxemia and a potential for perinatal

morbidity and mortality. *Variable decelerations* are abrupt in decline and return to baseline, vary in timing with the contraction, and usually represent cord compression. These are most ominous when repetitive and severe (below 60 bpm). A *prolonged deceleration* is a decrease of 15 bpm below the baseline lasting between 2 and 10 minutes.

Ancillary Tests

FETAL SCALP BLOOD SAMPLING

In the presence of a nonreassuring FHR pattern, a scalp blood sample for determination of pH or lactate can be considered. Although the specificity is high (normal values rule out asphyxia), the sensitivity and positive predictive value of a low scalp pH in identifying a newborn with hypoxic–ischemic encephalopathy is low. For these reasons, in addition to the technical skill and expense of the procedure, fetal scalp pH is no longer used in many institutions.

VIBROACOUSTIC STIMULATION/SCALP STIMULATION

The presence of an acceleration after a vaginal examination in which the examiner stimulates the fetal vertex with the examining finger or after vibroacoustic stimulation (as described above) confirms the absence of acidosis (pH > 7.2). Some clinicians prefer these methods over fetal scalp blood sampling because they are less invasive.

FETAL PULSE OXIMETRY

Fetal pulse oximetry, the measure of the fetus' oxygenation during labor, was developed with the goal of improving the specificity of FHR monitoring and decreasing the number of cesarean sections secondary to nonreassuring fetal status. It is performed using a sensor placed transcervically, resting against the fetal cheek. Normal oxygenation is 35–65%, and a metabolic acidosis does not develop until the oxygen saturation falls below 30% for at least 10–15 minutes. One randomized controlled trial showed that although fetal pulse oximetry did decrease the number of cesarean sections for nonreassuring fetal status, it was associated with an increased number of cesarian sections for dystocia and thus no difference overall in the rate of operative deliveries. Further studies suggest that nonreassuring fetal status may be a marker for later dystocia in labor, leading to the outcomes seen. The role of fetal pulse oximetry in practice is not yet defined.

CONCLUSION

Assessing pregnancy to determine risk, as well as careful monitoring of pregnancies with a recognized risk, begins early in the gestation. Preconceptual counseling of patients with known medical or genetic disorders helps to optimize outcomes. Early and frequent prenatal care allows the care provider to screen his or her patient population to identify pregnancies at risk and act accordingly. Additionally, pregnancies identified as complicated by 1 or more issues can be followed by assortments of maternal and fetal surveillance techniques to maximize therapeutic treatment.

As technology advances and our ability to both diagnose and treat improve, the methods for assessment and care of the pregnancy at risk will be a constantly changing field.

Current OB/GYN > Chapter 14. Early Pregnancy Risks >

SPONTANEOUS ABORTION

Essentials of Diagnosis

- Suprapubic pain, uterine cramping, and/or back pain.
- Vaginal bleeding.
- Cervical dilatation.
- Extrusion of products of conception.
- Disappearance of symptoms and signs of pregnancy.
- Quantitative β -human chorionic gonadotropin that is not properly increasing.
- Abnormal ultrasound findings (eg, empty gestational sac, fetal disorganization, lack of fetal growth).

General Considerations

Spontaneous abortion is the most common complication of pregnancy and is defined as the passing of a pregnancy prior to completion of the 20th gestational week. It implies delivery of all or any part of the products of conception, with or without a fetus weighing less than 500 g. Threatened abortion is bleeding of intrauterine origin occurring before the 20th completed week, with or without uterine contractions, without dilatation of the cervix, and without expulsion of the products of conception. Complete abortion is the expulsion of all of the products of conception before the 20th completed week of gestation, whereas incomplete abortion is the expulsion of some, but not all, of the products of conception. Inevitable abortion refers to bleeding of intrauterine origin before the 20th completed week, with dilatation of the cervix without expulsion of the products of conception. In missed abortion, the embryo or fetus dies, but the products of conception are retained in utero. In septic abortion, infection of the uterus and sometimes surrounding structures occur.

Incidence

Although the true incidence of spontaneous abortion is unknown, approximately 15% of clinically evident pregnancies and 60% of chemically evident pregnancies end in spontaneous abortion. Eighty percent of spontaneous abortions occur prior to 12 weeks' gestation.

The incidence of abortion is influenced by the age of the mother and by a number of pregnancy-related factors, including a history of a previous full-term normal pregnancy, the number of previous spontaneous abortions, a previous stillbirth, and a previous infant born with malformations or known genetic defects. Additionally, parental influences, including balanced translocation carriers and medical complications, may influence the rate of spontaneous abortion.

Etiology

An abnormal karyotype is present in approximately 50% of spontaneous abortions occurring during the first trimester. The incidence decreases to 20–30% in second-trimester losses and to 5–10% in third-

trimester losses. As discussed in the next section, the first-trimester losses are typically autosomal trisomies or monosomy X, whereas later losses reflect chromosomal abnormalities seen in neonates.

Other suspected causes of spontaneous abortion account for a smaller percentage of losses and include infection, anatomic defects, endocrine factors, immunologic factors, and maternal systemic diseases. In a significant percentage of spontaneous abortions, the etiology is unknown.

MORPHOLOGIC AND GENETIC ABNORMALITIES

Aneuploidy (an abnormal chromosomal number) is the most common genetic abnormality, accounting for at least 50% of early spontaneous abortions. Monosomy X or Turner's syndrome is the single most common aneuploidy, comprising approximately 20% of these gestations. As a group, the autosomal trisomies account for over half of aneuploid losses, with trisomy 16 being the most common. Autosomal trisomies have been noted for every chromosome except chromosome number 1.

Polyploidy, usually in the form of triploidy, is found in approximately 20% of all miscarriages. Polyploid conceptions typically result in empty sacs or blighted ova but occasionally can lead to partial hydatidiform moles.

The remaining half of early abortuses appear to have normal chromosomal complements. Of these, 20% have other genetic abnormalities that may account for the loss. Mendelian or polygenic factors resulting in anatomic defects may play a role. These factors tend to be more common in later fetal losses.

MATERNAL FACTORS

Systemic Disease

MATERNAL INFECTIONS

Organisms such as *Treponema pallidum*, *Chlamydia trachomatis*, *Neisseria gonorrhoeae*, *Streptococcus agalactiae*, herpes simplex virus, cytomegalovirus, and *Listeria monocytogenes* have been implicated in spontaneous abortion. Although these agents have been identified in early losses, a causal relationship has not been established.

OTHER DISEASES

Endocrine disorders such as hyperthyroidism and poorly controlled diabetes mellitus; cardiovascular disorders, such as hypertensive or renal disease; and connective tissue disease, such as systemic lupus erythematosus, may be associated with spontaneous abortion.

Uterine Defects

Congenital anomalies that distort or reduce the size of the uterine cavity, such as unicornuate, bicornuate, or septate uterus, carry a 25–50% risk of miscarriage. A diethylstilbestrol (DES)-related anomaly, such as a T-shaped or hypoplastic uterus, also carries an increased risk of miscarriage. Acquired anomalies, particularly submucous or intramural myomas, have been associated with spontaneous abortions as well.

Previous scarring of the uterine cavity following dilatation and curettage (D&C; Asherman's syndrome), myomectomy, or unification procedures has been implicated in spontaneous miscarriage, as has anatomic or functional incompetence of the uterine cervix.

Immunologic Disorders

Blood group incompatibility due to ABO, Rh, Kell, or other less common antigens has been associated with spontaneous abortions. Furthermore, similar maternal and paternal human leukocyte antigen (HLA) status may enhance the possibility of abortion by causing insufficient maternal immunologic recognition of the fetus.

Malnutrition

Severe malnutrition has been implicated in spontaneous losses.

Emotional Disturbances

Emotional causes of abortion are speculative. No valid evidence supports the concept that abortion may be induced by fright, grief, anger, or anxiety.

TOXIC FACTORS

Agents such as radiation, antineoplastic drugs, anesthetic gases, alcohol, and nicotine have been shown to be embryotoxic. Other agents such as lead, ethylene oxide, and formaldehyde have also been implicated.

TRAUMA

Direct trauma, such as injury to the uterus from a gunshot wound, or indirect trauma, such as surgical removal of an ovary containing the corpus luteum of pregnancy, may result in spontaneous abortion.

Pathology

In spontaneous abortion, hemorrhage into the decidua basalis often occurs. Necrosis and inflammation appear in the area of implantation. The pregnancy becomes partially or entirely detached. Uterine contractions and dilatation of the cervix result in expulsion of most or all of the products of conception.

Clinical Findings

THREATENED ABORTION

At least 20–30% of pregnant women have some first-trimester bleeding. In most cases, this is thought to represent an implantation bleed. The cervix remains closed, and slight bleeding with or without cramping may be noted.

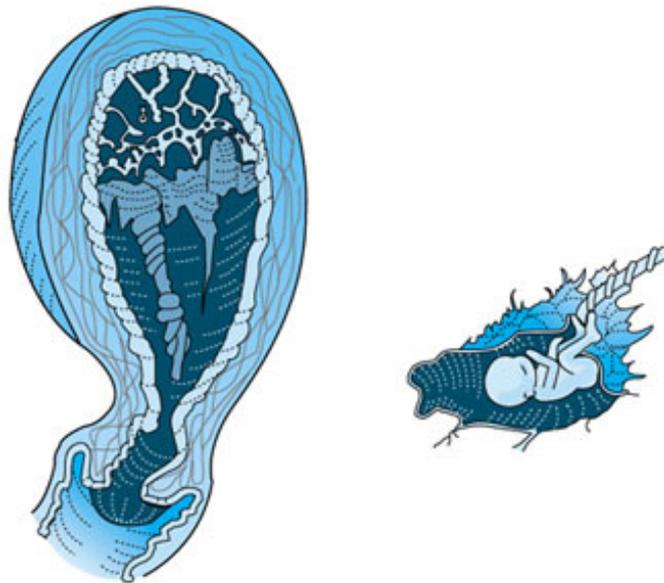

INEVITABLE ABORTION

Abdominal or back pain and bleeding with an open cervix indicate impending abortion. Abortion is inevitable when cervical effacement, cervical dilatation, and/or rupture of the membranes is noted.

INCOMPLETE ABORTION

(Fig 14–1) In incomplete abortion the products of conception have partially passed from the uterine cavity. In gestations of less than 10 weeks' duration, the fetus and placenta are usually passed together. After 10 weeks, they may be passed separately, with a portion of the products retained in the uterine cavity. Cramps are usually present. Bleeding generally is persistent and is often severe.

COMPLETE ABORTION

(Fig 14–2) Complete abortion is identified by passage of the entire conceptus. Slight bleeding may continue for a short time, although pain usually ceases after pregnancy has traversed the cervix.

MISSED ABORTION

Missed abortion implies that the pregnancy has been retained following death of the fetus. Why the pregnancy is not expelled is not known. It is possible that normal progesterone production by the placenta continues while estrogen levels fall, which may reduce uterine contractility.

BLIGHTED OVUM

Blighted ovum or anembryonic pregnancy represents a failed development of the embryo so that only a gestational sac, with or without a yolk sac, is present. An alternative hypothesis proposes that the fetal pole has been resorbed prior to ultrasound diagnosis.

Laboratory Findings

COMPLETE BLOOD COUNT

If significant bleeding has occurred, the patient will be anemic. Both the white blood cell count and the sedimentation rate may be elevated even without the presence of infection.

PREGNANCY TESTS

Falling or abnormally rising plasma levels of β -human chorionic gonadotropin (hCG) are diagnostic of an abnormal pregnancy, either a blighted ovum, spontaneous abortion, or ectopic pregnancy.

Ultrasonography

Transvaginal ultrasound is helpful in documenting intrauterine pregnancies as early as 4–5 weeks' gestation. Fetal heart motion should be seen in embryos > 5 mm from crown to rump or in embryos at least 5–6 weeks' gestation. Ultrasound is useful in determining which pregnancies are viable and which are most likely to miscarry.

In threatened abortion, ultrasound will reveal a normal gestational sac and viable embryo. However, a large or irregular sac, an eccentric fetal pole, the presence of a large (> 25% of sac size) retrochorionic bleed, and/or a slow fetal heart rate (< 85 bpm) carry a poor prognosis. Miscarriage becomes increasingly less likely the further the gestation progresses. If a viable fetus of 6 weeks or less is seen on ultrasound, the risk of miscarriage is approximately 15–30%. The risk decreases to 5–10% at 7–9 weeks' gestation and to less than 5% after 9 weeks' gestation.

In incomplete abortion, the gestational sac usually is deflated, and irregular, echogenic material representing placental tissue is seen in the uterine cavity. In complete abortion, the endometrium appears closely apposed, with no visible products of conception.

An embryo or fetus without heart motion is consistent with a missed abortion, whereas an abnormal gestational sac, without a yolk sac or embryo, is consistent with a blighted ovum (Figs 14-3, 14-4, 14-5, and 14-6). Most pregnancies are lost weeks before mothers complain of signs or symptoms.

Empty uterus (U) with an adnexal mass (A) suspicious for an ectopic pregnancy. β -hCG at the time of transabdominal ultrasound was just over 100 mIU/mL.

Ectopic pregnancy may cause similar symptoms of miscarriage, namely, menstrual abnormality and abdominal or pelvic pain. An adnexal mass may or may not be present. Ultrasound can virtually exclude an ectopic pregnancy by documenting an intrauterine pregnancy, as the chance of a simultaneous intrauterine and extrauterine pregnancy (heterotopic pregnancy) is exceedingly rare in spontaneous

pregnancies, occurring in only 1 in 15,000–40,000 pregnancies.

Hydatidiform mole usually ends in abortion before the fifth month. Theca lutein cysts, when present, cause bilateral ovarian enlargement; the uterus may be unusually large. Bloody discharge may contain hydropic villi.

Other entities that may be confused with abortion include cervical infection, extruding pedunculated myoma, and cervical neoplasia. However, the pregnancy test will be negative unless a pregnancy coexists.

Complications

Severe or persistent hemorrhage during or following abortion may be life threatening. The more advanced the gestation, the greater the likelihood of excessive blood loss. Sepsis develops most frequently after self-induced abortion. Infection, intrauterine synechia, and infertility are other complications of abortion. Perforation of the uterine wall may occur during D&C because of the soft and vaguely outlined uterine wall and may be accompanied by injury to the bowel and bladder, hemorrhage, infection, and fistula formation.

Multiple pregnancy with the loss of 1 fetus and retention of another ("vanishing twin") not only is possible but has been well documented in 20% of early pregnancies closely monitored by ultrasound. Usually the fetus is simply resorbed, but the loss of 1 fetus in multiple gestation may be accompanied by cramping or vaginal bleeding.

Even with very early miscarriage, a loss can have a significant effect on the family. The fact that most of these losses are unexpected intensifies this grief. Each person responds differently to his or her tragedy. It is the health care worker's responsibility to help parents mourn by acknowledging their loss and identifying potential support systems.

Prevention

Some losses can be prevented by early obstetric care, with adequate treatment of maternal disorders such as diabetes and hypertension, and by protection of pregnant women from environmental hazards and exposure to infectious diseases.

Treatment of Abortions

Successful management of spontaneous abortion depends upon early diagnosis. Every patient should receive a general physical examination, and a complete history should be taken. Laboratory studies should include a complete blood count, blood typing, and cervical cultures to determine pathogens in case of infection.

If the diagnosis of threatened abortion is made, bed rest and pelvic rest typically are recommended, although neither has been shown to be helpful in preventing subsequent miscarriage. Prognosis is good when bleeding and/or cramping resolve.

If the diagnosis of inevitable or incomplete abortion is made, evacuation of the uterus by a surgical method should be considered. Significant bleeding or retained products usually require a D&C; however, cases in which blood loss is minimal can be observed for spontaneous completion. A type and cross-match for possible blood transfusion and determination of Rh status should be obtained. The prognosis for the mother is excellent if the retained tissue is promptly and completely evacuated.

If the diagnosis of complete abortion is made, the patient should be observed for further bleeding. The products of conception should be examined. As with inevitable and incomplete abortion, the prognosis for the mother is excellent.

If abortion has occurred after the first trimester, hospitalization should be considered. Oxytocics are helpful in contracting the uterus, limiting blood loss, and aiding in expulsion of clots and tissue. Ergot preparations, which contract the cervix and the uterus, may also be given if needed. As with a first-trimester loss, a D&C may be necessary if significant bleeding persists or if products of conception are retained.

Treatment of Complications

Uterine perforation may be manifested by signs of intraperitoneal bleeding, rupture of the bowel or bladder, or peritonitis. Oftentimes, there are no clinical signs and no sequelae. When uterine perforation is suspected, however, laparoscopy and/or laparotomy are indicated to determine the extent of laceration or bowel injury.

RECURRENT ABORTION

General Considerations

Recurrent abortion in its broadest definition is defined as 2 to 3 or more consecutive pregnancy losses before 20 weeks of gestation, each with a fetus weighing less than 500 g. Approximately 1% of women are habitual aborters. Prognosis for a successful subsequent pregnancy is correlated with the number of previous abortions. The risk of having a spontaneous abortion for the first time is about 15%, and this risk is at least doubled in women experiencing recurrent abortion (Table 14–1).

Table 14–1. Probability of Spontaneous Abortion.

Type of Study	Number of Previous Abortions			
	0	1	2	3+
Retrospective studies				
Stevenson et al (1959)		16.3	19.2	26.2
Warburton and Fraser (1964)	12.3	26.2	32.2	30.2
Leridon (1976)	15.2	22.0	35.3	
Poland et al (1977)		19.0	35.0	47.0
Naylor and Warburton (1978)	11.0	20.3	29.2	37.0
Cohort studies				
Shapiro et al (1970)	10.9	18.0		
Awan (1974)	10.4	22.1	27.4	
Prospective studies				
Boué et al (1975)		13.8		
Harger et al (1983)			17.4	29.2
Fitzsimmons et al (1983)			31.3	45.7
Regan (1988)	5.6	11.5	29.4	36.4

Percentage of women aborting in relation to number of previous abortions.

Other factors with prognostic implications include maternal age and abortus karyotype. The former is directly correlated with the risk of abortion. A normal karyotype carries a higher recurrence risk than does an abnormal karyotype, as this subset presumably is susceptible to maternal etiologies.

Despite some controversy regarding the evaluation and management of recurrent abortion, the prognosis following repeated losses is good, with most couples having an approximately 60% chance of a viable pregnancy.

Etiology & Treatment

Chromosomal abnormalities, uterine malformations, and antiphospholipid syndrome are the three generally accepted etiologies of recurrent miscarriages. Currently evidence is insufficient to support routine evaluation of other causes, including hormonal abnormalities, infection, systemic disease, environmental agents, and alloimmune factors. Table 14–2 summarizes a diagnostic work-up and possible therapies for recurrent abortion.

Table 14–2. Diagnosis and Treatment of Recurrent Abortion.

Cause	Diagnosis	Treatment
Genetic error	Obtain a 3-generation pedigree and karyotype of both parents and any previously aborted material.	Artificial insemination by donor, embryo transfer, preimplantation diagnosis, or prenatal testing on subsequent conceptions.
Anatomic abnormalities of reproductive tract	Perform hysterosalpingogram or hysteroscopy.	Uterine operation: hysteroscopic resection, myomectomy. Cervical cerclage (abdominal or vaginal), reconstruction of cervical isthmus.
Hormonal abnormalities	Perform laboratory studies for T ₄ and TSH, serum progesterone or endometrial biopsy during luteal phase, and consider glucose tolerance test.	Thyroid replacement, progesterone or clomiphene citrate, diabetic diet and/or insulin, as indicated.
Infection	Obtain cervical cultures for <i>Chlamydia</i> and gonorrhea, and consider cultures for <i>Mycoplasma</i> and <i>Ureaplasma</i> .	Appropriate antibiotics.
Autoimmune disease	Evaluate blood pressure and kidney function, check for lupus anticoagulant and anticardiolipin antibody.	Low-dose aspirin and heparin.
Exogenous agents	Patient history and/or drug screen.	Discourage smoking, alcohol, and recreational drug use.
Immunologic factors	Testing not readily available.	Treatment under investigation.

GENETIC ERRORS

Genetic errors associated with recurrent abortion include parental structural chromosome abnormalities and recurrent aneuploidy. Balanced rearrangements of parental chromosomes are found in approximately 2–5% of couples with repetitive abortions. Of these, balanced translocations are the most common. In couples who have a normal chromosome analysis, recurrent fetal aneuploidy has been proposed as a distinct etiology.

A careful reproductive history and pedigree should be taken for both partners, and karyotype screening should be performed. Couples with a history of other reproductive problems, such as stillbirth or congenital anomalies, are more likely to be affected by a balanced structural chromosome abnormality. If the defect is paternal, artificial insemination by a donor is available. For a maternal defect, a donor egg may be fertilized by the husband's sperm. Preimplantation diagnosis is also an option.

UTERINE ABNORMALITIES

Anatomic abnormalities were the first described causes of habitual abortion and account for up to 15% of recurrent pregnancy losses. Defects include congenital uterine anomalies, cervical incompetence, submucous leiomyomas, abnormalities due to DES exposure in utero, and Asherman's syndrome. A major difficulty in counseling affected couples is that approximately 50% of women with uterine defects have no reproductive problem. Septate uteri account for the vast majority of patients with uterine malformations and recurrent pregnancy loss. Unicornuate and bicornuate uteri are less commonly associated. Submucous leiomyomas are responsible for a much smaller percentage of repeated losses. Generally, losses from anatomic abnormalities occur in the second trimester. Interference with implantation, lack of an adequate blood supply, and growth restriction are possible mechanisms for recurrent loss.

Diagnosis of uterine anatomic abnormalities usually is accomplished by hysterosalpingography or hysteroscopy. Treatment is primarily surgical, with reported success rates of 70–85% after surgical correction.

Cervical incompetence may be due to congenital abnormalities (eg, DES exposure), trauma from a vigorous D&C or cone biopsy, and/or possibly hormonal influences. It classically presents in mid-second or early third trimester with rapid, painless cervical dilatation. If other causes of recurrent losses are excluded and the presumed etiology is incompetent cervix, a cervical cerclage is recommended between 12 and 14 weeks' gestation. Success rates with cerclage are 85–90%. Complications include risks from anesthesia, bleeding, infection, rupture of membranes, and miscarriage. Contraindications to cerclage placement include bleeding of unknown etiology, infection, labor, ruptured membranes, and congenital anomalies.

HORMONAL CAUSES

Possible hormonal causes of habitual abortion include hypothyroidism and hyperthyroidism, progesterone insufficiency, and uncontrolled diabetes mellitus.

Progesterone deficiency or luteal phase defect (LPD) is a controversial etiology of habitual abortion. A defective endometrium resulting in faulty implantation is the proposed mechanism. Inadequate hormonal support of the embryo may also be involved. The diagnosis usually is made by luteal phase endometrial biopsies, which attempt to identify a lag in endometrial development when compared to menstrual age. Critics of the diagnosis of LPD note intraobserver and interobserver variations in biopsy results, the presence of LPD in normal women, and the inconsistent occurrence in women affected by LPD. Furthermore, controlled studies demonstrating an improvement in pregnancy outcome with progesterone treatment are lacking. For these reasons, many experts are skeptical about the importance of LPD as an etiology of recurrent pregnancy loss.

INFECTION

Infectious agents that have been implicated in repetitive losses include *Mycoplasma hominis*, *Ureaplasma urealyticum*, *Toxoplasma gondii*, *C trachomatis*, *T pallidum*, *Borrelia burgdorferi*, *N gonorrhoeae*, *S agalactiae*, *L monocytogenes*, herpes simplex, and cytomegalovirus. Although these agents have been identified in early losses, a causal relationship has not been demonstrated.

SYSTEMIC DISEASE

Systemic causes of recurrent abortion include uncontrolled diabetes, uncontrolled thyroid disease, and collagen vascular disease. The incidence of systemic disease as a cause of habitual abortion is unknown but probably is low. Furthermore, in patients without risk factors, asymptomatic disease is an unlikely culprit, precluding routine screening. Therapy involves treatment of the specific disease.

IMMUNOLOGIC FACTORS

Antiphospholipid antibodies (lupus anticoagulant and anticardiolipin antibodies) may damage platelets and vascular endothelium, resulting in thrombosis. This may account for the relationship to miscarriage when found in combination with clinical features of antiphospholipid syndrome. Low-dose aspirin and/or heparin are beneficial in this situation.

Compared to women who carry a pregnancy to term, women who are habitual aborters share more HLAs with their partners and have blunted responses to paternal antigen with lower levels of blocking antibodies or antileukocytotoxic antibodies. The maternal immunologic response may not be as effective in protecting the pregnancy, resulting in pregnancy loss.

Diagnostic tests for immunologic abnormalities are available in few centers. The efficacy of leukocyte immunotherapy is unknown, and treatment such as paternal leukocyte immunization is still experimental.

In up to 50% of women with recurrent abortion, a definitive cause may not be found. However, although the loss rate may be higher than that in the general population, the majority of these women will have a successful pregnancy in their reproductive lifetime.

SEPTIC ABORTION

General Considerations

Septic abortion is manifested by fever, malodorous vaginal discharge, pelvic and abdominal pain, and cervical motion tenderness. Peritonitis and sepsis may be seen. Trauma to the cervix or upper vagina may be recognized if there has been a criminal abortion.

A complete blood count, urinalysis, endometrial cultures, blood cultures, chest x-ray, and abdominal x-ray to rule out uterine perforation should be obtained. Ultrasound may be helpful in ruling out retained products of conception.

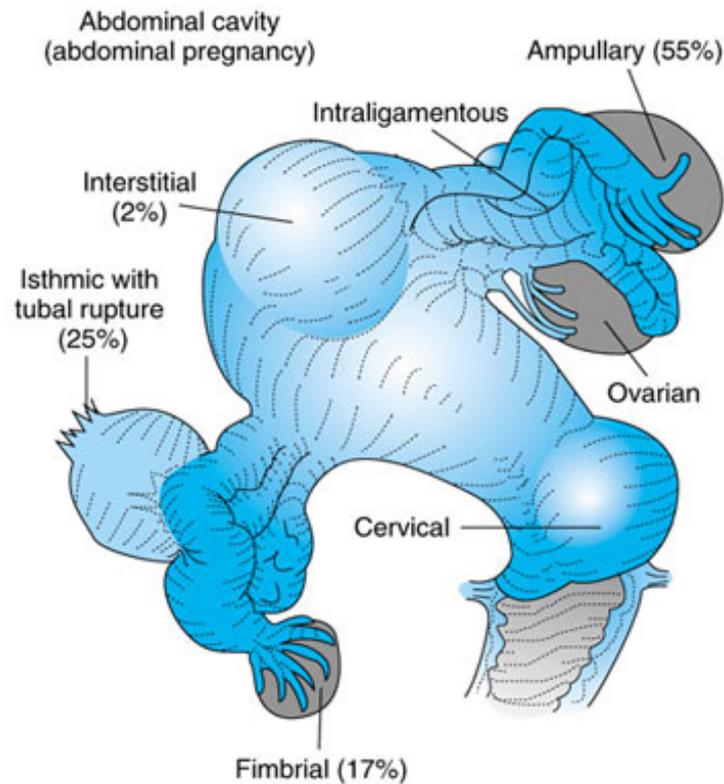

Treatment

Treatment of septic abortion involves hospitalization and intravenous antibiotic therapy. Selection of antibiotic agents should provide for both anaerobic and aerobic coverage. A D&C should be performed, and a hysterectomy may be necessary if the infection does not respond to treatment.

ECTOPIC PREGNANCY

In ectopic pregnancy, a fertilized ovum implants in an area other than the endometrial lining of the uterus (Fig 14–7). More than 95% of extrauterine pregnancies occur in the fallopian tube.

Figure 14–7.

Sites of ectopic pregnancies.

(Adapted, with permission, from Benson RC: *Handbook of Obstetrics & Gynecology*, 8th ed. Lange, 1983.)

The incidence of ectopic pregnancy has increased from 4.5 in 1000 in 1970 to 19.7 in 1000 in 1992. This may be due, at least in part, to a higher incidence of salpingitis, an increase in ovulation induction and assisted reproductive technology, and more tubal sterilizations.

Ectopic pregnancy is a significant cause of maternal morbidity and mortality, as well as fetal loss. It is the leading cause of pregnancy-related death in the first trimester and accounts for 9% of all pregnancy-related deaths. The development of sensitive β -hCG assays, along with the increasing use of ultrasound and laparoscopy, has allowed for earlier diagnosis of ectopic pregnancy. This has resulted in a decrease in both maternal morbidity and mortality.

Classification & Incidence

Ectopic pregnancy can be classified as follows (Fig 14–7).

1. **Tubal (> 95%)**—Includes ampullary (55%), isthmic (25%), fimbrial (17%), and interstitial (2%).
2. **Other (< 5%)**—Includes cervical, ovarian, and abdominal (primary abdominal pregnancies have been reported, but most abdominal pregnancies are secondary pregnancies, from tubal abortion or rupture and subsequent implantation in the bowel, omentum, or mesentery). Cesarean delivery scar pregnancy is becoming an increasingly recognized clinical entity, with its incidence presumably paralleling a rise in cesarean section rates.

3. Intraligamentous

4. **Heterotopic pregnancy**—An ectopic pregnancy occurs in combination with an intrauterine pregnancy in 1 in 15,000–40,000 spontaneous pregnancies and in up to 1% of patients undergoing in vitro fertilization.

5. **Bilateral ectopic**—These pregnancies have occasionally been reported.

Etiology

The etiology of ectopic pregnancy is not well understood. However, several risk factors have been found to be associated with ectopic pregnancy (Table 14–3).

Table 14–3. Risk Factors for Ectopic Pregnancy.

Risk Factor	Odds Ratio ¹
High risk	
Tubal surgery	21.0
Sterilization	9.3
Previous ectopic pregnancy	8.3
In utero exposure to diethylstilbestrol	5.6
Use of IUD	4.2–45.0
Documented tubal pathology	3.8–21.0
Moderate risk	
Infertility	2.5–21.0
Previous genital infections	2.5–3.7
Multiple sexual partners	2.1
Slight risk	
Previous pelvic/abdominal surgery	0.9–3.8
Cigarette smoking	2.3–2.5
Vaginal douching	1.1–3.1
Early age at first intercourse (< 18 years)	1.6

¹Single values indicate common odds ratio from homogeneous studies; point estimates indicate range of values from heterogeneous studies.

Reproduced, with permission, from Pisarska MD, Carson SA, Buster JE: Ectopic pregnancy. *Lancet* 1998; 351: 1115.

TUBAL FACTORS

Ectopic pregnancy is 5–10 times more common in women who have had salpingitis. In women with ectopic pregnancies, up to 50% will have had salpingitis previously, and in most of these patients, the uninvolved tube is also abnormal. Other tubal factors that interfere with the progress of the fertilized ovum include adherent folds of tubal lumen due to salpingitis isthmica nodosa, developmental abnormalities of the tube or abnormal tubal anatomy due to DES exposure in utero, previous tubal surgery including tubal ligation with a 16–50% ectopic pregnancy rate if pregnancy occurs after tubal ligation, conservative treatment of an unruptured ectopic with a recurrent ectopic rate of 4–16%, and

tubal anastomosis with a 4% ectopic rate. Adhesions from infection or previous abdominal surgery, endometriosis, and even leiomyomas have been associated with ectopic pregnancy. Most of these abnormalities are bilateral and irreversible.

ZYGOTE ABNORMALITIES

A variety of zygote abnormalities have been reported in ectopic pregnancy, including chromosomal abnormalities, gross malformations, and neural tube defects. In theory, these abnormal pre-embryos are more likely to result in abnormal or ectopic implantation.

OVARIAN FACTORS

Ovarian factors that may result in the development of an ectopic pregnancy are fertilization of an unextruded ovum, transmigration of the ovum into the contralateral tube with subsequent delayed and faulty implantation, and postmidcycle ovulation and fertilization.

EXOGENOUS HORMONES

Abnormal hormonal stimulation and/or exogenous hormones may play a role in ectopic gestation. For example, 4–6% of pregnancies occurring in women taking progestin-only oral contraceptives are ectopic. This may be due to progesterone's smooth muscle relaxant effects and subsequent "ovum trapping." Patients with DES exposure are also at risk, as are patients undergoing ovulation induction.

OTHER FACTORS

Intrauterine device (IUD) users are at risk for ectopic pregnancy if pregnancy occurs, although the risk of ectopic pregnancy is still lower than if no contraceptive method is used. Whether the IUD prevents intrauterine but not ectopic pregnancy or whether an associated salpingitis is responsible for this increased risk is unclear. Smoking and increasing age are also associated with ectopic pregnancy. Multiple previous elective abortions are also believed to be a risk factor for ectopic pregnancy, as postabortal infection may lead to salpingitis.

Time of Rupture

Rupture usually is spontaneous. Isthmic pregnancies tend to rupture earliest, at 6 to 8 weeks' gestation, because of the small diameter of this portion of the tube. Ampullary pregnancies rupture later, generally at 8–12 weeks. Interstitial pregnancies are the last to rupture, usually at 12–16 weeks, as the myometrium allows more room to grow than the tubal wall. Interstitial rupture is quite dangerous because its proximity to uterine and ovarian vessels can result in massive hemorrhage.

After rupture, the conceptus may be resorbed or remain as a mass in the abdominal cavity or cul-de-sac. Rarely, if not damaged during rupture, it may implant elsewhere in the abdominal cavity and continue to grow.

Clinical Findings

No specific symptoms or signs are pathognomonic for ectopic pregnancy, and many disorders can present similarly. Normal pregnancy, threatened or incomplete abortion, rupture of an ovarian cyst, ovarian torsion, gastroenteritis, and appendicitis can all be confused with ectopic pregnancy. Because early diagnosis is crucial, a high index of suspicion should be maintained when any pregnant woman in the first trimester presents with bleeding and/or abdominal pain. Fifteen to twenty percent of ectopic gestations will present as surgical emergencies.

SYMPTOMS

The following symptoms may assist in the diagnosis of ectopic pregnancy.

- 1. Pain**—Pelvic or abdominal pain is present in close to 100% of cases. Pain can be unilateral or bilateral, localized or generalized. The presence of subdiaphragmatic or shoulder pain is more variable, depending

on the amount of intra-abdominal bleeding.

2. Bleeding—Abnormal uterine bleeding, usually spotting, occurs in roughly 75% of cases and represents decidual sloughing. A decidua cast is passed in 5–10% of ectopic pregnancies and may be mistaken for products of conception.

3. Amenorrhea—Secondary amenorrhea is variable. Approximately half of women with ectopic pregnancies have some spotting at the time of their expected menses and thus do not realize they are pregnant.

4. Syncope—Dizziness, lightheadedness, and/or syncope is present in one-third to one-half of cases and represent advanced stages of intra-abdominal bleeding.

SIGNS

On examination, the following signs are important in the diagnosis of ectopic gestation.

1. Tenderness—Diffuse or localized abdominal tenderness is present in over 80% of ectopic pregnancies. Adnexal and/or cervical motion tenderness is present in over 75% of cases.

2. Adnexal mass—A unilateral adnexal mass is palpated in one-third to one-half of patients. Occasionally, a cul-de-sac mass is present. The patient's discomfort may preclude an adequate examination, and effort should be made to avoid an iatrogenic tubal rupture from an overzealous assessment.

3. Uterine changes—The uterus may undergo typical changes of pregnancy, including softening and a slight increase in size.

4. Hemodynamic instability—Vital signs will reflect hemodynamic status of patients with tubal rupture and massive intra-abdominal hemorrhage.

Laboratory Findings

Hematocrit: The hematocrit will vary depending on the patient population and the degree, if any, of intraabdominal bleeding.

β-hCG: The qualitative serum or urine β-hCG assay is positive in virtually 100% of ectopic pregnancies. The value of this test is limited, however, because a positive result does not help to elicit the location of the pregnancy. More helpful is a quantitative β-hCG value that, in conjunction with transvaginal ultrasound, can usually make the diagnosis. In an unclear clinical picture, serial titers can be followed that, in the face of a normal pregnancy, should double every 2 days. Two-thirds of ectopic pregnancies have abnormally rising values, whereas the remaining third show a normal progression.

Special Examinations

Several special procedures are helpful in diagnosing ectopic pregnancy.

1. Ultrasound—Ultrasound is useful in evaluating patients at risk for ectopic pregnancy, namely, by documenting the presence or absence of an intrauterine pregnancy. β-hCG titers and ultrasound complement each another in detecting ectopic pregnancy and have led to earlier detection with a subsequent decrease in adverse outcome. By correlating β-hCG titers with ultrasound findings, an ectopic pregnancy often can be differentiated from an intrauterine pregnancy. Furthermore, ultrasound can help distinguish a normal intrauterine pregnancy from a blighted ovum, incomplete abortion, or complete abortion.

A normal intrauterine sac appears regular and well defined on ultrasound. It has been described as a "double ring," which represents the decidual lining and the amniotic sac. In ectopic pregnancy, ultrasound may reveal only a thickened, decidualized endometrium. With more advanced ectopics, decidual sloughing with resultant intracavitary fluid or blood may create a so-called "pseudogestational sac," a small and irregular structure that may be confused with an intrauterine gestation.

An intrauterine sac should be visible by transvaginal ultrasound when the β -hCG level is approximately 1000 mIU/mL and by transabdominal ultrasound approximately 1 week later, when the β -hCG level is 1800–3600 mIU/mL. Thus, when an empty uterine cavity is seen with a β -hCG titer above this threshold, an ectopic pregnancy is more likely.

The presence of an adnexal mass with an empty uterus raises the suspicion for an ectopic pregnancy, especially if the β -hCG titers are above the discriminatory zone. Although direct visualization of an adnexal gestational sac along with a yolk sac or embryo secures the diagnosis, it is more likely to detect a "tubal ring" or complex mass adjacent to, but separate from, both the uterus and ovary. If rupture has occurred, a dilated fallopian tube with fluid in the cul-de-sac may be visualized. Ultrasound is increasingly being relied upon to differentiate several less common types of ectopic pregnancies. Both interstitial tubal and cesarean section scar pregnancies can masquerade as intrauterine gestations because of their proximity to the intrauterine cavity.

The most likely alternative diagnosis to an adnexal mass in early pregnancy is a corpus luteum cyst, which can rupture and bleed, thus contributing to a highly confusing clinical picture.

2. Laparoscopy—The need for laparoscopy in the diagnosis of ectopic pregnancy has declined with the increasing use of ultrasound. However, it still is useful in certain situations where a definitive diagnosis is difficult, especially in the case of a desired, potentially viable intrauterine pregnancy when a D&C is contraindicated. Laparoscopy may also be used as definitive management in early ectopic gestation.

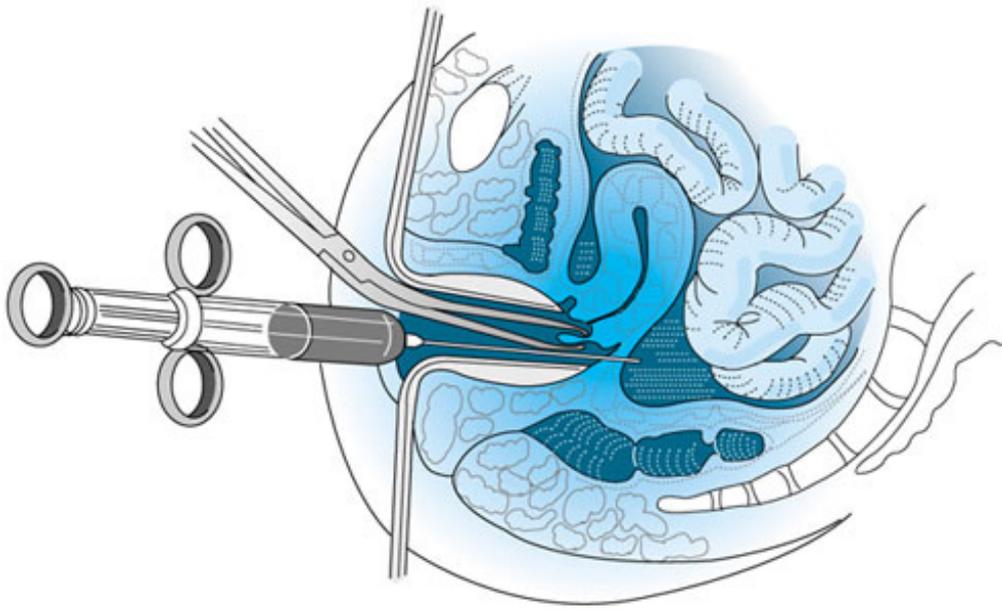

3. D&C—D&C may confirm or exclude intrauterine pregnancy in the case of an undesired pregnancy. D&C may interrupt an intrauterine gestation and should not be performed if the pregnancy is desired, unless the β -hCG titers have plateaued or fallen and the pregnancy is definitely abnormal. When chorionic villi are recovered, the diagnosis of an intrauterine pregnancy is confirmed. On the other hand, if only decidua is obtained on D&C, ectopic pregnancy is highly likely.

4. Laparotomy—Laparotomy is indicated when the presumptive diagnosis of ectopic pregnancy in an unstable patient necessitates immediate surgery, or when definitive therapy is not possible by medical management or laparoscopy.

5. Culdocentesis—Culdocentesis, the transvaginal passage of a needle into the posterior cul-de-sac in order to determine whether free blood is present in the abdomen (Fig 14–8), has largely been replaced by transvaginal ultrasound.

6. Magnetic resonance imaging—Magnetic resonance imaging is a useful adjunct to ultrasound in cases where an unusual ectopic location is suspected. An accurate diagnosis of cervical, cesarean scar, or interstitial pregnancy urges conservative intervention with methotrexate (MTX) in order to avoid the potentially catastrophic hemorrhage associated with surgical management of these sites.

Culdocentesis.

Pathology

In tubal ectopic pregnancy, implantation typically occurs in the wall of the tube, in the connective tissue beneath the serosa. There may be little or no decidual reaction and minimal defense against the permeating trophoblast. The trophoblast invades blood vessels, causing local hemorrhage. A hematoma in the subserosal space enlarges as pregnancy progresses. Progressive distention of the tube eventually leads to rupture.

Vaginal bleeding is of uterine origin and is caused by endometrial involution and decidual sloughing. Atypical changes in the endometrium may be suggestive of ectopic pregnancy. The Arias-Stella reaction consists of hyperchromatic, hypertrophic, irregularly shaped nuclei, and foamy, vacuolated cytoplasm. These changes can be seen in normal pregnancy and in miscarriage and therefore are not diagnostic of ectopic pregnancy.

Occasionally, endometrial tissue may be passed as a so-called decidual cast. Superficial secretory endometrium usually is present, but no trophoblastic cells are seen.

Prevention

Prevention of sexually transmitted disease, with early and vigorous treatment of cases that do occur, may avoid tubal damage with subsequent ectopic pregnancy. Other risk factors for ectopic pregnancy are more difficult to control. Early diagnosis of unruptured tubal pregnancy by maintaining a high index of suspicion and liberal use of β -hCG titers, ultrasound, and laparoscopy will minimize potential problems of hemorrhage, infertility, and extensive surgery.

Treatment

EXPECTANT MANAGEMENT

Because many ectopic pregnancies resolve spontaneously, it may be reasonable to manage an

asymptomatic, compliant patient expectantly if β -hCG titers are low (< 200 mIU/mL) or decreasing, and the risk of rupture is low.

MEDICAL MANAGEMENT

MTX, a folinic acid antagonist, has been shown to destroy proliferating trophoblast and may be effective in the medical management of small, unruptured ectopic pregnancies in asymptomatic women. Exclusion criteria include a patient who is noncompliant or has completed childbearing, peptic ulcer disease, immunodeficiency, pulmonary disease, liver disease, renal disease, blood dyscrasias, hemodynamic instability, free fluid in the cul-de-sac plus pelvic pain, or known sensitivity to MTX. Relative contraindications include an adnexal mass ≥ 3.5 cm or an extrauterine gestation with fetal heart motion, because of the higher failure rate. In select cases, approximately 90% of ectopics resolve, taking on average just under 1 month. Protocols vary from single to multiple injections, typically given systemically. The dose of MTX depends on the patient's body surface area, and nomograms are available for determining the correct dose. Follow-up β -hCG levels, along with a complete blood count, serum creatinine, and serum aspartate transaminase, are obtained for comparison with baseline values. β -hCG levels should decrease by at least 15% between days 4 and 7 after MTX administration. Failure of MTX therapy is suggested by a persistent rise or plateau in β -hCG titer and can be managed by a second dose of MTX or surgery. A recurrent episode of abdominal pain or enlargement of the adnexal mass during the first week of therapy may be part of a normal response to successful MTX treatment. Vigilant observation should be the rule, and follow-up ultrasound should be used liberally. Persistent and worsening pain in conjunction with a hemoperitoneum on ultrasound, and/or hemodynamic instability, mandates immediate surgical intervention.

Available studies comparing MTX to traditional surgical management report similar subsequent tubal patency and fertility rates. Arguments against its use include its toxicity, namely, marrow suppression, dermatitis, and stomatitis, as well as potential for treatment failure and tubal rupture.

Chronic ectopics, with decreasing but persistent β -hCG titers, pose a management dilemma. Some will resolve on their own, whereas others will require surgery. Unfortunately, at present it is impossible to predict which patients will fail expectant management.

SURGICAL TREATMENT

Once the mainstay of therapy for ectopic pregnancy, surgery is now mainly reserved for patients with contraindications to medical management. The extent of surgery depends on the degree of damage to the uterus and adnexa. Preservation of the ovary should be attempted if feasible. Conservative surgery (ie, preservation of the fallopian tube) may be indicated in the hemodynamically stable patient with an ampullary pregnancy who wishes to preserve fertility.

A linear salpingostomy may be performed with a small (< 3 cm), intact ampullary pregnancy. The linear incision is allowed to heal by secondary intention, minimizing recurrent ectopics as compared to salpingotomy. Both methods yield similar subsequent pregnancy rates of 40–90%.

Depending on operator skill and comfort level, both of these procedures can be performed through the laparoscope, assuming the pregnancy is < 3 cm, unruptured, and easily accessible. With both salpingostomy and salpingotomy, a β -hCG titer should be obtained weekly after surgery to ensure adequate removal of trophoblast and rule out a persistent ectopic. In stable patients, laparoscopy is preferred over laparotomy because of the associated reduction in morbidity and cost.

"Milking" the pregnancy out of the distal end of the tube is often tempting but has been associated with persistent trophoblast and need for re-exploration, as well as increased risks of recurrent ectopic pregnancy.

With an isthmic ectopic pregnancy, segmental resection with subsequent anastomosis (usually at a later date) is typically recommended. As opposed to ampullary ectopics, the muscularis is well developed, forcing the pregnancy to grow in the lumen. More conservative treatment, such as salpingostomy or salpingotomy, would likely cause scarring and compromise of the lumen. Furthermore, a tubal fistula may result if the tube were allowed to heal by secondary intention.

With fimbrial pregnancy, products of conception are often visible at the most distal end of the tube, which may be "plucked out." As with ampullary ectopics, "milking" should be avoided.

Interstitial pregnancies pose a high surgical risk with the potential for massive intra-abdominal bleeding. Most cases are managed with a cornual wedge resection, uterine reconstruction, and, sometimes, salpingectomy on the affected side. If extensive tissue damage is present or if the patient is unstable, a hysterectomy may be needed. Likewise, cervical ectopics may be associated with massive vaginal bleeding with the potential for hysterectomy. Attempts at medical management with MTX should be considered for both.

Ovarian pregnancy requires oophorectomy and sometimes salpingectomy on the affected side.

Abdominal pregnancy involves delivery of the fetus (sometimes at term) with ligation of the umbilical cord close to the placenta. The placenta is usually left in place to avoid hemorrhage following removal.

EMERGENCY TREATMENT

Immediate surgery is indicated when the diagnosis of ectopic pregnancy with hemorrhage is made. Blood products should be available because transfusion is often necessary. There is no place for conservative therapy in a hemodynamically unstable patient.

Rh₀ (D) immunoglobulin should be given to any Rh-negative mother with the diagnosis of ectopic pregnancy because sensitization may occur.

EXPOSURE TO FETOTOXIC AGENTS

Many variations occur in the complex process of human development. Although population heterogeneity is based on such events, some deviations from the usual developmental process result in aberrations of normal structure and function. These adverse alterations have been scrutinized in an effort to determine their cause. The clinician investigating the effects of exposure to fetotoxic agents must consider whether the patient is known to have reproductive risks, whether the patient has been exposed to fetotoxic agents during pregnancy, and whether structural or functional abnormalities are likely to develop in the fetus.

Many harmful agents are responsible for altering the biologic process of human development (eg, radiation, viruses, medications, and drugs). Aberrations that result from fetal exposure to harmful agents is especially tragic because such exposure often is preventable. However, even the most careful investigation will fail to reveal the cause in the majority of developmental handicaps.

Approximately 3–5% of newborns in the United States have abnormalities at birth that are serious enough to require some form of treatment. Moreover, full recognition of malformations, anomalies, or defects may take years. Thus, estimates that as much as 10% of the total population suffers from some structural or functional developmental disability do not appear unreasonable.

Evaluation

The timing of exposure is crucial, as fetal organs or structures are most vulnerable to adverse influences during organogenesis. Table 14–4 lists some of the potential adverse effects related to the timing of fetotoxic exposure. The route of exposure, the length of exposure, and the total dose received during exposure may also influence the outcome of the pregnancy.

Table 14–4. Potential Adverse Effects of Fetotoxic Exposure at Selected Stages of Development.

Week Since Ovulation	Potential Adverse Effect
1–8	Miscarriage, structural malformations
9–40	Central nervous system abnormalities, growth restrictions, neurobehavioral abnormalities, reproductive effects

Evaluation of studies of potential toxic exposures is difficult because of the large number of possible fetotoxic agents and interactive effects of certain agents, the retrospective nature of most studies, the difficulty evaluating damage, the presence or absence of influences that may alter the effects of an agent, and the presence or absence of certain genotypes that might alter an individual's susceptibility. Therefore, specific criteria for recognizing teratogens in humans have been defined (Table 14–5). Table 14–6 summarizes the known mechanisms of abnormal development and outlines a working hypothesis of the pathogenesis, common pathways, and final manifestations of abnormal development.

Table 14–5. Criteria Used to Recognize Teratogens in Humans.

Abrupt increase in the incidence of a particular defect or association of defects
Known environmental change coincident with this increase.
Known exposure to the environmental change early in pregnancy, yielding characteristically affected infants.
Absence of other factors common to all pregnancies, yielding infants with the characteristic defects.

Table 14–6. General Principles of Teratology.

Mechanisms	<ul style="list-style-type: none"> Mutation Chromosome disruption Mitotic interference Altered nucleic acid integrity or function Precursor or substrate deprivation Altered energy sources Changed membrane characteristics Altered osmolar balance Enzyme inhibition
Pathogenesis	<ul style="list-style-type: none"> Excessive or reduced cell interactions Failed cell interactions Reproduced biosynthesis

	Impeded morphogenetic movement Mechanical disruption of tissues
Common pathways	Too few cells or cell products to affect localized morphogenesis or functional maturation Other imbalances in growth and differentiation
Final defects	Malformation Growth retardation Functional disorder Death

Counseling of parents should include review of the exposure history and discussion of the particular agent involved, as well as possible sequelae. In some cases, intervention may be possible. In other cases, if an abnormal pregnancy is found, the parents may elect to abort an affected fetus. Effective counseling should provide the best information available to assist the parents in what is always a very difficult decision.

The United States Food and Drug Administration (FDA) standards for drug labeling with regard to teratogenicity are listed in Table 14–7.

Table 14–7. Teratogenicity Drug Labeling Now Required by the FDA.¹

Category A: Well-controlled human studies have not disclosed any fetal risk.

Category B: Animal studies have not disclosed any fetal risk; or have suggested some risk not confirmed in controlled studies in women; or no adequate studies in women are available.

Category C: Animal studies have revealed adverse fetal effects; no adequate controlled studies in women are available.

Category D: Some fetal risk, but benefits may outweigh risk (eg, life-threatening illness, no safer effective drug).

Category X: Fetal abnormalities in animal and human studies; risk not outweighed by benefit.
Contraindicated in pregnancy.

¹The FDA has established 5 categories of drugs based on their potential for causing birth defects in infants born to women who use them during pregnancy. By law, the label must provide available information on teratogenicity.

Current OB/GYN >Chapter 15. Late Pregnancy Complications>

PRETERM LABOR

Essentials of Diagnosis

- Estimated gestational age of greater than 20 weeks and less than 37 weeks.
- Regular uterine contractions at frequent intervals.
- Documented cervical change or appreciable cervical dilatation or effacement (at least 2 cm dilated without previous examination).

General Considerations

Labor is the process of coordinated uterine contractions leading to progressive cervical effacement and dilatation by which the fetus and placenta are expelled. Preterm labor is defined as labor occurring after 20 weeks' but before 37 weeks' gestation. Although there is no strict definition in the literature regarding the amount of uterine contractions required for preterm labor, there is consensus that contractions need to be regular and at frequent intervals. Generally, more than 4 contractions per hour are needed to cause cervical change. The uterine contractions need not be painful to cause cervical change and may manifest themselves as abdominal tightening, lower back pain, or pelvic pressure. In addition, there must be demonstrated cervical effacement or dilatation to meet a diagnosis of preterm labor.

It is important to distinguish preterm labor from other similar clinical entities such as cervical incompetence (cervical change in the absence of uterine contractions) and preterm uterine contractions (regular contractions in the absence of cervical change) because the treatment for these situations differs. Cervical incompetence may require cerclage placement, and preterm uterine contractions without cervical change is generally a self-limited phenomenon that resolves spontaneously and requires no intervention. If ruptured membranes accompany preterm labor, these cases are classified as preterm premature rupture of membranes (for discussion of diagnosis see Premature Rupture of Membranes).

Preterm birth complicates 10–15% of all pregnancies. It is the number 1 cause of neonatal morbidity and mortality and causes 75% of neonatal deaths that are not due to congenital anomalies.

Thirteen percent of all infants are classified as low birth weight (< 2500 g). Three percent of these are mature low-birth-weight infants and about 10% are truly premature. The latter group accounts for nearly two-thirds of infant deaths (approximately 25,000 annually in the United States). Approximately 30% of premature births are due to miscalculation of gestational age or to medical intervention required by the mother or fetus.

The care of premature (birth weight 1000–2500 g) and immature (birth weight < 1000 g) infants is costly. Compared with term infants, those born prematurely suffer greatly increased morbidity and mortality (eg, functional disorders, abnormalities of growth and development). Thus, every effort is made to prevent or inhibit premature labor. If preterm labor cannot be inhibited or is best allowed to continue, it should be conducted with the least possible trauma to the mother and infant.

Pathogenesis

Many obstetric, medical, and anatomic disorders are associated with preterm labor. Some of the risk factors are listed in Table 15–1. Detailed discussions of these conditions are given in other chapters. The cause of preterm labor in 50% of pregnancies, however, is idiopathic. Although several prospective risk-scoring tools are in use, they have not been convincingly demonstrated to be of value.

Table 15–1. Risk Factors Associated with Preterm Labor.

Obstetric complications

In previous or current pregnancy

Severe hypertensive state of pregnancy

Anatomic disorders of the placenta (eg, abruptio placentae, placenta previa, circumvallate placenta)

Placental insufficiency

Premature rupture of membranes

Polyhydramnios or oligohydramnios

Previous premature or low-birth-weight infant

Low socioeconomic status

Maternal age < 18 years or > 40 years

Low prepregnancy weight

Non-Caucasian race

Multiple pregnancy

Short interval between pregnancies (< 3 months)

Inadequate or excessive weight gain during pregnancy

Previous abortion

Previous laceration of cervix or uterus

Medical complications

Pulmonary or systemic hypertension

Renal disease

Heart disease

Infection: pyelonephritis, acute systemic infection, urinary tract infection, genital tract infection (eg, gonorrhea, herpes simplex, mycoplasmosis), fetotoxic infection (eg, cytomegalovirus infection, toxoplasmosis, listeriosis), maternal systemic infection (eg, pneumonia, influenza, malaria), maternal intra-abdominal sepsis (eg, appendicitis, cholecystitis, diverticulitis)

Heavy cigarette smoking

Alcoholism or drug addiction

Severe anemia

Malnutrition or obesity

Leaking benign cystic teratoma

Perforated gastric or duodenal ulcer

Adnexal torsion

Maternal trauma or burns

Surgical complications

Any intra-abdominal procedure

Conization of cervix

Previous incision in uterus or cervix (eg, cesarean delivery)

Genital tract anomalies

Bicornuate, subseptate, or unicornuate uterus

Congenital cervical incompetency

Clinical Findings

SYMPTOMS AND SIGNS

Uterine Contractions

Regular uterine contractions at frequent intervals as documented by tocometer or uterine palpation, generally more than 2 in one-half hour.

Dilatation and Effacement of Cervix

Documented cervical change in dilatation or effacement of at least 1 cm or a cervix that is well effaced and dilated (at least 2 cm) on admission is considered diagnostic.

Vaginal Bleeding

Many patients present with bloody mucous vaginal discharge or "bloody show." More significant vaginal bleeding should be evaluated for abruptio placentae or placenta previa.

EVALUATION

Evaluation should include determination of the following:

Gestational Age

Gestational age must be between 20 and 37 weeks' estimated gestational age (EGA), which should be calculated based upon the patient's last menstrual period (LMP) or date of conception, if known, or the previous sonographic estimation if these dates are uncertain.

Fetal Weight

Care must be taken to determine fetal size by ultrasonography.

Presenting Part

The presenting part must be noted because abnormal presentation is more common in earlier stages of gestation.

Fetal Monitoring

Continuous fetal monitoring should be performed to ascertain fetal well-being.

LABORATORY STUDIES

1. Complete blood count with differential.
2. Urine obtained by catheter for urinalysis, culture, and sensitivity testing.
3. Ultrasound examination for fetal size, position, and placental location.
4. Amniocentesis may be useful to ascertain fetal lung maturity in instances where EGA is uncertain, the size of the fetus is in conflict with the estimated date of conception (EDC) (too small, suggesting intrauterine growth restriction, IUGR, or too large, suggesting more advanced EGA), or the fetus is more than 34 weeks' EGA. Specifically, the amniotic fluid can be tested for lecithin/sphingomyelin (L/S) ratio, the presence of phosphatidylglycerol, fluorescence polarization assay, or lamellar body count. Amniocentesis should also be performed in instances where chorioamnionitis is suspected; the fluid should be tested for Gram's stain, bacterial culture, glucose levels, cell count, and, if available, interleukin-6 level.
5. Speculum examination should be performed. Cervical cultures should be sent for gonorrhea and chlamydia. A wet mount should be performed to look for signs of bacterial vaginosis. Group B streptococcus (GBS) cultures should be taken from the vaginal and rectal mucosa.
6. Hematologic work-up in cases associated with vaginal bleeding (see Chapter 20).
7. Fetal fibronectin enzyme immunoassay kits have been approved by the Food and Drug Administration (FDA) as a means to assess the risk of preterm birth in patients with preterm labor. A cervical swab is taken to look for fetal fibronectin. A negative test is effective at ruling out imminent delivery (within 2 weeks). A positive test result, however, is less sensitive at predicting preterm birth.

Treatment

Decisions regarding management are made based on EGA, estimated weight of the fetus, and existence of contraindications to suppressing preterm labor. Table 15–2 lists factors indicating that preterm labor should be allowed to continue. Once the patient is determined to not have any of these contraindications, the management of preterm labor depends on fetal age and size. Generally, management falls into 1 of 2 categories: expectant management (observation) or intervention. In pregnancies between 24 and 34 weeks' EGA or estimated fetal weight (EFW) between 600 and 2500 g, intervention with corticosteroids has been shown to be of benefit in reducing fetal morbidity and mortality rates. Although the efficacy of tocolysis has been much debated, it is generally accepted that a delay in delivery of 48 hours may be achieved at a minimum. Because this window can be used for corticosteroid administration, tocolysis is favored in many centers.

Table 15–2. Some Cases in Which Preterm Labor Should Not Be Suppressed.

Maternal factors

Severe hypertensive disease (eg, acute exacerbation of chronic hypertension, eclampsia, severe preeclampsia)

Pulmonary or cardiac disease (eg, pulmonary edema, adult respiratory distress syndrome, valvular disease, tachyarrhythmias)

Advanced cervical dilatation (> 4 cm)

Maternal hemorrhage (eg, abruptio placentae, placenta previa, disseminated intravascular coagulation)

Fetal factors

Fetal death or lethal anomaly

Fetal distress

Intrauterine infection (chorioamnionitis)

Therapy adversely affecting the fetus (eg, fetal distress due to attempted suppression of labor)

Estimated fetal weight \geq 2500 g

Erythroblastosis fetalis

Severe intrauterine growth retardation

Extremes of preterm gestational age pose special problems. Fetuses of very preterm pregnancies (20–23 weeks EGA or EFW less than 550g) are generally not considered to be viable. If these pregnancies can be continued for several more weeks, the fetuses will become viable but have a high risk for significant morbidity if they are born in this periviable period and survive. Furthermore, intervention carries significant risks to the

mother, including the risks of prolonged bed rest and side effects of tocolysis. Given these risks, expectant management is an acceptable and, in certain instances, preferable alternative to intervention. Mothers who choose intervention as opposed to expectant management should be extensively counseled by a multidisciplinary team, including the neonatologist, obstetrician, and social worker.

Conversely, once a pregnancy has continued beyond 34–37 weeks' EGA or EFW greater than 2500 g, the fetal survival rate is within 1% of the survival rate at 37 weeks. Fetal morbidity is less severe and is rarely a cause of long-term sequelae. Furthermore, corticosteroids have not been shown to be of benefit in fetuses of this age or size. Therefore, expectant management is usually the recommended course of action. Several factors should be considered when deciding between intervention and expectant management, including the certainty of the patient's dates, EFW, presence of maternal problems that could delay fetal lung maturity such as diabetes mellitus, and family history of late-onset respiratory distress syndrome (RDS).

There are other cases in which maternal or fetal factors indicate that preterm labor should be allowed to continue regardless of gestational age. Table 15–2 lists cases in detail.

The following is a protocol for management of pregnancies with preterm labor between 24 and 34 weeks' gestation or EFW 600–2500 g.

BED REST

Bed rest should be instituted immediately upon presentation. It is common practice for patients to receive hydration as well, although randomized trials have not shown a specific benefit.

The risk of preterm birth can be assessed using fibronectin and transvaginal scanning of the cervix. A negative fibronectin and a long cervix (> 1.5 cm) are strong negative predictors of imminent preterm birth. Decisions about tocolysis and administration of corticosteroids can be based in part on whether these tests indicate a low or high risk of preterm birth.

CORTICOSTEROIDS

The administration of corticosteroids to accelerate fetal lung maturity has become the standard of care in the United States for all women at risk of preterm delivery between 24 and 34 weeks' EGA. It has been shown to decrease the incidence of neonatal respiratory distress, intraventricular hemorrhage, and neonatal mortality. Steroids can be given according to 1 of 2 protocols: (1) betamethasone 12 mg IM every 24 hours for a total of 2 doses; or (2) dexamethasone 6 mg IM every 12 hours for a total of 4 doses.

The optimal benefits of antenatal corticosteroids are seen 24 hours after administration, peak at 48 hours, and continue for at least 7 days. If therapy for preterm labor is successful and the pregnancy continues beyond 1 week, there appears to be no added benefit with repeated courses of corticosteroids. In fact, multiple courses may be associated with growth abnormalities and delayed psychomotor development in the infant. In terms of safety of a single course of antenatal steroids, there does not appear to be an increased risk of infection or suppression of the fetal adrenal glands with steroid administration, and long-term follow-up of fetuses who received antenatal steroids shows no sequelae that can be attributed directly to steroid administration.

TOCOLYSIS

If the patient continues to contract and falls into a high-risk group based on a history of preterm birth, positive fibronectin, short cervix on transvaginal sonography (TVS), or changing dilatation on cervical examination, tocolytic therapy may be initiated. When using tocolysis to treat preterm labor, it is important to keep the following goals in mind. The short-term goal is to continue the pregnancy for 48 hours after steroid administration, after which the maximum effect of the steroids can be achieved. The long-term goal is to continue the pregnancy beyond 34–36 weeks (depending on the institution), at which point fetal morbidity and mortality are dramatically reduced and tocolysis can be discontinued.

Tocolytic therapy should be considered in the patient with cervical dilatation less than 5 cm. Successful tocolysis is generally considered fewer than 4–6 uterine contractions per hour without further cervical change.

The beta-mimetics and magnesium sulfate are the most commonly used tocolytic agents. The decision to use a specific tocolytic should be carefully considered because of contraindications and side effects associated with each agent (Table 15–3).

Table 15–3. Side Effects and Complications of Common Tocolytics.

Beta–mimetics (ritodrine, terbutaline)

Pulmonary edema

Hypotension

Tachycardia

Nausea/vomiting

Hyperglycemia

Hypokalemia

Cardiac arrhythmias

Tachycardia

Hyperglycemia

Hypoglycemia

Ileus

Possible increased risk for intraventricular hemorrhage

Magnesium sulfate

Flushing

Nausea/vomiting

Headache

Generalized muscle weakness

Shortness of breath

Diplopia

Pulmonary edema

Chest pain

Hypotension

Tetany

Respiratory depression

Lethargy

Hypotonia

Respiratory depression

Indomethacin

Gastrointestinal effects: Nausea/vomiting, heartburn, bleeding

Coagulation disturbances

Thrombocytopenia

Renal failure

Hepatitis

Elevated blood pressure in hypertensive patients

Renal dysfunction

Oligohydramnios

Pulmonary hypertension

Postpartum patent ductus arteriosus

Premature constriction of ductus arteriosus in utero

Increased risk for necrotizing enterocolitis and intraventricular hemorrhage

Nifedipine

Hypotension

Tachycardia

Headache

Flushing

Dizziness

Nausea/vomiting

Tachycardia

Hypotension

Tocolytic	Maternal Effects	Fetal/Neonatal Effects
-----------	------------------	------------------------

Beta-Mimetic Adrenergic Agents

Beta-mimetic adrenergic agents act directly on beta receptors (β_2) to relax the uterus. Their use is limited by dose-related cardiovascular side effects, including pulmonary edema, adult RDS, elevated systolic blood pressure and reduced diastolic blood pressure, and both maternal and fetal tachycardia. Other dose-related effects are decreased serum potassium level and increased blood glucose and plasma insulin levels and lactic acidosis. Maternal medical contraindications to the use of β -adrenergic agents include cardiac disease, hyperthyroidism, uncontrolled hypertension or pulmonary hypertension, asthma requiring sympathomimetic drugs or corticosteroids for relief, uncontrolled diabetes, and chronic hepatic or renal disease. Commonly observed effects during intravenous administration are palpitations, tremors, nervousness, and restlessness. Beta-mimetics in common use are ritodrine and terbutaline. Because of the side effects, beta-mimetic tocolysis in the United States is now limited almost exclusively to subcutaneous intermittent injections as a method of temporizing and triaging patients prior to definitive therapy with other agents.

TERBUTALINE

Although not approved by the FDA, terbutaline has been studied in the United States and is used widely as a tocolytic agent. In tocolysis it is administered via subcutaneous boluses, subcutaneous pump, by mouth, or, less commonly, by intravenous bolus. The most common regimen is subcutaneous injection of 0.25 mg every 3–4 hours for 12 hours.

Magnesium Sulfate

Although its exact mechanism of action is unknown, magnesium sulfate appears to inhibit calcium uptake into smooth muscle cells, reducing uterine contractility. The efficacy of magnesium is debated, but several small studies have shown an effect comparable to that of beta-mimetics. Magnesium sulfate is better tolerated than the beta-mimetics and, as a result, has become the first-line agent for tocolysis in many institutions in the United States. A protocol for use of magnesium sulfate is given in Table 15–4. Magnesium sulfate may appear less likely to cause serious side effects than the beta-mimetics, but its therapeutic range is close to the range at which it will cause respiratory and cardiac depression. Therefore, patients receiving magnesium sulfate should be monitored closely for signs of toxicity, with frequent checks of deep tendon reflexes, pulmonary examinations, and strict calculations of the patient's fluid balance. These effects may be reversed by calcium gluconate (10 mL of a 10% solution given intravenously), and this antidote should be kept at the bedside when magnesium sulfate is used.

Table 15–4. Protocol for Use of Magnesium Sulfate in Suppression of Preterm Labor.

Criteria for admission to protocol
Preterm labor has been confirmed.

Gestational age of 20–34 weeks has been confirmed.

Examinations and tests have ruled out any cases of maternal or fetal diseases or disorders in which it would be best to allow labor to continue.

Any specific contraindications to magnesium sulfate therapy have been ruled out.

Protocol

Begin intravenous infusion of magnesium sulfate, 4 g (40 mL of 10% solution). The rate of infusion should be slow enough to prevent flushing or vomiting. Then, continuous infusion of magnesium sulfate should be started at 2 g/h (magnesium sulfate 10% solution, 200 mL, in 5% dextrose, 800 mL, at a rate of 100 mL/h). This infusion can be titrated up by increments of 0.5 g/h to a maximum of 4.0 g/h until adequate tocolysis is achieved (< 4–6 uterine contractions per hour). Infusion should be continued until labor subsides or progresses to an irreversible stage (cervical dilatation of 5 cm).

Reduce the rate of infusion if magnesium toxicity is observed.

Protocol for recurrent preterm labor

If contraindications recur after discontinuation of the infusion, the procedure may be repeated.

Calcium Channel Blockers

Calcium channel blockers such as nifedipine work as tocolytics by inhibiting calcium uptake into uterine smooth muscle cells via voltage-dependent channels, thereby reducing uterine contractility. Several studies have shown nifedipine to be equally or more efficacious than beta-mimetics in preterm labor. Other advantages are its low incidence of maternal side effects and ease of administration. Nifedipine can be given by mouth. A common regimen for tocolysis is nifedipine 20 mg by mouth, then 10–20 mg by mouth every 6 hours until contractions

diminish sufficiently.

Prostaglandin Synthase Inhibitors

Prostaglandin synthase inhibitors such as indomethacin have been shown to be as effective as ritodrine for tocolysis, but their use has been limited by potentially serious fetal effects. Indomethacin works as a tocolytic by inhibiting prostaglandin synthesis, an important mediator in uterine smooth muscle contractility. The advantages of indomethacin are its ease of administration (it can be given by rectum or by mouth) and its potent tocolytic activity. However, it has been associated with oligohydramnios and premature closure of the ductus arteriosus. In preterm infants delivered prior to 30 weeks' EGA, some studies have demonstrated an increased risk of intracranial hemorrhage, necrotizing enterocolitis, and patent ductus arteriosus after birth. A common regimen for tocolysis is indomethacin 100 mg per rectum loading dose (or 50 mg by mouth), then 25–50 mg by mouth or rectum every 4–6 hours. Ultrasound should be performed every 48–72 hours to check for oligohydramnios. Because of the potentially serious fetal effects, many centers limit its use to infants less than 32 weeks' EGA and its duration of use to less than 48 hours.

Treatment with Multiple Tocolytics

All tocolytics have significant failure rates; therefore, if 1 tocolytic appears to be failing, that agent should be stopped and another agent should be tried. The use of multiple tocolytics at the same time appears to have an additive tocolytic effect but also appears to increase the risk of serious side effects. For example, magnesium sulfate used in combination with nifedipine theoretically can cause serious maternal hypotension. Likewise, magnesium sulfate supplemented by 1–2 doses of subcutaneous terbutaline can be safe and effective, but sustained treatment with the 2 can increase the patient's risk of pulmonary edema. It should be remembered that the patient who is difficult to tocolyze may have an unrecognized chorioamnionitis or placental abruption, conditions that may be contraindications to use of any tocolysis at all.

Results of Tocolytic Therapy

With all tocolytics, a point may be reached where further therapy is not indicated. This may be due to adverse maternal or fetal response to the progress of labor. Thus, if cervical dilatation reaches 5 cm, the treatment should be considered a failure and abandoned. Conversely, if labor resumes after a period of quiescence, treatment should be carefully considered because the recrudescence of contractions may be a sign of intrauterine infection. In some cases, therapy may be reinstated using the same or a different drug.

ANTIBIOTICS

Antibiotic therapy as a treatment of preterm labor and a means of prolonging pregnancy has been studied and, for the most part, has shown no benefit in delaying preterm birth in this population of patients. Patients with preterm labor should be started on antibiotics for prevention of neonatal GBS infection if the patient's GBS status is positive or unknown. Penicillin or ampicillin is used as first-line agents; cefazolin, clindamycin, erythromycin, or vancomycin can be used if the patient is allergic to penicillin. If the patient is successfully tocolyzed and there is no sign of imminent delivery, GBS prophylaxis can be discontinued.

Conduct of Labor & Delivery

Premature infants less than 34 weeks should be delivered in a hospital equipped for neonatal intensive care whenever possible, because transfer following birth is more hazardous. Premature breech infants weighing less than 2000 g are generally delivered by cesarean section. Although the route of delivery for very-low-birth-weight infants has been hotly debated, there is no conclusive evidence of a benefit to routine cesarean delivery. A generous episiotomy should be considered to further reduce the risk of injury.

If cesarean delivery is indicated, the decision to operate is based on maturity of the fetus and prognosis for survival. In borderline cases (23–24 weeks' gestation and 500–600 g EFW), the wishes of the parents with regard to intervention assume an important place. When performing a cesarean delivery, it is important to

ascertain that the uterine incision is adequate for extraction of the fetus without delay or unnecessary trauma. This often requires a vertical incision when the lower uterine segment is incompletely developed. Trauma to the newborn may be minimized by en caul delivery.

When birth follows the unsuccessful use of parenteral tocolytic agents, keep in mind the potential residual adverse effects of these drugs. β -Adrenergic agents may cause neonatal hypotension, hypoglycemia, hypocalcemia, and ileus. Magnesium sulfate may be responsible for respiratory and cardiac depression.

Cord pH & Blood Gases

Apgar scores are often low in low-birth-weight babies. This finding does not indicate asphyxia or compromised status but merely reflects the immaturity of the physiologic systems. Therefore, it is crucial to obtain cord pH and blood gas measurements for premature (and other high-risk) infants in order to document the status at birth. Cord pH and blood gas measurements may also be helpful in reconstructing intrapartum events, clarifying resuscitative measures, and determining the need for more intensive neonatal care.

Prognosis

Excellent neonatal care in the delivery room and nursery will do much to ensure a good prognosis for the preterm infant (see Chapter 32). Lower-birth-weight babies have a lesser chance of survival and a greater chance of permanent sequelae in direct relationship to size. Making generalizations regarding survival rates and sequelae is difficult because of the many causes of preterm delivery, the different levels of perinatal care, and the institutional differences in reported series. However, general figures for survival and morbidity have been reported and are helpful in counseling patients (Table 15–5).

Table 15–5. Approximate Neonatal Survival of Preterm Infants.¹

24–25	500–750	60	35
25–27	751–1000	75	60
28–29	1000–1250	90	80
30–31	1251–1500	96	90
32–33	1500–1750	99	98
>34	1751–2000	100	99

Gestation Age (weeks)	Birth Weight (g)	Survivors (%)	Intact ² Survivors (%)

¹ Delivered in a tertiary care center.

² Intact defined as not blind, deaf, retarded, or with cerebral palsy.

PREMATURE RUPTURE OF MEMBRANES

Essentials of Diagnosis

- History of a gush of fluid from the vagina or watery vaginal discharge.
- Demonstration of amniotic fluid leakage from the cervix.

General Considerations

Rupture of the membranes may occur at any time during pregnancy. It becomes a problem if the fetus is preterm (preterm premature rupture of membranes [PROM]) or, in the case of a term fetus, if the period of time between rupture of the membranes and the onset of labor is prolonged. If 24 hours elapse between rupture of the membranes and the onset of labor, the problem is one of prolonged PROM.

The exact cause of rupture is not known, although many conditions are associated with PROM (Table 15–6). PROM occurs in approximately 10.7% of all pregnancies. In approximately 94% of cases, the fetus is mature (approximately 20% of these are cases of prolonged rupture). Premature fetuses (1000–2500 g) account for about 5% of the total number (about 50% of cases are prolonged), whereas immature fetuses (< 1000 g) account for less than 0.5% (about 75% of cases are prolonged).

Table 15–6. Diseases and Disorders Associated with Premature Rupture of the Membranes.

Maternal infection (eg, urinary tract infection, lower genital tract infection, sexually transmitted diseases)

Intrauterine infection

Cervical incompetency

Multiple previous pregnancies

Hydramnios

Nutritional deficit

Decreased tensile strength of membranes

Familial history of premature rupture of membranes

Pathology & Pathophysiology

PROM is an important cause of preterm labor, prolapse of the cord, placental abruption, and intrauterine infection. Chorioamnionitis is an important sequela of PROM and may precede endomyometritis or puerperal sepsis.

In extremely prolonged rupture of the membranes, the fetus may have an appearance similar to that of Potter's syndrome (ie, flattened facial features, wrinkling of the skin). If rupture of membranes occurs early in pregnancy at less than 26 weeks' EGA, it can cause pulmonary hypoplasia and limb positioning defects in the newborn.

Clinical Findings

SYMPTOMS

The diagnostic evaluation must be efficient and impeccably conducted to minimize the number of vaginal examinations and the risk of chorioamnionitis. Symptoms are the key to diagnosis; the patient usually reports a sudden gush of fluid or continued leakage. Additional symptoms that may be useful include the color and consistency of the fluid and the presence of flecks of vernix or meconium, reduced size of the uterus, and increased prominence of the fetus to palpation.

STERILE SPECULUM EXAMINATION

A most important step in accurate diagnosis is examination with a sterile speculum. This examination is the key to differentiating PROM from hydrorrhea gravidarum, vaginitis, increased vaginal secretions, and urinary incontinence. The examiner should look for the 3 hallmark confirmatory findings associated with PROM:

1. Pooling—the collection of amniotic fluid in the posterior fornix.
2. Nitrazine test—a sterile cotton-tipped swab should be used to collect fluid from the posterior fornix and apply it to Nitrazine (phenolphthazine) paper. In the presence of amniotic fluid, the Nitrazine paper turns blue, demonstrating an alkaline pH (7.0–7.25).
3. Ferning—Fluid from the posterior fornix is placed on a slide and allowed to air-dry. Amniotic fluid will form a fernlike pattern of crystallization.

Together, these 3 findings confirm ruptured membranes, although several factors may produce false-positive results. Alkaline pH on Nitrazine test can also be caused by vaginal infections or the presence of blood or semen in the sample. Cervical mucus can cause ferning, but usually patchy and less extensive than with PROM. During the speculum examination, the patient's cervix should be visually inspected to determine the degree of dilatation and effacement and the presence of cord prolapse. If vaginal pool is significant, the pool can be collected and sent for fetal lung maturity determination if the gestational age is greater than 32 weeks. Cervical secretions should also be sent for culture, and a wet mount should be performed.

If no free fluid is found, a dry pad should be placed under the patient's perineum and observed for leakage. Other confirmatory tests for PROM include observed loss of fluid from the cervical os when the patient coughs or performs a Valsalva maneuver during speculum examination and oligohydramnios on ultrasound examination. If the examiner still cannot confirm rupture of membranes and the patient's history is highly suspicious for PROM, it may be necessary to perform amniocentesis and inject a dilute solution of Evans blue or indigo carmine dye. This is done following removal of amniotic fluid for physiologic maturity testing, analysis for white blood cells or bacteria, and possible culture and sensitivity testing. After 15–30 minutes, examination of the patient's perineal pad will reveal blue dye if the membranes are ruptured.

PHYSICAL EXAMINATION

Once PROM is confirmed, a careful physical examination is necessary to search for other signs of infection. Given the risk of infection, there is no indication for digital cervical examination if the patient is in early labor. The sterile speculum examination is sufficient to distinguish between early and advanced labor.

LABORATORY STUDIES

Initial laboratory studies should include a complete blood count with differential. In preterm pregnancies, evaluation should also include urine collected by catheterization for urinalysis, culture, and sensitivity testing; ultrasound examination for fetal size and amniotic fluid index; and amniocentesis in some cases to determine

fetal lung maturity and the presence of infection.

CHORIOAMNIONITIS

In all cases of chorioamnionitis, it is safer for the fetus to be delivered than to be retained in utero. The most common organisms causing chorioamnionitis are those that ascend from the vagina (eg, *Escherichia coli*, *Bacteroides*, GBS, group D streptococcus, and other anaerobes). The most reliable signs of infection include the following: (1) Fever—the temperature should be checked every 4 hours. (2) Maternal leukocytosis—a daily leukocyte count and differential can be obtained. An increase in the white blood cell count or neutrophil count may indicate the presence of intra-amniotic infection. (3) Uterine tenderness—check every 4 hours. (4) Tachycardia—either maternal pulse > 100 bpm or fetal heart rate > 160 bpm—is suspicious. (5) Foul-smelling amniotic fluid.

A number of confounding factors may complicate the diagnosis of chorioamnionitis. For example, corticosteroid administration may cause mild leukocytosis (increase of 20–25%), and labor is associated with leukocytosis. If the diagnosis of chorioamnionitis is equivocal, amniocentesis can be performed to evaluate for evidence of infection as described earlier in this chapter.

Treatment

The management of PROM depends on several factors, including gestational age and the presence or absence of chorioamnionitis.

CHORIOAMNIONITIS

If chorioamnionitis is present in the patient with PROM, the patient should be actively delivered *regardless of gestational age*. Broad-spectrum antibiotics should be started to treat the chorioamnionitis. If the patient is not in labor, labor should be induced to expedite delivery.

TERM PREGNANCY WITHOUT CHORIOAMNIONITIS

The term pregnancy (EGA greater than 37 weeks) with PROM in the absence of infection can be managed expectantly or actively. Expectant management entails nonintervention while waiting for the patient to go into labor spontaneously, whereas active management entails induction of labor with an agent such as oxytocin (Pitocin). Nonintervention is an acceptable initial course of treatment, but if the patient does not go into labor within 6–12 hours after PROM, labor should be induced to minimize the risk of infection.

PRETERM PREGNANCY WITHOUT CHORIOAMNIONITIS

The principles of managing the preterm PROM patient are similar to those for managing the preterm labor patient. The key difference is the much increased risk of developing chorioamnionitis associated with preterm PROM. Pregnancies beyond 34 weeks' EGA can be managed as a term pregnancy because there is no evidence that antibiotics, corticosteroids, or tocolytics improve outcome in these patients. These patients can be managed expectantly as long as they show no signs of chorioamnionitis.

Rupture of membranes prior to viability can be managed by active termination of pregnancy because of the poor prognosis. Nevertheless, many case series have documented substantial survival rates (15–50%) with PROM at 18–22 weeks. Although many patients may be unwilling to accept the risk of chorioamnionitis (30%) and even sepsis, they should be informed of the option of expectant management with antibiotic therapy.

For pregnancies with PROM between 24 and 32 weeks' EGA, several interventions have been shown to prolong pregnancy and improve outcome. After chorioamnionitis has been ruled out and a specimen of amniotic fluid from vaginal pool collection or amniocentesis sent for determination of fetal lung maturity, management should consist of the following interventions.

Antibiotics

Over the past decade, antibiotics have emerged as an important treatment for preterm PROM. In contrast to

preterm labor where antibiotics have shown no benefit in prolonging pregnancy, antibiotics appear to be effective in prolonging the latency period from rupture of membranes to delivery in patients with preterm PROM. They have also been shown to decrease the infection rate in these patients. A number of well-designed studies have shown improved neonatal outcomes with antibiotics alone and with antibiotics combined with corticosteroid therapy. Table 15–7 provides 1 recommended protocol for antibiotic use in preterm PROM.

Table 15–7. Antibiotic Therapy for Preterm Premature Rupture of Membranes.

Once preterm PROM is confirmed, start:

Ampicillin 2 g IV every 6 hours

plus

Erythromycin 250 mg IV every 6 hours

After 48 hours, if the patient is still undelivered, this regimen should be changed to:

Amoxicillin 250 mg by mouth every 8 hours

plus

Erythromycin 333 mg by mouth every 8 hours

These antibiotics should be continued for 7 days if the patient remains undelivered. Women with GBS-positive cultures should receive prophylaxis intrapartum.

From Mercer BM et al: Antibiotic therapy for reduction of infant morbidity after preterm premature rupture of the membranes. *JAMA* 1997; 278:989.

Corticosteroids

The National Institutes of Health (NIH) consensus development panel recommends the use of steroids in PROM patients prior to 32 weeks' EGA in the absence of intra-amniotic infection. In this patient population, corticosteroids have been shown to decrease the rate of RDS, necrotizing enterocolitis, and intraventricular hemorrhage.

Tocolytics

The role of tocolytics in the preterm PROM patient is controversial. No study has shown that tocolytics alone improve fetal outcome. In general, the use of tocolytics in the preterm PROM patient should be limited to 48 hours' duration, to permit administration of corticosteroids and antibiotics.

If after starting these interventions the fetal lung profile returns as mature, the tocolytics should be abandoned and delivery considered. Again, if at any time the patient shows signs of chorioamnionitis, she should be delivered.

ROLE OF OUTPATIENT MANAGEMENT

In rare selected cases, patients who remain undelivered may be candidates for outpatient management. If leakage of fluid stops, the amniotic fluid volume normalizes, and the patient remains afebrile without evidence

of increasing uterine irritability, she can be discharged home. These patients should be monitored very closely on an outpatient basis. They must be reliable and compliant with follow-up appointments. They also must take their temperature 4 times per day and be counseled on the warning signs of chorioamnionitis. These patients should also be monitored with frequent biophysical profiles; some sources recommend daily testing.

PROLONGED PREGNANCY

Essentials of Diagnosis

- Confirmation of gestational age greater than 42 completed weeks.

General Considerations

Prolonged pregnancy is defined as pregnancy that has reached 42 weeks of completed gestation from the first day of the LMP or 40 weeks' gestation from the time of conception. Most fetuses will show effects of impaired nutritional supply (weight loss, reduced subcutaneous tissue, scaling, parchmentlike skin). This condition is referred to as dysmaturity. The most common cause of prolonged pregnancy is incorrect dating due to variable length of the menstrual cycle. This has been reduced in recent years with widespread use of first-trimester ultrasound for dating. The cause of most cases of true prolonged pregnancy remains unknown. Experiments of nature, such as anencephalic fetuses and those with placental sulfatase deficiency, suggest that changes in placental steroid metabolism due to fetal hormonal signaling play a central role in the timing of delivery. At least 3% of infants are born after 42 completed weeks' gestation (in some series, as many as 12%). Because of the potential risks of dysmaturity, these infants deserve particular attention.

The maternal risks usually relate to extraordinary fetal size (ie, dysfunctional labor, arrested progress of labor, fetopelvic disproportion). Extraordinary fetal size may result in birth injury (eg, shoulder dystocia). Placental insufficiency is thought to be associated with aging of the placenta and is the basis for another group of fetal problems. Oligohydramnios, which is more common in postterm gestation, may lead to cord compromise.

Complications resulting from prolonged pregnancy result in a sharp rise in perinatal mortality and morbidity rates (2–3 times those of infants born at 37–42 weeks). Complications in the survivors increase the chance of neurologic sequelae.

Diagnosis

The diagnosis of prolonged pregnancy is made by confirmation of the gestational age by referring to records of early pregnancy tests and ultrasound examinations, the exact time of conception (if known), and clinical parameters (eg, LMP, quickening, detection of fetal heart tones).

To adequately assess the risk of fetal compromise, the following is a useful protocol for pregnancies beyond 41 weeks' gestation:

1. Perform nonstress testing 2 times weekly. (Some authorities believe that contraction stress testing, a biophysical profile, or both are necessary to detect the jeopardized fetus and recommend weekly or semiweekly testing.)
2. Perform ultrasonic monitoring at least twice weekly to assess amniotic fluid volume (biophysical profiles may be obtained at the same time).
3. Have the mother count fetal movements each day.

Treatment

The principal risk of labor induction has been thought to be an increased rate of cesarean birth. It has now been conclusively demonstrated, however, that induction of labor at 41 weeks does not increase the cesarean rate compared to expectant management with antepartum testing. Therefore, many authorities offer induction of labor at 41 completed weeks, reserving expectant management for those patients who refuse induction. If

the choice is to continue the pregnancy, it may be advisable to have the patient monitor fetal activity. The following precautions should be taken:

1. Decreased fetal movement warrants an immediate biophysical profile evaluation.
2. Abnormalities in the nonstress test mandate induction or a backup test such as the full biophysical profile.
3. An abnormal contraction stress test, decreased amniotic fluid volume, abnormal biophysical profile, or other signs of fetal require delivery.
4. A large or compromised fetus may require cesarean delivery (see discussion of macrosomia in Chapter 16)
5. In the absence of fetopelvic disproportion or fetal distress, labor can be induced. Fetal monitoring should be continuous.

RH ISOIMMUNIZATION & OTHER BLOOD GROUP INCOMPATIBILITIES

Essentials of Diagnosis

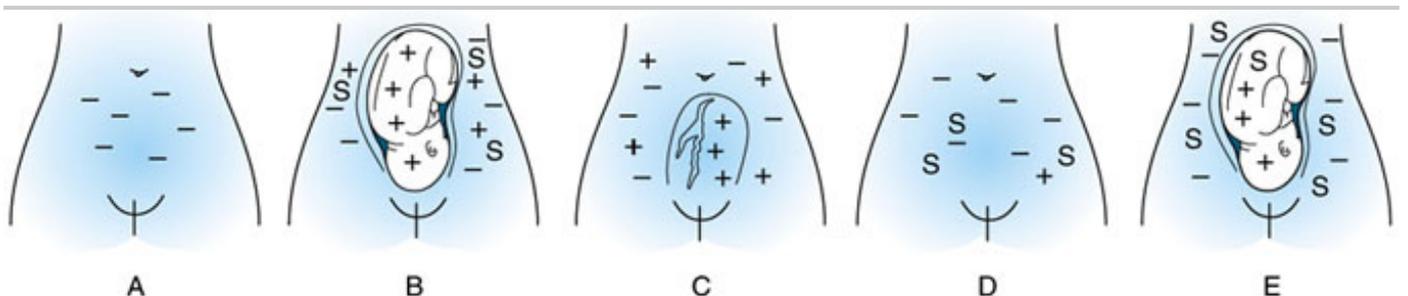

- Maternal Rh-negativity and presence of antibody on indirect Coombs' test.
- Rh or other antibody titer posing fetal risk.
- May have a previous infant with hemolytic disease of the newborn.
- Postnatal fetal cord blood findings of Rh-positivity and anemia (hemoglobin < 10 g).

General Considerations

A fetus receives half of its genetic components from its mother and half from its father; therefore, the fetus may have different blood groups than those of its mother. Some blood groups may act as antigens in individuals not possessing those blood groups. The antigens reside on red blood cells. If enough fetal cells cross into the maternal blood, a maternal antibody response may be provoked. If these maternal antibodies cross the placenta, they then can enter the fetal circulation and destroy the fetal erythrocytes, causing hemolytic anemia. This leads to fetal responses to meet the challenge of enhanced blood cell breakdown. These changes in the fetus and newborn are called erythroblastosis fetalis. Several blood groups are capable of producing fetal risk, but those in the Rh group have caused the overwhelming majority of cases of erythroblastosis fetalis, so the Rh group is used as the example.

The Rh blood group is the most complex human blood group. The Rh antigens are grouped in 3 pairs: Dd, Cc, and Ee. The major antigen in this group, Rh_o (D), or Rh factor, is of particular concern. A woman who is lacking the Rh factor (Rh-negative) may carry an Rh-positive fetus. If fetal red blood cells pass into the mother's circulation in sufficient numbers, maternal antibodies to the Rh-positive antigen may develop and cross the placenta, causing hemolysis of fetal blood cells (Fig 15–1). Hemolytic disease of the newborn may occur, and severe disease may cause fetal death.

Figure 15–1.

A: Rh-negative woman before pregnancy. B: Pregnancy occurs. The fetus is Rh-positive. C: Separation of the placenta. D: Following delivery, Rh isoimmunization occurs in the mother, and she develops antibodies (S) to the Rh-positive antigen. E: The next pregnancy with an Rh-positive fetus. Maternal antibodies cross the placenta, enter the fetal bloodstream, and attach to Rh-positive red cells, causing hemolysis.

In standard testing when the father is Rh-positive, 2 possibilities exist: he is either homozygous or heterozygous. Forty-five percent of Rh-positive persons are homozygous for D and 55% are heterozygous. If the father is homozygous, all of his children will be Rh-positive; if he is heterozygous, his children will have a 50% chance of being Rh-positive. By way of contrast, the Rh-negative individual is always homozygous.

Incidence

Basque populations have the highest incidence of Rh-negativity (30–35%). Caucasian populations in general have a higher incidence than other ethnic groups (15–16%). Blacks in the United States have a rate of 8%, African blacks 4%, Indo-Europeans 2%, and North American Indians 1%.

In mothers who do not receive prophylaxis with Rh immunoglobulin, the overall risk of isoimmunization for an Rh-positive ABO-compatible infant with an Rh-negative mother is about 16%. Of these, 1.5–2% of reactions will occur antepartum and 7% within 6 months of delivery; the remainder (7%) manifest early in the second pregnancy, most likely as the result of an amnestic response. ABO incompatibility between an Rh-positive fetus and an Rh-negative mother provides some protection against Rh isoimmunization; in these cases the overall incidence is 1.5–2%. In mothers who receive prophylaxis with Rh immunoglobulin, the risk of isoimmunization is reduced to 0.2%.

Pathogenesis

MATERNAL RH ISOIMMUNIZATION

Rh antigens are lipoproteins that are confined to the red cell membrane. Isoimmunization may occur by 2 mechanisms: (1) following incompatible blood transfusion or (2) following fetomaternal hemorrhage between a mother and an incompatible fetus. Fetomaternal hemorrhage may occur during pregnancy or at delivery. With no apparent predisposing factors, fetal red cells have been detected in maternal blood in 6.7% of women during the first trimester, 15.9% during the second trimester, and 28.9% during the third trimester.

Predispositions to fetomaternal hemorrhage include spontaneous or induced abortion, amniocentesis, chorionic villus sampling, abdominal trauma (eg, due to motor vehicle accidents or external version), placenta previa, abruptio placentae, fetal death, multiple pregnancy, manual removal of the placenta, and cesarean section.

Although the exact number of Rh-positive cells necessary to cause isoimmunization of the Rh-negative pregnant woman is unknown, as little as 0.1 mL of Rh-positive cells can cause sensitization. Even with delivery, this amount occurs in less than half of cases.

Fortunately, there are other mitigating factors to Rh isoimmunization. A very important factor is that about 30% of Rh-negative persons never become sensitized (nonresponders) when given Rh-positive blood. ABO incompatibility also confers a protective effect (see Incidence).

The initial maternal immune response to Rh sensitization is low levels of immunoglobulin (Ig) M. Within 6 weeks to 6 months, IgG antibodies become detectable. In contrast to IgM, IgG is capable of crossing the placenta and destroying fetal Rh-positive cells.

OTHER BLOOD GROUP ISOIMMUNIZATION

Of the other blood groups that may evoke an immunoglobulin capable of crossing the placenta (often called atypical or irregular immunizing antibodies), those that may cause severe fetal hemolysis (listed in descending order of occurrence) are Kell, Duffy, Kidd, MNSs, and Diego. P, Lutheran, and Xg groups may also cause fetal hemolysis, but it usually is less severe.

FETAL EFFECTS

Hemolytic disease of the newborn occurs when the maternal antibodies cross the placenta and destroy the Rh-positive fetal red blood cells. Fetal anemia results, stimulating extramedullary erythropoietic sites to produce high levels of nucleated red cell elements. Immature erythrocytes are present in the fetal blood because of poor maturation control. Hemolysis produces heme, which is converted to bilirubin; both of these substances are neurotoxic. However, while the fetus is in utero, heme and bilirubin are effectively removed by the placenta and metabolized by the mother.

When fetal red blood cell destruction far exceeds production and severe anemia occurs, erythroblastosis fetalis may result. This is characterized by extramedullary hematopoiesis, heart failure, edema, ascites, and pericardial effusion. Tissue hypoxia and acidosis may result. Normal hepatic architecture and function may be disturbed by extensive liver erythropoiesis, which may lead to decreased protein production, portal hypertension, and ascites.

NEONATAL EFFECTS

In the immediate neonatal interval, the primary problem may relate to anemia and the sequelae mentioned above. However, hyperbilirubinemia may also pose an immediate risk and certainly poses a risk as further red cell breakdown occurs. The immature (and often compromised) liver, with its low levels of glucuronyl transferase, is unable to conjugate the large amounts of bilirubin. This results in a high serum bilirubin level, with resultant kernicterus (bilirubin deposition in the basal ganglia).

Management of the Unsensitized Rh-Negative Pregnancy

PREPREGNANCY OR FIRST PRENATAL VISIT

On the first prenatal visit, all pregnant women should be screened for the ABO blood group and the Rh group, including Du. They should also undergo antibody screening (indirect Coombs' test). Unless the father of the baby is known to be Rh-negative, all Rh-negative mothers should receive prophylaxis according to the following protocol.

VISIT AT 28 WEEKS

Antibody screening is performed. If negative, 300 µg of Rh immunoglobulin (RhIgG) is given. If positive, the patient should be managed as Rh-sensitized.

VISIT AT 35 WEEKS

Antibody screening is repeated. If negative, the patient is merely observed. If screening is positive, the patient is managed as Rh-sensitized.

POSTPARTUM

If the infant is Rh-positive or Du-positive, 300 µg of RhIgG is administered to the mother (provided maternal antibody screening is negative). Although RhIgG should generally be given within 72 hours after delivery, it has been shown to be effective in preventing isoimmunization if given up to 28 days after delivery. If the antibody screen is positive, the patient is managed as if she will be Rh-sensitized during the next pregnancy.

SPECIAL FETOMATERNAL RISK STATES

Several circumstances that may occur during pregnancy mandate administration of RhIgG to the unsensitized patient outside the management protocol described.

Abortion

Sensitization will occur in 2% of spontaneous abortions and 4–5% of induced abortions. In the first trimester, because of the small amount of fetal blood, 50 µg of RhIgG apparently is sufficient to prevent sensitization. However, because the cost of RhIgG has dropped, a full 300-µg dose is usually given. The same dose is recommended for exposure after the first trimester. The risk of Rh isoimmunization after threatened abortion is less well understood, but many experts agree that RhIgG should also be given to these patients.

Amniocentesis, Chorionic Villus Sampling, and Cord Blood Sampling

If the placenta is traversed by the needle, there is up to an 11% chance of sensitization. Therefore, administration of 300 µg of RhIgG is recommended when these procedures are performed in the unsensitized patient.

Antepartum Hemorrhage

In cases of placenta previa or abruptio placentae, administration of 300 µg of RhIgG is recommended. If the pregnancy is carried more than 12 weeks from the time of RhIgG administration, a repeat prophylactic dose is recommended.

External Cephalic Version

Fetomaternal hemorrhage occurs in 2–6% of patients who undergo external cephalic version, whether failed or successful; therefore, these patients should receive 300 µg of RhIgG.

DELIVERY WITH FETOMATERNAL HEMORRHAGE

Fetomaternal hemorrhage so extensive that it cannot be managed with 300 µg of RhIgG occurs in only about 0.4% of patients. If the sensitive screening test is positive for persistent antibody after RhIgG administration, the amount of hemorrhage is quantitated by the Kleihauer-Bethke test and additional doses of RhIgG given according to the amount of excess hemorrhage.

Evaluation of the Pregnancy with Isoimmunization

Evaluation of the pregnancy complicated by isoimmunization is guided by 2 factors: whether the patient has a history of an affected fetus in a previous pregnancy (ie, fetus with severe anemia or hydrops) and maternal antibody titers.

NO HISTORY OF PREVIOUS FETUS AFFECTED BY RH ISOIMMUNIZATION

Once the antibody screen is positive for isoimmunization, these patients should be followed by antibody titers at intake, 20 weeks' EGA, and then every 4 weeks. As long as antibody titers remain below the critical titer (<1:32 in our laboratory, but each laboratory must establish its own norms), there is no indication for further intervention. Once antibody titers reach 1:32, amniocentesis should be performed because a titer of 1:32 places the fetus at significant risk for demise before 37 weeks. An alternative to serial amniocentesis in patients with abnormal antibody titers or a history of a prior affected fetus is assessment of blood flow in the fetal middle cerebral artery (MCA) by Doppler. Ultrasound is performed to identify the circle of Willis, and blood flow in the proximal third of the MCA can be estimated using Doppler. High peak velocity blood flow in this area (> 1.5 multiples of the median) correlates well with severe fetal anemia. This test can be performed at 2-week intervals in these patients, so more invasive diagnostic interventions can be avoided until evidence of severe anemia is observed.

HISTORY OF A PRIOR FETUS AFFECTED BY RH ISOIMMUNIZATION

Antibody titers need not be followed in these pregnancies because amniocentesis is indicated by the history of prior affected fetus. Amniocentesis should be performed 4–8 weeks earlier than the gestational age in the previous pregnancy when Rh-associated morbidity was first identified. Amniocentesis, when determined to be necessary, should be performed under ultrasound guidance to minimize the risk of transplacental hemorrhage.

The amniotic fluid is analyzed by spectrophotometry. The optical density of the fluid at a wavelength of 450 nm is plotted on a semilogarithmic scale versus gestational age. The amniotic fluid concentration of bilirubin in the unsensitized patient gradually decreases as pregnancy progresses. Thus, the severity of fetal affliction may be approximated and this information used as a guide for further studies and treatment. The alternative of MCA Doppler peak velocity assessment is now more widely used.

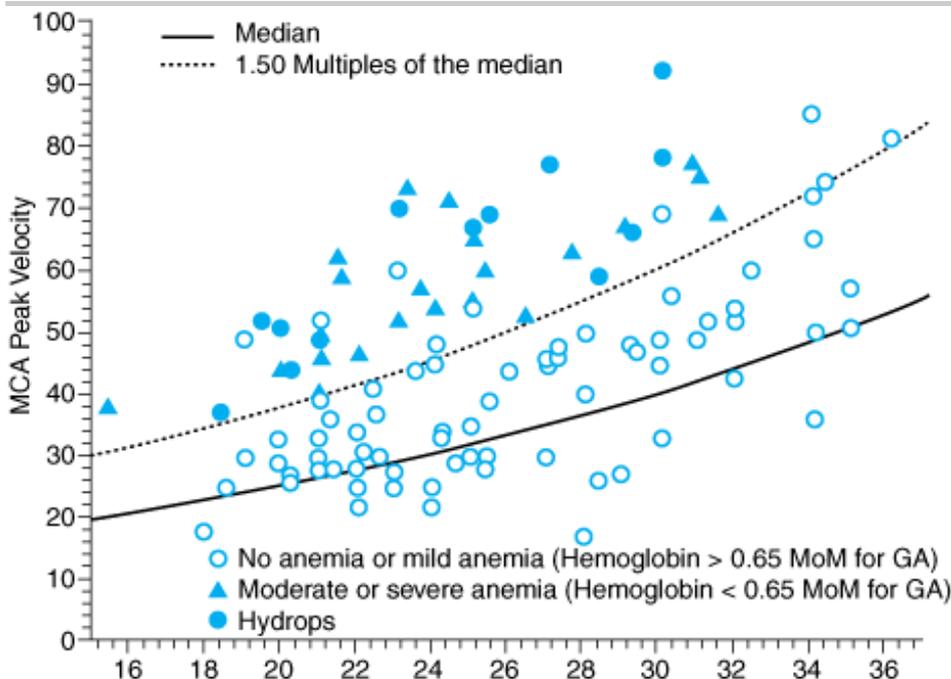

In addition to MCA Doppler, ultrasound plays an important role in evaluating the isoimmunized patient for hydrops. Ultrasound can be used to evaluate fetal heart size and amniotic fluid index and to detect edema,

pericardial effusion, and ascites. Serial ultrasounds can document the progression or reversal of disease.

Management of the Pregnancy with Isoimmunization

Management of these patients is dictated by amniocentesis or MCA Doppler results (Fig 15–2).

Figure 15–2.

Peak velocity of systolic blood flow in the middle cerebral artery in 111 fetuses at risk for anemia due to maternal red-cell alloimmunization. (From Mari G et al: Noninvasive diagnosis by Doppler ultrasonography of fetal anemia due to maternal red-cell alloimmunization. Collaborative Group for Doppler Assessment of the Blood Velocity in Anemic Fetuses. *N Engl J Med* 2000; 342:9.)

MILDLY AFFECTED FETUS

The fetus that falls into zone 1 on the Liley curve or has normal MCA Doppler studies is considered to be unaffected or mildly affected. Testing should be repeated every 2–3 weeks, and delivery should be near term and after the fetus has achieved pulmonary maturity.

MODERATELY AFFECTED FETUS

The fetus that falls into zone 2 or has MCA Doppler studies nearing 1.5 multiples of the median (Fig 15–2) should be tested more frequently, every 1–2 weeks. Delivery may be required prior to term, and the fetus is delivered as soon as pulmonary maturity is reached. In some cases, enhancement of pulmonary maturity by use of corticosteroids may be necessary.

SEVERELY AFFECTED FETUS

The severely affected fetus falls into zone 3 on the Liley curve, has MCA Doppler studies > 1.5 multiples of the median, or has frank evidence of hydrops (eg, ascites, pleural or pericardial effusion, subcutaneous edema). Intervention usually is needed to allow the fetus to reach a gestational age at which delivery and neonatal risks are fewer than the risks of in utero therapy.

If the fetus is preterm, cordocentesis or percutaneous umbilical cord blood sampling (PUBS) is recommended at this stage to directly assess the fetal hematocrit. Once severe anemia is confirmed, intrauterine transfusion can

be performed directly into the umbilical vein. The transfusion is performed using O-negative, cytomegalovirus-negative, washed, leukocyte-depleted, irradiated packed red cells. The intraperitoneal technique was used in years past but has largely been replaced by intravascular fetal transfusion secondary to its more predictable absorption.

After transfusion, repeat transfusions or delivery usually will be necessary as production of fetal blood markedly decreases or ceases. Timing of these transfusions may be assisted by ultrasonic determination of MCA Doppler studies. Delivery should take place when the fetus has documented pulmonary maturity.

ABO HEMOLYTIC DISEASE

ABO hemolytic disease is much milder than the isoimmunization evoked by Rh_o and the other antigens. The reason for this difference is poorly understood, because both IgG and IgM are produced antenatally. Although 20–25% of pregnancies have potential maternal–infant ABO incompatibility, a recognizable process in the neonate occurs in only 10% of those cases. Those affected are almost always group A (especially A1) or B infants of group O mothers. The neonatal direct Coombs' test may be positive or negative, and maternal antibodies are also variable.

In Rh isoimmunization, only 1–2% of cases occur in the first-born infant, whereas 40–50% of ABO incompatibilities occur in the first-born infant. Serious fetal sequelae (eg, stillbirth, hydrops) almost never occur, and severe fetal anemia is rare.

ABO hemolytic disease is primarily manifest following birth, with early neonatal onset of jaundice (at < 24 hours) and variable elevation of the indirect bilirubin level. Management of ABO incompatibility relates to bilirubin surveillance and phototherapy (required in 10% of cases). The infants may have hepatosplenomegaly. Exchange transfusion is necessary in only 1% of cases, and the incidence of late anemia is rare. Sequelae such as kernicterus almost never occur.

Current OB/GYN > Chapter 16. Disproportionate Fetal Growth >

DISPROPORTIONATE FETAL GROWTH: INTRODUCTION

Weight at delivery once was considered evidence of prematurity (birthweight < 2500 g) or postmaturity (macrosomia; birthweight > 4500 g). These criteria later were revised upon the realization that abnormal growth was reflected in factors other than birthweight. Normative standards such as birthweight, length, and head circumference (HC) according to gestational age were developed. Abnormal fetal growth now is defined according to percentiles: infants \leq 10th percentile are classified as having intrauterine growth restriction (IUGR) and those \geq 90th percentile are classified as large for gestational age (LGA). Standards also vary among different populations.

Both IUGR and LGA fetuses have increased risk for perinatal morbidity and mortality (Tables 16–1 and 16–2). The pathogenesis, differential diagnosis, and treatment are different for the two extremes of growth.

Table 16–1. Some Complications Associated with IUGR Pregnancy.

Maternal Complications

Complications due to underlying disease, preeclampsia, premature labor, cesarean delivery

Fetal Complications

Stillbirth, hypoxia and acidosis, malformations

Neonatal Complications

Hypoglycemia, hypocalcemia, hypoxia and acidosis, hypothermia, meconium aspiration syndrome, polycythemia, congenital malformations, sudden infant death syndrome

Long-Term Complications

Lower IQ, learning and behavior problems, major neurologic handicaps (seizure disorders, cerebral palsy, mental retardation), hypertension

Table 16–2. Some Complications of LGA Pregnancy.

Maternal Complications

Cesarean section, postpartum hemorrhage, shoulder dystocia, perineal trauma, operative vaginal delivery

Fetal Complications

Stillbirth, anomalies, shoulder dystocia

Neonatal Complications

Low Apgar score, hypoglycemia, birth injury, hypocalcemia, polycythemia, jaundice, feeding difficulties

Long-Term Complications

Obesity, type 2 diabetes, neurologic or behavioral problems

INTRAUTERINE GROWTH RESTRICTED PREGNANCY

Terminology

Many terms have been used to describe fetuses with disproportionately small growth. These include small for gestational age (SGA), IUGR, and fetal growth restriction (FGR). Most often, SGA refers to the infant, whereas IUGR refers to the fetus. *Intrauterine growth restriction* is defined as estimated fetal weight (EFW) at or below the 10th percentile for gestational age. By definition, 10% of infants in any population will be at or below the 10th percentile. Approximately 70% of fetuses with EFW below the 10th percentile are simply constitutionally small, thus the term IUGR is inaccurate for many fetuses. Distinguishing between normal and pathologic growth can be difficult. Some nonpathologic factors that affect fetal birthweight are maternal height, paternal height, parity, ethnicity, and fetal sex.

Pathophysiology

Compared with an average-for-gestational-age (AGA) fetus, the IUGR fetus has altered body composition (including decreased body fat, total protein, whole body DNA and RNA, glycogen, and free fatty acids), altered distribution of weight among organs, and altered body proportions. Approximately 20% of IUGR infants are symmetrically small, with a relatively proportionate decrease in many organ weights. Eighty percent are asymmetrically small, with relative sparing of brain weight, especially when compared with that of the liver or thymus.

In asymmetric IUGR infants, brain weight is decreased only slightly compared with that of AGA controls, primarily as a result of decreased brain cell size and not to decreased brain cell numbers. Cerebral abnormalities include decreased myelination, decreased utilization of metabolic substrates other than glucose, and altered protein synthesis. In experimental animals, these changes are more likely to produce adverse effects in the brainstem and cerebellum. This differential sparing is particularly prominent when deprivation occurs in the latter half of pregnancy. Deprivation early in pregnancy is associated with less cerebral sparing and diffusely slowed brain growth.

Symmetric IUGR infants have proportionately small brains, usually because of a decreased number of brain cells. Although this may be the result of early, severe nutritional deprivation, the cause is more often a genetic disorder, infection, or other problem. Usually the thymus is small, with an average decrease of 25%. This decrease may explain in part the decreased cellular immunity seen in IUGR

infants.

The liver is frequently affected, at least partly because of diminished glycogen deposition. The liver also may have functional (metabolic) abnormalities, as manifested by abnormal cord blood and neonatal serum chemistries. Such abnormalities often reflect the underlying cause of decreased size.

Blood flow to the lungs may be decreased, lessening the pulmonary contribution to amniotic fluid volume. This may be partly responsible for the often-encountered oligohydramnios. Decreased pulmonary blood flow may also be associated with accelerated functional pulmonary maturity.

Renal blood flow frequently is reduced in asymmetric IUGR pregnancies. The resultant diminished glomerular filtration rate may further contribute to oligohydramnios.

Differential Diagnosis

A classification of IUGR pregnancy delineated by cause is given in Table 16–3. Any inference of suboptimal growth requires, by definition, serial observations. It cannot be emphasized too strongly that a pregnancy cannot be described as IUGR unless the gestational age is known with certainty.

Table 16–3. Pathogenic Classification of IUGR Pregnancy.

A. Fetoplacental Causes

Genetic disorders

Autosomal: trisomy 13, 18, 21; ring chromosomes; chromosomal deletions; partial trisomies

Sex chromosomes: Turner's syndrome, multiple chromosomes (XXX, XYY)

Neural tube defects

Skeletal dysplasias: achondroplasia, chondrodystrophies, osteogenesis imperfecta

Abdominal wall defects

Other rare syndromes

Congenital infection

Viral: cytomegalovirus, rubella, herpes, varicella-zoster

Protozoan: toxoplasmosis, malaria

Bacterial: listeriosis

Placental disorders: placenta previa, placental infarction, chorionic villitis, chronic partial separation, placental malformations (circumvallate placenta, battledore placenta, placental hemangioma, twin-twin transfusion syndrome)

Multiple gestation

B. Maternal Factors

Coexistent maternal disease: hypertension, anemia (hemoglobinopathy, decreased normal hemoglobin [especially < 12 g/dL]), renal disease (hypertension, protein loss), malnutrition (inflammatory bowel disease [ulcerative colitis, regional enteritis], pancreatitis, intestinal parasites), cyanotic cardiopulmonary disease

Substance abuse/drugs: alcohol, cigarette smoking, cocaine, heroin, warfarin, folic acid antagonists (methotrexate, aminopterin), anticonvulsants

Small maternal stature

Numerous authors have differentiated between symmetric and asymmetric IUGR pregnancy in terms of cause and prognosis. *Symmetric IUGR* refers to infants in which all organs are decreased proportionally. Symmetric IUGR infants are more likely to have an endogenous defect that results in impairment of early fetal cellular hyperplasia. *Asymmetric IUGR* refers to infants in which all organs are decreased disproportionately (abdominal circumference is affected to a greater degree than is HC). Asymmetric IUGR more likely is caused by intrauterine deprivation that results in redistribution of flow to the brain and heart at the expense of less important organs, such as the liver and kidneys. Although this classification is helpful in establishing a differential diagnosis and framework for discussion, it is not sufficiently precise to serve as a basis for decisions regarding intervention or viability.

FETOPLACENTAL CAUSES

Congenital Abnormalities

Genetic disorders account for approximately one-third of IUGR infants. Data from the Metropolitan Atlanta Congenital Defects Program suggest that 38% of chromosomally abnormal infants are IUGR and that the risk of an IUGR infant having a major congenital anomaly is 8–19%. An infant with an autosomal trisomy is more likely to be IUGR. The most common trisomy is trisomy 21 (Down syndrome), with an incidence of 1.6 per 1000 live births. At term, such infants weigh an average of 350 g less than comparable normal infants and are 4 times more likely to be IUGR. This decrease is most apparent in the last 6 weeks of pregnancy. A similar decrease in birthweight occurs in translocation Down syndrome, whereas mosaic Down syndrome is associated with an intermediate decrease in birthweight.

The second most common autosomal trisomy is trisomy 18 (Edwards' syndrome), which occurs in 1 in 6000–8000 live births. Eighty-four percent of these infants are IUGR. Ultrasound evaluation may reveal associated anomalies. The condition is associated with an increased likelihood of breech presentation, polyhydramnios, fetal neural tube defects, and visceral anomalies. The average birthweight of infants with trisomy 18 is almost 1000 g less than that of controls. In contrast to the placental weight in infants with trisomies 13 and 21, the placental weight in infants with trisomy 18 also is markedly reduced.

Trisomy 13 occurs in 1 in 5000–10,000 live births. More than 50% of affected infants have IUGR. Birthweights average 700–800 g less than those of controls.

Other more rare autosomal chromosome abnormalities, such as ring chromosomes, deletions, and partial trisomies, are associated with an increased likelihood of IUGR. Sex chromosome abnormalities may be associated with lower birthweight. Extra X chromosomes (> 2) are associated with a 200-g to 300-g decrease in birthweight for each extra X. Turner's syndrome is associated with an average birthweight of approximately 400 g below average. Fetuses with mosaic Turner's syndrome are intermediately affected.

Growth impairment as a result of fetal chromosome abnormalities usually occurs earlier than impairment

caused by placental abnormalities. However, there is considerable clinical overlap, so gestational age at the time of diagnosis is not always of clinical value.

Fetuses with neural tube defects frequently are IUGR, weighing approximately 250 g less than controls. Anencephalic fetuses are IUGR, even considering the absent brain and skull, with average third-trimester birthweights of approximately 1000 g less than matched controls. Certain dysmorphic syndromes are associated with an increased incidence of IUGR fetuses. Achondroplasia may be associated with low birthweight if either parent is affected but usually is associated with normal birthweight if a spontaneous mutation is the cause. Osteogenesis imperfecta consists of a spectrum of diseases, all of which result in IUGR fetuses.

Infants born with abdominal wall defects are characteristically IUGR, particularly those with gastroschisis.

Other autosomal recessive syndromes associated with IUGR include Smith-Lemli-Opitz syndrome, Meckel's syndrome, Robert's syndrome, Donohue's syndrome, and Seckel's syndrome. These conditions are rare and are most likely to be diagnosed antepartum in families with a previously affected child. Infants with renal anomalies such as renal agenesis (Potter's syndrome) or complete urinary tract outflow obstruction often have IUGR.

Other congenital anomalies associated with an increased incidence of IUGR outcome are duodenal atresia and pancreatic agenesis.

Congenital Infections

Chronic intrauterine infection is responsible for 5–10% of IUGR pregnancies (Table 16–3). The most commonly identified pathogen is cytomegalovirus (CMV). Although CMV can be isolated from 0.5–2% of all newborns in the United States, clinically obvious infection at the time of birth affects only 0.2–2 in 1000 live births. Active fetoplacental infection is characterized by cytolysis, followed by secondary inflammation, fibrosis, and calcification. Only infants with clinically apparent infection at birth are likely to be IUGR. Signs of congenital infection are nonspecific but include central nervous system involvement (eg, microcephaly), chorioretinitis, intracranial (periventricular) calcifications, pneumonitis, hepatosplenomegaly, and thrombocytopenia.

Congenital rubella infection increases the risk of IUGR. Infection in the first trimester results in the most severely affected fetuses, primarily as a result of microvascular endothelial damage. Such infants are likely to have structural cardiovascular and central nervous system defects such as microcephaly, deafness, glaucoma, and cataracts.

Other viruses implicated in causing IUGR are herpesvirus, varicella-zoster virus, influenza virus, and poliovirus, but the number of such cases is small. As expected by virtue of their chronic, indolent nature, protozoan infections are associated with IUGR. The most common protozoan, *Toxoplasma gondii*, usually is acquired by ingestion of raw meat. Only women with a primary infection are at risk for having an affected infant. The average incidence is 1 in 1000 live births in the United States, but the incidence varies widely among locations and social populations. Approximately 20% of newborns with congenital toxoplasmosis will have IUGR. Malaria is another protozoan infection associated with IUGR.

Although bacterial infections occur commonly in pregnancy and frequently are implicated in premature delivery, they are not commonly associated with IUGR. Chronic infection from *Listeria monocytogenes* is an exception. Infants usually are critically ill at the time of delivery and often have encephalitis, pneumonitis, myocarditis, hepatosplenomegaly, jaundice, and petechiae.

Placental Factors

The placenta plays an important role in normal fetal growth. Placental weight has shown to be less in IUGR infants than in AGA infants irrespective of birthweight, suggesting that appropriate fetal growth may depend on the size or weight of the placenta. Several placental abnormalities are associated with an increased likelihood of an IUGR fetus. Placenta previa is associated with an increased incidence of IUGR, probably because of the unfavorable site of placental implantation. Complete placenta previa is associated with a higher incidence of IUGR than is partial placenta previa. Decreased functional exchange area as a result of placental infarction also is associated with an increased incidence of IUGR fetuses. Premature placental separation may occur at any time during pregnancy, with variable effects. When not associated with fetal death or premature labor, premature placental separation may increase the risk of IUGR. Malformations of the placenta or umbilical cord, such as single umbilical artery (UA), velamentous umbilical cord insertion, circumvallate placenta, placental hemangioma, battledore placenta, and twin-twin transfusion syndrome, also are associated with an increased risk of IUGR. Chronic villitis, chronic inflammation of placental villi, is seen with increased frequency when the placentas of IUGR pregnancies are examined histologically. Finally, uterine anomalies may result in impaired fetal growth, primarily because of the likelihood of suboptimal uterine blood flow.

Multiple Gestation

Multiple gestation has long been associated with premature delivery. However, it also is associated with a 20–30% increased incidence of IUGR fetuses, possibly as a result of placental insufficiency, twin-twin transfusion syndrome, or anomalies. Serial ultrasound estimates of fetal weights should be considered in a multiple gestation pregnancy.

MATERNAL FACTORS

Numerous maternal diseases are associated with suboptimal fetal growth. Any woman who has borne 1 IUGR infant is at increased risk for recurrence, with a 2-fold and 4-fold increased risk for IUGR birth after 1 or 2 IUGR births, respectively.

Hypertension

Hypertension is the most common maternal complication causing IUGR. Systemic hypertension results in decreased blood flow through the spiral arterioles and decreased delivery of oxygen and nutrients to the placenta and fetus. Hypertension may be associated with placental infarction.

Drugs

Both social drugs and prescribed medications can affect fetal growth. Alcohol use has long been known to be associated with impaired fetal growth. Virtually all infants with fetal alcohol syndrome exhibit signs of growth restriction.

Cigarette smoking is much more common among women of childbearing age in the United States than is alcoholism. Smoking causes one-third of IUGR cases and is the single most preventable cause of IUGR pregnancy in the United States today. Women who smoke have a 3-fold to 4-fold increase in IUGR infants. Birthweight is reduced by approximately 200 g, with the amount of growth restriction proportional to the number of cigarettes smoked per day. Women who quit smoking at 7 months' gestation have newborns with higher mean birthweights than do women who smoke throughout the entire pregnancy. Women who stop smoking before 16 weeks' gestation are not at increased risk for having an IUGR infant.

Heroin and cocaine addicts have an increased incidence of IUGR infants, but confounding variables make determination of a direct cause-and-effect relationship difficult. Methadone use has not been shown to be associated with an increased incidence of IUGR.

Pharmacologic agents have been associated with an increased incidence of IUGR, primarily as a result of

teratogenic effects. Warfarin has been associated with an increased incidence of IUGR fetuses, primarily as a result of the sequelae of intrauterine hemorrhage. Folic acid antagonists are associated with an increased risk of spontaneous abortion stillbirth, severe malformations, and IUGR infants.

IUGR fetuses are more common with maternally administered immunosuppressive drugs (eg, cyclosporine, azathioprine, corticosteroids), but when controlled for the underlying maternal disease, the medications per se probably have little effect on fetal growth.

Malnutrition and Malabsorption

Poor maternal weight gain is associated with an increased risk of having an IUGR infant. Studies of infants borne by women who were pregnant during the Siege of Leningrad during World War II showed that daily intake must be reduced to less than 1500 kcal/d before a measurable effect on birthweight becomes evident. Maternal malabsorption may predispose to IUGR pregnancy. The most common clinical situations are inflammatory bowel disease (ulcerative colitis or regional enteritis), pancreatitis, and intestinal parasites.

Vascular Disease

Diseases that affect maternal microvascular perfusion can be associated with IUGR. These include collagen vascular disease, insulin-dependent diabetes mellitus associated with microvasculopathy, and preeclampsia.

Maternal Features

A small woman may have a smaller-than-normal infant because of reduced uterine growth potential. These mothers and infants are completely normal and healthy, but they are small because of genetic variation. The infants are described by the ponderal index (PI), which is calculated using the following formula:

$$PI = \text{Birthweight} \times 1000 / (\text{crown-heel length})^3$$

Asymmetric IUGR infants will have a low ponderal index (ie, they will be long, lightweight infants), whereas small normal infants will have a normal ponderal index. (A normal index at 28 weeks is 1.8. This value increases by 0.2 every 4 weeks to reach 2.4 at 40 weeks.)

Maternal parity exerts a modest effect on birthweight. First-born infants tend to be smaller and more often categorized as IUGR. This effect decreases with successive deliveries and is not seen beyond the third birth.

Sex of Fetus

At term, female fetuses are an average 5% (150 g) smaller and 2% (1 cm) shorter than male fetuses. Referring to separate norms for male and female fetuses may increase the power of biometry in assessing IUGR.

Antenatal Diagnosis

In any pregnancy at risk for IUGR outcome, baseline studies should be obtained early in gestation. Careful attention should always be given to gestational dating (menstrual history, serial examinations, biochemical pregnancy testing, quickening, ultrasound). An IUGR outcome also may develop in pregnancies without identified risk factors. Careful attention to fundal height measurements is associated with a diagnostic sensitivity of 46–86%.

Ultrasound examination early in pregnancy is accurate in establishing the estimated date of confinement (EDC) and may sometimes identify genetic or congenital causes of IUGR pregnancy. Serial ultrasound examinations are important in documenting growth and excluding anomalies. Antenatal diagnosis of

IUGR is not precise given that EFW cannot be measured directly and must be calculated from a combination of directly measured parameters. Overall prediction of weight via birthweight formulas can have a 10–20% error rate. Selection of the most useful biometric parameter depends on the timing of measurements. The crown–rump length is the best parameter for early dating of pregnancy. The biparietal diameter (BPD) and HC are most accurate in the second trimester, with a margin of error of 7–11 days for BPD and 3–5 days for HC. Head circumference is more useful in establishing gestational age in the third trimester because BPD loses its accuracy secondary to variations in shape. Abdominal circumference measurements are less accurate than BPD, HC, and femur length but is the most useful measurement for evaluating fetal growth. The fetal abdominal circumference reflects the volume of fetal subcutaneous fat and the size of the liver, which in turn correlates with the degree of fetal nutrition. Acidemia and hypoxemia are more common when the abdominal circumference is below the 5th percentile for gestational age.

The femur length is not helpful for identifying IUGR but can identify skeletal dysplasia. Because the definition of IUGR ultimately depends on birthweight and gestational age criteria, formulas that optimally predict birthweight in a given population will be the most important contributor to ultrasonographic criteria.

Fetuses from different populations show different growth patterns. The growth curves developed by Battaglia and Lubchenco in the 1960s do not reflect the variation in birthweight for various ethnic populations. The growth curves used today also do not reflect the median birthweight increase over the last 3 decades. Racial and ethnic anthropometric variations may suggest a need for specific charts for different communities. Ultrasound evaluation should also be used to identify the development of oligohydramnios in fetuses at risk for, or diagnosed with, IUGR. Decreased amniotic fluid volume is clinically associated with IUGR and may be the earliest sign detected on ultrasound. This finding is thought to result from decreased perfusion of the fetal kidneys, which leads to decreased urine production. Oligohydramnios is present in the majority of IUGR infants, but the presence of a normal amniotic fluid index (AFI) should not preclude the diagnosis of IUGR.

In fetuses with known IUGR, UA Doppler velocimetry can estimate the likelihood of adverse perinatal outcome and may be useful in determining the intensity of fetal surveillance. Placental circulatory insufficiency is associated with increased placental resistance, which causes a fall in umbilical flow and therefore hypoxia. During the compensated stage, diastolic flow in the UA is reduced or absent. Retrograde diastolic flow in the UA is a sign that severe hypoxemia and acidemia are present. Although the use of UA Doppler studies for general population screening remains unproven, Doppler studies can be helpful in following already identified IUGR fetuses. Doppler flow studies help in reducing interventions and improving overall fetal outcome in IUGR pregnancies. A recent study showed that of fetuses with suspected IUGR evaluated by Doppler studies, none of those with normal Doppler flow measurements (UA systolic/diastolic [S/D] ratio) were delivered with metabolic acidemia. This finding suggests that intense antenatal surveillance may be unnecessary in a fetus with a normal UA S/D ratio and normal AFI.

Abnormal UA flow is associated with a higher risk for fetal growth restriction and an increased likelihood of requiring cesarean or operative delivery. In fetuses with suspected IUGR, abnormal middle cerebral artery (MCA) and UA S/D ratios are strongly associated with low gestational age at delivery, low birthweight, and low UA pH. Also, mean birthweight, interval to delivery, need for emergent delivery, and occurrence of fetal distress all are related to the severity of abnormal Doppler findings after correction for gestational age. Abnormal Doppler cerebroplacental ratio (MCA pulsatile index divided by UA pulsatile index) also has been associated with a statistically significant increase in perinatal morbidity and mortality. Respiratory distress syndrome and intracranial hemorrhage are not associated with abnormal

Doppler studies.

In addition to the UA and MCA, the descending aorta has altered perfusion in fetuses with growth restriction. The redistribution of systemic blood flow in order to maintain perfusion to the brain at the expense of abdominal organs is believed to result in increased vascular resistance in the perfusion area of the descending aorta and decreased vascular resistance in the cerebrum. An elevated pulsatility index of the descending aorta is associated with both IUGR and adverse outcomes, such as necrotizing enterocolitis, fetal distress, and perinatal mortality. Absent end-diastolic flow of the descending aorta is associated with a higher rate of cesarean delivery and perinatal mortality.

Elevated maternal serum α -fetoprotein (MSAFP) levels predict increased risk for IUGR outcome, regardless of maternal weight. Elevated MSAFP levels also predict an increased risk for other obstetric problems, including preeclampsia, placental abruption, preterm labor, and stillbirth.

In some centers, fetal blood sampling has been advocated for severe fetal growth restriction. Although this procedure can provide useful information on fetal karyotype, acid–base balance, fetal metabolism, and possible fetal infection, it is associated with much increased morbidity and mortality in the presence of IUGR. With advances in molecular diagnosis of amniotic fluid, most diagnostic information can be obtained rapidly by amniocentesis. If clinically indicated, studies should be performed to exclude infection. Initially this process usually involves determining maternal immune status (immunoglobulin [Ig] M antibodies against cytomegalovirus, rubella virus, and *T gondii*). If these levels are suggestive of recent infection, direct assessment of the amniotic fluid by polymerase chain reaction and culture may be required. A careful targeted ultrasound examination should be performed to determine the degree of fetal involvement, particularly of the central nervous system.

Complications

Numerous maternal and perinatal complications occur more frequently in IUGR pregnancy (Table 16–1). Underlying maternal disease is more likely to be present (Table 16–3), and these women require more intensive prenatal care. Premature labor or preeclampsia is more common. IUGR fetuses at any gestational age are less likely to tolerate labor well, and the need for operative delivery is increased.

Perinatal morbidity and mortality are significantly increased in low-birthweight infants, with an inverse relationship between neonatal weight and perinatal mortality. At any given gestational age, IUGR neonates have a higher mortality than do AGA neonates. However, at any given birthweight, outcomes are similar for IUGR and AGA neonates. Perinatal morbidity and mortality are especially increased in infants born at term with birthweights at or below the 3rd percentile. Increased risk of mortality is affected by the primary etiology of growth restriction and may be modified by the severity and progression of maternal factors (eg, hypertension control). With the advent of fetal surveillance, perinatal mortality rate has decreased to 2–3 times that of the AGA population. The past decade has witnessed increased attention to minimizing the perinatal complications of surviving IUGR neonates. With continued improvements in antenatal surveillance and neonatal care, the perinatal mortality rate for IUGR pregnancies in most centers now is 1.5–2 times that of the AGA population. Unfortunately, this rate likely will not reach that of the AGA population in the near future because of the persistent occurrence of lethal anomalies and severe congenital infections.

IUGR fetuses are at risk for in utero complications, including hypoxia and metabolic acidosis, which may occur at any time but are likely to occur during labor. Up to 50% of growth-restricted fetuses exhibit abnormal fetal heart rate patterns, most often variable decelerations. Hypoxia is the result of increasing fetal oxygen requirements during pregnancy, with a rapid increase during the third trimester. If the fetus receives inadequate oxygen, hypoxia and subsequent metabolic acidosis will ensue. If undetected or

untreated, this condition will lead to decreased glycogen and fat stores, ischemic end-organ damage, meconium-stained amniotic fluid, and oligohydramnios, eventually resulting in vital organ damage and intrauterine death.

IUGR infants are at increased risk for neonatal complications, including meconium aspiration syndrome, low Apgar scores, UA pH < 7.0, need for intubation in the delivery room, seizures, sepsis, polycythemia, hypoglycemia, hypocalcemia, temperature instability, apneic episodes, and neonatal death. All IUGR infants require a thorough evaluation for congenital anomalies.

Prevention

Because many causes of IUGR are nonpreventable, few interventions have proved effective for prevention. Interventions that have shown benefit include smoking cessation, antimalarial chemoprophylaxis, and balanced protein and energy supplementation. Smoking is the single most common preventable cause of IUGR in infants born in the United States. As discussed in Maternal Factors, women who quit smoking at 7 months' gestation have newborns with higher mean birthweights than do women who smoke throughout the pregnancy. Women who quit smoking before 16 weeks' gestation are not at any increased risk for an IUGR infant. Limited data suggest that balanced nutritional supplementation improves mean birthweight. As expected, such supplementation more likely will benefit those with poor nutrition or adolescent pregnancies. Pregnant women should avoid close contact with individuals known to be infected or colonized with rubella virus or cytomegalovirus. Nonpregnant women of reproductive age should be tested for immunity to rubella virus and, if susceptible, should be immunized. Currently no vaccine exists for cytomegalovirus.

Women of childbearing age should be tested for immunity to *T gondii* if this protozoan infection is clinically suspected. If the woman is immune, her risk of having an affected infant is remote. However, if she is susceptible, she should be cautioned to avoid cat feces and uncooked meat. If the screening IgM for toxoplasma is positive, no action should be taken based on this result without confirmation by a regional reference laboratory with expertise in toxoplasma testing.

Therapeutic medications are not a major cause of IUGR pregnancy, but benefits and risks should be weighed whenever medications are prescribed. Any woman of childbearing age should be questioned about the possibility of pregnancy before receiving therapeutic or diagnostic radiation to the pelvis.

Placental factors causing IUGR pregnancies are not generally preventable. It has been postulated that low-dose aspirin and dipyridamole may increase prostacyclin production in certain patients and thus prevent idiopathic uteroplacental insufficiency. The role of these agents in preventing IUGR resulting from placental insufficiency in at-risk populations is unclear at this time.

Preventive measures for the maternal diseases listed in Table 16–3 are beyond the scope of this chapter. Treatment of many of these conditions may decrease the likelihood of IUGR pregnancy. Treatment of hypertension has a positive effect on birthweight, at least in the third trimester. However, strict bed rest and hospitalization do not seem to have any beneficial effects for patients with a history of hypertension. Although a complex issue, protein supplements for patients with significant proteinuria may increase the amount of protein available for placental transfer. Correction of maternal anemia (of whatever cause) improves oxygen delivery to the fetus, thus improving fetal growth. However, routine supplements, such as with iron, have not been shown to be associated with any altered clinical outcomes.

Treatment of malabsorption syndrome (of whatever cause) can be expected to improve nutrient absorption and subsequent nutrient transfer to the fetus. Inflammatory bowel disease should be treated if required, but if possible, pregnancy should be deferred until the disease has been quiescent for approximately 6 months. Intestinal parasites should be appropriately treated and negative cultures

confirmed prior to pregnancy.

Treatment

Treatment of IUGR pregnancy presupposes an accurate diagnosis. Even with the history, physical examination, and ultrasound examination, diagnosis remains difficult, and some IUGR pregnancies will not be detected.

All pregnant women should discontinue cigarette smoking as well as use of alcohol and all recreational drugs. Cessation should be accomplished before conception to allow time for clearance of toxins, particularly if the woman previously had an IUGR infant. Although bed rest often is recommended, no evidence shows that bed rest results in improved outcome or increased fetal birthweight for fetuses with suspected IUGR. The increased uterine blood flow that occurs when the patient is in the lateral recumbent position theoretically may result in some benefit for fetuses with asymmetric IUGR. However, a paucity of data support this theory.

Because IUGR fetuses are at risk for antepartum or intrapartum compromise, they should be followed carefully. The best method for monitoring a fetus with suspected IUGR is not established. Because the diagnosis of IUGR most often is made relatively late in pregnancy, patients are seen every 1 to 2 weeks. In addition to fetal kick counts, antepartum testing with nonstress test and assessment of amniotic fluid volume are performed once or twice weekly in conjunction with UA Doppler velocimetry. The significance of abnormal UA Doppler results can be clarified by investigations of middle cerebral circulation and Doppler studies of venous structures, including the ductus venosus. If a nonstress test is nonreactive or if variable or spontaneous decelerations are seen, further assessment of fetal well-being is indicated with either a contraction stress test or a fetal biophysical profile. Because the contraction stress test is more cumbersome to perform and difficult to interpret, it has largely been replaced by the biophysical profile as a backup test.

Ultrasound examinations to assess adequacy of fetal growth should be performed at least every 3–4 weeks. Measurements should include BPD, HC, abdominal circumference, and femur length, especially in patients in whom an asymmetric IUGR fetus is suspected. Probably the most sensitive index of an asymmetric IUGR fetus is the abdominal circumference. The femur length/abdominal circumference ratio is a gestational age-independent ratio (normal 0.20–0.24). Asymmetric IUGR fetuses generally have a ratio > 0.24 .

In selected cases, amniocentesis may be indicated for determination of fetal pulmonary maturity with an uncertain EDC, for assessment of fetal karyotype, or for diagnosis of fetal infection.

Every IUGR pregnancy must be individually assessed for the optimal time of delivery (ie, the point at which the baby will do as well or better outside the uterus than inside). This would be whenever surveillance indicates fetal maturity, fetal compromise, or gestational age of 38 weeks (beyond which time there is no advantage to an IUGR fetus remaining in utero). Data are conflicting as to whether IUGR accelerates pulmonary maturity. Therefore, the current recommendation is to administer glucocorticoids to women likely to deliver before 34 weeks, as would be done with any other pregnancy.

IUGR pregnancies are at increased risk for intrapartum problems, so whenever possible delivery should take place in a center where appropriate obstetric care, anesthesia, and neonatal care are readily available. Cesarean delivery may be necessary, and the presence of meconium-stained amniotic fluid or a compromised infant should be anticipated.

The mode of delivery must be individualized. Cesarean section delivery is often indicated, especially when fetal monitoring reveals fetal compromise, malpresentation, or situations where traumatic vaginal

delivery might be expected.

Continuous electronic fetal heart rate monitoring should be performed during labor in all cases, even if recent antepartum testing has been reassuring. Arteriovenous cord blood gas determinations also are useful; as many as 50% of IUGR infants have some degree of metabolic acidosis. Minimization of anesthesia is generally preferable, but controlled epidural anesthesia usually is safe. Maternal hypotension or hypovolemia must be avoided.

Prognosis

IUGR pregnancy per se is not considered life-threatening for the mother. However, increased maternal morbidity and mortality may result from an underlying condition (eg, hypertension or renal disease). Most women who deliver IUGR infants can be expected to have long-term prognoses equivalent to those of women delivering AGA infants. Infants with a low birthweight have a relatively high morbidity and mortality. Studies have shown that the rate of neonatal death, Apgar score at 5 minutes < 3, UA pH < 7.0, seizures during the first day of life, and incidence of intubation are significantly increased when the fetus is at or below the 3rd percentile for birthweight.

As for long term-prognosis, reports of national survey data show that IUGR infants appear to catch up in weight in the first 6 months of life. However, IUGR infants tend to remain physically small and are shorter, lighter, and have smaller HCs than do AGA infants.

Taken as a group, IUGR infants have more neurologic and intellectual deficits than do their AGA peers. IUGR infants have lower IQs as well as a higher incidence of learning and behavioral problems. Major neurologic handicaps, such as severe mental retardation, cerebral palsy, and seizures, are more common in IUGR infants. The incidence of sudden infant death syndrome (SIDS) is increased in IUGR infants, who account for 30% of all SIDS cases. Adults who were IUGR at birth are at higher risk for developing ischemic heart disease and related disorders, including hypertension, stroke, diabetes, and hypercholesterolemia.

LARGE-FOR-GESTATIONAL-AGE PREGNANCY

Terminology

Although LGA pregnancy is defined according to the same concept as IUGR pregnancy (LGA = heaviest 10% of newborns), LGA pregnancy has received substantially less attention. *Large for gestational age* is defined as above the 90th percentile of weight for any specific gestational age. Macrosomia generally refers to fetuses with an EFW of at least 4500 g. The risk of morbidity is greater for infants born weighing between 4000 and 4500 g compared to the average population. However, the risk of infant morbidity is substantially increased at birthweights greater than 4500 g. Although there are numerous reports and studies regarding macrosomia, few data regarding large for gestational age as defined here are available. Therefore, this section concentrates on fetal macrosomia, with additional comments regarding LGA pregnancies.

Pathophysiology

Numerous endocrinologic changes occur during pregnancy to ensure an adequate fetal glucose supply. In the second half of pregnancy, increased concentrations of human placental lactogen, free and total cortisol, and prolactin combine to produce modest maternal insulin resistance, which is countered by postprandial hyperinsulinemia. In those who are unable to mount this hyperinsulinemic response, relative hyperglycemia may develop (ie, gestational diabetes). Because glucose crosses the placenta by facilitated diffusion, fetal hyperglycemia ensues. This in turn produces fetal hyperinsulinemia with resultant intracellular transfer of glucose, leading to fetal macrosomia.

Differential Diagnosis

Factors that predispose to LGA pregnancy are listed in Table 16–4. As with IUGR pregnancy, diagnosis of LGA pregnancy depends on knowing with certainty the gestational age of the fetus.

Table 16–4. Factors That May Predispose to Fetal Macrosomia or LGA Pregnancy.

Maternal factors

Diabetes (gestational, chemical, or insulin-dependent), obesity, postdatism, multiparity, advanced age, previous LGA infant, large stature

Fetal Factors

Genetic or congenital disorders, male gender

MATERNAL DIABETES

Maternal diabetes, whether gestational, chemical, or insulin dependent, is the condition classically associated with fetal macrosomia. The "Pedersen hypothesis" was long assumed to account for fetal macrosomia, that is, the condition was the result of inadequate management of diabetes during pregnancy. Initial reports suggested that careful control of blood glucose level in insulin-dependent diabetic women would prevent fetal macrosomia, but recent studies have suggested that the problem is not so simple and that the incidence may correlate better with cord blood concentrations of maternally acquired anti-insulin IgG antibodies and/or increased serum levels of free fatty acids, triglycerides, and the amino acids alanine, serine, and isoleucine. Cord serum epidermal growth factor concentrations also have been found to be higher than normal in pregnancies complicated by prepregnancy diabetes and gestational diabetes.

A significant correlation exists between plasma leptin levels and neonatal birthweight, which suggests that leptin levels are directly related to the quantity of body fat tissue in fetal macrosomia.

MATERNAL OBESITY

Maternal obesity is associated with a 3- to 4-fold increased likelihood of fetal macrosomia. This situation may result in part from associated gestational or chemical diabetes, although these disorders are not present in most obese women who deliver macrosomic babies. One study showed a significantly higher rate of cesarean delivery for obese mothers, even after comorbidities such as diabetes were excluded.

POSTDATISM

Prolonged pregnancy is more likely to result in a macrosomic fetus, presumably because of continued delivery of nutrients and oxygen to the fetus. Placental sulfatase deficiency or congenital adrenal hypoplasia are rare causes of postdatism.

GENETIC AND CONGENITAL DISORDERS

Several genetic and congenital syndromes are associated with an increased incidence of macrosomia. Beckwith-Wiedemann syndrome is frequently associated with fetal macrosomia, usually because of pancreatic islet cell hyperplasia (nesidioblastosis). Affected infants usually have hypoglycemia, macroglossia, and omphalocele. They also may have intestinal malrotation or visceromegaly. Although usually a sporadic event, other inheritance patterns have been suggested in a few families. Other rare syndromes include Weaver's syndrome, Sotos' syndrome, Nevo's syndrome, Ruvalcaba-Myhre syndrome, and Marshall's syndrome. Carpenter's syndrome and the fragile X syndrome may be associated with an increased incidence of LGA infants.

CONSTITUTIONALLY LARGE FETUS

Fetuses who are suspected of being large for gestational age may simply be large secondary to constitutional factors. Large maternal stature should be considered as contributing to macrosomia because birthweight tends to correlate more closely with maternal height than maternal weight. Male gender fetuses are more likely to be considered LGA because male fetuses are an average of 150 g heavier than appropriately matched female fetuses at each gestational week during late pregnancy. Series addressing fetal macrosomia generally report an increased incidence of male fetuses, usually approximately 60–65%. One recent study showed that male fetuses were twice as likely to be diagnosed with macrosomia as compared with female fetuses.

Complications

Macrosomic pregnancies are at increased risk for many complications (Table 16–2). Macrosomic pregnancies are more likely to require cesarean delivery, usually because of failure to progress. In particular, primigravidas delivering a macrosomic infant are at increased risk for complications such as prolonged labor, postpartum hemorrhage, operative vaginal delivery, and emergency cesarean section as compared to delivering a normal weight infant. Primigravidas also have a higher risk of prolonged labor, operative delivery, and emergency cesarean sections compared with multiparous women delivering a macrosomic infant. Fetal distress, as determined by electronic fetal monitoring, is not more common in macrosomic pregnancies.

Shoulder dystocia occurs in 5–24% of vaginally delivered macrosomic fetuses. The incidence of shoulder dystocia correlates not only with progressive fetal weight but also with increasing chest circumference to HC. Shoulder dystocia of macrosomic infants also is related to maternal stature, but the association is not as clear. From 10–15% of infants with shoulder dystocia experience brachial plexus injury; facial nerve injury and fractures of the humerus or clavicle also may be seen. The risk of brachial plexus injury in macrosomic infants delivered vaginally is 0.3–4%. Brachial plexus injury with shoulder dystocia is approximately 7% in infants whose birthweights exceed 4000 g but is 14% for mothers with gestational diabetes. The doubled risk may be secondary to increased abdominal obesity in diabetic mothers. In diabetic patients, a correlation exists between the level of fetal truncal asymmetry (abdominal circumference/biparietal diameter ratio) as measured by ultrasound and the incidence and severity of shoulder dystocia. In addition to macrosomia, risk factors for shoulder dystocia include previous shoulder dystocia and maternal diabetes (3- to 4-fold increase compared to nondiabetic mothers). Lesser risk factors that are mediated through fetal size include previous delivery of a large fetus and excessive maternal weight gain during pregnancy. The risk of shoulder dystocia is similar in primigravidas and multigravidas delivering macrosomic infants. Perineal trauma is more likely with a macrosomic pregnancy and is related to an increased incidence of shoulder dystocia and operative vaginal delivery. Vaginal delivery of a macrosomic infant increases by 5-fold the risk of third- or fourth-degree laceration.

Although gestational diabetes and postdatism predispose to fetal macrosomia, no evidence indicates that fetal macrosomia or an LGA fetus predisposes to gestational diabetes or postdatism.

The incidence of stillbirth remains higher in macrosomic fetuses than in controls of average weight. This problem has persisted even with the availability of fetal monitoring and presumably reflects the increased incidence of maternal diabetes and postdatism. Stillbirths are known to be increased in nonanomalous diabetic mothers, but the cause is not understood. Additionally, excessive prepregnancy weight is an independent risk factor for unexplained death. In fact, large for gestational age is statistically associated with unexplained fetal death even after controlling for maternal age, diabetes, and hypertension.

Many of the neonatal complications of fetal macrosomia are the result of underlying maternal diabetes or

birth trauma and include low Apgar scores, hypoglycemia, hypocalcemia, polycythemia, jaundice, and feeding difficulties. Large-for-gestational-age infants have significantly higher absolute nucleated red blood cell counts, lymphocyte counts, and packed cell volumes. These hematologic abnormalities are the same for all LGA infants regardless of whether they are infants of nondiabetic mothers, insulin-dependent diabetic mothers, or non-insulin-dependent gestational diabetics. This situation is believed to reflect a compensatory increase in erythropoiesis as a result of chronic intrauterine hypoxia resulting from increased placental oxygen consumption and decreased fetal oxygen delivery.

LGA infants of diabetic mothers have an increased incidence of cardiac septal hypertrophy.

Prevention

Prevention of macrosomia and ensuing complications requires early detection of risk factors. Risk factors for having a macrosomic infant include multiparity, advanced maternal age, and previous delivery of a macrosomic infant. When controlled for gestational age and fetal gender, the average birthweight with successive pregnancies increases by 80–120 g up to the fifth pregnancy. Multiparity is also associated with other risk factors (eg, obesity, diabetes) and therefore may be a confounding variable. Advanced maternal age also contributes to increased birthweight. However, as with multiparity, it is also associated with obesity and diabetes.

Patients with the risk factors noted in Table 16–4 should be evaluated for possible fetal macrosomia with an ultrasound estimate of fetal size and weight. EFW by ultrasound is not very accurate. More than 30 different formulas for EFW calculation have been proposed, attesting to the inadequacy of each individual method. No single formula has been consistently better than the others. Even in skillful hands, the error of fetal weight estimates by ultrasound is 10–20%. One review of ultrasonographic diagnosis of macrosomia shows sensitivity ranging from 24–88% and specificity from 60–98%. The margin of error in estimating fetal weight means that the EFW by ultrasound must be at least 4750 g in order to predict a birthweight of 4000 g with a confidence interval of 90%. The best single measurement in evaluating macrosomia in diabetic mothers is abdominal circumference. An initial abdominal circumference above the 70th percentile is significantly associated with subsequent delivery of an LGA infant. Fetal body composition and fetal shoulder width cannot be accurately assessed by ultrasound.

Adequate control of maternal glucose levels is thought to prevent the development of macrosomia in gestational diabetics, although neonatal complications despite excellent metabolic control have been reported. Prepregnancy weight and degree of weight gain are strong indicators for macrosomia regardless of glycemic control. However, the rates of macrosomia and complications are reduced overall when postprandial levels are monitored. Studies have shown that the risk of macrosomia is reduced to near normal in diabetic women who monitor 1-hour postprandial glucose levels and that 1-hour postprandial glucose levels are directly related to fetal abdominal circumference values. One study showed that when postprandial glucose levels were kept below 104 mg/dL, macrosomia rates of diabetic women were similar to those of nondiabetics. Furthermore, high carbohydrate intake is associated with a decreased incidence of newborn macrosomia. Essential management principles in known diabetics includes nutrition and exercise counseling beginning in the preconception period. Furthermore, euglycemia is crucial in the first trimester, a period when insulin requirements are frequently less than prepregnancy, and intake can be altered by nausea and vomiting. Insulin adjustments are frequently necessary.

Infants of women who participate in regular aerobic exercise programs have lower average birthweights compared with infants in the general population but no demonstrable adverse effects. To date, no studies have evaluated the potential efficacy of exercise programs as a means of decreasing birthweight in women at risk for LGA pregnancy.

Treatment

Although widely recommended, labor induction in at-risk pregnancy for reducing the incidence of fetal macrosomia and intrapartum complications remains an unproven hypothesis. Intrapartum treatment considerations center on the increased likelihood of traumatic vaginal delivery.

Several published reviews of fetal macrosomia suggest routine cesarean delivery for fetuses with estimated weights of 5000 g or more (or estimated weights \geq 4500 g in diabetic pregnancies). This suggestion is based in part on the data given in Table 16–2 and in part on anthropometric studies suggesting that very macrosomic fetuses have bisacromial circumferences in excess of HCs. Because of current limitations in the sensitivity and specificity of ultrasound-derived fetal weight calculations, decisions regarding scheduled abdominal delivery must be partially based on clinical grounds. Such considerations are particularly warranted in women who are obese or are diabetic or in postdate pregnancies. Maternal age and maternal preference also should be considered when deciding on delivery method. Vacuum-assisted vaginal delivery increases the risk of shoulder dystocia. If the estimate of fetal weight is greater than 4000 g, the vacuum should be avoided if the second stage is prolonged, and in general the vacuum should be used with caution. Some physicians have adopted the practice of discussing the option of vaginal delivery versus cesarean delivery if the EFW is greater than 4500 g in nondiabetic women or greater than 4000–4250 g in diabetic women. No firm data indicate that this practice offers greater benefit in preventing complications such as shoulder dystocia than risks associated with many unnecessary cesarean births. Because of these factors, women at risk for macrosomic or LGA babies should deliver in facilities where adequate obstetric care, pediatric care, and anesthesia are available. Large-bore intravenous access must be established, and blood must be available. Delivery should occur in a setting where immediate operation can be accomplished. In many situations, delivery should occur in a delivery room.

Prognosis

Any woman who delivers an LGA baby should be informed that the risk of her having another LGA baby is increased by 2.5- to 4-fold. Such women should be screened for previously undiagnosed chemical or insulin-dependent diabetes and, even if screening is negative, should be followed carefully in any subsequent pregnancy to rule out gestational diabetes.

Obese women should be strongly encouraged to lose weight prior to becoming pregnant. Any woman who has delivered an LGA infant should be encouraged to seek early care for any subsequent pregnancy, if for no other reason than early confirmation of the EDC, which can minimize the likelihood of subsequent postdatism. Women who deliver an LGA infant with an underlying genetic or congenital disorder should receive genetic counseling regarding recurrence risks and the feasibility of antepartum diagnosis.

In addition to the many neonatal complications previously noted, infants of mothers with gestational or chemical diabetes are at increased risk for subsequent obesity, type 2 diabetes, or both. Infants who suffer from neonatal complications are at increased risk for subsequent neurologic or behavioral problems.

FUTURE DIAGNOSIS OF IUGR & LGA PREGNANCIES

Although much more is known about the risks of IUGR than of LGA pregnancy, both are known to be associated with increased risks of in utero, intrapartum, neonatal, and long-term compromise. The ability to diagnose and optimally manage these pregnancies remains poor. Further effort must be directed toward precise diagnosis at a point in the pregnancy when intervention can still be effective.

Current OB/GYN >Chapter 17. Multiple Pregnancy>

Multiple Pregnancy: Introduction

Monozygotic twins ("identical twins") result from the division of a single fertilized ovum. Monozygotic twinning occurs in approximately 2.3–4 of 1000 pregnancies in all races. The rate is remarkably constant and is not influenced by heredity, mother's age, or other factors. Dizygotic twins ("fraternal twins") are produced from separately fertilized ova. Slightly more than 30% of twins are monozygotic; nearly 70% are dizygotic. Although monozygosity is random (ie, it does not fit any discernible genetic pattern), dizygosity has hereditary determinants.

In North America, spontaneous dizygotic twinning occurs in approximately 1 in 83 conceptions and triplets in approximately 1 in 8000 conceptions. A traditional approximation of the incidence of multiple pregnancies is as follows:

Twins

1:80

Triplets

$1:80^2 = 1:6400$

Quadruplets (etc.)

$1:80^3 = 1:512,000$

The incidence of twin and higher-order multiple gestations has increased significantly over the past 15 years primarily because of the availability and increased use of ovulation-inducing drugs and assisted reproductive technology (ART). Multiple gestations now compose 3% of all pregnancies, and twins compose 25–30% of deliveries resulting from ART. Significant maternal and neonatal effects result from this increase in multiple births. The financial costs are staggering, with combined costs of ART plus pregnancy care and delivery averaging \$39,249.

Maternal morbidity and mortality rates are much higher in multiple pregnancy than in singleton pregnancy because of preterm labor, hemorrhage, and pregnancy-induced hypertension. Approximately two-thirds of twin pregnancies end in a single birth; the other embryo is lost from bleeding, is absorbed within the first 10 weeks of pregnancy, or becomes mummified (fetus papyraceous). Moreover, the perinatal mortality rate of twins is 3–4 times higher—and for triplets much higher still—than in singleton pregnancies as a result of chromosomal abnormalities, prematurity, anomalies, hypoxia, and trauma. This is particularly true of monozygotic twins.

Pathogenesis

MONOZYGOTIC MULTIPLE GESTATION

Monozygotic twins, which result from the fertilization of a single ovum by a single sperm, are always of the same sex. However, the twins may develop differently depending on the time of preimplantation division. Normally, monozygotic twins share the same physical characteristics (skin, hair and eye color, body build) and

the same genetic features (blood characteristics: ABO, M, N, haptoglobin, serum group; histocompatible genes; skin grafting possible), and they are often mirror images of one another (one left-handed, the other right-handed, etc.). However, their fingerprints differ.

The paradox of "identical" twins is that they may be the antithesis of identical. The very earliest splits are sometimes accompanied by a simultaneous chromosomal error, resulting in heterokaryotypic monozygotes, 1 with Down syndrome and the other normal.

Monozygotic triplets result from repeated twinning (also called *supertwinning*) of a single ovum. Trizygotic triplets develop by individual fertilization of 3 simultaneously expelled ova. Triplets also may be produced by the twinning of 2 ova and the elimination of 1 of the 4 resulting embryos. Similarly, quadruplets may be monozygotic, paired dizygotic, or quadrizygotic (ie, they may arise from 1–4 ova).

DIZYGOTIC MULTIPLE GESTATION

Dizygotic twins are the product of 2 ova and 2 sperm. The 2 ova are released from separate follicles (or, very rarely, from the same follicle) at approximately the same time. Dizygotic (fraternal) twins may be of the same or different sexes. They bear only the resemblance of brothers or sisters and may or may not have the same blood type. Significant differences usually can be identified over time.

Approximately 75% of dizygotic twins are the same sex. Both twins are males in approximately 45% of cases (a lesser preponderance of males in twins than in singletons) and both females in approximately 30%.

Many factors influence dizygotic twinning. Race is a factor, with multiple pregnancy most common in blacks, least common in Asians, and of intermediate occurrence in whites. The incidence of spontaneous dizygotic twinning varies from 1.3 in 1000 in Japan to 49 in 1000 in western Nigeria. The rate in the United States is approximately 12 in 1000.

Dizygotic multiple pregnancy tends to be recurrent. Women who have borne dizygotic twins have a 10-fold increased chance of subsequent multiple pregnancy. Dizygotic twinning probably is inherited via the female descendants of mothers of twins; the father's genetic contribution plays little or no part. White women who are dizygotic twins or who are siblings of dizygotic twin mothers have a higher twinning rate among their offspring than do women in the general population.

Parity does not influence the incidence of dizygotic twinning but aging does, with the rate of dizygotic twinning peaking between 35 and 40 years of age and then declining sharply. In women who are twins or daughters of twins, the twinning rate peaks at approximately age 35 years, at which time it plateaus until almost age 45 years and then declines. Black women, whether or not they are twins or siblings of twins, have a prolonged period of dizygotic twinning from 35–45 years of age.

Women of increased height and weight have a higher incidence of twinning, but the rate does not vary among social classes. Blood groups O and A are more prevalent in white mothers of twins than in the general population, for unknown reasons.

High fertility (polyovulation) is associated with multiple pregnancy. Excessive production of pituitary gonadotropins, relatively high frequency of coitus, and inability of 1 graafian follicle to inhibit others have been postulated as reasons for a higher incidence of dizygotic twinning. Undernutrition appears to be a negative factor. Women who conceive late in an ovulatory cycle have a greater chance of multiple pregnancy, perhaps because of ovular "overripeness."

Dizygotic twinning is more common among women who become pregnant soon after cessation of long-term oral contraception. This may be a reflection of high "rebound" gonadotropin secretion. Induction of ovulation in previously infertile patients has resulted in many multiple pregnancies—even the gestation of septuplets and octuplets. The estrogen analogue clomiphene citrate increases the incidence of dizygotic pregnancy to

approximately 5–10%.

Clinically zygosity cannot be ascertained prenatally, so chorionicity seen on ultrasound is a useful marker.

OTHER FORMS OF MULTIPLE GESTATION

Other kinds of twinning are theoretically possible in humans. Dispermic mosaicism may result from fertilization of 2 ova that were not independently released but have instead developed from the same oocyte. Another possibility is the fertilization of 1 ovum by 2 sperms. Twinning of discordant twins may be explained by meiotic abnormalities, including polar body twinning, delayed implantation of the embryo, retarded or arrested intrauterine development, or superfetation.

Superfecundation is the fertilization of 2 ova, released at approximately the same time, by sperm released at intercourse on 2 different occasions. The rare cases in which the fetuses are of disparate size or skin color and have blood groups corresponding to those of the mother's 2 male partners lend credence to (but do not conclusively validate) this possibility.

Superfetation is the fertilization of 2 ova released in different menstrual cycles. This is virtually impossible in humans because the initial corpus luteum of pregnancy would have to be suppressed to allow for a second ovulation approximately 1 month later.

Pathologic Factors Associated with Twinning

Although the blood volume is increased in multiple pregnancy, maternal anemia often develops because of greater demand for iron by the fetuses. However, prior anemia, poor diet, and malabsorption may precede or compound iron deficiency during multiple pregnancy. Respiratory tidal volume is increased, but the woman pregnant with twins often is "breathless" (possibly because of increased progesterone levels).

Marked uterine distention and increased pressure on the adjacent viscera and pelvic vasculature are typical of multiple pregnancy. Lutein cysts and even ascites are the result of abnormally high levels of chorionic gonadotropin in occasional multiple pregnancies. Placenta previa develops more frequently because of the large size of the placenta or placentas.

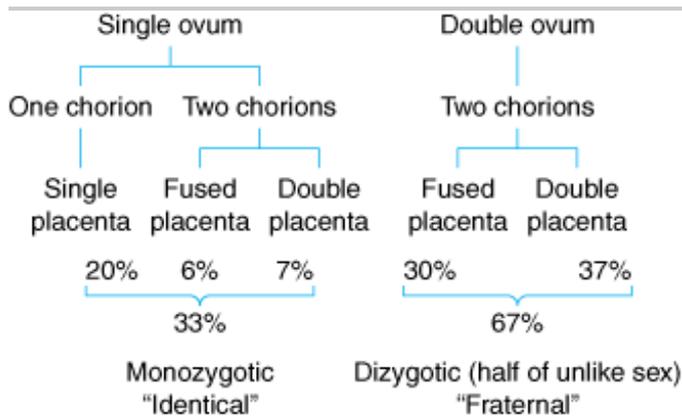

The maternal cardiovascular, respiratory, gastrointestinal, renal, and musculoskeletal systems are especially subject to stress in multiple pregnancy, combined with greater maternal–fetal nutritional requirements. Multiple pregnancy is classified as high risk because of the increased incidence of maternal anemia, urinary tract infection, preeclampsia–eclampsia, hemorrhage (before, during, and after delivery), and uterine atony.

PLACENTAL AND CORD

The placenta and membranes of monozygotic twins may vary considerably (Fig 17–1), depending on the time of initial division of the embryonic disk. Variations are noted here.

1. Division prior to the morula stage and differentiation of the trophoblast (day 3) results in separate or fused placentas, 2 chorions, and 2 amnions. (This process grossly resembles dizygotic twinning and accounts for almost one-third of monozygotic twinning.) This is clinically relevant as dichorionic twins have a much lower rate of complications.
2. Division after differentiation of the trophoblast but before formation of the amnion (days 4–8) yields a single placenta, a common chorion, and 2 amnions. (This accounts for about two-thirds of monozygotic twinning.)
3. Division after differentiation of the amnion (days 8–13) results in a single placenta, 1 (common) chorion, and 1 (common) amnion. This is rare.
4. Division later than day 15 may result in incomplete twinning. Just prior to that time (days 13–15), division may result in conjoined twins.

At delivery, the membranous T-shaped septum or dividing membrane of the placenta between the twins must be inspected and sectioned for evidence of the probable type of twinning (Fig 17–2). Monozygotic twins most commonly have a transparent (< 2 mm) septum made up of 2 amniotic membranes only (no chorion and no decidua). Dizygotic twins almost always have an opaque (thick) septum made up of 2 chorions, 2 amnions, and intervening decidua.

Amniotic membranes of twins.

(Reproduced, with permission, from Benson RC: *Handbook of Obstetrics & Gynecology*, 8th ed. Lange, 1983.)

A monozygotic placenta can be identified by stripping away the amnion or amnions to reveal a single chorion over a common placenta. In virtually every case of monozygotic placenta, vascular communications between the 2 parts of the placenta can be identified by careful dissection or injection. In contrast, dizygotic placentas (of dizygotic twinning) only rarely have an anastomosis between the fetal blood vessels.

Placental and membrane examination is a certain indicator of zygosity in twins with monozygotic placentas

because these are always monozygotic. Overall, approximately 1% of twins are monoamniotic, and these too are monozygotic. Determination of zygosity is clinically significant in case intertwin organ transplantation is needed later in life, as well as for assessing obstetric risks. Monozygotic twins can rarely be discordant for phenotypic sex when 1 twin is phenotypically female as a result of Turner's syndrome (45,XO) and its sibling is male (46,XY).

Monochorionic placentation is associated with more disease processes as a result of placental vascular problems. Inequities of the placental circulation in 1 area (marginal insertion, partial infarction, or thinning) may lead to growth discordance between the twins. Because of vascular anastomoses in monochorionic placentation, multifetal reduction can only be performed with dichorionic placentation.

The most serious problem with monochorionic placentas is local shunting of blood—also called twin-twin transfusion syndrome. This occurs because of vascular anastomoses to each twin that are established early in embryonic life. The possible communications are artery to artery, vein to vein, and combinations of these. Artery-to-vein communication is by far the most serious; it is most likely to cause twin-twin transfusion. In uncompensated cases, the twins, although genetically identical, differ greatly in size and appearance. The recipient twin is plethoric, edematous, and hypertensive. Ascites and kernicterus are likely. The heart, liver, and kidneys are enlarged (glomerulotubular hypertrophy). Hydramnios follows fetal polyuria. Although ruddy and apparently healthy, the recipient twin with hypervolemia may die of heart failure during the first 24 hours after birth. The donor twin is small, pallid, and dehydrated (from growth restriction, malnutrition, and hypovolemia). Oligohydramnios may be present. Severe anemia, due to chronic blood loss to the other twin, may lead to hydrops and heart failure.

Various modes of treatment have been advocated for twin transfusion syndrome, including amnioreduction, amniotic septotomy, and laser ablation of communicating vessels. In a recent randomized trial, laser ablation has been shown to be the superior treatment, although access to the procedure is limited because experience with the technique is not broadly available.

Both twins are threatened by prolapse of the cord. The second twin may be harmed by premature separation of the placenta, hypoxia, constriction ring dystocia, operative manipulation, or prolonged anesthesia.

Velamentous insertion of the cord occurs in approximately 7% of twins but in only 1% of singletons. There is a corresponding increase in the potentially catastrophic vasa previa. The incidence of 2-vessel cord (single umbilical artery) is 4–5 times higher in monozygotic twins than in singletons.

Monochorionic, monoamniotic twins (1:100 sets of twins) have a < 90% likelihood of both surviving because of cord entanglement that compromises fetoplacental blood flow. Some authors advocate planned cesarean delivery at 32–34 weeks in an attempt to prevent in utero demise due to cord accidents, as well as continuous external fetal monitoring from approximately 27 weeks until delivery.

FETAL

Earlier and more precise sonography has revealed the incidence of multiple gestation is 3.29–5.39% before 12 weeks. However, in > 20% of such cases, 1 or more of the pregnancies spontaneously disappears ("vanishing twin"). Although this event may be associated with vaginal bleeding, the prognosis remains good for the remaining twin.

Major malformations are present in approximately 2% of twin infants, compared with 1% of singletons, whereas minor malformations are found in 4% of twins compared with approximately 2.5% in singletons. Monozygotic twins are at higher risk than dizygotic twins.

Conjoined or Siamese twins result from incomplete segmentation of a single fertilized ovum between the 13th and 14th days; if cleavage is further postponed, incomplete twinning (2 heads, 1 body) may occur. Lesser

abnormalities are also noted, but they occur without regard to specific organ systems. Conjoined twins are described by site of union: pygopagus (at the sacrum), thoracopagus (at the chest), craniopagus (at the heads), and omphalopagus (at the abdominal wall). Curiously, conjoined twins usually are female. Numerous conjoined twins have survived separation.

Each twin and its placenta generally weigh less than the newborn and placenta of a singleton pregnancy after the 30th week, but near term the aggregate weight may approach twice that of a singleton. In general, the larger the number of fetuses, the greater the degree of growth restriction. Interestingly, multifetal reduction of triplets to twins before 12 weeks results in a growth pattern typical of twins rather than triplets, who are growth restricted compared with twins. Thus the number of fetuses residing in the uterus later in pregnancy, and not their embryonic potential, seems to govern growth. Normal-weight twins that differ considerably in birthweight commonly have diamniotic-dichorionic placentas. This suggests independent intrauterine growth of co-twins. The converse is true of twins with fused diamniotic-dichorionic placentas. Low-birth-weight monochorionic twins are the rule rather than the exception. Low birthweight in the various types of multiple pregnancy probably is evidence of growth restriction due to inadequate nutrition. This is at least partially responsible for the much higher early neonatal mortality rate of newborns from multiple births.

Prematurity is the major reason for the increased risk of neonatal death and morbidity in twins. Growth restriction, competition for nutrition, cord compression and entanglement, and operative delivery also are responsible for a significant part of the perinatal mortality rate in multiple pregnancy.

In growth-restricted human fetuses, the brain and heart seem to be relatively less affected than the liver or peripheral musculature. Because placental growth and function are limited, hormone alterations may develop to trigger early labor. Moreover, restricted fetal growth has a small but lasting effect on postnatal physical development.

In late pregnancy, the fetus is jeopardized by the frequency of premature delivery, abnormal presentation and position, and hydramnios.

A fetus acardiacus is a parasitic monozygotic fetus without a heart. It is thought to develop from reversed circulation, perfused by 1 arterial-arterial and 1 venous-venous anastomosis. This represents twin reversed arterial perfusion (TRAP) syndrome. The otherwise normal donor twin is at risk for cardiac hypertrophy and failure and has a 35% mortality. Various methods of cord occlusion can be accomplished by in utero therapy.

Fetus papyraceus is a small, blighted, mummified fetus usually discovered at the delivery of a well-developed newborn. This occurs in 1 in 17,000–20,000 pregnancies. The cause is thought to be death of 1 twin, amniotic fluid loss, or reabsorption and compression of the dead fetus by the surviving twin.

Clinical Findings

With the ready availability of ultrasound, twin gestations are not commonly undiagnosed before labor and delivery. Early diagnosis facilitates appropriate prenatal care.

SYMPTOMS AND SIGNS

All of the common annoyances of pregnancy are more troublesome in multiple pregnancy. The effects of multiple pregnancy on the patient include earlier and more severe pressure in the pelvis, nausea, backache, varicosities, constipation, hemorrhoids, abdominal distention, and difficulty in breathing. A "large pregnancy" may be indicative of twinning (distended uterus). Fetal activity is greater and more persistent in twinning than in singleton pregnancy.

Considering the possibility of multiple pregnancy is essential to early diagnosis. In most clinical settings, the diagnosis of twins is made by routine ultrasound examination. If routine ultrasound is not performed, the following signs should alert the physician to the possibility or definite presence of multiple pregnancy:

1. Uterus larger than expected (> 4 cm) for dates.
2. Excessive maternal weight gain that is not explained by edema or obesity.
3. Polyhydramnios, manifested by uterine size out of proportion to the calculated duration of gestation, is almost 10 times more common in multiple pregnancy.
4. Outline or ballottement of more than 1 fetus.
5. Multiplicity of small parts.
6. Simultaneous recording of different fetal heart rates, each asynchronous with the mother's pulse and with each other and varying by at least 8 bpm. (The fetal heart rate may be accelerated by pressure or displacement.)

Some of the common complications in early pregnancy may also occur as a result of multiple gestation. For example, maternal bleeding in the first trimester can indicate threatened or spontaneous abortion; however, the dead fetus may be 1 of twins, as demonstrated by real-time ultrasonography (1 anechoic or hypoechoic amniotic sac and 1 normal sac). In the second and third trimesters, the demise of 1 fetus in a multiple gestation may trigger disseminated intravascular coagulation ("dead fetus syndrome"), just as a singleton intrauterine demise might. This complication is very rarely seen and generally becomes a problem only 3 weeks or more after fetal demise.

LABORATORY FINDINGS

The majority of multiple pregnancies are currently identified by ultrasound or by maternal serum screening. Indeed, identification of multiple gestation is so important for the institution of appropriate care that many authorities recommend routine ultrasonic scanning at 18–20 weeks. First-trimester ultrasonography is even more helpful for determining chorionicity.

The hematocrit and hemoglobin values and the red cell count usually are considerably reduced, in direct relationship to the increased blood volume. Indeed, maternal hypochromic normocytic anemia occurs so frequently in multiple pregnancy that it has been suggested that all patients with the process be suspected of having a multiple gestation. Fetal demand for iron increases beyond the mother's ability to assimilate iron in the second trimester.

Glucose tolerance tests demonstrate that both gestational diabetes mellitus and gestational hypoglycemia are much higher in multiple gestation compared with findings in singleton pregnancy. Glucose screening is the standard of care in multiple pregnancy.

PRENATAL DIAGNOSIS

The usual indications for prenatal diagnosis and counseling in a singleton pregnancy also apply to twin and higher-order gestations. Because the incidence of twin gestation increases with maternal age, women with multiple gestations are often candidates for prenatal genetic diagnosis. As the risk of aneuploidy is increased, some centers offer invasive testing to all patients carrying multiple gestation who will be older than 33 years at delivery. Genetic counseling should make clear to the patient the need to obtain a sample from each fetus, the risk of a chromosomal abnormality, potential complications of the procedure, the possibility of discordant results, and the ethical and technical concerns when 1 fetus is found to be abnormal.

In twin pregnancies not accompanied by neural tube defects, the median maternal serum α -fetoprotein level will be 2.5 that of the median level for singleton pregnancies at 14–20 weeks' gestation. The levels in triplets and quadruplets are 3 and 4 times as high, respectively. A value > 4.5 times the median is considered abnormal and requires a targeted ultrasound and possible amniocentesis for determination of amniotic fluid α -fetoprotein and acetylcholinesterase levels. Serum screening is less effective in multiple pregnancy, with triple screening detecting only 47% of Down syndrome pregnancies. Nuchal translucency screening with first-

trimester serum markers can detect approximately 70% of Down syndrome fetuses in twin pregnancies.

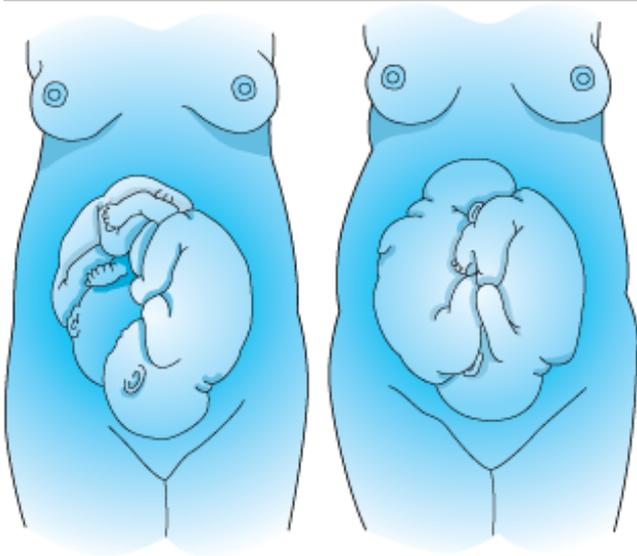

Both amniocentesis and chorionic villus sampling (CVS) can be performed in women with multiple gestation in experienced centers. Documentation of the location of the fetuses and the membrane separating the sacs is important in case of discordance for aneuploidy. Selective termination of an aneuploid fetus can be performed via ultrasound-guided intracardiac injection of potassium chloride. The pregnancy then can continue carrying the normal twin only. Multifetal reduction may be performed to decrease the risk of serious perinatal morbidity and mortality associated with preterm delivery by reducing the number of fetuses from 3 or more to twins.

ULTRASOUND FINDINGS

Ultrasonography is the preferred imaging modality for diagnosis of multiple gestation and is potentially able to differentiate multiple gestation as early as 4 weeks (by intravaginal probe). Dichorionicity is suggested by fetuses of different genders, separate placentas, a thick (> 2 mm) dividing membrane, or a "twin peak sign" in which the membrane inserts into 2 fused placentas. In the absence of these findings, monochorionicity is likely. A first-trimester scan is highly recommended because definitive diagnosis of chorionicity may not be possible with second- and third-trimester scans.

Both twins present as vertex in almost 50% of cases. Twin A will be vertex and twin B will be breech in slightly > 33% of cases (Fig 17–3). Both fetuses will be breech presentations in 10% of cases, and almost that many will be single (or double) transverse presentations. Approximately 70% of first twins present by the vertex. Breech presentation occurs in slightly > 25%. Overall, nonvertex presentation occurs 10 times more often in multiple pregnancy than in singleton pregnancy.

Differential Diagnosis

Multiple pregnancy must be distinguished from the following conditions.

SINGLETON PREGNANCY

Inaccurate dates may give a false impression of the duration of the pregnancy, and the fetus may be larger

than expected.

POLYHYDRAMNIOS

Either single or multiple pregnancy may be associated with excessive accumulation of fluid.

HYDATIDIFORM MOLE

Although usually easily distinguished from multiple gestation, this complication must be considered in diagnosis early in pregnancy.

ABDOMINAL TUMORS COMPLICATING PREGNANCY

Fibroid tumors of the uterus, when present in great numbers, are readily identified. Ovarian tumors are generally single, discrete, and harder to diagnose. A distended bladder or full rectum may elevate the pregnant uterus.

COMPLICATED TWIN PREGNANCY

If 1 dizygotic twin dies early in pregnancy and the other lives, the dead fetus may become flattened and mummified (fetus papyraceous; see section on Pathologic Factors Associated with Twinning, Fetal). Its portion of a fused placenta will be pale and atrophic, but remnants of 2 sacs and 2 cords may be found. If 1 twin dies in late pregnancy, considerable enlargement of the uterus persists, although the findings on palpation may be unusual and only 1 fetal heartbeat will be heard. Ultrasonography can confirm the diagnosis.

Prevention

MULTIPLE PREGNANCY

Although ovulation induction agents result in fewer multiple pregnancies when used by experts, even in the best of hands some multiple pregnancies inevitably will occur. For example, clomiphene citrate induction of multiple ovulation increases the rate of dizygotic pregnancy to 5–10%.

With many forms of ART (eg, ovulation induction, in vitro fertilization), iatrogenic multiple pregnancies regularly occur in which the number of fetuses is so great that they may preclude any being carried to the point of viability. When this occurs, many authorities recommend multifetal pregnancy reduction by transabdominal intracardiac potassium injection. Efforts are underway to recommend limiting the number of embryos transferred; legislation to this effect has been enacted in the United Kingdom.

COMPLICATIONS OF MULTIPLE PREGNANCY

To prevent the complications of multiple pregnancy, it is imperative to make the diagnosis as early in pregnancy as possible. Later in pregnancy, ultrasonography is useful for monitoring the growth of the fetuses and for detecting gross anomalies. Routine growth scans on twins are recommended every 4 weeks in the third trimester or more frequently if growth restriction is detected. Recall that the risk of fetal anomalies in twins is approximately 3 times that in singleton pregnancy.

Enhanced antenatal care assists in improving outcome. The most commonly used techniques are iron and calcium supplementation, vitamin and folic acid administration (in an attempt to prevent anemia), a high-protein diet, and more weight gain than usual (ideal weight for height plus 35–45 lb). Supplementation with magnesium, zinc, as well as essential fatty acids also have been recommended.

Insufficient evidence is available to suggest a policy of routine hospitalization for bed rest in multiple pregnancy because no reduction in the risk of preterm birth or perinatal death is observed. There is also no evidence that prophylactic cerclage improves outcome. More frequent antenatal visits are scheduled, and several authorities recommend closely following cervical length by ultrasound. Rescue cerclage can be offered for a short cervix (< 1.5 cm) or a large funnel of membranes prior to 24 weeks. Early and prompt therapy for any complications (eg, vaginal infections, preeclampsia–eclampsia) should be instituted, bearing in mind that preeclampsia–eclampsia is a common complication of multiple pregnancy.

Tocolytic drugs may suppress premature labor and extend gestation by 48 hours so that the effects of steroids can be realized. There is no evidence that long-term oral or intravenous tocolysis improves outcome. Most authorities recommend starting with intravenous magnesium sulfate. If terbutaline is used, very close monitoring for pulmonary edema must be maintained, because this complication is much more likely with administration of β -mimetic agents in multiple gestation. Also, because indomethacin may influence fetal ductal constriction, it should not be used after 32 weeks' gestation. Fetal fibronectin can be helpful, particularly when negative, to determine how aggressively to administer tocolytics.

In cases of antepartum bleeding or hydramnios, try to delay the delivery until each twin weighs at least 2000 g or until fetal lung maturity can be documented, usually after 34 weeks' gestation.

All patients with multiple pregnancy should be delivered in a well-equipped hospital by an experienced physician who has adequate assistance. It is desirable to have a pediatrician (or neonatologist) in attendance. Delivery must be done in the operating room in case an emergent cesarean section is needed for twin B. An early epidural is recommended; in case of emergent cesarean section, anesthesia is already established and general anesthesia can usually be avoided. Prematurity, trauma of manipulative delivery, and associated asphyxia are the major preventable causes of morbidity and mortality in twins, especially the second twin.

Treatment

LABOR AND DELIVERY

Admit the patient to the hospital at the first sign of labor or if leakage of amniotic fluid or significant bleeding occurs. An ultrasound evaluation should be performed to ascertain the presentation of each fetus and its estimated fetal weight. Routine, continuous electronic fetal heart rate monitoring is recommended. Labor should be conducted so that immediate cesarean section can be performed if required. A pediatric team for each infant plus obstetric and anesthesiologic attendants should be present. Insert an intravenous line and send a specimen of blood for typing, antibody screening, and complete blood count.

If either twin shows signs of persistent compromise, proceed promptly to cesarean delivery. Other indications for primary cesarean section include (but are not limited to) compound or monoamniotic twins and probable twin-twin transfusion syndrome (gross disparity in fetal size) and placenta previa. In the United States, all triplets warrant cesarean delivery.

In a woman with a previous lower-segment cesarean scar, limited literature suggests that delivery of twins does not mandate a repeat cesarean section in the absence of other complications. Concomitant with increasing rates of elective and nonelective cesarean section, cesarean delivery by patient request is becoming more common. In addition, less resident training in vaginal breech delivery can decrease a clinician's comfort with breech extraction of a second twin.

Management of twins that are candidates for vaginal delivery may proceed as outlined in the following. Intrapartum twin presentations may be classified (1) twin A and twin B vertex (slightly > 40% of all twins), (2) twin A vertex and twin B nonvertex (almost 40%), or (3) twin A nonvertex and twin B vertex, breech, or transverse (approximately 20%).

The current intrapartum management of twins is as follows. For vertex-vertex presentations in labor (category 1), vaginal delivery of both twins may be chosen in the absence of standard indications for cesarean section delivery. Of course, if either twin develops fetal distress, cesarean delivery should be performed. Category 2 twins, each weighing more than 2000 g, can usually be managed successfully by vaginal delivery of both. This is generally accomplished by total breech extraction of twin B immediately after the delivery of twin A. External cephalic version of twin B has also been described. When either twin A or both twins are nonvertex (category 3), primary cesarean section should be performed. This is also sometimes recommended in cases of nonvertex twin B where the estimated fetal weight is much greater than that of twin A. The ultrasound machine should be

present in the operating room to confirm the presentation of twin B after the delivery of twin A.

Difficult forceps operation or rapid extraction should be avoided, but forceps to protect the aftercoming premature head may be useful. The umbilical cord should be clamped promptly to prevent the second twin of a monozygotic twin pregnancy from exsanguinating into the first born.

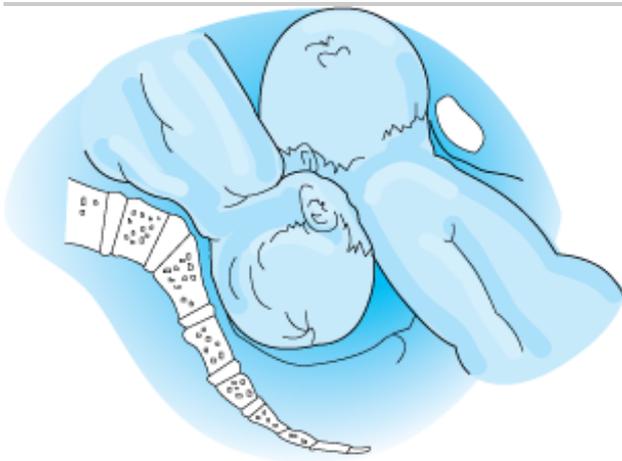

Perform a vaginal examination immediately after delivery of twin A to note the presentation of the second twin, the presence of a second sac, an occult cord prolapse, or cord entanglement.

Cut the cord as far outside the vagina as possible so that it can hang loose to permit vaginal examination or manipulation. This eliminates inadvertent cord traction on the placenta. Tag and label the cords (twin A and twin B) so that they can be associated with the proper placenta or placentas.

Use external version whenever possible for conversion of twin B from breech to vertex. Cautious rupture of the second sac will allow slow loss of fluid while twin B's vertex is being gently guided into the inlet. The amount of time between delivery of twin A and twin B is still a matter of controversy. If electronic fetal monitoring suggests fetal well-being, delivery of twin B within 30 minutes is not necessary.

One twin may obstruct the delivery of both fetuses in locked twins. In this circumstance, twin A is always a breech and twin B is a vertex presentation. The heads become impacted in the pelvis. Locked twins can be avoided by cesarean delivery in all cases in which twin A is not vertex. However, if the obstetrician is presented with a case of locked twins (Fig 17–4), having an assistant support the twin already partially delivered as a breech while pushing both heads upward out of the pelvis with rotation of both fetuses may accomplish delivery of the first twin. This process may require deep anesthesia. If this cannot be done, cesarean with abdominal delivery of both fetuses may be the safest route. An alternative procedure while cesarean preparations are underway is to elevate the partially delivered twin, establish an airway, and protect the cord.

Figure 17–4.

Locked twins.

(Reproduced, with permission, from Benson RC: *Handbook of Obstetrics & Gynecology*, 4th ed. Lange, 1971.)

Postpartum hemorrhage is common in multiple pregnancy. Increased intravenous oxytocin, elevation, and light massage of the fundus and an intravenous ergot or prostaglandin product (only after the last fetus is delivered) may be required. After delivery, if separation of the placenta is delayed or bleeding is brisk, manual extraction of the placenta may be necessary. Send the placenta, cord, and membranes to the pathology laboratory to assist in determining whether the fetuses are monozygotic or dizygotic.

Preeclampsia–eclampsia and premature labor and delivery are managed as outlined in Chapters 15 and 19.

Complications

MATERNAL

The incidence of spontaneous abortion of at least 1 of several fetuses is increased in multiple pregnancy. Stillbirth occurs twice as often among twins as among singleton pregnancies. Premature labor and delivery as well as premature rupture of the membranes are also greatly increased. The average gestational age at delivery is 36–37 weeks for twins, 33 weeks for triplets, and 31 weeks for quadruplets. Efforts to reduce the incidence of prematurity thus far have been largely unsuccessful.

Placenta previa may be responsible for antepartum bleeding, malpresentation, or unengagement of the first fetus. A large placenta (or placentas) and possibly fundal scarring or tumor may lead to low implantation of the placenta. Premature separation of the placenta may occur antepartum, perhaps in association with preeclampsia–eclampsia or rupture of membranes of twin A and the initiation of strong uterine contractions, or after the delivery of the first twin. Careless traction on the first cord may encourage early partial separation of the placenta.

Hypochromic normocytic anemia is 2–3 times more common in multiple pregnancy than in singleton pregnancy. Urinary tract infection is at least twice as frequent in multiple pregnancy as in singleton pregnancy because of increased ureteral dilatation secondary to a higher serum progesterone level and greater uterine pressure on the ureters. Preeclampsia–eclampsia occurs approximately 3 times more often in multiple pregnancy than in singleton pregnancy.

A thinned uterine wall, secondary to unusually large uterine contents, is associated with hypotonic uterine contractions and a longer latent stage of labor. However, prolonged labor is uncommon in multiple pregnancy because rupture of the membranes generally is followed by improvements in the uterine contraction pattern. Uterine atony often is accompanied by excessive loss of blood postpartum owing to inability of the overdistended uterus to contract well and remain contracted after delivery.

When 2 separate placentas are present, 1 of them may deliver immediately after the first twin. Although the second twin may not be compromised, it is best to proceed with its delivery, both for its protection and to conserve maternal blood.

Operative intervention is more likely in multiple pregnancy because of increased obstetric problems such as malpresentation, prolapsed cord, and fetal distress.

FETAL

Fetal death is approximately 3 times more common in multiple pregnancy than in singleton pregnancy. Death may be the result of developmental anomalies, cord compression, or placental disorders. The greatest hazard from cord compression is cord entanglement of monozygotic twins with only 1 amniotic sac. Developmental anomalies and polyhydramnios are common in monozygotic twins.

Almost twice as many monozygotic as dizygotic twins die in the perinatal period. Attrition is even greater for triplets, quadruplets, and higher-order pregnancies. Even so, preterm delivery and intrapartum complications are the most common causes of fetal loss in multiple pregnancy. All too frequently preterm delivery is occasioned by premature rupture of the membranes, which occurs in approximately 25% of twin, 50% of triplet, and 75% of quadruplet pregnancies.

Abnormal and breech presentation, circulatory interference by 1 fetus with the other, and operative delivery all increase fetal loss. Prolapse of the cord occurs 5 times more often in multiple pregnancy than in singleton pregnancy. Premature separation of the placenta before delivery of the second twin may cause death of the second twin by hypoxia.

Neonatal outcome is very much dependent on gestational age at delivery. In general, morbidity and mortality rates are similar for twins and singletons of equivalent gestational ages. Many outcome data are stratified according to birthweight. Therefore, the slowing of growth in the third trimester can give twin fetuses the advantage of increased gestational age for weight. Advances in neonatal intensive care have made survival possible even at 23 weeks' gestation, although usually with considerable morbidity, including but not limited to intraventricular hemorrhage, chronic lung disease, and necrotizing enterocolitis. Because intact survival is much more likely after 34 weeks, prolonging gestation at least to this point when possible is desirable. The adage "1 day in utero saves 2 days in intensive care" applies to the economic as well as the emotional costs of caring for premature infants.

It is imperative that an experienced physician be present for resuscitation and stabilization of each infant born premature. Antenatal diagnosis of multiple gestation facilitates delivery at an appropriate center. Delivery before week 36 is twice as frequent in twin pregnancies as in singleton pregnancies. Intracranial injury is more common in premature infants, even those delivered spontaneously. An increased risk of cerebral palsy is found in twins, especially very low-birthweight babies, and in liveborn co-twins of fetuses who died in utero.

Treatment of twin-twin transfusion syndrome in utero remains experimental. After delivery, therapy includes replacing blood in the donor twin to correct fluid and electrolyte imbalance. In the recipient twin, phlebotomy is necessary until normal venous pressure is restored. Often, other therapy for cardiac failure (eg, digitalis) is necessary.

Prognosis

The U.S. maternal mortality rate for multiple pregnancy is only slightly higher than for singleton pregnancy. A history of previous dizygotic twins increases the likelihood of subsequent multiple pregnancy 10-fold. Hemorrhage is approximately 5 times as frequent in multiple pregnancies as in single pregnancies. The probability of abnormal presentation and of operative delivery and its complications is increased in multiple pregnancy. Premature rupture of the membranes and premature labor, often with a long prodromal phase, are common occurrences in multiple pregnancy. A gravida with a multiple pregnancy has approximately 5 times the likelihood of having a morbid (febrile, complicated) course as an average patient of the same parity with a single fetus.

Hydramnios is 5 times more frequent in multiple pregnancies as in singleton pregnancies, principally because of fetal abnormality. Perinatal mortality and morbidity rates are increased in multiple pregnancy, mainly because of preterm delivery and its complications (eg, trauma or asphyxia).

Almost 50% of twins weigh < 2500 g, but the majority of these twins are of 36 weeks' gestational age or more. Directly or indirectly, multiple pregnancies are responsible for approximately 15% of premature births and approximately 9% of perinatal deaths, a rate 7 times that of single births. Approximately 55% of twins are premature; 80% of perinatal deaths occur in those born before 31 weeks' gestation, and 93% of deaths are in those with birthweight < 1500 g. The incidence of intrauterine growth restriction is increased in multiple gestation, and multiple gestations account for 17% of infants with intrauterine growth restriction. Congenital malformations and abnormal presentation are more serious in monozygous twins. Preeclampsia–eclampsia, diabetes mellitus, and other disorders may further jeopardize the fetuses.

Efforts to reduce the incidence of prematurity have not met with much success in singletons or in multiple gestations. In order to maximize fetal growth, good nutrition, frequent rest periods, and cessation of smoking are encouraged. Approximately 90% of twins born at greater than 28 weeks survive.

Recent studies have found that neonatal morbidity is reduced when delivery occurs at approximately 38 weeks, so routine induction at that time is recommended.

The comparative occurrence of perinatal death (per 1000) for single and multiple pregnancy are as follows: singletons, 39; twins, 152; triplets, 309; and quadruplets, 509. The rates are proportionately higher for higher-order pregnancies.

Central nervous system disease and respiratory disease are frequently diagnosed in the surviving second twin.

Discordance noted at birth is associated with a slower weight gain during extrauterine life. A twin whose birthweight is < 20% that of its partner will not gain as rapidly and may never catch up with the other twin with regard to weight and height. The IQ of the larger monozygotic twin is likely to be higher than that of the smaller twin if the weight difference is > 300 g at birth. The female twin of a female–male pair who survives cross-transfusion is not sterile (in contrast to the situation encountered in the bovine freemartin).

Concordance of placental examination, clinical comparisons, and hematologic and serologic tests provides presumptive evidence of monozygotic twinning. The total probability of diagnosis of zygosity is > 95% using ABO, MNSs, Rh, Kell, Kidd, Duffy, and Lewis A and B antigens, and approaches 100% using chromosomal analysis.

In comprehensive perinatal care centers, morbidity and mortality rates decrease greatly. In a report of triplets receiving optimal care, the mean weight at delivery was 1779 g, and the incidence of neonatal mortality was only 23 in 1000. First twins have an approximately 3% greater chance of survival than do second twins.

Current OB/GYN > Chapter 18. Diabetes Mellitus & Pregnancy >

DIABETES MELLITUS & PREGNANCY: INTRODUCTION

Diabetes mellitus is the most common medical complication of pregnancy. The Centers for Disease Control and Prevention estimated that 20.8 million persons in the United States had diabetes in 2005. Minority groups are disproportionately affected. Diabetes is undiagnosed in nearly one-third of adults with the condition.

Preexisting (type 1 or type 2) diabetes mellitus affects approximately 1–3 per 1000 pregnancies. Although preconception care and glycemic control are advised, pregnancy will be the first time many women present for medical care. Gestational diabetes mellitus (GDM) is defined as any degree of glucose intolerance with first recognition during pregnancy. GDM complicates approximately 4% of pregnancies. Women with GDM have an approximately 50% risk of developing type 2 diabetes over the next 10 years. Pregnancy affords a unique opportunity to diagnose or possibly prevent diabetes among women at risk to develop type 2 diabetes later in life.

Diabetes during pregnancy poses significant risks to the mother and fetus. With poorly controlled diabetes, spontaneous abortion risk is high, and the rate of major congenital anomalies is 6–12% among women with pregestational diabetes. Diabetic ketoacidosis (DKA) is an immediate threat to maternal and fetal life. Fetal death occurs in approximately 10% of pregnant patients with DKA, which is an improvement from rates of 30–50% in the recent past. GDM increases the risk of fetal macrosomia, which is associated with secondary complications such as operative delivery, shoulder dystocia, and birth trauma. There is an increase in neonatal complications, such as hypoglycemia, respiratory distress syndrome (RDS), hypocalcemia, and hyperbilirubinemia.

Before the introduction of insulin in 1922, diabetic patients often died during the course of their pregnancy. Just 20 years ago, delivery of an unexplained stillbirth from a mother with type 1 diabetes was not uncommon. Today this tragedy is rare, with a reduction in perinatal mortality rate to less than 5%. When diabetic patients receive preconception care, including medical nutrition therapy and insulin therapy as needed to achieve near-normal glycemic goals as well as antepartum fetal surveillance, morbidity and mortality approach that of women with uncomplicated pregnancies. Two decades ago, most diabetics required prolonged hospitalization, but today few require more than a brief hospital stay. This is partly due to the accessibility of self-monitoring of blood glucose level with its concomitant effect on glycemic control.

Currently, the priorities for diabetes care providers are first to identify and control diabetes prior to conception and second to appropriately screen and treat even mild gestational diabetes during pregnancy.

Pathophysiology: Metabolism in Normal & Diabetic Pregnancy

Insulin is an anabolic hormone with essential roles in carbohydrate, fat, and protein metabolism. It promotes the uptake of glucose, storage of glucose as glycogen, lipogenesis, and uptake and utilization of amino acids. The lack of insulin results in hyperglycemia and lipolysis. Elevation of free fatty acids

leads to an increase in the formation of ketone bodies, acetoacetate and β -hydroxybutyrate. When blood glucose levels exceed the renal threshold for absorption of filtered glucose, glycosuria occurs and causes an osmotic diuresis with dehydration and electrolyte losses.

Insulin sensitivity decreases as gestation advances in all pregnant women, mainly due to anti-insulin signals produced by the placenta. In the first trimester, increasing maternal estrogen and progesterone levels are associated with a decrease in fasting glucose levels, which reach a nadir by the 12th week. The decrease averages 15 mg/dL; thus, fasting values of 70–80 mg/dL are common by the 10th week of pregnancy.

In the second trimester, as the placenta increases secretion of anti-insulin hormones, higher fasting and postprandial glucose levels occur that facilitate transfer of glucose from mother to fetus. Glucose transfer occurs via a carrier-mediated active transport system that becomes saturated at 250 mg/dL. Fetal glucose levels are 80% of maternal levels. In contrast, maternal amino acid levels are lowered due to active placental transfer to the fetus. Lipid metabolism in the second trimester shows continued storage until midgestation, then enhanced mobilization (lipolysis) as fetal fuel demands increase.

Human placental lactogen (hPL) is the hormone mainly responsible for insulin resistance and lipolysis. hPL also decreases the hunger sensation and diverts maternal carbohydrate metabolism to fat metabolism in the third trimester. hPL is similar in structure to growth hormone and acts by reducing the insulin affinity to insulin receptors. The net effect is to favor placental transfer of glucose to the fetus and to reduce the maternal use of glucose. The hPL levels rise steadily during the first and second trimesters, with a plateau in the late third trimester.

Cortisol levels rise during pregnancy and stimulate endogenous glucose production and glycogen storage and decrease glucose utilization. The "dawn phenomenon" (elevated fasting glucose to facilitate brain metabolism) is marked in normal pregnancies and enhanced even more in women with polycystic ovarian syndrome (PCOS) who conceive. Therefore, pregestational and early pregnancy screening for prediabetes and diabetes are advised for women with PCOS.

Prolactin levels are increased 5- to 10-fold during pregnancy and may impact carbohydrate metabolism. Thus, women with hyperprolactinemia also should undergo early glucose screening.

Fetal Effects

Elevated glucose levels are toxic to the developing fetus, producing an increase in miscarriages and major malformations in direct proportion to the glucose level. These birth defects (Table 18–1) are fatal or seriously deleterious to quality of life and are preventable by preconceptional glucose control. Because malformations occur within the first 8 weeks of gestation, when most women are just beginning prenatal care, preconceptional care is essential for women with diabetes. The hemoglobin A_{1c} level, which reflects the blood glucose concentration over the previous 2 months, can predict the risk for malformations when measured in the first trimester (Table 18–2).

Table 18–1. Some Congenital Anomalies of Infants of Diabetic Mothers.

Cardiac	Atrial septal defects Ventricular septal defects Transposition of the great vessels Coarctation of the aorta Tetralogy of Fallot Truncus arteriosus Dextrocardia Cardiomegaly
Central nervous system	Neural tube defects Anencephaly Holoprosencephaly
Renal	Hydronephrosis Renal agenesis Ureteral duplication
Gastrointestinal	Duodenal atresia Anorectal atresia Omphalocele
Spinal	Caudal regression syndrome, sacral agenesis

Table 18–2. Relationship between Initial Pregnancy Value of Glycosylated Hemoglobin and Rate of Major Fetal Congenital Malformations.

Initial Maternal Hemoglobin A _{1c} Level	Major Congenital Malformations (%)
≤ 7.9	3.2
8.9–9.9	8.1
≥ 10	23.5

The fetus continues to experience the effects of hyperglycemia beyond the period of organogenesis. Whereas glucose crosses the placenta, insulin does not, leading to increased fetal production of insulin to compensate for its hyperglycemic environment. Higher insulin levels promote increased fetal somatic growth, leading not only to macrosomia and central fat deposition but also to enlargement of internal organs such as the heart.

Diagnostic Criteria for Diabetes Mellitus Prior to Pregnancy

The 3 ways of diagnosing preexisting diabetes mellitus are as follows:

1. Symptoms of diabetes plus random plasma glucose concentration equal to or greater than 200 mg/dL. The classic symptoms of diabetes include polyuria, polydipsia, and unexplained weight loss.
2. Fasting plasma glucose (FPG) equal to or greater than 126 mg/dL. Fasting is defined as no caloric intake for at least 8 hours.
3. Two-hour postload glucose level equal to or greater than 200 mg/dL during an oral glucose tolerance test (OGTT). The test uses a glucose load containing the equivalent of 75 g anhydrous glucose dissolved in water.

In the absence of unequivocal hyperglycemia, these criteria should be confirmed by repeat testing on a different day. The third measure (OGTT) is not recommended for routine clinical use in nonpregnant adults.

Diagnostic Criteria for Gestational Diabetes Mellitus

Risk assessment for GDM is performed at the first prenatal visit in all women who do not already have diagnosed diabetes. Women with risk factors should be screened as soon as feasible. Risk factors include obesity (nonpregnant body mass index ≥ 30), prior history of GDM, heavy glycosuria ($> 2+$), unexplained stillbirth, prior infant with major malformation, and family history of diabetes in a first-degree relative. If results of testing do not demonstrate diabetes, these women should be retested between 24 and 28 weeks' gestation. All women of ordinary or high risk should be screened between 24 and 28 weeks' gestation. In the United States, a 2-step approach usually is taken. The first step is a screening test consisting of a 50-g oral glucose challenge test (GCT). Plasma or serum glucose level is measured 1 hour later. The GCT can be performed at any time of day and without regard to time of prior meal. The sensitivity and specificity of the test are related to the cutoff value designated to be an "abnormal" result. A cutoff value of 140 mg/dL has a sensitivity of approximately 80% and results in progression to definitive testing in 14% of patients; a cutoff value of 130 mg/dL has a sensitivity of 90% and results in definitive testing in 24% of patients. Either cutoff value is acceptable. If the GCT result is 180 mg/dL or more, then the FPG should be obtained the next day, before the 3-hour, 100-g OGTT because many of these women can be diagnosed by FPG alone if the FPG is 95 or more.

Screening can be omitted for the small group of women with low risk. The low-risk group comprises women who fulfill all of the following criteria: age less than 25 years, normal body weight, no family history (first-degree relatives) of diabetes, no history of abnormal glucose metabolism or poor obstetric outcome, and not a member of an ethnic/racial group with a high prevalence of diabetes (eg, Hispanic American, Native American, Asian American, African American, Pacific Islander). The American Diabetes Association (ADA) diagnoses GDM based on 2 abnormal results on the 3-hour, 100-g OGTT or on the 2-hour, 75-g OGTT (Table 18–3).

Table 18–3. Diagnostic Criteria for Gestational Diabetes Mellitus.

	100-g Glucose Load (mg/dL)	75-g Glucose Load (mg/dL)
Fasting	95	95
1 hour	180	180
2 hour	155	155
3 hour	140	—

Diagnosis based on ≥ 2 values above listed cutoff values.

There is increasing evidence that 1 abnormal value is sufficient to adversely affect the fetus; some physicians now use a single abnormal value to initiate treatment. Outside the United States, a 1-step approach using a 75-g oral glucose load is widely used.

During the antenatal period, clinical findings that suggest maternal hyperglycemia, such as fetal weight 70% or greater for gestational age or polyhydramnios (amniotic fluid index ≥ 24 cm) should prompt re-evaluation for GDM.

PREGESTATIONAL DIABETES

TYPE 1 DIABETES (INSULIN-DEPENDENT)

Type 1 diabetes mellitus (T1DM) results from beta cell destruction, usually leading to absolute insulin deficiency. Onset often occurs in the young. T1DM may appear in older persons and may rarely present during pregnancy. Profound thirst, increased urination, and weight loss or even overt ketoacidosis are the usual symptoms prompting medical evaluation.

T1DM has multiple identified genetic predispositions. Susceptibility to T1DM is increased by a gene or genes located near or within the human leukocyte antigen (HLA) locus on the short arm of chromosome 6 (6p). The risk to offspring of developing T1DM with an affected sibling is 5% if 1 haplotype is shared, 13% for 2 haplotypes, and 2% if no haplotypes are shared. If both parents are affected, the risk of T1DM is 33%. The incidence of type 1 diabetes is 0.1–0.4% (1–4 per 1000) in the general population.

TYPE 2 DIABETES (NONINSULIN DEPENDENT)

Type 2 diabetes mellitus (T2DM) is characterized by insufficient insulin receptors to effect proper glucose control after insulin is released (insulin resistance). Women with T2DM typically have a body habitus consisting of increased abdominal girth, often described as an "apple shape."

T2DM is a multifactorial illness that is influenced by heredity, environment, and lifestyle choices. Although several genes have been associated with T2DM, progression to frank disease can be modified by factors such as diet and exercise. With T2DM, the risk of diabetes in a first-degree relative is almost 15%, and approximately 30% more will have impaired glucose tolerance. If both parents have T2DM, the incidence of diabetes in the offspring is 60–75%, although lifestyle modification can decrease the risk.

GESTATIONAL DIABETES

GDM is defined as any degree of glucose intolerance with onset or first recognition during pregnancy. In the majority of GDM cases, glucose levels return to normal after delivery. The risk of recurrence in future pregnancies is at least 60%. The definition applies regardless of which therapies—insulin, diet, activity, or oral hypoglycemics—are used during pregnancy. Clinically unrecognized glucose intolerance may have antedated, or begun concomitantly with, the pregnancy.

Significance

Normal growth and maturation of the fetus are closely associated with the normal delivery of maternal nutrients, especially glucose. The duration and degree of hyperglycemia are directly related to excessive growth, especially in the third trimester. There is an increase in miscarriages, congenital malformations, preterm birth, pyelonephritis, preeclampsia, in utero meconium, fetal heart rate abnormalities, cesarean deliveries, and stillbirths.

Incidence & Etiology

The incidence of gestational diabetes ranges from 1% in rural areas with a predominantly white population to 12% in racially heterogeneous urban regions. However, the increasing prevalence of obesity, metabolic syndrome, and prediabetes make it likely that the incidence of gestational diabetes also will increase.

Pathophysiology

GDM is pathophysiologically similar to T2DM. Women most likely to develop GDM are those who are overweight, with a body habitus often described as an "apple shape." hPL increases insulin resistance and increases in direct relation to the length of gestation. Normally, insulin release by pancreatic beta cells is increased in an attempt to maintain glucose homeostasis. Women with GDM continue to demonstrate postpartum defects in insulin action. These defects include the regulations of glucose clearance, glucose production, and plasma free fatty acid concentrations, together with defects in pancreatic beta-cell function, which precede the development of T2DM.

APPROACH TO DIABETES IN PREGNANCY

Prevention of hyperglycemia through rigorous control of blood glucose level is the mainstay of treatment in the pregnant woman with pregestational diabetes. This is best accomplished by careful preconceptional counseling and achievement of normal hemoglobin A_{1c} levels before pregnancy in pregestational diabetics, frequent (usually 4–5 times per day) home glucose level monitoring, adjustment of diet, and regular exercise.

Nonweight-bearing or low-impact exercise can be initiated or continued. Even short episodes of exercise will sensitize the patient's response to insulin for approximately 24 hours. All care providers should stress the importance of diet. Soluble fiber provides satiety and improves both the number of insulin receptors and their sensitivity. Carbohydrate restriction improves glycemic control and may enable a patient to achieve her glycemic goals using diet and activity. Calories are prescribed at 25–35 kcal/kg of actual body weight, generally 1800–2400 kcal/day. The diet should be 40–50% carbohydrate, 30–40% fat, and 20% protein. Morbidly obese women may have a lower metabolism rate; therefore, begin low and increase calories as needed. When postprandial values exceed the targets, review all recent food intake to adjust food choice, preparation, and portion size.

Self-monitoring of fasting, 1- or 2-hour postprandial, and nighttime blood glucose levels using a glucose meter provides instant feedback to assess the patient's diet and behavior. When the glycemic goals are met, the feedback is a powerful motivator. Diet and/or activity errors are identified and corrected as

needed. Optimal glucose levels during pregnancy are fasting levels of 70–95 mg/dL and 1-hour postprandial values less than 140 mg/dL or 2-hour postprandial values less than 120 mg/dL.

A minimum of 2 visits to a dietitian improves education and active participation regarding diet. Food records are useful. The dietitian reviews content and calories and suggests how to include favorite ethnic foods to improve compliance. Other family members should be encouraged to participate in the dietary education because their understanding and support increase the chance for a successful diet. Often, the other family members will benefit from the healthful diet changes. Additional follow-up visits between patient and dietitian are important when glycemic goals are not reached, weight change is too great or too small, or the patient is having difficulty maintaining the diet.

Insulin therapy is added when necessary to achieve goals. The addition of insulin should not be presented or perceived as a failure or a punishment. Insulin is simply the next rational step to achieving worthwhile glycemic goals. Patient resistance should be addressed with support, reassurance, and education by diabetes health provider team members. There are different approaches to introducing insulin, but the plan should be as simple as possible.

Subcutaneous insulin pumps may be considered in highly motivated patients and should not be discontinued in women who began the pump prior to conception. Use of subcutaneous pumps during pregnancy has been associated with better control of hyperglycemia and increased patient satisfaction.

When pharmacologic therapy is required during pregnancy, insulin has long been the treatment of choice. However, recent evidence suggests that glyburide or metformin are safe and effective alternatives. Until further research is done, treatment with oral hypoglycemics should be limited and individualized.

ANTEPARTUM CARE

Care of the insulin-dependent pregestational diabetic must be intensive. The initial evaluation of a patient, ideally done prior to conception, includes assessment of other end-organ damage. A comprehensive eye examination for retinopathy should be performed annually. When a patient is already pregnant at time of presentation, the rapid introduction of tight glycemic control may worsen retinopathy. Thus, gradual achievement of euglycemia is best accomplished before conception. If needed, laser therapy can be performed during pregnancy. Renal function is assessed with a serum creatinine level and a 24-hour urine collection or urinary albumin/creatinine ratio to measure protein excretion. In patients with T1DM, thyroid function should be evaluated because of increased rates of thyroid disease. Electrocardiography can be performed on patients older than 30 years or who have disease duration of more than 5 years. Prenatal vitamins should be started with supplementation of at least 0.4 mg of folate daily.

Gestational age should be confirmed with a first-trimester ultrasound examination. In all pregestational diabetics, a fetal ultrasound for anatomy, including the heart, should be completed at 18–20 weeks. Additional tests to screen for anomalies should be offered, if available, such as first-trimester nuchal translucency and serum screening and/or second-trimester triple or quadruple screening.

Women with diabetes have triple the rate of asymptomatic bacteriuria compared to other pregnant women. A urine culture is obtained at the initial visit. After administration of a complete course of appropriate antibiotic treatment, a repeat culture (test of cure) is performed to confirm cure. The development of edema, including carpal tunnel syndrome, is monitored because of the increased risk of preeclampsia in patients with diabetes.

Evaluation of maternal glycemic control by self-monitoring of blood glucose level and of fetal growth and development by ultrasound are essential. Excellent glycemic control in a nonsmoking woman without

end-organ disease from the diabetes increases the chance for a more normal outcome. Patients with poor glycemic control, often suggested by fetal macrosomia or polyhydramnios, are at increased risk for poor pregnancy outcome. Surveillance for fetal well-being often begins at 32 weeks' gestation in patients with end-organ disease using a twice-weekly nonstress test (NST) or the modified biophysical profile (BPP) done twice weekly by measuring the fetal heart rate and the amniotic fluid volume. A weekly BPP is similarly useful. Women without end-organ disease who require insulin often begin fetal monitoring at 32–34 weeks. Women with diet-controlled gestational diabetes usually begin testing at 36–40 weeks until delivered.

Maternal fetal movement monitoring ("kick counts") using a count to 10 or similar method is recommended for all pregnant women, including those with diabetes, to reduce the stillbirth rate.

When fetal assessment is not reassuring, the mature fetus should be delivered. In such cases near term, amniocentesis to obtain amniotic fluid for pulmonary maturity may be helpful. If the fetus is mature, delivery may proceed. If the fetus is immature, then a decision must be made in which the risk of fetal jeopardy is balanced against the risks of preterm birth. Participation of the patient, her partner, and the neonatology and perinatology departments may facilitate a plan. Assessment of fetal lung maturity is recommended for elective delivery at less than 38 weeks' gestation or when maternal glycemic control has been inadequate and there is risk of delay in fetal lung maturity.

Preterm labor is more frequent among patients with diabetes. The main goal of tocolysis is to delay delivery so that glucocorticoid therapy to accelerate fetal lung maturation can be administered over 48 hours. Magnesium sulfate tocolysis is widely used. Nifedipine is a reasonable alternative. β -Adrenergic mimetics such as terbutaline should be avoided if possible because these drugs may cause severe hyperglycemia and, rarely, ketoacidosis. Because glucocorticoids also cause hyperglycemia, a continuous intravenous infusion of insulin often is necessary to maintain normal glucose levels.

Many obstetricians induce the patient if she reaches 39 weeks' gestation. One prospective randomized controlled study demonstrated that patients requiring insulin for GDM or class B diabetes benefited from induction of labor at 38.5–39 weeks' gestation compared to expectant care. These pregnancies had excellent dates and good glycemic control. Lung maturity was not assessed, but RDS was not a complication. Patients with poor glycemic control may be evaluated for delivery at 38 weeks, although demonstrating fetal lung maturity in these cases is prudent. Patients with pregestational diabetes and vascular complications often require induction at or near term if preeclampsia, fetal growth restriction, or fetal heart rate abnormalities occur. The practice of offering cesarean delivery to prevent traumatic birth injury at a given estimated fetal weight (EFW) is controversial. Although a clear benefit outweighing the risk has not been firmly established, some practitioners have adopted a threshold EFW above which they counsel patients about the risks of vaginal delivery and offer cesarean delivery.

SEVERE HYPERGLYCEMIA & KETOACIDOSIS

During pregnancy, severe hyperglycemia and ketoacidosis are treated exactly the same as in the nonpregnant state. Insulin therapy, careful monitoring of potassium level, and fluid replacement are crucial for maternal survival. Fetal heart rate monitoring often demonstrates recurrent late decelerations, but these improve as maternal ketoacidosis is corrected.

INTRAPARTUM MANAGEMENT

Glucose infusion is provided to all patients in labor as 5% dextrose in lactated Ringer's solution or a similar crystalloid. The rate usually is 125 mL/h (providing 6.25 g of glucose per hour) unless the patient requires more. Intravenous fluid bolus prior to conduction anesthesia should not contain glucose. A bedside glucose monitor can be used to monitor glucose levels every 2–4 hours in early labor and every

1–2 hours in active labor. Patients requiring insulin may receive a continuous infusion of regular insulin, often prepared as 25 U in 250 mL saline (0.1 unit/mL) according to the institution's protocol for intravenous insulin. Most patients require approximately 0.5–2.0 U/h, although rates are adjusted based on the capillary glucose level.

Cervical ripening for induction of labor, if indicated, is conducted in the same manner as for nondiabetic parturients. Continuous electronic fetal monitoring is used. In diabetic pregnancies, the fetus's ability to tolerate the stress of labor may be limited. Fetal heart rate abnormalities should be evaluated with acoustic or scalp stimulation or fetal oxygen saturation monitoring. If fetal well-being cannot be demonstrated, expeditious delivery, often by cesarean section, is indicated. If fetal macrosomia is suspected, operative vaginal delivery should be considered with great caution, if at all. The infant of the diabetic is at increased risk for shoulder dystocia, and this should be anticipated with adequate personnel, obstetric anesthesia, and neonatal resuscitation available at delivery.

If a repeat cesarean delivery or other elective surgery is planned, the patient can take her evening insulin doses on the preceding night, but she cannot take the morning dose. The morning of surgery, glucose level is monitored and basal insulin needs usually are treated with continuous intravenous insulin to maintain a glucose between 70 and 120 mg/dL.

POSTPARTUM CARE

Postpartum, the patient should start back on an ADA diet as soon as clinically indicated. The dose of insulin should be reduced because insulin sensitivity increases markedly postpartum. The general rule is two-thirds of the prepregnancy dose or one-half of the present dose. If the patient underwent surgery, a sliding scale may be implemented until oral intake can be established. The glucose levels should be kept below 140–150 mg/dL to assist the patient in healing. Breastfeeding is encouraged, and snacks can be used to decrease the risk of hypoglycemia.

If hypoglycemic agents are necessary postpartum, insulin is continued for those women who are breastfeeding, whereas oral agents can be used in the non–breastfeeding mothers. Postpartum weight loss is encouraged. All patients with a history of diabetes or with risk factors should be re-evaluated prior to the next planned pregnancy.

CONTRACEPTION

Contraceptive options for diabetic women without vascular complications are the same as for nondiabetic women. In women with an increased risk for embolism, hormonal contraception containing estrogen is not recommended, but progesterone-only methods, including the levonorgestrel intrauterine system, can be offered. Permanent sterilization should be made available to women with diabetes who have completed childbearing.

NEONATAL COMPLICATIONS

Hyperglycemia at the time of conception results in enhanced rates of spontaneous abortion and major congenital malformations. Hyperglycemia in later pregnancy increases the risks for macrosomia, hypocalcemia, polycythemia, respiratory difficulties, cardiomyopathy, and congestive heart failure. Macrosomia is associated with increased risk for fetal intolerance to continued intrauterine existence and the stress of labor and of birth trauma. RDS and transient tachypnea are more common in infants of women with poorly controlled diabetics. Excellent antepartum glycemic control eliminates any delay in fetal lung maturity. Maternal hyperglycemia causes excess glycogen deposition and hypertrophy of the fetal heart muscle, which may cause fetal cardiomyopathy and congestive heart failure.

The fetus responds to maternal hyperglycemia with pancreatic hyperplasia and increased basal insulin

secretion, which are associated with a lifetime increased risk of diabetes. Mothers with diabetes during pregnancy have offspring with higher rates of diabetes at age 20–24 years than do women who develop diabetes after the pregnancy (45% vs 8.6%). This observation suggests that the hyperglycemia during pregnancy had an effect beyond the mother's genetic tendency.

PROGRESSION FROM GDM TO T2DM

Women diagnosed with GDM are at increased risk to develop diabetes (in nearly all cases type 2) in the future. They have a 50–60% risk of developing diabetes within 10–15 years. Lifestyle modification may delay or entirely prevent the onset of diabetes in adults with impaired glucose tolerance.

All patients with GDM should have a 2-hour, 75-g OGTT approximately 6 weeks postpartum. Those with normal glucose tolerance should be reassessed every 3 years. Those with prediabetes should be re-evaluated annually (Table 18–4).

Table 18–4. Diagnostic Criteria for Diabetes and Prediabetes in the Nonpregnant State.

Diabetes	Prediabetes with Impaired Fasting Glucose (mg/dL)	Prediabetes with Impaired Glucose Tolerance (mg/dL)	Normal (mg/dL)
FPG \geq 126	126 \geq FPG \geq 100		FPG < 100
2-hour OGTT \geq 200		2-hour OGTT \geq 140 and < 200	2-hour OGTT < 140

FPG, fasting plasma glucose; OGTT, oral glucose tolerance test with 75 g of glucose.

If the patient is breastfeeding, the same calorie ADA diet is continued postpartum. All women should be encouraged to eliminate or reduce any other risk factors (in addition to glucose intolerance) for cardiovascular disease. In practice, this means referral to programs, as needed, to cease smoking and to avoid environmental smoke; to engage in regular physical activity; to consume an appropriate diet; to achieve and maintain a normal weight; and to be treated for individual cardiovascular disease risk factors.

Current OB/GYN > Chapter 19. Hypertension in Pregnancy >

HYPERTENSION IN PREGNANCY: INTRODUCTION

Hypertension is a common medical disorder that affects 20–30% of adults in the United States and complicates as many as 5–8% of all pregnancies. Hypertensive disorders of pregnancy rank among the leading causes of maternal morbidity and mortality. Approximately 15% of maternal deaths are attributable to hypertension, making it the second leading cause of maternal mortality in the United States. Severe hypertension increases the mother's risk of heart attack, cardiac failure, cerebral vascular accidents, and renal failure. The fetus and neonate also are at increased risk from complications such as poor placental transfer of oxygen, fetal growth restriction, preterm birth, placental abruption, stillbirth, and neonatal death.

Hypertension is defined as a sustained blood pressure higher than 140/90 mm Hg. In the nonpregnant patient, essential hypertension accounts for more than 90% of cases; however, many other conditions must be considered (Table 19–1). In the pregnant patient, hypertension may be attributable to any of the conditions summarized in Table 19–1. In addition, a unique form of hypertension, "preeclampsia," occurs only during pregnancy. Preeclampsia is characterized by the onset of hypertension and proteinuria, usually during the third trimester of pregnancy. The National High Blood Pressure Education Program Working Group recently stated that edema occurs too frequently in normal pregnant women to be a useful marker in the diagnosis of preeclampsia. Therefore, edema is no longer recommended as a diagnostic criterion for preeclampsia. Management of preeclampsia differs from the management of other forms of hypertension during pregnancy. Therefore, it is important to distinguish preeclampsia from other forms of hypertension that may complicate pregnancy.

Table 19–1. Causes of Chronic Hypertension.

Idiopathic
Essential hypertension
Vascular disorders
Renovascular hypertension
Aortic coarctation
Endocrine disorders
Diabetes mellitus
Hyperthyroidism
Pheochromocytoma
Primary hyperaldosteronism
Hyperparathyroidism
Cushing's syndrome

Renal disorders
Diabetic nephropathy
Chronic renal failure
Acute renal failure
Tubular necrosis
Cortical necrosis
Pyelonephritis
Chronic glomerulonephritis
Nephrotic syndrome
Polycystic kidney
Connective tissue disorders
Systemic lupus erythematosus

Classification of hypertension during pregnancy can be viewed as a continuum. On one end of the spectrum is the patient with hypertension that was present before pregnancy (or was recognized during the first half of pregnancy), does not worsen appreciably during pregnancy, and persists after delivery. This condition would be classified as *chronic hypertension*. On the other end of the spectrum is the patient with no evidence of chronic hypertension who experiences the abrupt onset of hypertension and proteinuria late in pregnancy followed by complete resolution postpartum. In this case, the hypertension observed during pregnancy may be the result of factors related entirely to pregnancy and *not* to an underlying medical cause. This condition would be classified as *preeclampsia*. Between these 2 extremes are cases in which varying degrees of preeclampsia are superimposed upon varying degrees of chronic hypertension. These broad categories have some value in estimating risk. Isolated mild to moderate chronic hypertension may have little effect on pregnancy outcome. On the other hand, severe hypertension of any cause may increase the risk to mother and fetus. The highest risks are associated with preeclampsia or eclampsia. The classification system of hypertension in pregnancy proposed by the National High Blood Pressure Education Program Working Group is summarized in Table 19–2.

Table 19–2. Classification of Hypertension in Pregnancy.

Definition of hypertension	
Mild:	Systolic blood pressure \geq 140 mm Hg
	Diastolic blood pressure \geq 90 mm Hg
Severe:	Systolic blood pressure \geq 180 mm Hg
	Diastolic blood pressure \geq 110 mm Hg
Chronic hypertension	
Hypertension with onset before pregnancy or before 20th week gestation	
Use of antihypertensive medications before pregnancy	
Persistence of hypertension beyond 12 weeks postpartum	
Preeclampsia	
Hypertension that occurs after 20 weeks of gestation in a woman with previously normal blood pressure. Systolic blood pressure \geq 140 mm Hg or diastolic blood pressure \geq 90 mm Hg on two occasions at least 6 hours apart	
Proteinuria, defined as urinary excretion of \geq 0.3 g protein in a 24-hour urine specimen. This finding usually correlates with a finding of 1+ or greater on dipstick	
Note edema is no longer a diagnostic criterion	
Note a systolic rise of 30 mm Hg or a diastolic rise of 15 mm Hg is no longer a diagnostic criterion	
Eclampsia	
New-onset grand mal seizures in a woman with preeclampsia that cannot be attributed to other causes	
Superimposed preeclampsia–eclampsia	
Preeclampsia or eclampsia that occurs in a woman with a pre-existing chronic hypertension	
Gestational hypertension	
Hypertension detected for the first time after midpregnancy	
Distinguished from preeclampsia by the absence of proteinuria	
Working diagnosis only during pregnancy	
Transient hypertension of pregnancy	
Gestational hypertension that resolves by 12 weeks postpartum	
If proteinuria develops in a patient with gestational hypertension, the diagnosis is preeclampsia	
If gestational hypertension does not resolve by 12 weeks postpartum, the diagnosis is chronic hypertension	

CHRONIC HYPERTENSION

Chronic hypertension complicates as many as 5% of pregnancies. It is characterized by a history of high blood pressure before pregnancy, elevation of blood pressure during the first half of pregnancy, or high blood pressure that lasts for longer than 12 weeks after delivery. The search for an underlying cause should include a complete history and physical examination, taking into account the normal changes that accompany pregnancy. During normal pregnancy, maternal blood volume increases by 40% to 60%. Cardiac output and renal blood flow increase significantly. Blood pressure normally decreases throughout the first half of pregnancy under the influence of progesterone, reaching a nadir in midpregnancy and returning to prepregnancy levels by the end of the third trimester.

In women with hypertension, underlying disorders must be excluded (Table 19–1). Blood pressure should be measured in both arms with the patient in a sitting position and the arm at the level of the heart, and multiple measurements should be obtained on different occasions. If possible, measurements should be obtained outside of the office setting. The fifth Korotkoff sound should be used to determine diastolic pressure. Auscultation of the flanks may reveal a renal artery bruit. Funduscopic examination may reveal typical findings associated with long-standing hypertension or possibly diabetes. An enlarged thyroid gland may indicate thyroid disease. Absent peripheral pulses suggest coarctation of the aorta. Heart, skin, and joints should be evaluated thoroughly. After evaluating the possible causes of chronic hypertension, further assessment is directed at end-organs and systems most likely to be affected by hypertension, including the eyes, heart, kidneys, uteroplacental circulation, and the fetus.

Laboratory tests include a complete blood count, glucose screen, electrolyte panel, serum creatinine, urinalysis, and urine culture. In some cases, additional tests may be needed. In patients with possible renal disease (serum creatinine \geq 0.8 mg/dL, urine protein > 1+ on dipstick), a 24-hour urine collection for creatinine clearance and total protein will provide baseline information that may be helpful in diagnosing the onset of preeclampsia later in pregnancy. Diabetes should be excluded. Antinuclear antibody may help confirm a diagnosis of collagen vascular disease. A suppressed thyroid-stimulating hormone level suggests hyperthyroidism. Rarely, elevated urinary catecholamine levels may point to pheochromocytoma. An electrocardiogram may reveal left ventricular hypertrophy in the patient with long-standing hypertension. Chest radiography with abdominal shielding may reveal cardiomegaly.

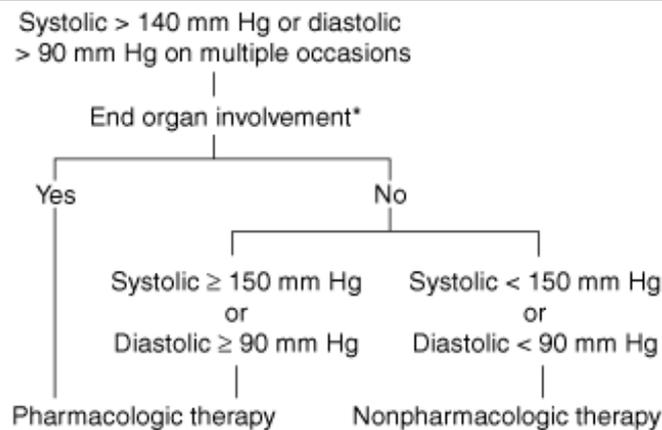

Fetal Assessment in Chronic Hypertension

Pregnancies complicated by chronic hypertension, regardless of the cause, are at increased risk for poor fetal growth. An initial ultrasound examination should be performed as early as possible to confirm the due date and to ensure that no obvious fetal anomalies are present. Thereafter, fetal growth may be assessed by ultrasound as needed, usually no more frequently than every 2–4 weeks. Antepartum fetal monitoring usually is started by 32–34 weeks. If the nonstress test is used as the method of surveillance, it should be accompanied by assessment of amniotic fluid volume. Doppler velocimetry of the umbilical, uterine, and middle cerebral arteries are helpful in optimizing the timing of delivery, particularly in cases of suspected fetal growth restriction.

Management of Mild Chronic Hypertension

In pregnant women with mild hypertension and no evidence of renal disease, serious medical complications are rare. Moreover, there is no consensus that antihypertensive medication can reduce the risk of fetal death, growth restriction, placental abruption, preeclampsia, or eclampsia in these women. Therefore, antihypertensive medication is not usually necessary. Avoidance of alcohol and tobacco is encouraged. Sodium restriction may be considered (2–3 g/d). Rigorous activity should be avoided, as should weight reduction. Despite the lack of evidence supporting the benefit of antihypertensive therapy in women with blood pressure < 180/110 mm Hg, many clinicians are reluctant to withhold medication when the blood pressure remains \geq 150/100 mm Hg despite lifestyle modifications. A practical management algorithm using a blood pressure of 150/100 mm Hg as the threshold for initiation of antihypertensive therapy in women without evidence of end-organ involvement and 140/90 mm Hg as the threshold in women with evidence of renal involvement is summarized in Figure 19–1. Prenatal visits are scheduled every 2–4 weeks until 34–36 weeks, and weekly thereafter. At each visit, blood pressure, urine protein, and fundal height are evaluated. Patients are questioned regarding signs and symptoms of preeclampsia, including headache, abdominal pain, blurred vision, scotomata, rapid weight gain, or marked swelling of the hands and/or face. Antepartum fetal monitoring usually is started around 32–34 weeks, and, in most cases, delivery is accomplished by 39–40 weeks' gestation.

Figure 19–1.

*Abnormal renal function
Proteinuria (> 300 mg/24 hr, > 1+ dip, > 30 mg/dL)
Clcr < 110 ml/min, serum creatinine > 0.8 mg/dL

Management algorithm for severe chronic hypertension in pregnancy.

Management of Severe Chronic Hypertension

Women with sustained blood pressure $\geq 180/110$ mm Hg or those with evidence of renal disease may be at higher risk for serious complications, such as heart attack, stroke, or progression of renal disease, and are candidates for antihypertensive medication. As summarized in Figure 19–1, many clinicians would use a lower threshold of 150/100 mm Hg for instituting antihypertensive therapy during pregnancy.

Frequent prenatal visits may be needed to check the effectiveness of the medication. Fetal growth, blood pressure, and proteinuria are assessed at each visit, and evidence of superimposed preeclampsia is aggressively sought. Management of preeclampsia is described later in this chapter. In women with evidence of renal disease, some clinicians measure creatinine clearance and 24-hour urinary protein excretion each trimester. Sonographic assessment of fetal growth is performed every 2–4 weeks, antepartum testing is initiated by 32–34 weeks, and delivery is accomplished after 38 weeks or when fetal lung maturity is demonstrated. In some cases, hypertension worsens significantly during pregnancy without the development of overt preeclampsia. If exacerbation of chronic hypertension necessitates preterm delivery, corticosteroids should be considered in attempt to accelerate fetal maturity.

Antihypertensive Therapy in Chronic Hypertension

Several choices for initial antihypertensive therapy during pregnancy are available. Methyldopa has been studied extensively and is recommended by many as the first-line antihypertensive agent in pregnancy. It is a centrally acting α -adrenergic agonist that appears to inhibit vasoconstricting impulses from the medullary vasoregulatory center. The total daily dosage of 500 mg to 2 g is administered in 2–4 divided doses. Peak plasma levels occur 2–3 hours after administration, and the maximum effect occurs 4–6 hours after an oral dose. The agent is excreted primarily by the kidney. Sedation and postural

hypotension are the most common side effects. A positive direct Coombs' test may be seen, usually after 6–12 months of therapy. Hemolytic anemia may occur in these patients and is an indication to stop the medication. Fever, liver function abnormalities, granulocytopenia, and thrombocytopenia are rare side effects.

Labetalol is an α_1 -adrenergic blocker and a nonselective β -adrenergic blocker. The β -blockade/ α -blockade ratio is 7:1. A large body of clinical evidence suggests that use of labetalol is safe during pregnancy. It appears to lack teratogenicity and crosses the placenta in small amounts. One randomized study showed no advantages of labetalol over methyldopa. Another study reported a higher incidence of small for gestational age (SGA) newborns in patients treated with labetalol. The usual starting dose is 100 mg BID, and the dose can be increased weekly to a maximum of 2400 mg daily. Titration increments should not exceed 200 mg BID.

Nifedipine is a calcium channel blocker that has been used during pregnancy for tocolysis and treatment of hypertension. Several reports suggest that nifedipine use is safe during pregnancy; however, the cumulative experience with this agent is not as extensive as with methyldopa and labetalol. When nifedipine is used for treatment of chronic hypertension during pregnancy, the long-acting formulation (Procardia XL, Adalat CC) may improve patient compliance. The principal benefit of this agent is once-daily dosing. The usual starting dose is 30 mg daily. If necessary, the dose may be increased to 60–90 mg daily. The neuromuscular-blocking action of magnesium may be potentiated by simultaneous calcium channel blockade; therefore, nifedipine should be used with caution in patients receiving magnesium sulfate. The sublingual route of administration is associated with unpredictable blood levels and should be avoided.

Other antihypertensive medications used in pregnancy include atenolol, metoprolol, prazosin, minoxidil, hydralazine, thiazide diuretics, and clonidine. Published experience with these agents is limited, and they should not supplant methyldopa, labetalol, or nifedipine as first-line agents in pregnancy.

Use of angiotensin-converting enzyme inhibitors (enalapril, captopril) during pregnancy is associated fetal hypocalvaria, renal defects, anuria, and fetal and neonatal death. These agents are contraindicated in pregnancy. With few exceptions, diuretics (furosemide, hydrochlorothiazide) should be avoided during pregnancy. Fetal bradycardia, growth retardation, and neonatal hypoglycemia have been reported in patients treated with blockers.

Prognosis

Pregnancy outcome usually is good in patients with mild chronic hypertension and no other serious medical conditions. Fetal growth restriction, superimposed preeclampsia, placental abruption, and preterm delivery are the most common complications. The outlook is less favorable in women with severe hypertension early in pregnancy and in those with evidence of end-organ compromise, such as renal insufficiency and/or cardiovascular disease. By necessity, management is individualized. Close monitoring for development of fetal growth restriction and superimposed preeclampsia is indicated.

PREECLAMPSIA

Preeclampsia complicates 5–7% of all pregnancies. The classic diagnostic triad included hypertension, proteinuria, and edema. Recently, the National High Blood Pressure Education Working Group recommended eliminating edema as a diagnostic criterion because it is too frequent an observation during normal pregnancy to be useful in diagnosing preeclampsia. Preeclampsia occurs with increased frequency among young, nulliparous women. However, the frequency distribution is bimodal, with a second peak occurring in multiparous women greater than 35 years of age. Among daughters of preeclamptic women, the risk of preeclampsia is significantly higher than the population risk. Other

predisposing factors for preeclampsia are listed in Table 19–3.

Table 19–3. Risk Factors for Preeclampsia.

Age < 20 years or > 35 years
Nulliparity
Multiple gestation
Hydatidiform mole
Diabetes mellitus
Thyroid disease
Chronic hypertension
Renal disease
Collagen vascular disease
Antiphospholipid syndrome
Family history of preeclampsia

Normal pregnancy is associated with decreased maternal sensitivity to endogenous vasopressors. Apparent early in gestation, this effect leads to expansion of the maternal intravascular space and a decline in blood pressure throughout the first half of pregnancy, with a nadir at midgestation. Thereafter, continued expansion of intravascular volume leads to a gradual rise in the blood pressure to prepregnancy levels by term. Women destined to develop preeclampsia do not exhibit normal refractoriness to endogenous vasopressors. As a result, normal expansion of the intravascular space does not occur, and the normal decline in blood pressure during the first half of pregnancy may be absent or attenuated. Despite normal to elevated blood pressure, intravascular volume is reduced. In addition to the classic findings of hypertension and proteinuria, women with preeclampsia may complain of scotomata, blurred vision, or pain in the epigastrium or right upper quadrant. Examination often reveals brisk patellar reflexes and clonus. Laboratory abnormalities include elevated levels of hematocrit, lactate dehydrogenase, serum transaminases and uric acid, and thrombocytopenia. Although biochemical evidence of disseminated intravascular coagulation (DIC) may be detected with increased fibrin degradation products, hypofibrinogenemia and prolongation of the prothrombin time and activated partial thromboplastin time usually are seen only in cases complicated by abruption or multiple organ failure.

Pathophysiology

BRAIN

Pathologic findings in preeclampsia-induced cerebral injury include fibrinoid necrosis, thrombosis, microinfarcts, and petechial hemorrhages, primarily in the cerebral cortex. Cerebral edema may be observed. Head computed tomographic findings include focal white matter hypodensities in the posterior cerebral hemispheres, temporal lobes, and brainstem, possibly reflecting petechial hemorrhage with resultant local edema. Magnetic resonance imaging may reveal occipital and parietal abnormalities in the watershed distribution of the major cerebral arteries, as well as lesions in the brainstem and basal ganglia. Subarachnoid or intraventricular hemorrhage may occur in severe cases.

HEART

Preeclampsia is characterized by the absence of normal intravascular volume expansion, a reduction in normal circulating blood volume, and a loss of normal refractoriness to endogenous vasopressors, including angiotensin II. Invasive hemodynamic monitoring in preeclamptic patients has yielded

conflicting information. Depending upon disease severity, effects of previous therapy, and other factors, preeclampsia has been described variously as a state of abnormally high cardiac output and low systemic vascular resistance, a state of abnormally low cardiac output and high systemic vascular resistance, or a state of high cardiac output and high systemic vascular resistance. These divergent observations underscore the complexity of the disorder.

LUNGS

Alterations in colloid oncotic pressure, capillary endothelial integrity, and intravascular hydrostatic pressure in preeclampsia predispose to noncardiogenic pulmonary edema. In women with preeclampsia superimposed on chronic hypertension, preexisting hypertensive cardiac disease may exacerbate the situation, superimposing cardiogenic pulmonary edema on noncardiogenic, preeclampsia-related pulmonary edema. Excessive administration of intravenous (IV) fluid and postpartum mobilization of accumulated extravascular fluid also increase the risk of pulmonary edema. In eclampsia, pulmonary injury may result from aspiration of gastric contents, leading to pneumonia, pneumonitis, or adult respiratory distress syndrome.

LIVER

Histologic lesions in the liver are characterized by sinusoidal fibrin deposition in the periportal areas with surrounding hemorrhage and portal capillary thrombi. Centrilobular necrosis may result from reduced perfusion. Inflammation is not characteristic. Subcapsular hematomas may develop. In severe cases involving hepatocellular necrosis and DIC, intrahepatic hematomas may progress to liver rupture. Right upper quadrant pain or epigastric pain are classic symptoms attributed to stretching of Glisson's capsule. Elevation of serum transaminases is a hallmark of HELLP (hemolysis, elevated liver enzymes, and low platelets) syndrome.

KIDNEYS

Distinct histologic changes have been described in the kidneys of women with preeclampsia. The classic renal lesion of preeclampsia, "glomeruloendotheliosis," is characterized by swelling and enlargement of glomerular capillary endothelial cells, leading to narrowing of the capillary lumen. There is an increased amount of cytoplasm containing lipid-filled vacuoles. Mesangial cells may be swollen as well. Immunoglobulins, complement, fibrin, and fibrin degradation products have been observed in the glomeruli, but their presence is variable.

EYES

Retinal vasospasm, retinal edema, serous retinal detachment, and cortical blindness may occur in the setting of preeclampsia. Blindness is uncommon and usually transient, resolving within hours to days of delivery.

Etiology

The etiology of preeclampsia is not known; however, a growing body of evidence suggests that maternal vascular endothelial injury plays a central role in the disorder. Some reports suggest that endothelial damage in preeclampsia results in decreased endothelial production of prostaglandin I_2 (prostacyclin), a potent vasodilator and inhibitor of platelet aggregation. Endothelial cell injury exposes subendothelial collagen and can trigger platelet aggregation, activation, and release of platelet-derived thromboxane A_2 (TXA₂), a potent vasoconstrictor and stimulator of platelet aggregation. Decreased prostacyclin production by dysfunctional endothelial cells and increased TXA₂ release by activated platelets and trophoblast may be responsible for reversal of the normal ratio of prostacyclin and TXA₂ observed in preeclampsia. The predominance of TXA₂ may contribute to the vasoconstriction and hypertension that are central features of the disorder. Elevated intravascular pressure combined with damaged vascular endothelium results in movement of fluid from the intravascular to the extravascular spaces, leading to

edema in the brain, retinae, lungs, liver, and subcutaneous tissues. Hypertension and glomerular endothelial damage lead to proteinuria. The resultant decrease in intravascular colloid oncotic pressure contributes to further loss of intravascular fluid. Hemoconcentration is reflected in a rising hematocrit. Consumption of platelets and activation of the clotting cascade at the sites of endothelial damage may lead to thrombocytopenia and DIC. Soluble fibrin monomers produced by the coagulation cascade may precipitate in the microvasculature, leading to microangiopathic hemolysis and elevation of the serum lactate dehydrogenase level. Cerebral edema, vasoconstriction, and capillary endothelial damage may lead to hyperreflexia, clonus, convulsions, or hemorrhage. Hepatic edema and/or ischemia may lead to hepatocellular injury and elevation of serum transaminases and lactate dehydrogenase levels. The right upper quadrant or epigastric pain observed in severe preeclampsia is thought to be caused by stretching of Glisson's capsule by hepatic edema or hemorrhage. Intravascular fluid loss across damaged capillary endothelium in the lungs may result in pulmonary edema. In the retinae, vasoconstriction and/or edema may lead to visual disturbances, retinal detachment, or blindness. Movement of fluid from the intravascular space into the subcutaneous tissues produces the characteristic nondependent edema of preeclampsia.

Endothelial damage appears to be capable of triggering a cascade of events culminating in the multiorgan system dysfunction observed in preeclampsia. However, the mechanism of endothelial injury remains speculative. In one theory, decreased placental oxygenation triggers the placenta to release an unknown factor into the maternal circulation. This circulating factor is capable of damaging or altering the function of maternal endothelial cells and triggering the cascade of events described. In support of this theory, cultured trophoblasts exposed to a hypoxic environment release a variety of potentially vasoactive factors, including thromboxane, interleukin-1, and tumor necrosis factor. Moreover, serum from preeclamptic women, when applied to human endothelial cell cultures, alters the release of a variety of procoagulant, vasoactive, and mitogenic factors, including endothelin, nitric oxide, and prostacyclin. Serum from the same woman 6 weeks after delivery does not produce this effect. Likewise, serum from a nonpreeclamptic woman at the same gestational age fails to trigger these endothelial changes. In many cases, reduced placental oxygenation may be explained by maternal vasculopathy (chronic hypertension, renal disease, collagen vascular disease) and in others by abnormal placental mass (multiple gestation, diabetes, hydatidiform mole). In another subset of patients, reduced placental oxygenation late in pregnancy may be the result of abnormal endovascular trophoblast invasion early in pregnancy. In the first trimester of a normal pregnancy, proliferating trophoblast invades the decidual segments of the maternal spiral arteries, replacing endothelium and destroying the medial elastic and muscular tissue of the arterial wall. The arterial wall is replaced by fibrinoid material. During the second trimester, a second wave of endovascular trophoblastic invasion extends down the lumen of the spiral arteries deeper in the myometrium. The endothelium and musculoelastic architecture of the spiral arteries are destroyed, resulting in dilated, thin-walled, funnel-shaped vessels that are passive conduits of the increased uteroplacental blood flow of pregnancy. In some women destined to develop preeclampsia, the first wave of endovascular trophoblastic invasion may be incomplete, and the second wave does not occur. As a result, the deeper segments of the spiral arteries are not remodeled but instead retain their musculoelastic architecture and their ability to respond to endogenous vasoconstrictors, reducing maternal perfusion of the placenta and predisposing to relative placental hypoxia later in pregnancy. In addition, myometrial portions of the spiral arteries exhibit a unique abnormality characterized by vessel wall damage, fibrinoid necrosis, lipid deposition, and macrophage and mononuclear cell infiltration of vessel walls and surrounding tissues. These changes, histologically similar to those observed in atherosclerosis, are referred to as acute atherosclerosis and may lead to vascular lumen obliteration and placental infarction. Importantly, these changes are attributed to abnormal endovascular trophoblastic invasion during the second trimester of pregnancy, predisposing the fetus to suboptimal placental

perfusion early in gestation. Interestingly, the clinical manifestations are observed most often in the third trimester, possibly due to increasing fetal and placental oxygen demands with advancing gestation.

The reason that endovascular trophoblastic invasion progresses normally in most pregnancies but abnormally in others is unclear. One theory maintains that maternal antibodies directed against paternal antigens on invading trophoblasts are necessary to shield those antigens from recognition by decidual natural killer cells, protecting the invading trophoblast from attack and rejection by the cellular arm of the maternal immune system. Supporting this theory is the observation that preeclampsia appears to be associated with primipaternity and the presumed lack of previous maternal exposure and sensitization to paternal trophoblast antigens in a previous pregnancy. Additional support for this theory is provided by the observation that preeclampsia is more common among women using barrier contraception than among those using nonbarrier forms of contraception prior to pregnancy. This suggests that maternal exposure (and presumably sensitization) to paternal antigens on sperm is protective against preeclampsia. The observed inverse relationship between duration of cohabitation before pregnancy and the incidence of preeclampsia provides further evidence that maternal sensitization to paternal antigens is protective against preeclampsia. The interplay between immunology and genetics is underscored by the observation that preeclampsia may be more common in pregnancies in which the father was the product of a preeclamptic pregnancy. Applied to the theory under discussion, this suggests that some genetically determined paternal antigens are less antigenic than others and therefore less likely to provoke an antibody response in an exposed mother, decreasing maternal production of "blocking" antibodies and increasing the likelihood of abnormal placental invasion and preeclampsia. Alternatively, paternally inherited genes may code for altered fetal production of insulinlike growth factor-2, an insulin homologue related to placental invasion. Other genes that may be inherited from the father and play a role in the development of preeclampsia include genes coding for angiotensinogen, methylenetetrahydrofolate reductase, and the factor V Leiden mutation.

Some studies have demonstrated that invading trophoblastic cells in normal pregnancy undergo an "antigenic shift" to resemble vascular endothelial antigens, masking them from recognition and rejection by decidual natural killer cells. Invading trophoblasts in preeclamptic pregnancies may fail to make this antigenic shift, exposing them to recognition by natural killer cells and halting normal invasion.

Recent work has demonstrated that soluble fms-like tyrosine kinase-1 (sFlt-1) is increased in the placenta and serum of women with preeclampsia. This protein adheres to placental growth factor and vascular endothelial growth factor (VEGF), preventing their interaction with endothelial receptors and causing endothelial dysfunction. Interrupted angiogenesis may contribute to faulty placental invasion early in pregnancy and subsequent risk for placental hypoxia–ischemia and preeclampsia. Unbound placental growth factor and VEGF have been found in decreased concentration during and even before the development of clinical preeclampsia.

Genetic, immunologic, and other factors govern the complex interaction between the maternal host and the invading trophoblast. Detailed discussion of these and other possible etiologies of the entity of preeclampsia are beyond the scope of this chapter. Regardless of the etiology, thorough familiarity with the clinical aspects of the disorder can help guide thoughtful and coherent management.

Management

In the management of preeclampsia, with few exceptions, maternal interests are best served by immediate delivery. However, this approach may not be in the best interest of the fetus. In the case of extreme prematurity, for example, the fetus may benefit from a period of expectant management during which corticosteroids are administered to accelerate fetal maturation. The decision to proceed with immediate delivery versus expectant management is based upon several factors, including disease

severity, fetal maturity, maternal and fetal condition, and cervical status. For the purposes of management, preeclampsia may be classified as mild or severe, as outlined in Table 19–4.

Table 19–4. Classification of Preeclampsia.

Mild Preeclampsia	Severe Preeclampsia
Blood pressure \geq 140/90 mm Hg but $<$ 160/110 mm Hg on two occasions at least 6 hours apart while the patient is on bed rest	Blood pressure \geq 160 mm Hg systolic or \geq 110 mm Hg diastolic on two occasions at least 6 hours apart while the patient is on bed rest
Proteinuria \geq 300 mg/24 h but $<$ 5 g/24 h	Proteinuria of 5 g or higher in 24-hour urine specimen or 3+ or greater on two random urine samples collected at least 4 hours apart
Asymptomatic	Oliguria $<$ 500 mL in 24 hours
	Cerebral or visual disturbances
	Pulmonary edema or cyanosis
	Epigastric or right upper quadrant pain
	Impaired liver function
	Thrombocytopenia
	Fetal growth restriction

MILD PREECLAMPSIA

Women with mild preeclampsia are hospitalized for further evaluation and, if indicated, delivery. If mild preeclampsia is confirmed and the gestational age is 40 weeks or greater, delivery is indicated. At gestational ages of 37–40 weeks, cervical status is assessed and, if favorable, induction is initiated. If the cervical status is unfavorable, preinduction cervical ripening agents are used as needed. Occasionally, women with very unfavorable cervical examinations between 37 and 40 weeks may be managed expectantly for a limited time with bed rest, antepartum fetal surveillance, and close monitoring of maternal condition, including blood pressure measurement every 4–6 hours and daily assessment of patellar reflexes, weight gain, proteinuria, and symptoms. A complete blood count and levels of serum transaminases, lactate dehydrogenase, and uric acid should be checked weekly to twice weekly. Delivery is indicated if the cervical status becomes favorable, antepartum testing is abnormal, the gestational age reaches 40 weeks, or evidence of worsening preeclampsia is seen. If expectant management is undertaken after 37 weeks, the patient should understand that the only known benefit is a possible reduction in the rate of cesarean birth.

Women with mild preeclampsia before 37 weeks are managed expectantly with bed rest, twice-weekly antepartum testing, and maternal evaluation as described. Corticosteroids are administered if the gestational age is less than 34 weeks; amniocentesis is performed as needed to assess fetal pulmonary maturity. When extended expectant management is undertaken, fetal growth is assessed with ultrasound every 3–4 weeks. Occasionally, outpatient management is reasonable in carefully selected, reliable, asymptomatic patients with minimal proteinuria and normal laboratory test results. This approach includes bed rest at home, daily fetal movement counts, twice-weekly antepartum testing, serial evaluation of fetal growth, and frequent assessment, often by a visiting nurse, of blood pressure, proteinuria, weight gain, patellar reflexes, and symptoms. Any evidence of disease progression constitutes an indication for hospitalization and consideration of delivery. Regardless of severity, all women with preeclampsia at the University of Southern California receive prophylactic intrapartum

magnesium sulfate to prevent convulsions. The benefit of prophylactic magnesium sulfate in preventing convulsions in patients with mild preeclampsia has not been demonstrated conclusively in the literature.

SEVERE PREECLAMPSIA

Severe preeclampsia mandates hospitalization. Delivery is indicated if the gestational age is 34 weeks or greater, fetal pulmonary is confirmed, or evidence of deteriorating maternal or fetal status is seen. Acute blood pressure control may be achieved with hydralazine, labetalol, or nifedipine. The goal of antihypertensive therapy is to achieve a systolic blood pressure < 160 mm Hg and a diastolic blood pressure < 105 mm Hg. Overly aggressive control of the blood pressure may compromise maternal perfusion of the intervillous space and adversely impact fetal oxygenation. Hydralazine is a peripheral vasodilator that can be given in doses of 5–10 mg IV. The onset of action is 10–20 minutes, and the dose can be repeated in 20–30 minutes if necessary. Labetalol can be administered in doses of 5–20 mg by slow IV push. The dose can be repeated in 10–20 minutes. Nifedipine is a calcium channel blocker that can be used in doses of 5–10 mg orally. The sublingual route of administration should not be used. The dose can be repeated in 20–30 minutes, as needed.

Management of severe preeclampsia before 34 weeks is controversial. In some institutions, delivery is accomplished regardless of fetal maturity. At the University of Southern California, delivery often is delayed for a limited period of time to permit the administration of corticosteroids. Magnesium sulfate is initiated, fetal status is monitored continuously, and antihypertensive agents are used as needed to maintain a systolic blood pressure < 160 mm Hg and a diastolic blood pressure < 105 mm Hg. Between 33 and 35 weeks, consideration should be given to amniocentesis for pulmonary maturity studies. If mature, immediate delivery is indicated. If immature, corticosteroids are administered and, if possible, delivery is delayed 24–48 hours. Between 24 and 32 weeks, antihypertensive therapy is instituted as indicated, corticosteroids are administered, and extensive maternal counseling is undertaken to clarify the risks and benefits of pregnancy prolongation. Neonatology consultation is helpful to delineate the neonatal risks specific to gestational age and estimated fetal weight. The duration of expectant management is determined on an individual basis, taking into account maternal wishes, estimated fetal weight, gestational age, and maternal and fetal status. Expectant management is contraindicated in the presence of fetal compromise, uncontrollable hypertension, eclampsia, DIC, HELLP syndrome, cerebral edema, pulmonary edema, or evidence of cerebral or hepatic hemorrhage. When severe preeclampsia is diagnosed before 24 weeks of gestation, the likelihood of a favorable outcome is low. Thorough counseling should address realistically the risks and anticipated benefits of expectant management and should include the option of pregnancy termination. If an appropriately informed patient declines the option of pregnancy termination, expectant management should proceed as outlined above.

INTRAPARTUM MANAGEMENT OF PREECLAMPSIA

In women with preeclampsia without contraindications to labor, vaginal delivery is the preferred approach. Cervical ripening agents and oxytocin are used as needed. During labor, magnesium sulfate is administered for seizure prophylaxis as an IV loading dose of 4–6 g over 20–60 minutes, followed by a maintenance dose of 1–2 g/h. Urine output and serum creatinine level are monitored, and the magnesium dose is adjusted accordingly to prevent hypermagnesemia. Patellar reflexes and respiratory rate should be assessed frequently. In the presence of patellar reflexes, serum magnesium levels usually are unnecessary. Therapeutic magnesium levels range from 4–8 mg/dL. Loss of patellar reflexes is observed at magnesium levels of 10 mg/dL or higher, respiratory paralysis may occur at levels of 15 mg/dL or above, and cardiac arrest is possible with levels in excess of 25 mg/dL. Calcium gluconate (10 mL of 10% solution) should be available in the event of hypermagnesemia. To avoid pulmonary edema, total IV fluids should not exceed 100 mL/h. Pain control is achieved with regional anesthesia or with intramuscular or IV narcotic analgesics. Invasive hemodynamic monitoring is reserved for refractory

pulmonary edema, adult respiratory distress syndrome, or oliguria unresponsive to fluid challenge. If cesarean section is required, platelets should be available for possible transfusion for patients with platelet counts $< 50,000/\text{mm}^3$. Use of other blood products is guided by clinical and laboratory findings.

Eclampsia

The estimated incidence of eclampsia is 1–3 in 1000 preeclamptic patients. Leveno reported no seizures among 1049 preeclamptic women receiving magnesium sulfate prophylaxis. Nonetheless, tonic–clonic convulsions may occur despite magnesium sulfate therapy. In most cases seizures are self-limited, lasting 1–2 minutes. The first priorities are to ensure that the airway is clear and to prevent injury and aspiration of gastric contents. Diazepam or lorazepam should be used only if seizures are sustained. Nearly all tonic–clonic seizures are accompanied by a prolonged fetal heart rate deceleration that resolves after the seizure has ended. If possible, a 10- to 20-minute period of in utero resuscitation should be permitted prior to delivery. Convulsions alone do not constitute an indication for cesarean section. However, if vaginal birth is not possible within a reasonable period of time, cesarean delivery is performed in most cases.

HELLP Syndrome

The HELLP syndrome is a variant of preeclampsia that is characterized by hemolysis, elevated liver enzymes, and low platelets. It complicates 10% of cases of severe preeclampsia and up to 50% of cases of eclampsia. Right upper quadrant pain, nausea, vomiting, and malaise are common. Hypertension and proteinuria are variable. The hallmark of the disorder is microangiopathic hemolysis leading to elevation of serum lactate dehydrogenase level and fragmented red blood cells on peripheral smear. Transaminase levels are elevated, thrombocytopenia is present, and DIC may be evident. Management is similar to that of severe preeclampsia. Recent reports suggest that dexamethasone may hasten the improvement of HELLP syndrome following delivery. Dexamethasone is administered IV in 4 doses of 10 mg, 10 mg, 5 mg, and 5 mg at 12-hour intervals or in doses of 10 mg IV at 12-hour intervals until improvement. In another protocol, dexamethasone is administered in doses of 10 mg IV every 6 hours for 2 doses, followed by 6 mg every 6 hours for 2–4 doses. If elevated transaminase levels or thrombocytopenia persist beyond the fourth postpartum day, alternative explanations should be considered, including thrombotic thrombocytopenic purpura, hemolytic uremic syndrome, acute fatty liver of pregnancy, viral- or drug-induced hepatitis, and systemic lupus erythematosus.

Prevention of Preeclampsia

The observed alteration in the ratio of vasoconstrictive and vasodilatory prostaglandins in preeclampsia led investigators to study the effectiveness of prostaglandin synthesis inhibitors in preventing the disorder. Several small trials of low-dose aspirin reported significant reductions in the incidence of preeclampsia in high-risk populations. However, in 1994 the Collaborative Low-Dose Aspirin Study in Pregnancy (CLASP) Collaborative Group reported a large randomized trial comparing low-dose aspirin to placebo in more than 9300 high-risk patients. Low-dose aspirin did not reduce the incidence of preeclampsia in this high-risk population. Hauth reported a significant reduction in preeclampsia among low-risk women treated with low-dose aspirin. However, a larger trial by Sibai reported no benefit. Reviewing all the conflicting evidence, investigators for the Cochrane Collaboration concluded there may be a small to moderate benefit of low-dose aspirin in preventing preeclampsia. Because the risks of the regimen are few, some physicians may reasonably choose to use it.

Calcium is essential in the synthesis of nitric oxide, a potent vasodilator believed to contribute to the maintenance of reduced vascular tone in pregnancy. Although several small studies suggested a possible benefit of calcium supplementation in preventing preeclampsia, a large trial by Levine that included more than 4400 women reported no benefit.

CONCLUSION

Hypertensive disorders of pregnancy remain among the most common causes of adverse maternal and perinatal outcome. These disorders can be regarded as a spectrum of disease, ranging from isolated chronic hypertension to pure preeclampsia–eclampsia. Isolated mild or moderate chronic hypertension appears to have little effect on pregnancy outcome. Morbidity and mortality are highest among patients with severe preeclampsia or eclampsia.

Appropriate management of newly diagnosed chronic hypertension entails a thorough search for an underlying cause. Use of antihypertensive medications are reserved for women with severe chronic hypertension. Close maternal and fetal surveillance is necessary, and a high index of suspicion must be maintained for the development of superimposed preeclampsia.

The management of preeclampsia is influenced by many factors, including disease severity, gestational age, and fetal condition. Optimal management requires an appreciation of the complexity of the disease process and familiarity with its manifestations in multiple organ systems. Maternal and fetal risks and benefits must be assessed thoroughly. Individualized treatment plans should be formulated and discussed with the patient, and she should be encouraged to participate in major decisions regarding her care. In atypical cases, alternative diagnoses must be considered.

Current OB/GYN > Chapter 20. Third-Trimester Vaginal Bleeding >

THIRD-TRIMESTER VAGINAL BLEEDING: INTRODUCTION

Third-trimester hemorrhage continues to be one of the most ominous complications of pregnancy. Bleeding in late pregnancy is common and requires medical evaluation in 5–10% of pregnancies. The seriousness and frequency of obstetric hemorrhage make third-trimester hemorrhage one of the 3 leading causes of maternal death and a major cause of perinatal morbidity and mortality in the United States. Fortunately, most patients have only slight blood loss. However, even minor bleeding may be caused by a life-threatening disorder.

Differentiation must be made between obstetric causes of bleeding (usually more hazardous) and nonobstetric causes (usually less hazardous) (Table 20–1). Nonobstetric causes usually result in relatively little blood loss and little threat to mother or fetus. An exception is invasive carcinoma of the cervix. Obstetric causes are of more concern. Most serious hemorrhages (2–3% of pregnancies) result in loss of more than 800 mL of blood and are due to premature separation of the placenta or placenta previa. Less common but still dangerous causes of bleeding are circumvallate placenta, abnormalities of the blood clotting mechanism, and uterine rupture. Bleeding from the peripheral portion of the intervillous space, or marginal sinus rupture, is a diagnosis of exclusion. Extrusion of cervical mucus ("bloody show") is the most common cause of bleeding in late pregnancy. Although blood loss in this setting occasionally is heavy, medical intervention almost never is necessary.

Table 20–1. Common Causes of Third-Trimester Bleeding.

Obstetric Causes	Nonobstetric Causes
Bloody show	Cervical cancer or dysplasia
Placenta previa	Cervicitis ¹
Abruptio placentae	Cervical polyps
Vasa previa	Cervical eversion
Disseminated intravascular coagulopathy (DIC)	Vaginal laceration
Uterine rupture	Vaginitis
Marginal sinus bleed ²	

¹Due to trichomoniasis, *Chlamydia trachomatis*, *Neisseria gonorrhoeae*, herpes simplex virus, etc.

²Marginal sinus bleed is a form of abruptio placentae.

Although almost all of the blood loss from placental accidents is maternal, some fetal loss is possible, particularly if the substance of the placenta is traumatized. Bleeding from vasa praevia is the only cause of pure fetal hemorrhage but fortunately is rare. If fetal bleeding is suspected, the presence of fetal

hemoglobin can be confirmed by elution or electrophoretic techniques.

This chapter focuses on 3 major causes of hemorrhage: premature separation of the placenta, placenta previa, and uterine rupture. Circumvallate placenta and marginal sinus rupture (usually self-limited) are considered variants of premature separation of the placenta.

INITIAL EVALUATION

Principles of Management

Two principles in the investigation of third-trimester hemorrhage must be followed. (1) Any woman experiencing vaginal bleeding in late pregnancy must be evaluated in a hospital capable of dealing with maternal hemorrhage and a compromised perinate. (2) A vaginal or rectal examination must not be performed until placenta previa has been ruled out. Vaginal or rectal examination is extremely hazardous because of the possibility of provoking an uncontrollable, catastrophic hemorrhage.

Life-Threatening Hemorrhage Associated with Hypovolemic Shock

Early recognition of hypovolemia is essential. Signs and symptoms of hypovolemic shock include pallor, clammy skin, syncope, thirst, dyspnea, restlessness, agitation, anxiety, confusion, falling blood pressure, tachycardia, thready pulse, and oliguria. Abnormalities in the fetal heart tracing (decelerations of change in baseline) occur as the mother decompensates (Table 20–2).

Table 20–2. Clinical Picture in Hemorrhagic Shock and Expected Response to Volume Replacement.

Clinical Sign	Primary Shock		Secondary Shock
	Early	Late	
Mental state	Alert and anxious	Confused	Coma
General appearance	Normal and warm	Pale and cold	Cyanotic and cold
Blood pressure	Slightly hypotensive	Moderately hypotensive	Markedly hypotensive
Respiratory system	Slight tachypnea	Tachypnea	Tachypnea and cyanosis
Urinary output	30 to 60 mL/h (0.5–1.0 mL/kg/h)	< 30 mL/h (<0.5 mL/kg/h)	Anuria
Effect of volume challenge on			
Bood pressure	Increased	Slightly increased	No response
Urinary output	Increased	Slightly increased	No response

Most healthy gravidas remain hemodynamically stable until they lose approximately 1500 mL (25%) of their blood volume. If adequate treatment is not provided, the patient will rapidly decompensate.

In the unstable patient, the standard ABCDs of resuscitation should be initiated. Guarantee a patent airway. Place the patient in Trendelenburg position with a left tilt, which will maximize venous return by preventing the gravid uterus from compressing the inferior vena cava. Two large-bore (16-gauge or larger) intravenous catheters should be placed and fluid replacement with crystalloid or colloid volume expanders initiated. In this case, the "D" in the ABCDs represents continuous electronic fetal monitoring while the mother is being stabilized.

BLOOD TRANSFUSION

The initial hematocrit may be deceptively normal until equilibration is reached in a patient with rapid blood loss hemoconcentration. Therefore, the clinical evaluation should be the primary guide in managing the patient with hemorrhage.

When clinically indicated, whole blood or packed red blood cells (PRBCs) should be administered rapidly. When packed cells are used, it is important to be aware of the potential for dilution coagulopathy. After 4 units of PRBCs are transfused, a coagulation panel in addition to calcium and potassium levels should be obtained and electrolytes replenished if needed. If fluid overload is a concern, such as in the preeclamptic patient, cryoprecipitate can be used in place of fresh-frozen plasma. Invasive hemodynamic monitoring may be necessary in extraordinary cases.

VASOACTIVE DRUGS

Vasoactive drugs should be used only when specific pharmacologic effects are desired (eg, to increase myocardial contractility), when volume expanders are not available, or when volume expansion and other measures are ineffective. Even in these cases, efficacy may be questioned; these agents should be used only when their benefit clearly outweighs their potential risks. Delivery will have been accomplished prior to use of these agents in almost all cases. The most commonly used agent is dopamine (a mixed α - and β -adrenergic stimulant), 200 mg in 500 mL sodium chloride intravenously, starting at 2–5 μ g/kg/min and increasing gradually by 5–10 μ g/kg/min to 20–50 μ g/kg/min. Other agents that might be given by experienced personnel include levarterenol bitartrate, isoproterenol, metaraminol bitartrate, and phenylephrine. Intra-arterial blood pressure monitoring usually is required when these medications are given.

Nonemergency Bleeding

HISTORY AND ABDOMINAL EXAMINATION

Once the patient is evaluated and found to be hemodynamically stable, the cause of bleeding must be quickly identified. After a brief history is obtained, the patient's abdomen should be examined and a bedside ultrasound performed to evaluate the location of the placenta and the fetal status.

If ultrasound is not immediately available, fetal heart tones should be obtained and the fundal height marked on the abdomen with a ballpoint or other indelible pen. This aids in determining gestational age and later aids in ascertaining if the uterus is rapidly expanding from concealed hemorrhage due to abruptio placentae. Leopold's maneuvers assist in determination of fetal size, presentation, position, and engagement. It is crucial to determine whether the presenting part is well engaged in the pelvis. When there is engagement, total placenta previa is unlikely. Palpation for uterine contractions, tone, and tenderness should be conducted. Hemodynamic status can change after initial assessment and therefore should be continuously re-evaluated.

LABORATORY EVALUATION

Laboratory evaluation should include blood type and cross-match for 2–6 units, depending on the hemodynamic status, as well as a complete blood count with platelets and baseline coagulation status (prothrombin time and partial thromboplastin time). D-Dimer or fibrin split products are useful when abruptio placentae is suspected. These are the most sensitive tests to confirm coagulopathy; however, they are qualitative studies and provide little information about the severity of abruption.

VAGINAL EXAMINATION

Once placenta previa has been ruled out, both a speculum and a manual vaginal examination should be performed to evaluate for the presence of either a nonobstetric etiology or labor. When other causes have been excluded, placental abruption (including marginal sinus bleed) becomes the assumed diagnosis.

ULTRASOUND EXAMINATION

Ultrasound is the most accurate way to confirm a diagnosis of placenta previa. A translabial or transvaginal study can be safely performed if the diagnosis is unclear from a transabdominal scan. Transvaginal ultrasound is the most accurate means to evaluate for placenta previa and has been demonstrated to be safe in experienced hands. The addition of color flow Doppler to real-time ultrasound increases the sensitivity. Ultrasound has limited sensitivity in diagnosing a retroplacental clot (caused by abruption), even in experienced hands. However, it occasionally is useful for diagnosis of a concealed hemorrhage.

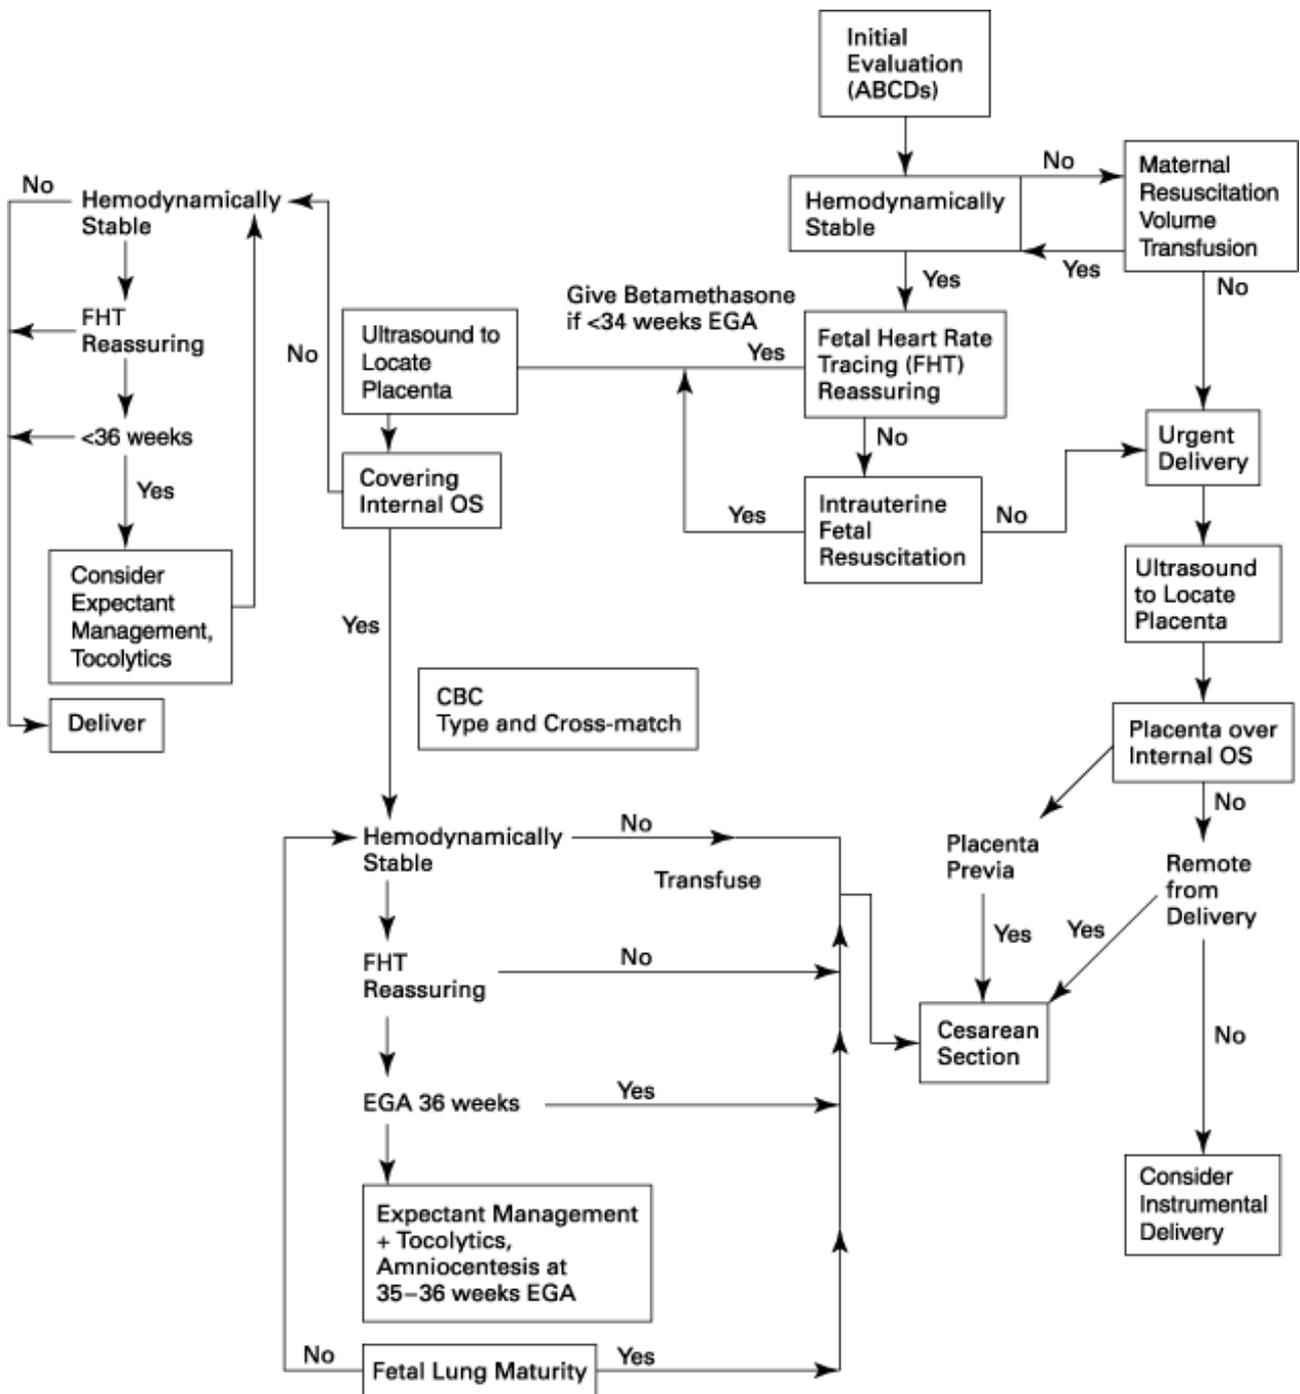

Ultrasound evaluation should be performed in the labor and delivery suite if possible. Fetal heart rate (FHR) monitoring should continue at regular intervals throughout the study. Assessment of amniotic fluid volume and confirmation of fetal age should be obtained at the time of ultrasound study.

MANAGEMENT OF BLEEDING

At this point, findings regarding the status of the mother, fetus, and placenta and evaluation of labor should be combined to provide a diagnosis and to plan the course of management. The 3 general management options are immediate delivery, continued labor, and expectant management, depending on the diagnosis.

If the fetus is immature, the patient should be treated expectantly unless additional complications (eg, continuing bleeding, evidence of fetal compromise, labor, or spontaneous rupture of the membranes) appear. In approximately 90% of cases, third-trimester bleeding subsides within 24 hours. If placental studies signify a high placental implantation and bleeding stops, repeat vaginal examination is indicated prior to patient discharge to exclude nonobstetric causes of bleeding (Fig 20–1).

Algorithm for evaluating third-trimester vaginal bleeding.

Nonobstetric causes of bleeding in late pregnancy usually result only in spotting that does not increase with activity. There are no uterine contractions, and the definitive diagnosis usually is made by speculum examination, Papanicolaou smear, culture, or colposcopy. Only advanced cancer is associated with a poor maternal prognosis. Vaginal lacerations and varices may require repair but have a good prognosis. Most infections causing bleeding clear readily when treated with appropriate agents. Benign neoplasias and eversions require simple treatment and have a good prognosis.

PREMATURE SEPARATION OF THE PLACENTA (ABRUPTIO PLACENTAE,

MARGINAL SINUS BLEED)

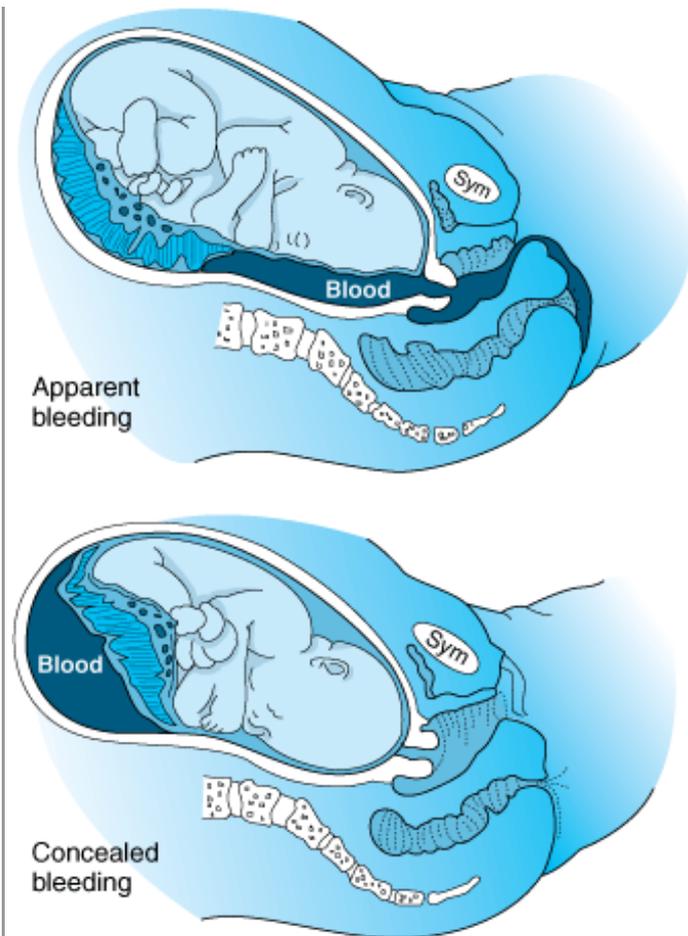

Essentials of Diagnosis

- Unremitting abdominal (uterine) or back pain.
- Irritable, tender, and often hypertonic uterus.
- Visible or concealed hemorrhage.
- Evidence of fetal distress may or may not be present, depending on the severity of the process.

General Considerations

Premature separation of the placenta is defined as separation from the site of uterine implantation before delivery of the fetus (approximately 1 in 77–89 deliveries). The severe form (resulting in fetal death) has an incidence of approximately 1 in 500–750 deliveries. Two principal forms of premature separation of the placenta can be recognized, depending on whether the resulting hemorrhage is external or concealed (Fig 20–2). In the concealed form (20%), the hemorrhage is confined within the uterine cavity, detachment of the placenta may be complete, and the complications often are severe. Approximately 10% of abruptions are associated with clinically significant coagulopathies (disseminated intravascular coagulation [DIC]), but 40% of those severe enough to cause fetal death are associated with coagulopathy. In the external form (80%), the blood drains through the cervix, placental detachment is more likely to be incomplete, and the complications are fewer and less severe. Occasionally, the placental detachment involves only the margin or placental rim. Here, the most important complication is the possibility of premature labor.

Figure 20–2.

Types of premature separation of the placenta.

Approximately 30% of cases of third-trimester bleeding are due to placental separation, with the initial hemorrhage usually encountered after the 26th week. Placental separation in early pregnancy cannot be distinguished from other causes of abortion. Approximately 50% of separations occur before the onset of labor, and 10–15% are not diagnosed before the second stage of labor.

Etiology

The exact causes of placental separation are often difficult to ascertain, although there are a number of predisposing and precipitating factors. A common predisposing factor is previous placental separation. Following 1 episode, the incidence of recurrence is 10–17%. Following 2 episodes, the incidence of recurrence exceeds 20%. The hypertensive states of pregnancy are associated with 2.5–17.9% incidence of placental separation. In abruptio placentae extensive enough to cause fetal death, approximately 50% of cases are associated with hypertensive states of pregnancy. Approximately half of these cases have chronic hypertension and half pregnancy-induced hypertension. Other predisposing factors include advanced maternal age, multiparity, uterine distention (eg, multiple gestation, hydramnios), vascular disease (eg, diabetes mellitus, systemic lupus erythematosus), thrombophilias, uterine anomalies or tumors (eg, leiomyoma), cigarette smoking, alcohol consumption (> 14 drinks per week), cocaine use, and possibly maternal type O blood.

Precipitating causes of premature separation of the placenta, although more direct and definable, are no less diverse. All are rare. Circumvallate placenta, trauma (eg, external or internal version, automobile

accident, abdominal trauma directly transmitted to an anterior placenta), sudden reduction in uterine volume (eg, rapid amniotic fluid loss, delivery of a first twin), abnormally short cord (usually only a problem during delivery, when traction is exerted on the cord as the fetus moves down the birth canal), and increased venous pressure (usually only problematic with abrupt or extreme alterations) are included in this category.

Pathophysiology & Pathology

Several mechanisms are thought to be important in the pathophysiology of premature placental separation. One mechanism is local vascular injury that results in vascular rupture into the decidua basalis, bleeding, and hematoma formation. The hematoma shears off adjacent denuded vessels, producing further bleeding and enlargement of the area of separation. Another mechanism is initiated by an abrupt rise in uterine venous pressure transmitted to the intervillous space. This results in engorgement of the venous bed and separation of all or a portion of the placenta. Conditions predisposing to vascular injury and known to be associated with an increased incidence of placental separation are preeclampsia–eclampsia, chronic hypertension, diabetes mellitus, chronic renal disease, cigarette smoking, and cocaine use. Factors that may predispose to a disturbed vascular equilibrium and the possibility of passive congestion of the venous bed in response to an abrupt rise in uterine venous pressure are vasodilatation secondary to shock, compensatory hypertension as a result of aortic compression, and paralytic vasodilatation of conduction anesthesia.

Mechanical factors causing premature separation are rare (1–5%). They include transabdominal trauma, sudden decompression of the uterus, such as with the delivery of a first twin or rupture of the membranes in hydramnios, or traction on a short umbilical cord.

Another possible mechanism is initiation of the coagulation cascade. This may occur, for example, with trauma causing release of tissue thromboplastin. These activated coagulation factors in turn may act to initiate clot formation in the relative hemodynamic stasis occurring in the placental pool.

Anatomically, placental abruption may occur by hemorrhage into the decidual basalis, which splits, leaving a thin layer adjacent to the myometrium. This decidual hematoma leads to separation, compression, and further bleeding. Alternatively, a spiral artery may rupture, creating a retroplacental hematoma. In either case, bleeding occurs, a clot forms, and the placental surface can no longer provide metabolic exchange between mother and fetus.

The clot depresses the adjacent placenta. Nonclotted blood courses from the site of injury. In concealed hemorrhage, this effusion may be totally retained behind the placental margins, behind the membrane attachment to the uterine wall, or behind a closely applied fetal presenting part. The blood may rupture through the membranes or placenta and gain access to the amniotic fluid (and vice versa). The tissue disruption by bleeding may allow maternofetal hemorrhage, fetomaternal hemorrhage, maternal bleeding into the amniotic fluid, or amniotic fluid embolus, depending on the areas disrupted and their relative pressure differences.

Concealed hemorrhage is more likely to be associated with complete placental detachment. If the placental margins remain adherent, central placental separation may result in hemorrhage that infiltrates the uterine wall. Uterine tetany may follow. Occasionally, extensive intramyometrial bleeding results in uteroplacental apoplexy—so-called Couvelaire uterus, a purplish and copper-colored, ecchymotic, indurated organ that may lose its contractile force because of disruption of the muscle bundles.

In the more severe cases of separation, there may be a clinically significant amount of DIC associated with depletion of fibrinogen and platelets as well as other clotting factors. The mother may then develop a hemorrhagic diathesis that is manifested by widespread petechiae, active bleeding, hypovolemic shock,

and failure of the normal clotting mechanism. In addition, fibrin deposits in small capillaries (along with the hypoxic vascular damage of shock) can result in potentially lethal complications, including acute cor pulmonale, renal cortical and tubular necrosis, and anterior pituitary infarction (Sheehan's syndrome).

The likelihood of fetal hypoxia and fetal death depends on the amount and duration of placental separation and, in severe cases, the loss of a significant amount of fetal blood.

Clinical Findings

SYMPTOMS AND SIGNS

In general, the clinical findings correspond to the degree of separation. Approximately 30% of separations are small, produce few or no symptoms, and usually are not noted until the placenta is inspected. Larger separations are accompanied by abdominal pain and uterine irritability. Hemorrhage may be visible or concealed. If the process is extensive, evidence of fetal distress, uterine tetany, DIC, or hypovolemic shock may be seen. Increased uterine tonus and frequency of contractions may provide early clues of abruption.

Approximately 80% of patients will present with vaginal bleeding, and two-thirds will have uterine tenderness and abdominal or back pain. One-third will have abnormal contractions; about half of these will have high-frequency contractions and half hypertonus. More than 20% of patients with abruptio placentae will be diagnosed erroneously as having idiopathic premature labor. Fetal distress will be present in more than 50% of cases, and 15% will present with fetal demise.

If placental separation is marginal, there will be only minimal irritability and no uterine tenderness or fetal distress. There may be a limited amount of external bleeding (50–150 mL), either bright or dark red depending on the rapidity of its appearance.

LABORATORY AND IMAGING FINDINGS

The degree of anemia probably will be considerably less than would seem to be justified by the amount of blood loss because changes in hemoglobin and hematocrit are delayed during acute blood loss until secondary hemodilution has occurred. A peripheral blood smear may show a reduced platelet count; the presence of schistocytes, suggesting intravascular coagulation; and fibrinogen depletion with release of fibrin split products. If serial laboratory determinations of fibrinogen levels are not available, the clot observation test, a simple but invaluable bedside procedure, can be performed. A venous blood sample is drawn every hour, placed in a clean test tube, and observed for clot formation and clot lysis. Failure of clot formation within 5–10 minutes or dissolution of a formed clot when the tube is gently shaken is proof of a clotting deficiency that almost surely is due principally to a lack of fibrinogen and platelets.

More sophisticated studies should be available on an emergency basis in most hospitals. The following tests will assist in determining coagulation status: prothrombin time and partial thromboplastin time, platelet count, fibrinogen, and fibrin split products.

Ultrasonography may be considered in the diagnosis of placental abruption but often is inconclusive. Possible findings include hyperechoic foci posterior to the placenta suggestive of a collection of fresh blood or a hypoechoic area suggestive of a formed clot. Lack of findings does not provide reassurance, and use of ultrasound should not be substituted for clinical judgment, especially in the face of a concerning clinical situation.

Treatment

EXPECTANT THERAPY

Expectant management of suspected placental abruption is the exception, not the rule. This management pathway should be attempted only with careful observation of the patient and a clear clinical picture. In

general, expectant management may be appropriate when the mother is stable, the fetus is immature, and the fetal heart tracing is reassuring. The patient should be observed in the labor and delivery suite for 24–48 hours to ensure that further placental separation is not occurring. Continuous fetal and uterine monitoring should be maintained. Changes in fetal status may be the earliest indication of an expanding abruption.

In retrospective studies of women with placental abruption, tocolytic use was associated with increasing gestational age at delivery. Tocolytic use did not increase the incidence of hemorrhage, fetal distress, or stillbirth. Currently no prospective trials addressing the efficacy of tocolytic therapy in preventing an abruption from expanding have been reported.

Once the patient is stable, the decision to manage the patient as an outpatient should be tailored to the clinical situation. If outpatient surveillance is selected, the fetus should be followed closely with nonstress testing.

EMERGENCY MEASURES

Most cases of placental abruption are diagnosed as an acute event (upon presentation to labor and delivery or during the intrapartum period), making immediate intervention necessary. If the patient exhibits clinical findings that become progressively more severe or if a major placental separation is suspected as manifested by hemorrhage, uterine spasm, or fetal distress, an acute emergency exists.

Blood should be drawn for laboratory studies and at least 4 units of PRBCs typed and crossed. Two large-bore intravenous catheters should be placed and crystalloid administered.

VAGINAL DELIVERY

An attempt at vaginal delivery is indicated if the degree of separation appears to be limited and if the continuous FHR tracing is reassuring. When placental separation is extensive but the fetus is dead or of dubious viability, vaginal delivery is indicated. The exception to vaginal delivery is the patient in whom hemorrhage is uncontrollable and operative delivery is necessary to save the life of the fetus or mother.

Induction of labor with an oxytocin infusion should be instituted if active labor does not begin shortly after amniotomy. In practice, augmentation often is not needed because usually the uterus is already excessively irritable. If the uterus is extremely spastic, uterine contractions cannot be clearly identified unless an internal monitor is used, and the progress of labor must be judged by observing cervical dilatation. Pudendal block anesthesia is recommended. Conduction anesthesia is to be avoided in the face of significant hemorrhage because profound, persistent hypotension may result. However, in the volume-repleted patient in early labor, a preemptive epidural should be considered because rapid deterioration of maternal or fetal status can occur as labor progresses.

CESAREAN SECTION

The indications for cesarean section are both fetal and maternal. Abdominal delivery should be selected whenever delivery is not imminent for a fetus with a reasonable chance of survival who exhibits persistent evidence of distress. Cesarean section also is indicated if the fetus is in good condition but the situation is not favorable for rapid delivery in the face of progressive or severe placental separation. This includes most nulliparous patients with less than 3–4 cm of cervical dilatation. Maternal indications for cesarean section are uncontrollable hemorrhage from a contracting uterus, rapidly expanding uterus with concealed hemorrhage (with or without a live fetus) when delivery is not imminent, uterine apoplexy as manifested by hemorrhage with secondary relaxation of a previously spastic uterus, or refractory uterus with delivery necessary (20%).

Complications

DISSEMINATED INTRAVASCULAR COAGULATION

Placental abruption can lead to initiation of the coagulation cascade by release of tissue thromboplastin into the maternal circulation. Consumption of coagulation factors and platelets is followed by coagulopathic hemorrhage. A cycle ensues as further bleeding worsens the depletion of coagulation factors. Continuous monitoring for evidence of a clotting deficiency is mandatory from the time the diagnosis of placental abruption is considered well into the postpartum period. Treatment will depend not only on the demonstration of hematologic deficiencies but also on the amount of active bleeding and the anticipated route of delivery.

1. Fresh whole blood—Fresh whole blood is generally reserved for massive hemorrhage (more than 5–6 L blood loss in a 24-hour period). Each unit has a volume of 500 cc and contains red blood cells, white blood cells, coagulation factors, and other plasma proteins. Like PRBCs, 1 unit can be expected to raise the hematocrit by 3%.
2. Packed red blood cells—PRBCs are satisfactory for immediate replacement of blood loss, but they do not contain clotting factors. Each unit has a volume of 250 cc. Because the amount of white blood cells and plasma proteins is less than in whole blood, the chance of transfusion reaction is decreased.
3. Fresh-frozen plasma—Fresh-frozen plasma is a preparation of unconcentrated clotting factors without platelets. Each unit has a volume of 250 cc and can be expected to raise any clotting factor concentration by 2–3%. Fibrinogen concentration is raised by 10 mg% per unit. Fresh-frozen plasma usually is given in increments of 2 units.
4. Cryoprecipitate packs—Cryoprecipitate is prepared as a concentrate of fresh-frozen plasma and contains all the necessary labile coagulation factors. Because each unit contains a volume of only 40 cc, it is useful in avoiding fluid overload when treating hypofibrinogenemia.
5. Platelets—During active bleeding, transfusion of platelets often is the best practical means of counteracting a clotting deficiency. Each unit of platelets has a volume of 40–50 cc and can be expected to raise the platelet count by 10,000. Transfusions are customarily ordered as a minimum of 6–8 units.
6. Heparin—Prophylactic administration of heparin to block conversion of prothrombin to thrombin (and thereby reduce the consumption of coagulation factors) has been used successfully in the management of DIC associated with fetal death ("dead fetus syndrome"). With prompt diagnosis of fetal death and uterine evacuation, this syndrome is rarely seen. There is no role for heparin in treatment of DIC related to abruption.
7. Preparation for surgery—If cesarean section is indicated, preparation for surgery must be completed quickly. Two to 4 units of PRBCs should be secured from the moment the diagnosis is entertained. Fresh-frozen plasma can be ordered as indicated by coagulation studies. Empiric treatment of a clotting disorder may be necessary if intraoperative findings suggest abnormal coagulation and confirmatory laboratory results are not readily available. In cases of uncontrollable hemorrhage, despite maximal attempts to correct coagulopathy, alternatives include whole pelvis embolization, intrauterine balloon tamponade, and abdominal packing. Rarely, hysterectomy is necessary to control bleeding, even in the presence of some degree of coagulopathy.

RENAL CORTICAL AND TUBULAR NECROSIS

The possibility of renal cortical or tubular necrosis must be considered if oliguria persists after an adequate blood volume has been restored. An attempt should be made to improve renal circulation and promote diuresis by increasing fluid volume (with the aid of monitoring). If oliguria or anuria persists, renal necrosis is probable, and fluid intake and output must be carefully monitored. Continuing impairment of renal function may require peritoneal dialysis or hemodialysis.

UTERINE ATONY

Extensive infiltration of the myometrial wall with blood may result in loss of myometrial contractility. If, as a result, bleeding from the placental bed is not controlled, hysterectomy may be necessary. If future

childbearing is an important consideration, bilateral ligation of the ascending branches of the uterine arteries should be accomplished before resorting to hysterectomy. Not only will blood flow be reduced, but the relative ischemia produced may result in a satisfactory contraction of the damaged uterus. If ligation of the uterine vessels proves ineffective, bilateral ligation of the hypogastric arteries, reducing arterial pressure within the uterus to venous levels, may effect hemostasis. Following ligation of either the uterine or hypogastric arteries, collateral circulation should be adequate to preserve uterine function, including subsequent pregnancies.

A relatively new approach to uterine atony is the B-Lynch suture. This technique involves mechanical involution of an atonic uterus with chromic suture, mimicking the hemostasis obtained with bimanual compression. The B-Lynch technique is quick, easy to learn, and safe, providing a useful alternative to performing a hysterectomy.

Prognosis

External or concealed bleeding, excessive blood loss, shock, nulliparity, a closed cervix, absence of labor, and delayed diagnosis and treatment are unfavorable prognostic factors. Maternal mortality rates ranging from 0.5–5% are currently reported from various parts of the world. Most women die of hemorrhage (immediate or delayed) or cardiac or renal failure. A high degree of suspicion, early diagnosis, and definitive therapy should reduce the maternal mortality rate to 0.5–1%.

The perinatal mortality rate reported with abruption overall is approximately 5%. With severe abruption, the rate is much higher. In approximately 15% of cases, no fetal heartbeat can be heard on admission to the hospital, and in another 50% an abnormal FHR pattern is noted early. In cases in which transfusion of the mother is urgently required, the fetal mortality rate probably will be at least 50%. Liveborn infants have a high rate of morbidity resulting from predelivery hypoxia, birth trauma, and the hazards of prematurity (40–50%).

PLACENTA PREVIA

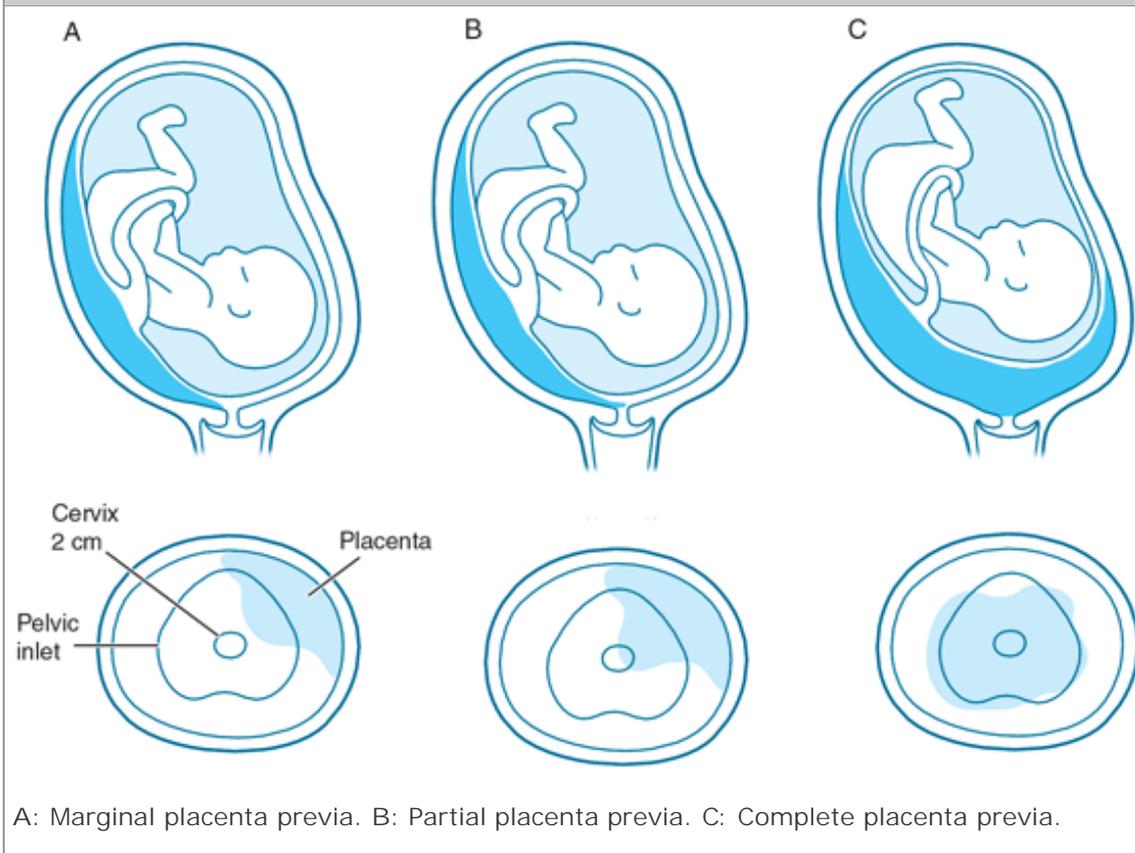

Essentials of Diagnosis

- Spotting during first and second trimesters.
- Sudden, painless, profuse bleeding in third trimester.
- Initial cramping in 10% of cases.

General Considerations

In placenta previa, the placenta is implanted in the lower uterine segment within the zone of effacement and dilatation of the cervix, constituting an obstruction to descent of the presenting part (Fig 20–3). Placenta previa is encountered in approximately 1 in 200 births, but only 20% are complete (placenta over the entire cervix). Approximately 90% of patients will be parous. Among grand multiparas the incidence may be as high as 1 in 20.

Figure 20–3.

Etiology

The incidence of placenta previa is increased by multiparity, advancing age, and previous cesarean delivery. Thus, possible etiologic factors include scarred or poorly vascularized endometrium in the corpus, a large placenta, and abnormal forms of placentation such as succenturiate lobe. The incidence of placenta previa is slightly higher in multiple gestation. A cesarean section scar triples the incidence of placenta previa. Another contributory factor is an increased average surface area of a placenta implanted in the lower uterine segment, possibly because these tissues are less well suited for nidation.

Bleeding in placenta previa may be due to any of the following causes: (1) mechanical separation of the placenta from its implantation site, either during the formation of the lower uterine segment or during effacement and dilatation of the cervix in labor, or as a result of intravaginal manipulation; (2) placentitis; or (3) rupture of poorly supported venous lakes in the decidua basalis that have become engorged with venous blood.

Classification

1. *Complete placenta previa*: The placenta completely covers the internal cervical os.
2. *Marginal placenta previa*: The placenta is implanted at the margin of the internal cervical os, within 2 cm. If the placenta is seen to be more than 2 cm from the internal os, the rate of antepartum or intrapartum hemorrhage is not increased.

Diagnosis

Every patient suspected of placenta previa should be hospitalized, and cross-matched blood should be at hand. To avoid provoking hemorrhage, both vaginal and rectal examination should not be performed.

SYMPTOMS AND SIGNS

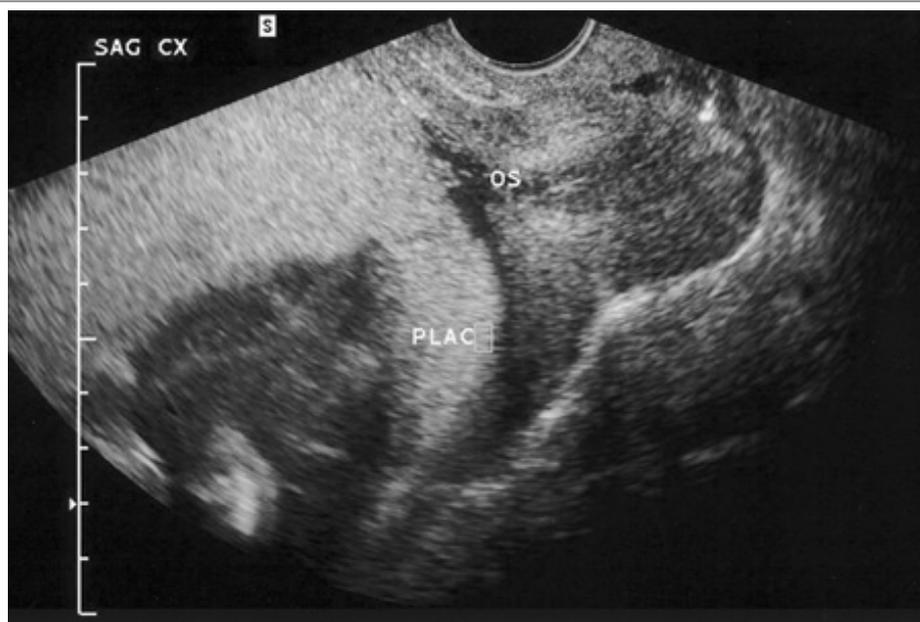

Painless hemorrhage is the cardinal sign of placenta previa. Although spotting may occur during the first and second trimesters of pregnancy, the first episode of hemorrhage usually begins after the 28th week and is characteristically described as sudden, painless, and profuse. With the initial bleeding episode, clothing or bedding may be soaked by an impressive amount of bright red, clotted blood, but the blood loss usually is not extensive, seldom produces shock, and almost never is fatal. In approximately 10% of cases there is some initial pain, probably because of coexisting placental separation and localized uterine contractions. Spontaneous labor can be expected over the next few days in 25% of patients. In a small minority of cases, bleeding is less dramatic or does not begin until after spontaneous rupture of the membranes or the onset of labor. A few nulliparous patients even reach term without bleeding, possibly because the placenta has been protected by an uneffaced cervix.

The uterus usually is soft, relaxed, and nontender. A high presenting part cannot be pressed into the pelvic inlet. The infant will present in an oblique or transverse lie in approximately 15% of cases. FHR abnormalities are unlikely unless there are complications such as hypovolemic shock, placental separation, or a cord accident.

ULTRASONOGRAPHY

(Fig 20–4) Bedside transabdominal ultrasonography can definitively identify 95% of placenta previas. Transvaginal or transperineal studies can make the diagnosis in virtually every case. This approach is particularly helpful with the posterior placenta previa.

Figure 20–4.

Total placenta previa at 18 weeks' gestation. Placenta (PLAC) completely overlies the cervical os.

(Courtesy of Dr. Rigoberto Santos.) (From Cunningham FG, Leveno KJ, Bloom SL, et al: Williams Obstetrics, 22nd ed. New York: McGraw-Hill, 2005.)

During the middle of the second trimester, the placenta is observed by ultrasound to cover the internal cervical os in approximately 30% of cases. With development of the lower uterine segment, almost all of these low implantations will be carried to a higher station. An early ultrasonic diagnosis of placenta previa requires the confirmation of an additional study before definitive action is taken.

Differential Diagnosis

Placental causes of bleeding other than placenta previa include partial premature separation of the normally implanted placenta or circumvallate placenta.

Treatment

The treatment depends on the amount of uterine bleeding; the duration of pregnancy and viability of the fetus; the degree of placenta previa; the presentation, position, and station of the fetus; the gravidity and parity of the patient; the status of the cervix; and whether or not labor has begun. The patient must be admitted to the hospital to establish the diagnosis and ideally should remain in the hospital once the diagnosis is made. Blood should be readily available for transfusion.

EXPECTANT THERAPY

The initial hemorrhage of placenta previa may occur before pulmonary maturity is established. In such cases, fetal survival can often be enhanced by expectant therapy. Early in pregnancy, transfusions to replace blood loss and the use of tocolytic agents to prevent premature labor are indicated to prolong pregnancy to at least 32–34 weeks. After 34 weeks, the benefits of further maturation must be weighed against the risk of major hemorrhage. The possibility that repeated small hemorrhages may be accompanied by intrauterine growth retardation also must be considered. Approximately 75% of cases of placenta previa are now delivered between 36 and 40 weeks.

In selecting the optimum time for delivery, tests of fetal lung maturation, including assessment of amniotic fluid surfactants and ultrasonic growth measurements, are valuable adjuvants.

If the patient is between 24 and 34 weeks' gestational age, a single course of betamethasone (2 doses of 12 mg intramuscularly separated by 24 hours) or dexamethasone (4 doses of 6 mg intravenously or intramuscularly separated by 12 hours) should be given to promote fetal lung maturity. Repeat courses of steroids are not necessary and usually are considered only for patients who initially present and receive treatment with steroids at less than 24 weeks.

Because of the costs of hospitalization, patients with a presumptive diagnosis of placenta previa are sometimes sent home on strict bed rest after their condition has become stable under ideal, controlled circumstances. Such a policy is always a calculated risk in view of the unpredictability of further hemorrhage, but the practice has been studied and is an acceptable alternative.

DELIVERY

Cesarean Section

Cesarean section is the delivery method of choice with placenta previa. Cesarean section has proved to be the most important factor in lowering maternal and perinatal mortality rates (more so than blood transfusion or better neonatal care).

If possible, hypovolemic shock should be corrected by administration of intravenous fluids and blood before the operation is started. Not only will the mother be better protected, but an at-risk fetus will recover more quickly in utero than if born while the mother is still in shock.

The choice of anesthesia depends on current and anticipated blood loss. A combination of rapid induction, endotracheal intubation, succinylcholine, and nitrous oxide is a suitable method for proceeding in the presence of active bleeding.

The choice of operative technique is of importance because of the placental location and the development of the lower uterine segment. If the incision passes through the site of placental implantation, there is a strong possibility that the fetus will lose a significant amount of blood—even enough to require subsequent transfusion. With posterior implantation of the placenta, a low-transverse incision may be

best if the lower uterine segment is well developed. Otherwise, a classic incision may be required to secure sufficient room and to avoid incision through the placenta. Preparations should be made for care and resuscitation of the infant if it becomes necessary. In addition, the possibility of blood loss should be monitored in the newborn if the placenta has been incised.

In a small percentage of cases, hemostasis in the placental bed is unsatisfactory because of the poor contractility of the lower uterine segment. Mattress sutures or packing may be required in addition to the usual oxytocin, prostaglandins, and methylergonovine. If placenta previa accreta is found, hemostasis may necessitate a total hysterectomy. Puerperal infection and anemia are the most likely postoperative complications.

Vaginal Delivery

Vaginal delivery usually is reserved for patients with a marginal implantation and a cephalic presentation. If vaginal delivery is elected, the membranes should be artificially ruptured prior to any attempt to stimulate labor (oxytocin given before amniotomy likely will cause further bleeding). Tamponade of the presenting part against the placental edge usually reduces bleeding as labor progresses.

Because of the possibility of fetal hypoxemia due to either placental separation or a cord accident (as a result of either prolapse or compression of low insertion of the cord by the descending presenting part), continuous fetal monitoring must be used. If FHR abnormalities develop, a rapid cesarean section should be performed unless vaginal delivery is imminent.

Deliver the patient in the easiest and most expeditious manner as soon as the cervix is fully dilated and the presenting part is on the perineum. For this purpose, a vacuum extractor is particularly valuable because it expedites delivery without risking rupture of the lower uterine segment.

Complications

MATERNAL

Maternal hemorrhage, shock, and death may follow severe antepartum bleeding resulting from placenta previa. Death may occur as a result of intrapartum and postpartum bleeding, operative trauma, infection, or embolism.

Premature separation of a portion of a placenta previa occurs in virtually every case and causes excessive external bleeding without pain; however, complete or wide separation of the placenta before full dilatation of the cervix is uncommon.

Placenta previa accreta is a serious abnormality in which the sparse endometrium and the myometrium of the lower uterine segment are penetrated by the trophoblast in a manner similar to placenta accreta higher in the uterus. In patients with 1 prior cesarean section, the rate of accreta in the presence of previa is 20–25% and rises to 50% with 2 or more prior cesarean sections.

FETAL

Prematurity (gestational age < 36 weeks) accounts for 60% of perinatal deaths due to placenta previa. The fetus may die as a result of decreased oxygen delivery intrapartum or birth injury. Fetal hemorrhage due to tearing of the placenta occurs with vaginal manipulation and especially upon entry into the uterine cavity as cesarean section is done for placenta previa. About half of these cesarean babies lose some blood. Fetal blood loss is directly proportional to the time that elapses between lacerating the cotyledon and clamping the cord.

Prognosis

MATERNAL

With rapid recourse to cesarean section, use of banked blood, and expertly administered anesthesia, the

overall maternal mortality has fallen to less than 1 in 1000.

FETAL

The perinatal mortality rate associated with placenta previa has declined to approximately 1%. Although premature labor, placental separation, cord accidents, and uncontrollable hemorrhage cannot be avoided, the mortality rate can be greatly reduced if ideal obstetric and newborn care is given.

RUPTURE OF THE UTERUS

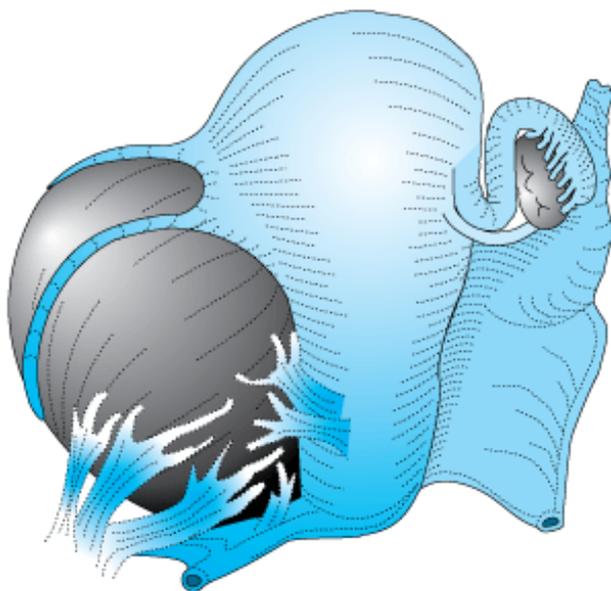

Essentials of Diagnosis

- Fetal heart rate abnormalities.
- Increased suprapubic pain and tenderness with labor.
- Sudden cessation of uterine contractions with a "tearing" sensation.
- Vaginal bleeding (or bloody urine).
- Recession of the fetal presenting part.

General Considerations

Rupture of the pregnant uterus is a potential obstetric catastrophe and a major cause of maternal death. The incidence of uterine rupture is 0.8% for women with a prior low-transverse uterine scar and 4–8% for women with a prior classic scar. Complete rupture includes the entire thickness of the uterine wall and, in most cases, the overlying serosal peritoneum (broad ligament) (Fig 20–5). *Occult* or *incomplete rupture* is a term usually reserved for dehiscence of a uterine incision from previous surgery, in which the visceral peritoneum remains intact. Such defects usually are asymptomatic unless converted to complete rupture during the course of pregnancy or labor.

Figure 20–5.

Rupture of the lower uterine segment into the broad ligament.

Risk factors for uterine rupture include history of hysterotomy (cesarean section, myomectomy,

metroplasty, cornual resection), trauma (motor vehicle accident, rotational forceps, extension of a cervical laceration), uterine overdistention (hydramnios, multiple gestation, macrosomia), uterine anomalies, placenta percreta, and choriocarcinoma.

Ruptures usually occur during the course of labor. One notable exception is scars from a classic cesarean section (or hysterotomy), one-third of which rupture during the third trimester before term and before the onset of labor. Other causes of rupture without labor are placenta percreta, invasive mole, choriocarcinoma, and cornual pregnancy.

Complete ruptures can be classified as traumatic or spontaneous. Traumatic ruptures occur most commonly as a result of motor vehicle accidents, improper administration of an oxytocic agent, or an inept attempt at operative vaginal delivery. Breech extraction through an incompletely dilated cervix is the type of operative vaginal delivery most likely to produce uterine rupture. Other maneuvers that impose risk of rupture are internal podalic version and extraction, difficult forceps, destructive operations, and cephalic replacement to relieve shoulder dystocia. Neglected obstructed labor may be responsible for rupture of the uterus. Causes of obstructed labor include contracted pelvis, fetal macrosomia, brow or face presentation, hydrocephalus, or tumors involving the birth canal. The vast majority of uterine ruptures are associated with prior uterine surgery. Previous uterine surgery includes both classic and low cervical section, intramural or submucous myomectomy, resection of the uterine cornu, metroplasty, and trachelectomy. Other operative procedures that may have damaged the uterus are vigorous curettage, induced abortion, and manual removal of the placenta.

Clinical Findings

There are no reliable signs of impending uterine rupture that occurs before labor, although the sudden appearance of gross hematuria is suggestive.

Rupture may produce local pain and tenderness associated with increased uterine irritability and, in some cases, a small amount of vaginal bleeding. Premature labor may follow. As the extent of the rupture increases, more pain, more bleeding, and perhaps signs of hypovolemic shock will occur. Exsanguination prior to surgery is unlikely because of the reduced vascularity of scar tissue, but the placenta may be completely separated and the fetus extruded partially or completely into the abdominal cavity.

By far the most common clinical setting for rupture of the uterus is rupture of a low cervical scar; this almost always occurs during active labor. Clearly identifiable signs and symptoms may be lacking. However 78–90% of patients have FHR abnormalities as the first sign of rupture. Although it is possible that labor will progress to the vaginal birth of an unaffected infant, rupture may lacerate a uterine artery, producing exsanguination, or the fetus may be extruded into the abdominal cavity. If a defect is palpated in the lower uterine segment following vaginal delivery, laparotomy may be necessary to assess the damage. Laparotomy is mandatory if continuing hemorrhage is present. If such a defect is palpated in a stable patient who does not require exploration, a subsequent trial of labor is contraindicated.

Although much less common than FHR abnormalities, other findings of spontaneous rupture during labor are suprapubic pain and tenderness, cessation of uterine contractions, disappearance of fetal heart tones, recession of the presenting part, and vaginal hemorrhage—followed by the signs and symptoms of hypovolemic shock and hemoperitoneum. Ultrasound examination might confirm an abnormal fetal position or extension of the fetal extremities. Hemoperitoneum can sometimes be seen on ultrasound.

The clinical picture depends on the extent of rupture. Unfortunately, valuable time is often lost because the rupture was not diagnosed at the time of initial examination. Whenever a newly delivered patient exhibits persistent bleeding or shock, the uterus must be carefully reexamined for signs of a rupture that may have been difficult to palpate because of the soft, irregular tissue surfaces.

Whenever an operative delivery is performed—especially if the history includes events or problems that increase the likelihood of uterine rupture—the initial examination of the uterus and birth canal must be diligent. A dehiscence of the lower uterine segment contained only by a layer of visceral peritoneum is not an uncommon finding at time of repeat cesarean section.

Treatment

Treatment is dictated by clinical scenario and can range from simply repairing the defect and obtaining hemostasis to removing the entire uterus. If hysterectomy is deemed necessary, either total hysterectomy or the subtotal operation can be performed, depending on the site of rupture and the patient's condition. The most difficult cases are lateral ruptures involving the lower uterine segment and a uterine artery with hemorrhage and hematoma formation obscuring the operative field. Care must be taken to avoid ureteral damage by blind suturing at the base of the broad ligament. If there is a question of ureteral occlusion by a suture, it is best to perform cystotomy to observe the bilateral appearance of an intravenously injected dye such as indigo carmine. If doubt still exists, a retrograde ureteral catheter can be passed upward through the cystotomy wound.

If childbearing is important and the risks—both short and long term—are acceptable to the patient, rupture repair can be attempted. Many ruptures can be repaired. Successful pregnancies have been reported following uterine repair; however, the risk of rupture in a subsequent pregnancy is at least as high as the risk with a prior classic cesarean section. Occult ruptures of the lower uterine segment encountered at repeat section can be treated by freshening the wound edges and secondary repair, but the newly repaired incision is at increased risk for rupture, and a subsequent trial of labor is contraindicated.

Prevention

Most causes of uterine rupture can be avoided by carefully selecting patients for trial of labor. Thorough and well-documented informed consent that includes mention of fetal or maternal death is needed. The ideal candidate will have a single prior low-transverse cesarean for a nonrepetitive indication (eg, breech), will have a prior vaginal delivery, will present in active labor, and will not require augmentation during labor. The further the characteristics diverge from those of this ideal patient, the greater the chance of a failed trial of labor and complications including uterine rupture. Continuous FHR monitoring by fetal scalp electrode as soon as feasible is the best means of detecting evolving rupture during labor. Two-layer closure of the uterine incision and increasing interval between pregnancies appears to decrease the risk of subsequent rupture of the low-transverse scar.

Complications

The complications of ruptured uterus are hemorrhage, shock, postoperative infection, bladder or ureteral damage, thrombophlebitis, amniotic fluid embolus, DIC, pituitary failure, and death.

Prognosis

The maternal mortality rate is 4.2%. The perinatal mortality rate is approximately 46%.

Current OB/GYN >Chapter 21. Malpresentation & Cord Prolapse>

BREECH PRESENTATION

Breech presentation, which complicates 3–4% of all pregnancies, occurs when the fetal pelvis or lower extremities engage the maternal pelvic inlet. Three types of breech are distinguished, according to fetal attitude (Fig 21–1) frank breech, the hips are flexed with extended knees bilaterally. In complete breech, both hips and knees are flexed. In footling breech, 1 (single footling breech) or both (double footling breech) legs are extended below level of the buttocks.

Figure 21–1.

Types of breech presentations.

(Reproduced, with permission, from Pernoll ML: *Benson and Pernoll's Handbook of Obstetrics and Gynecology*, 1 McGraw-Hill, 2001.)

In singleton breech presentations in which the infant weighs less than 2500 g, 40% are frank breech, 10% complete breech, and 50% footling breech. With birth weights of more than 2500 g, 65% are frank breech, 10% complete breech, and 25% footling breech. The incidences of singleton breech presentations by birth weight and gestational age are listed in Table 21–1.

Table 21–1. Incidence of Singleton Breech Presentations by Birthweight and Gestational Age.

1000	28	35
1000–1499	28–32	25
1500–1999	32–34	20
2000–2499	34–36	8
2500	36	2–3
All weights	3–4	

Birthweight (g)	Gestational Age (weeks)	Incidence (%)
-----------------	-------------------------	---------------

Fetal position in breech presentation is determined by using the fetal sacrum as the point of reference to the maternal pelvis. This is true for frank, complete, and footling breeches. Eight possible positions are recognized: sacrum anterior (SA), sacrum posterior (SP), left sacrum transverse (LST), right sacrum transverse (RST), left sacrum anterior (LSA), left sacrum posterior (LSP), right sacrum anterior (RSA), and right sacrum posterior (RSP). The station of the presenting part is the location of the fetal sacrum with regard to the maternal ischial spines.

Causes

Before 28 weeks, the fetus is small enough in relation to intrauterine volume to rotate from cephalic to breech presentation and back again with relative ease. As gestational age and fetal weight increase, the relative decrease in intrauterine volume makes such changes more difficult. In most cases, the fetus spontaneously assumes the cephalic presentation to better accommodate the bulkier breech pole in the roomier fundal portion of the uterus.

Breech presentation occurs when spontaneous version to cephalic presentation is prevented as term approaches and labor and delivery occur prematurely before cephalic version has taken place. Some causes include oligohydramnios, uterine anomalies such as bicornuate or septate uterus, pelvic tumors obstructing the birth canal, abnormal placentation, advanced multiparity, and a contracted maternal pelvis.

In multiple gestations, each fetus may prevent the other from turning, with a 25% incidence of breech in the first twin, nearly 50% for the second twin, and higher percentages with additional fetuses. Additionally, 6% of breech

presentations are found to have congenital malformations, which include congenital hip dislocation, hydrocephalus, anencephalus, familial dysautonomia, spina bifida, meningomyelocele, and chromosomal trisomies 13, 18, and 21. Thus, those conditions that alter fetal muscular tone and mobility increase the likelihood of breech presentation.

Diagnosis

PALPATION AND BALLOTTEMENT

Performance of Leopold's maneuvers and ballottement of the uterus may confirm breech presentation. The soft, more ill-defined breech may be felt in the lower uterine segment above the pelvic inlet. Diagnostic error is common, however, if these maneuvers alone are used to determine presentation.

PELVIC EXAMINATION

During vaginal examination, the round, firm, smooth head in cephalic presentation can easily be distinguished from the soft, irregular breech presentation if the presenting part is palpable. However, if no presenting part is discernible, further studies are necessary (ie, ultrasound).

RADIOGRAPHIC STUDIES

X-ray studies will differentiate breech from cephalic presentations and help determine the type of breech by localizing the position of the lower extremities. X-ray studies can reveal multiple gestation and skeletal defects. Fetal attitude may be seen, but fetal size cannot readily be determined by x-ray film. Because of the risks of radiation exposure to the fetus with this technique, ultrasonography is now used instead of radiography to determine fetal presentation and malformations.

ULTRASOUND

Ultrasonographic scanning by an experienced examiner will document fetal presentation, attitude, and size; multiple gestation; location of the placenta; and amniotic fluid volume. Ultrasound also will reveal skeletal and soft-tissue malformations of the fetus.

Management

ANTEPARTUM MANAGEMENT

Following confirmation of breech presentation, the mother must be closely followed to evaluate for spontaneous version to cephalic presentation. If breech presentation persists beyond 36 weeks, external cephalic version should be considered (see below).

In women considering a vaginal breech delivery, radiographic pelvimetry using x-ray, computed tomography, or magnetic resonance imaging should be performed to rule out women with a borderline or contracted pelvis. Attempts at vaginal delivery with an inadequate pelvis are associated with a high rate of difficulty and significant trauma to the mother and fetus. Difficult vaginal delivery may still occur in women with adequate pelvic measurements.

MANAGEMENT DURING LABOR

Examination

Patients with singleton breech presentations are admitted to the hospital with the onset of labor or when spontaneous rupture of membranes occurs because of the increased risk of umbilical cord complications. Upon admission, an ultrasound is obtained to confirm the type of breech presentation and to ascertain head flexion. The fetus is again screened for lethal congenital malformations, such as anencephaly, which would preclude cesarean delivery for fetal indications. A thorough history is taken, and a physical examination is performed to evaluate the status of mother and fetus. Based on these findings, a decision must be made regarding the route of delivery (see below).

Electronic Fetal Monitoring

Continuous electronic fetal heart rate monitoring is essential during labor. If a fetal electrocardiographic electrode is needed, care should be taken to avoid injury to the fetal anus, perineum, and genitalia when attaching the electrode to the breech presenting part. An intrauterine pressure catheter can be used to assess the frequency, strength, and duration of uterine contractions. With the catheter in place, fetal distress or dysfunctional labor can easily be identified.

and the decision to proceed with a cesarean section made expeditiously to optimize fetal outcome.

Oxytocin

The use of oxytocin in the management of breech labor is controversial. Although some obstetricians condemn it others use oxytocin with benefit and without complications. Generally, oxytocin should be administered only if uterine contractions are insufficient to sustain normal progress in labor. Continuous fetal and uterine monitoring should be used whenever oxytocin is administered.

DELIVERY

The decision regarding route of delivery must be made carefully on an individual basis. Criteria for vaginal or cesarean delivery are outlined in Table 21–2.

Table 21–2. Criteria for Vaginal or Cesarean Delivery in Breech Presentation.

Frank breech presentation

Estimated fetal weight of 3500 g or more, or less than 1500 g.

Gestational age of 34 weeks or more.

Contracted or borderline maternal pelvic measurements.

Estimated fetal weight of 2000–3500 g.

Flexed fetal head.

Adequate maternal pelvis as determined by x-ray pelvimetry (pelvic inlet with transverse diameter of 11.5 cm and anteroposterior diameter of 10.5 cm; midpelvis with transverse diameter of 10 cm and anteroposterior diameter of 11.5 cm).

No maternal or fetal indications for cesarean section.

Previable fetus (gestational age < 25 weeks and weight < 700 g).

Documented lethal fetal congenital anomalies.

Presentation of mother in advanced labor with no fetal or maternal distress, even if cesarean delivery was originally planned (a carefully performed, controlled vaginal delivery is safer in such cases than is a hastily executed cesarean section).

Deflexed or hyperextended fetal head.

Prolonged rupture of membranes.

Unengaged presenting part.

Dysfunctional labor.

Elderly primigravida.

Mother with infertility problems or poor obstetric history.

Premature fetus (gestational age of 25–34 weeks).

Most cases of complete or footling breech over 25 weeks' gestation without detectable lethal congenital malformation (to prevent umbilical cord prolapse).

Fetus with variable heart rate decelerations on electronic monitoring

Footling presentation

Vaginal Delivery	Cesarean Delivery
------------------	-------------------

Prior to 1975, virtually all viable singleton breech presentations were delivered vaginally. Cesarean section was

reserved for specific fetal indications, such as unremitting distress or prolapsed umbilical cord, or maternal indications such as placenta previa, abruptio placentae, or failure of progress in labor. However, breech infants delivered vaginally had a 5-fold higher mortality rate in comparison to cephalic presentations.

Recent studies have shown that planned cesarean delivery decreases perinatal and neonatal morbidity and mortality with no difference in maternal morbidity and mortality versus planned vaginal breech delivery. Thus, cesarean delivery has now become much more common in breech presentation. Only obstetricians skilled in breech techniques should attempt any breech delivery, whether vaginal or cesarean. Nevertheless, broader familiarity with the technique is needed because unanticipated vaginal breech delivery is still encountered.

Cesarean Delivery

The type of incision chosen is extremely important. If the lower uterine segment is well developed, as is usually the case in women at term in labor, a transverse "lower segment" incision is adequate for easy delivery. In preterm gestations, in an unlabored uterus, or in many cases of malpresentation, the lower uterine segment may be quite narrow, and a low vertical incision is almost always required for atraumatic delivery.

Vaginal Delivery

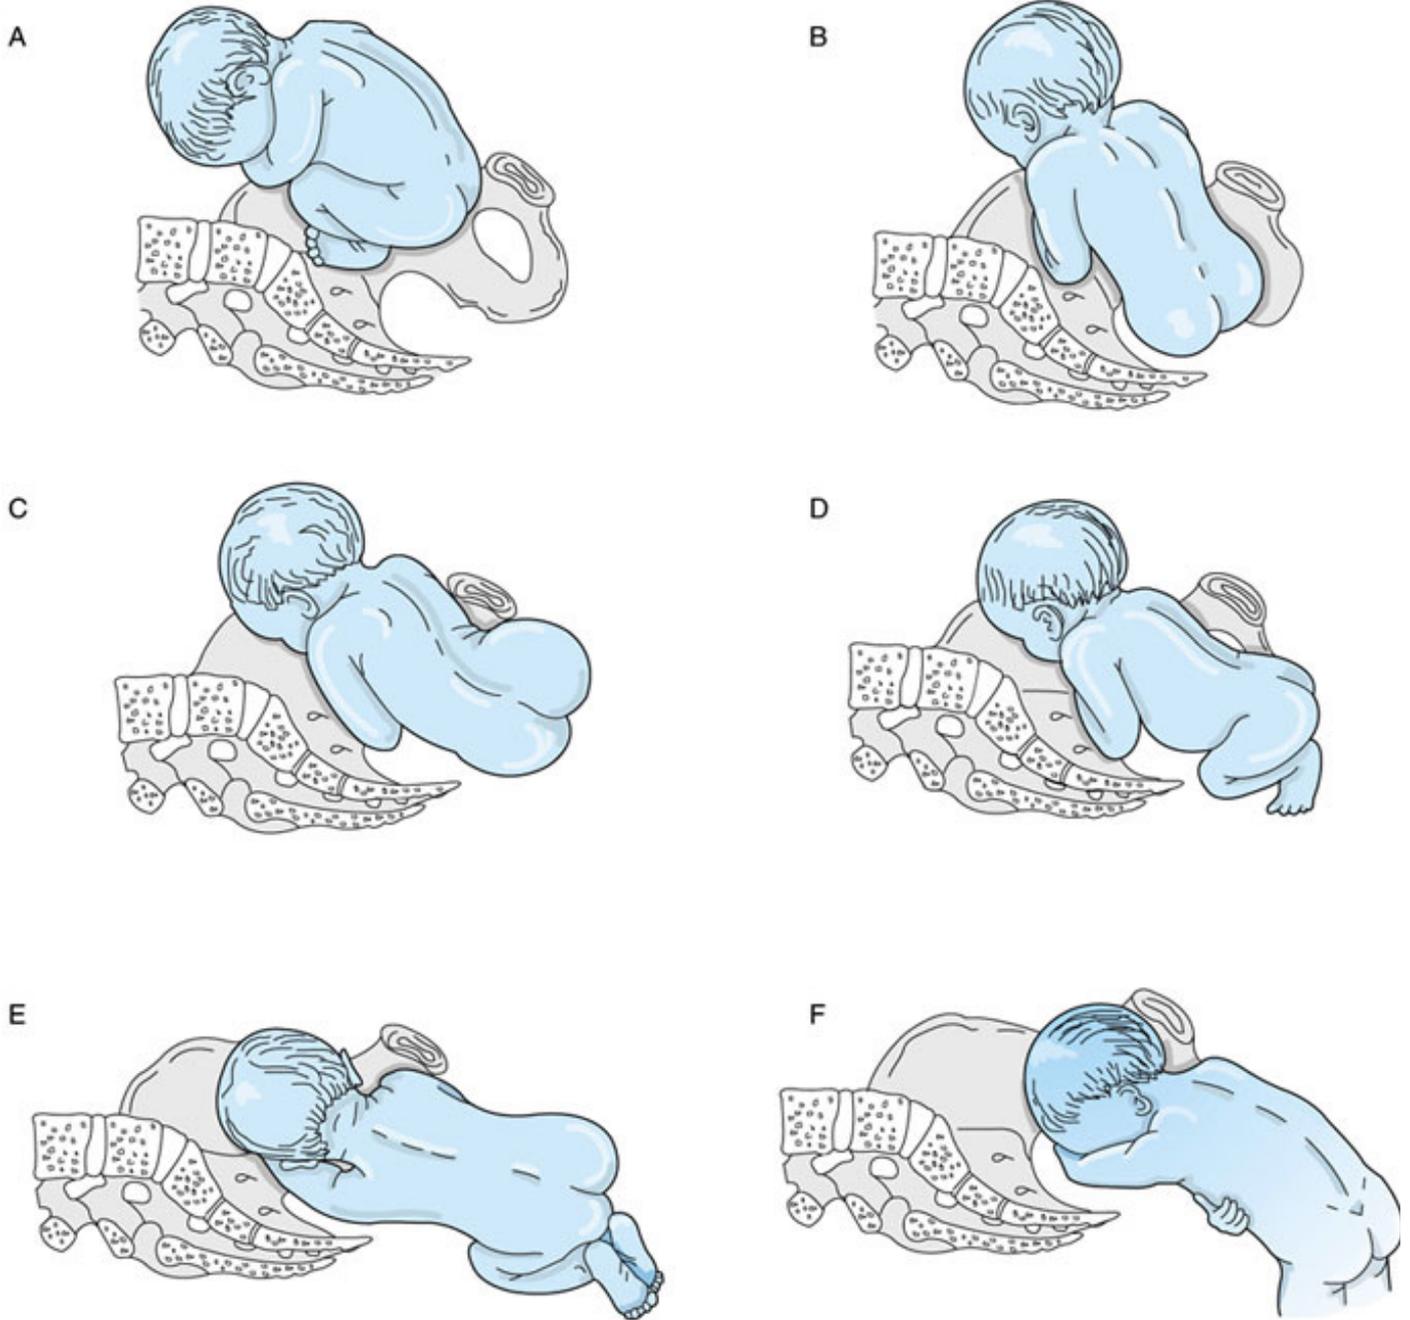

Obstetricians who contemplate performing a vaginal breech delivery should be experienced in the maneuver and should be assisted by 3 physicians: (1) an experienced obstetrician who will assist with delivery; (2) a pediatrician capable of providing total resuscitation of the newborn; and (3) an anesthesiologist, to ensure that the mother is comfortable and cooperative during labor and delivery. The type of anesthesia required depends on the type of delivery. Multiparous women undergoing spontaneous breech delivery may require no anesthesia or only intravenous analgesia for pain relief during labor and a pudendal anesthetic during delivery. Epidural anesthesia may also be administered during labor or in anticipation of partial breech extraction, including application of Piper forceps to the aftercoming head. In emergency circumstances, complete relaxation of the perineum and uterus is essential for successful outcome. This is accomplished by immediate induction of inhalation anesthesia or by administration of intravenous nitroglycerin.

SPONTANEOUS VAGINAL DELIVERY

During spontaneous delivery of an infant in the frank breech position, delivery occurs without assistance, and no obstetric maneuvers are applied to the body. The fetus negotiates the maternal pelvis as outlined below, while the operator simply supports the body as it delivers.

Engagement occurs when the bitrochanteric diameter of the fetus has passed the plane of the pelvic inlet. As the fetus descends into the pelvis (Fig 21–2), the buttocks reach the levator ani muscles of the maternal pelvis. At this point internal rotation occurs, whereby the anterior hip rotates beneath the pubic symphysis, resulting in a sacrum transverse position. The bitrochanteric diameter of the fetal pelvis is now in an anteroposterior position within the maternal pelvis. The breech then presents at the pelvic outlet and, upon emerging, rotates from sacrum transverse to sacrum anterior. Crowning occurs when the bitrochanteric diameter passes under the pubic symphysis. As this occurs, the shoulders enter the pelvic inlet with the bisacromial diameter in the transverse position. As descent occurs, the bisacromial diameter rotates to an oblique or anteroposterior diameter, until the anterior shoulder rests beneath the pubic symphysis. Delivery of the anterior shoulder occurs as it slips beneath the pubic symphysis. Upward flexion of the body allows for easy delivery of the posterior shoulder over the perineum.

Mechanism of labor in breech delivery. A: Mechanism of breech delivery. Right sacrum transverse (RST) at the beginning of labor; engagement of the buttocks usually occurs in the oblique or transverse diameter of the pelvic brim. B: Early second stage. The buttocks have reached the pelvic floor, and internal rotation has occurred so that the bitrochanteric diameter lies in the anteroposterior (AP) diameter of the pelvic outlet. C: Late second stage. The anterior buttock appears at the vulva by lateral flexion of the trunk around the pubic symphysis. The shoulders have not yet engaged the pelvis. D: The buttocks have been delivered, and the shoulders are adjusting to engage in the transverse diameter of the brim. This movement causes external rotation of the delivered buttocks so that the fetal back becomes uppermost. E: The shoulders have reached the pelvic floor and have undergone internal rotation so that the bisacromial diameter lies in the AP diameter of the pelvic outlet. Simultaneously, the buttocks rotate anteriorly by 90 degrees. This is called restitution. The head is engaging in the pelvic brim, and the sagittal suture is lying in the transverse diameter of the brim. F: The anterior shoulder is born from behind the pubic symphysis by lateral flexion of the delivered trunk.

As the shoulders descend, the head engages the pelvic inlet in a transverse or oblique position. Rotation of the fetal head to the occiput anterior position occurs as it enters the midpelvis. The occiput then slips beneath the pubic symphysis and the remainder of the head is delivered by flexion as the chin, mouth, nose, and forehead slip over the maternal perineum.

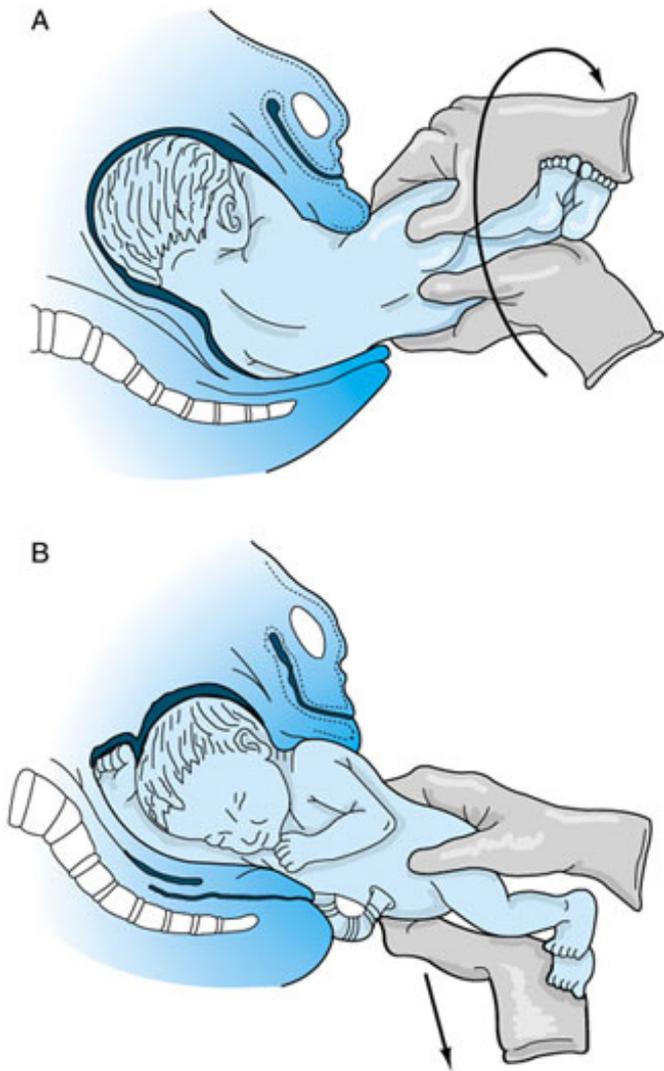

As delivery of the breech occurs, increasingly larger diameters (bitrochanteric, bisacromial, biparietal) of the fetus enter the pelvis, whereas in cephalic presentation, the largest diameter (biparietal diameter) enters the pelvis first. Particularly in preterm labors, the head is considerably larger than the body and provides a better "dilating wedge" that passes through the cervix and into the pelvis. The smaller bitrochanteric and bisacromial diameters may descend into the pelvis through a partially dilated cervix, but the larger biparietal diameter may be trapped. Delivery in these cases is described in the following.

PARTIAL BREECH EXTRACTION

Partial breech extraction (assisted breech extraction) is used when the operator discerns that spontaneous delivery will not occur or that expeditious delivery is indicated for fetal or maternal reasons. The body is allowed to deliver spontaneously up to the level of the umbilicus. The operator then assists in delivery of the legs, shoulders, arms, and head.

As the umbilicus appears at the maternal perineum, the operator places a finger medial to the right thigh and then the left thigh, pressing laterally as the fetal pelvis is rotated away from that side by an assistant. Thus, the thigh is externally rotated at the hip and results in flexion of the knee and delivery of one, then the other, leg. The fetal trunk is then wrapped in a towel to support the body. When both scapulae are visible, the body is rotated counterclockwise. The operator locates the right humerus and laterally sweeps the arm across the chest and out the perineum (Fig 21-3). In a similar fashion, the body is rotated clockwise to deliver the left arm. The head then spontaneously delivers by lifting the body upward and applying fundal pressure to maintain flexion of the fetal head (Fig 21-4). During partial breech extraction, the anterior shoulder may be difficult to deliver if it is impacted behind the pubic symphysis. In this event, the body is gently lifted upward toward the pubic symphysis, and the operator inserts one hand along the length of the maternal pelvis and identifies the posterior humerus of the fetus. By gentle downward traction on the humerus, the posterior arm can be easily delivered, thus allowing for easier delivery of the anterior shoulder and arm.

Maneuver for delivery of the head. The fingers of the left hand are inserted into the infant's mouth or over the inferior mandible; the right hand exerts pressure on the head from above.

The operator may elect to manually assist in delivery of the head by performing the Mauriceau-Smellie-Veit maneuver (Fig 21–5). In this procedure, the index and middle fingers of 1 of the operator's hands are applied to the maxilla as the body rests on the palm and forearm of the operator. Two fingers of the operator's other hand are applied on either side of the neck with gentle downward traction. At the same time, the body is elevated toward the pubic symphysis, allowing for controlled delivery of the mouth, nose, and brow over the perineum. Likewise, Piper forceps may be used electively or when the Mauriceau-Smellie-Veit maneuver fails to deliver the aftercoming head. Piper forceps may only be used when the cervix is completely dilated and the head is engaged in the pelvis. Ideally, the head is in a direct occiput anterior position, but a left or right occiput anterior position is acceptable. Piper forceps should not be attempted in the occiput transverse positions because this may result in significant fetal and maternal injury. An assistant supports and slightly elevates the fetal trunk while the operator places each forceps blade alongside the fetal parietal bones (Fig 21–6). After proper placement is confirmed, the forceps are locked, and gentle traction is applied to flex and deliver the head over the perineum. A midline episiotomy is often indicated to allow for easier application of the forceps and for delivery.

If, after delivery of the body, the spine remains in the posterior position and rotation is unsuccessful, extraction head in a persistent occiput posterior position may be accomplished by the modified Prague maneuver. One l

the operator supports the shoulders from below, while the other hand gently elevates the body upward toward the maternal abdomen. This action flexes the head within the birth canal and results in delivery of the occiput over the perineum.

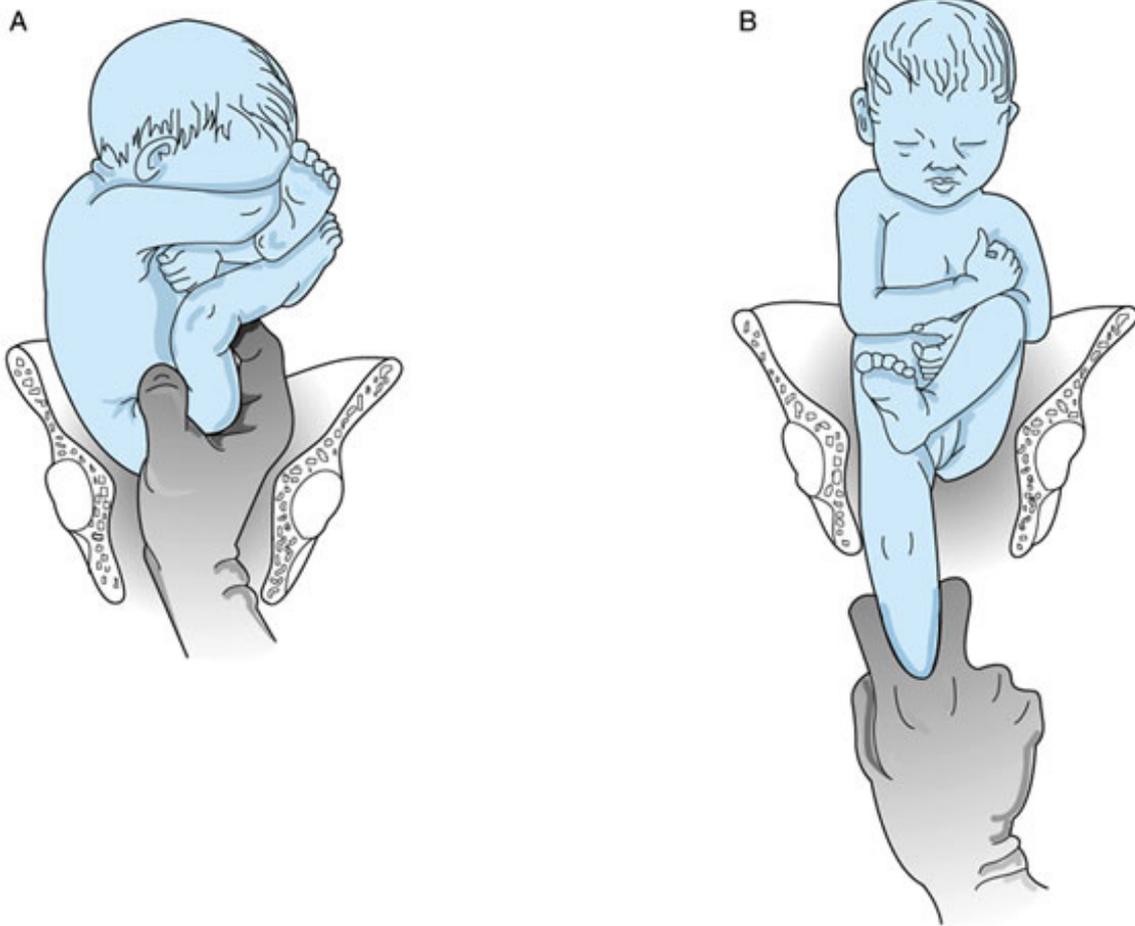

In premature breech presentations, the incompletely dilated cervix may allow delivery of the smaller body, but the relatively larger aftercoming head may be entrapped. Prompt delivery is mandatory because severe asphyxia and death may rapidly ensue. Gentle downward traction on the shoulders combined with fundal pressure applied by an assistant may effect delivery. If this fails, the anesthesiologist should administer nitroglycerin or inhalation anesthesia to obtain complete relaxation of the lower uterine segment and pelvic floor with reattempt at delivery.

If delivery is still not accomplished, Dehrssen's incisions must be considered to preserve fetal life. Incisions are made in the posterior cervix at the 6 o'clock position to loosen the entrapped head. Occasionally, additional incisions are necessary at the 2 and 10 o'clock positions. Dehrssen's incisions invariably release the fetal head, but the maternal consequences may be severe with resultant hemorrhage. Thus, this procedure should be performed only in an emergent situation. Prevention of head entrapment can be accomplished by delivering viable premature breech gestations by cesarean section.

TOTAL BREECH EXTRACTION

In total breech extraction (Fig 21-7), the entire body is manually delivered. This procedure is used only occasionally when fetal distress is encountered and an expeditious delivery is indicated, and under certain conditions in the case of delivery of a second twin in a nonvertex position following successful vaginal delivery of a first twin. Total breech extraction has been virtually replaced by cesarean delivery in modern obstetrics.

Figure 21-7.

Extraction of breech. A: Abduction of thigh and pressure in popliteal fossa cause the knee to flex and become accessible. B: Delivery of leg by traction on the foot.

For complete or footling presentation, total breech extraction is accomplished by initially grasping both feet and applying gentle downward pressure until the buttocks are delivered (Fig 21–8). A generous midline or mediolate episiotomy is then performed. The operator gently grasps the fetal pelvis, with both thumbs placed directly on either side of the sacrum. The spine is rotated, if necessary, until it rests under the pubic symphysis. Gentle, firm downward pressure is applied to the body until both scapulas are visible. The shoulders, arms, and head are delivered as in breech extraction.

Figure 21–8.

Extraction of breech. A: Buttocks brought to hollow of sacrum. B: Traction on anterior leg causes buttocks to advance and rotate into direct AP diameter of pelvis. Continued downward traction causes the back to rotate anteriorly. C Further downward traction causes the shoulders to engage in the transverse diameter of the inlet.

If the fetus is in frank breech presentation, the index finger of the right hand must initially be placed into the groin of the fetus and gentle downward pressure applied (Fig 21-9). As the fetus descends further into the birth canal the left index finger is inserted into the posterior groin, and additional gentle downward traction is applied, until buttocks are delivered through the vaginal introitus (Fig 21-10). The fetus is gently rotated until the spine rests directly under the pubic symphysis. To deliver the extended legs from the birth canal, the operator places the index finger in the popliteal fossa of 1 leg and applies pressure upward and outward, causing the knee to flex. As the knee flexes, the foot is often seen or easily palpated. The lower leg is grasped firmly and gently delivered, and the opposite leg is then delivered. The rest of the body is extracted as previously described for footling presentation.

Flexion and abduction of the thigh to deliver extended leg.

Complications of Breech Delivery

BIRTH ANOXIA

Umbilical cord compression and prolapse may be associated with breech delivery, particularly in complete (5%) and footling (15%) presentations. This is due to the inability of the presenting part to fill the maternal pelvis, either because of prematurity or poor application of the presenting part to the cervix so that the umbilical cord is allowed to prolapse below the level of the breech (see below). Frank breech presentation offers a contoured presenting part which is better accommodated to the maternal pelvis and is usually well applied to the cervix. The incidence of cord prolapse in frank breech is only 0.5% (the same as for cephalic presentations).

Compression of the prolapsed cord may occur during uterine contractions, causing moderate to severe variable decelerations in the fetal heart rate and leading to fetal anoxia or death. Continuous electronic monitoring is mandatory during labor in these cases to detect ominous decelerations. If they occur, immediate cesarean delivery must be performed.

BIRTH INJURY

The incidence of birth trauma during vaginal breech delivery is 6.7%, 13 times that of cephalic presentations (0.5%). Only high forceps and internal version and extraction procedures have higher rates of birth injury than do vaginal breech deliveries. The types of perinatal injuries reported in breech delivery include tears in the tentorium cerebelli, cephalohematomas, disruption of the spinal cord, brachial palsy, fracture of long bones, and rupture of the sternocleidomastoid muscles. Vaginal breech delivery is the main cause of injuries to the fetal adrenal glands, liver, anus, genitalia, spine, hip joint, sciatic nerve, and musculature of the arms, legs, and back.

Factors contributing to difficult vaginal breech delivery include a partially dilated cervix, unilateral or bilateral nuchal arms, and deflexion of the head. The type of procedure used may affect the neonatal outcome.

Partially Dilated Cervix

Delivery of a breech fetus may progress even though the cervix is only partially dilated because the bitrochanteric and bisacromial diameters are smaller than the biparietal diameter. This is true especially in prematurity. The hips and shoulders may negotiate the cervix, but the aftercoming head becomes entrapped, resulting in difficult delivery and birth injury.

Nuchal Arms

During partial breech extraction and more often in total breech extraction, excessive downward traction on the body results in a single or double nuchal arm. This occurs because of the rapid descent of the body, leading to extension of one or both arms, which become lodged behind the neck. When delivery of the shoulder is difficult to accomplish, a nuchal arm should be suspected. To dislodge the arm, the operator rotates the body 180 degrees to bring the elbow toward the face. The humerus can then be identified and delivered by gentle downward traction. In cases of double nuchal arm, the fetus is rotated counterclockwise to dislodge and deliver the right arm and rotated clockwise to deliver the left arm. If this action is unsuccessful, the operator must insert a finger into the pelvis, identify the humerus, and possibly extract the arm, resulting in fracture of the humerus or clavicle. Nuchal arms cause a delay in delivery and increase the incidence of birth asphyxia.

Deflexion of the Head

Hyperextension of the head is defined as deflexion or extension of the head posteriorly beyond the longitudinal axis of the fetus (5% of all breech deliveries). Causes of hyperextension include neck cysts, spasm of the neck musculature, and uterine anomalies, but over 75% have no known cause. Although deflexion may be documented by ultrasonographic or x-ray studies weeks before delivery, there is little apparent risk to the fetus until vaginal delivery is attempted. At that time, deflexion causes impaction of the occipital portion of the head behind the pubic symphysis which may lead to fractures of the cervical vertebrae, lacerations of the spinal cord, epidural and medullary

hemorrhages, and perinatal death. If head deflexion is diagnosed prior to delivery, cesarean section should be performed to avert injury. Cesarean section cannot prevent injuries such as minor meningeal hemorrhage or dislocation of the cervical vertebrae, which may develop in utero secondary to longstanding head deflexion.

Type of Delivery

More complex delivery procedures have a higher rate of birth trauma. Whereas few infants are injured during spontaneous breech births, as many as 6% are injured during partial breech extraction and 20% during total breech extraction. Injuries associated with total breech extraction usually are extensive and severe, and this procedure never be attempted unless fetal survival is in jeopardy and cesarean section cannot be immediately performed.

An additional important factor in breech injury and perinatal outcome is the experience of the operator. Inexperience may lead to hasty performance of obstetric maneuvers. Delay in delivery may result in birth asphyxia due to umbilical cord compression, but haste in the management of breech delivery results in application of excessive pressure on the fetal body, causing soft-tissue damage and fracture of long bones. Too-rapid extraction of the body from the birth canal causes the arms to extend above the head, resulting in unilateral or bilateral nuchal arms and difficult delivery of the aftercoming head. All breech deliveries should be performed slowly and methodically by experienced obstetricians who execute the maneuvers with gentleness and skill—not speed.

Prognosis

The incidence of cesarean section for breech delivery has been steadily increasing, from approximately 30% in 1985 to 85% in 1999. A recent review of breech deliveries in California revealed an 88% cesarean section rate, with more vaginal deliveries performed in public teaching hospitals and far fewer in private facilities. A decreased number of practitioners currently are skilled in vaginal breech delivery, and although academic faculty support its teaching, there are insufficient numbers of vaginal breech deliveries to properly teach this procedure at most institutions. It should be noted that cesarean section for the immature or malformed fetus does not improve chances for perinatal survival. Vaginal delivery should be performed in these cases.

The Term Breech Trial Collaborative Group recently conducted a randomized controlled trial to compare planned cesarean section with vaginal birth for selected breech presentation pregnancies. They found that fetuses of women who underwent planned cesarean sections were less likely to die or to experience poor outcomes in the immediate neonatal period than were fetuses of women who underwent vaginal birth. There was no difference in the 2 groups in terms of maternal mortality or serious morbidity. They concluded that a policy of planned cesarean section will result in 7 cesarean births to avoid 1 infant death or serious morbidity. Because of the results of this trial, the American College of Obstetricians and Gynecologists recommends planned cesarean delivery for persistent breech presentations at

VERSION

Version is a procedure used to turn the fetal presenting part from breech to cephalic presentation (cephalic version) or from cephalic to breech presentation (podalic version). Because cephalic version is performed by manipulating the fetus through the abdominal wall, the maneuver is known as external cephalic version. Podalic version is performed by means of internal maneuvers and is known as internal podalic version. External cephalic version is regaining popularity, whereas internal podalic version is rarely used.

EXTERNAL CEPHALIC VERSION

External cephalic version is used in the management of singleton breech presentations or in a nonvertex second trimester pregnancy. In carefully selected patients, it is safe for both mother and fetus. The goal is to increase the proportion of vertex presentations near term, thus increasing the chance for a vaginal delivery. In the past, external cephalic version was performed earlier in gestation but was accompanied by high reversion rates, making additional procedures necessary. Now it is performed in patients who have completed 36 weeks of gestation so that the risk of spontaneous reversion is decreased, and, if complications arise, delivery of a term infant can be accomplished. Current success rates for

external cephalic version range from 35–85% (mean 60%).

Indications

Patients with unengaged singleton breech presentations of at least 36 weeks' gestation are candidates for external cephalic version. The procedure is more successful in multigravidas and those with a transverse or oblique lie. Uterine and fetal heart rate monitoring and real-time ultrasonography are essential to document fetal well-being during the procedure. The use of tocolytics in external cephalic version is controversial. Recent evidence indicates that tocolytics offer an advantage in nulliparous women, but reports on which type of tocolytic confers the highest success rate are conflicting. Thus, these agents should be used at the discretion of the physician. Additionally, evidence regarding use of regional anesthesia is inconsistent. Recent randomized controlled trials have shown an increased success rate for those with epidural anesthesia. However, the ultimate decision should be based on physician experience.

Contraindications

Contraindications to external cephalic version include engagement of the presenting part in the pelvis, marked oligohydramnios, placenta previa, uterine anomalies, presence of nuchal cord, multiple gestation, premature rupture of membranes, previous uterine surgery (including myomectomy or metroplasty), and suspected or documented congenital malformations or abnormalities (including intrauterine growth retardation).

Complications

Complications are rare, occurring in only 1–2% of all external cephalic versions. Complications include placental abruption, uterine rupture, rupture of membranes with resultant umbilical cord prolapse, amniotic fluid embolism, preterm labor, fetal distress, fetomaternal hemorrhage, and fetal demise. Thus, given the potential for catastrophic outcome, this procedure should be performed in a facility where immediate access to cesarean delivery is available. Patients require extensive counseling regarding the version procedure, with disclosure of all risks, benefits, and alternatives so that an informed medicolegal decision can be made.

FETAL HEART RATE ABNORMALITIES

Fetal heart rate abnormalities can be readily documented during external cephalic version by intermittent electronic fetal monitoring (EFM) or ultrasonographic surveillance. Fetal bradycardia occurs in 20% of cases, but normal cardiac activity usually will return if the procedure is stopped for a short time. If significant unremitting fetal cardiac abnormalities occur, the attempt at version should be discontinued and preparation for cesarean delivery undertaken immediately.

FETOMATERNAL TRANSPLACENTAL HEMORRHAGE

Fetomaternal (transplacental) hemorrhage (FMH) may occur during version and has been reported to occur in 6–10% of patients undergoing external cephalic version, although the amount of hemorrhage rarely results in clinically significant anemia. The Kleihauer-Betke acid elution test should be performed if this condition is suspected. In cases of an Rh-negative–unsensitized woman, Rh immune globulin should be administered after external cephalic version to cover the calculated amount of FMH.

Technique

External cephalic version is performed as follows:

1. Obtain informed consent from the patient.
2. Perform an ultrasound examination to verify presentation and to rule out fetal or uterine abnormalities.
3. Perform a nonstress test. Results must be reactive.
4. If desired, administer a tocolytic to prevent contractions or irritability.
5. Administer anesthesia if desired.
6. Perform external cephalic version. Place both hands on the patient's abdomen, and perform a forward roll by lifting the breech upward while placing pressure on the head downward toward the pelvis. If this maneuver is unsuccessful, the procedure should be discontinued.

backward roll can be attempted.

7. Fetal well-being should be monitored intermittently with Doppler or real-time ultrasound scanning. The procedure should be abandoned in case of any significant fetal distress or patient discomfort, or if multiple attempts are unsuccessful.

8. Following the procedure, external fetal heart rate monitoring should be continued for 1 hour to ensure stability. If the patient is Rh-negative, administer anti-D immune globulin.

9. If the patient is stable, she can be sent home to await the onset of spontaneous labor if the version is successful. If unsuccessful, the patient can be scheduled for an elective cesarean section or a trial of labor with a breech vaginal delivery planned if the mother is a good candidate.

INTERNAL PODALIC VERSION

Internal podalic version is now rarely used because of the high fetal and maternal morbidity and mortality associated with the procedure. It is occasionally performed as a life-saving procedure or in cases of a noncephalic second twin (see Chapter 17 for delivery of a second twin).

Indications

Internal podalic version is the only alternative to cesarean section for rapid delivery of the second twin in a noncephalic presentation if external cephalic version fails. Thus, when cesarean section is unavailable or when a life-threatening condition arises (maternal hemorrhage due to premature placental separation, fetal distress, prolapsed umbilical cord), internal version may be required.

A life-threatening condition is the only indication for internal podalic version. The cervix must be completely dilated and the membranes must be intact. A skilled operator is crucial for safe performance of this procedure. In several French studies, internal podalic version was found to be a reliable and effective technique with excellent long-term maternal and fetal prognoses.

Contraindications

Internal podalic version is contraindicated in cases in which the membranes are ruptured or oligohydramnios is present, precluding easy version. This procedure should not be performed through a partially dilated cervix or if the uterus is firmly contracted down on the fetal body. However, recent studies have indicated that intravenous nitroglycerin can be used to provide transient uterine relaxation without affecting maternal or fetal outcome.

Complications

Internal podalic version is associated with considerable risk of traumatic injury to both fetus and mother. Prior to the 1970s, when this procedure was performed much more frequently than it is today, associated uterine rupture and hemorrhage caused 5% of all maternal deaths. Perinatal mortality rates were 5–25% (primarily due to traumatic intracerebral hemorrhage and birth asphyxia). Considerable birth trauma, including long bone fractures, dislocations, epiphyseal separations, and central nervous system deficits, was also linked to this procedure. For these reasons, internal podalic version has been abandoned with rare exceptions in favor of cesarean section.

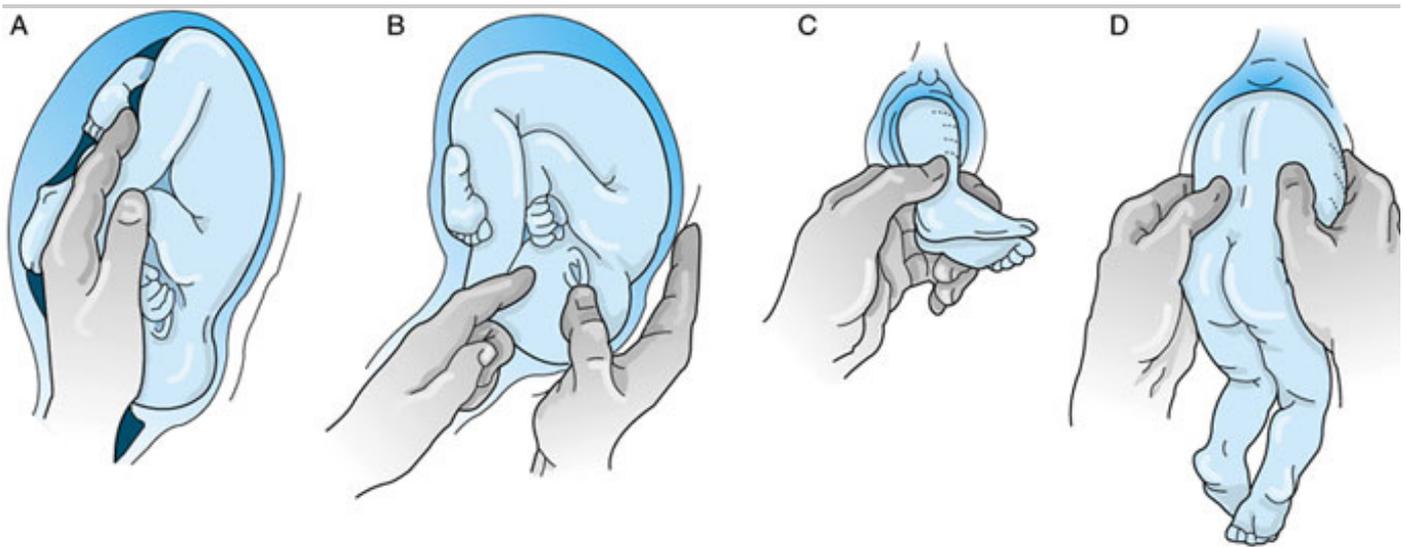

Technique

Internal podalic version is performed as follows:

1. Establish an intravenous line for administration of parenteral fluids, including blood. Cross-matched blood should be available in the hospital blood bank.
2. Administer anesthesia to achieve relaxation of the uterus.
3. Place the patient in the dorsolithotomy position. Insert a hand through the fully dilated cervix along the fetal back until both feet are identified, and apply traction to bring the feet into the pelvis and out the introitus. Then, grasp the feet firmly. Perform an amniotomy. Apply dorsal traction on both lower extremities until both feet are delivered to the introitus.

the vagina. Then, perform a total breech extraction for delivery of the body (Fig 21–11).

Internal podalic version and extraction. A: Feet are grasped. B: Baby is turned; hand on abdomen pushes head up toward uterine fundus. C: Feet are extracted. D: Torso is delivered. From this point onward, procedure is the same as for uncomplicated breech delivery.

COMPOUND PRESENTATION

Compound presentation is prolapse of a fetal extremity alongside the presenting part. Prolapse of the hand in cephalic presentation is most common, followed by prolapse of an upper extremity in breech presentation. Prolapse of a lower extremity in cephalic presentation is relatively rare. Compound presentations are uncommon, occurring in only 1 in 1000 pregnancies.

Causes

Obstetric factors that prevent descent of the presenting part into the pelvic inlet predispose to prolapse of an extremity alongside the presenting part (ie, prematurity, cephalopelvic disproportion, multiple gestation, grand multiparity, hydramnios). Prematurity occurs in over 50% of compound presentations. In twin gestations, over 90% of compound presentations are associated with the second twin.

Because of poor application of the presenting part to the cervix found in compound presentations, umbilical cord prolapse is common (occurring in 11–20% of cases) and is a major contributor to fetal loss during labor.

Diagnosis

The diagnosis of compound presentation is made by palpation of a fetal extremity adjacent to the presenting part during vaginal examination. The diagnosis is usually made during labor; as the cervix dilates, the prolapsed extremity is easily palpated alongside the vertex or breech. Compound presentation may be suspected if poor progress in labor is noted, particularly when the presenting part fails to engage during the active phase. If the diagnosis of compound presentation is suspected but uncertain, ultrasound can be used to locate the position of the extremities and detect malformations.

Management

Management of compound presentation depends on gestational age and type of presentation. Given that 50% of

compound presentations are associated with prematurity, viability of the fetus should be documented prior to delivery. If the fetus is considered nonviable, labor should be permitted and vaginal delivery anticipated. The small size of the fetus makes dystocia or difficult vaginal delivery uncommon.

Labor can be allowed and vaginal delivery anticipated in viable cephalic presentations with a prolapsed hand. These cases generally pose no difficulty in labor or delivery because the hand moves upward into the lower uterine segment as the vertex descends into the birth canal.

Umbilical cord prolapse is a risk in all cases of compound presentation, and continuous fetal heart rate monitoring should be performed to detect fetal distress or changes in the fetal heart rate. Umbilical cord complications should be managed by immediate cesarean delivery (see below).

Prognosis

Compound presentations have been associated historically with perinatal mortality rates ranging from 9–19%. Contributing factors are prematurity, prolapsed umbilical cord, and traumatic vaginal delivery.

SHOULDER DYSTOCIA

Shoulder dystocia is defined as an inability to deliver the shoulders after the head has delivered. Characteristically, after the head is delivered, the chin presses tightly against the perineum as the anterior shoulder becomes impacted behind the pubic symphysis. This condition is an acute obstetric emergency requiring prompt, skillful management in order to prevent significant fetal damage or death. The incidence of shoulder dystocia ranges from 0.15–1.7% of vaginal deliveries.

Risk Factors

Primary risk factors that can influence clinical management are fetal macrosomia, gestational or overt diabetes mellitus, a history of shoulder dystocia in a prior birth, a prolonged second stage of labor, and instrumental delivery, particularly a midpelvic delivery. Other risk factors, such as a history of a macrosomic infant, maternal obesity, multiparity, and postterm pregnancy, are mediated through the primary risk factors. However, most women who experience shoulder dystocia have no combination of risk factors that allows clinically useful identification.

Complications

Birth injuries related to shoulder dystocia include fracture of the humerus or clavicle and injury to the brachial plexus (Erb's palsy). Fractures of the humerus and clavicle generally heal without incident, and most injuries to the brachial plexus resolve with minimal or no neurologic deficit detectable during the neonatal period. However, 10–15% of Erb's palsies do not resolve. Studies attempting to distinguish the clinical course of patients with permanent injury from those with transient injuries have found no clinically distinct characteristics. Maternal complications of shoulder dystocia include postpartum hemorrhage and lacerations involving the cervix, vagina, and perineum.

Prevention

Efforts at prevention focus on patients with the clinically important risk factors: history of shoulder dystocia, fetal macrosomia by estimated fetal weight (EFW), diabetes, prolonged second stage of labor, and instrumental delivery. Although no study has shown conclusively that offering a cesarean birth in the presence of various combinations of these risk factors is advisable from a risk–benefit analysis, most practitioners apply some or all of these in an attempt to reduce the risk of shoulder dystocia. An example of 1 approach follows.

1. Prior shoulder dystocia: Offer cesarean.
2. Prior brachial plexus injury: Strongly suggest cesarean.
3. Nondiabetic with macrosomia by EFW (varying thresholds applied between 4500g and 5000g): Offer cesarean.
4. Diabetic with macrosomia (varying thresholds applied between 4000g and 4500g): Offer cesarean.

5. Macrosomia by EFW: Avoid instrumental delivery.

Management

Shoulder dystocia should be anticipated given any indications of macrosomia. The diagnosis is confirmed when gentle downward pressure on the head fails to deliver the anterior shoulder from behind the pubic symphysis. At this point the fetus is at risk for asphyxiation as the fetus cannot expand its chest to breathe, and umbilical cord circulation is compressed within the birth canal. Confronted with this terrifying dilemma, the inexperienced operator often continues to apply downward pressure on the head in a vain attempt to deliver the anterior shoulder. Such action should be avoided, not only because it is ineffective but also because it can potentially damage the brachial plexus and result in permanent Erb's palsy. A number of maneuvers designed to alleviate shoulder dystocia without increasing traction have been described. No specific sequence of these maneuvers has been shown to be superior to any other, but a commonsense approach based on ease of performance and limitations of risk can be described. Initially, the examiner places a hand in the birth canal to assess the posterior outlet. If inadequate, an episiotomy or a proctoepisiotomy is performed. At the same time, assistants including a pediatrician and an anesthesiologist are summoned to aid in delivery.

The McRoberts' maneuver should be used initially because it is simple and resolves shoulder dystocia in 42% of cases. The maternal legs are hyperflexed onto the maternal abdomen, resulting in flattening of the sacrum and cephalad rotation of the symphysis pubis. If the shoulders remain undelivered, suprapubic pressure is applied by an assistant to dislodge the anterior shoulder while gentle downward pressure on the head is applied. Suprapubic pressure and/or proctoepisiotomy increases success rates to between 54 and 58%. If these attempts are unsuccessful, the examiner can attempt to rotate the fetal shoulders into the oblique position by placing 2 fingers against the posterior shoulder and pushing it around toward the fetal chest (Rubin maneuver) or pushing the posterior shoulder arc toward the fetal back (Wood's maneuver) in a corkscrew fashion.

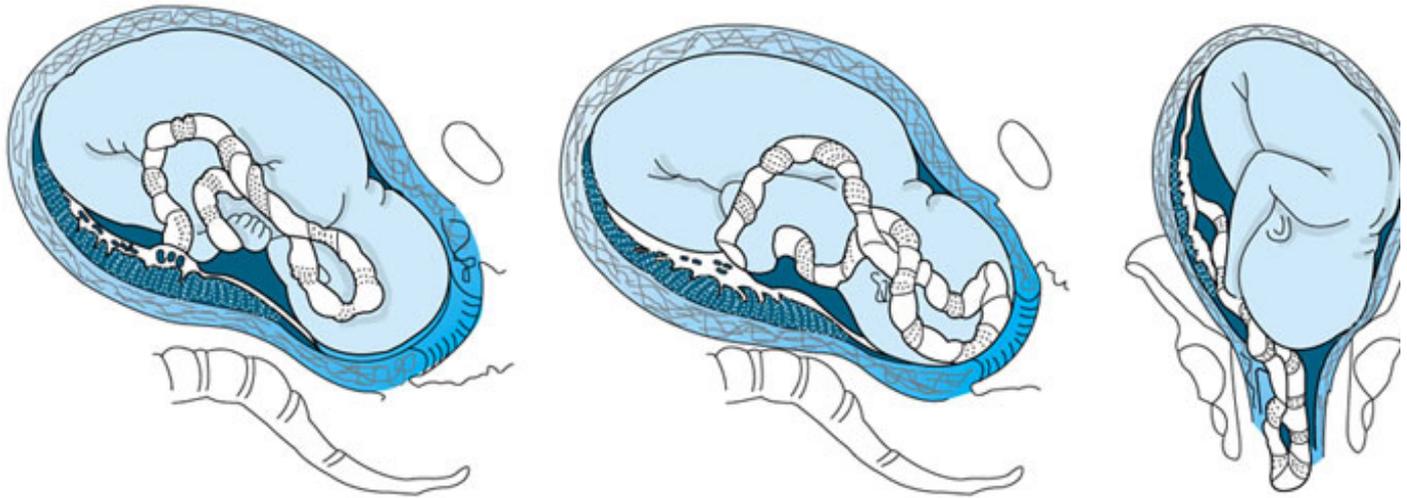

If the maneuvers to this point fail, delivery of the posterior arm (Barnum maneuver) is indicated. The obstetrician's hand is inserted posteriorly into the hollow of the maternal sacrum, and the posterior arm of the fetus is identified. Gentle pressure by the examiner's forefinger on the fetal antecubital fossa will cause flexion of the arm. As the arm flexes across the chest, the forearm is gently grasped, and the hand and forearm are gently delivered from the birth canal. If not, the trunk can be rotated to bring the free arm anteriorly, resulting in delivery. Deliberate fracture of the clavicle also can be performed, preferably in a direction away from the fetal lungs. This action diminishes the size of the shoulder girdle and should facilitate delivery.

Finally, if all previous techniques fail, a Zavanelli maneuver can be performed in which the fetal head is replaced into the uterus with anticipation of a cesarean delivery. A subcutaneous symphysiotomy also can be performed to allow disimpaction of fetal shoulders. Both of these procedures can be very difficult, are associated with high maternal and fetal morbidity, and should be performed only when other conventional maneuvers have failed.

UMBILICAL CORD PROLAPSE

Umbilical cord prolapse is defined as descent of the umbilical cord into the lower uterine segment, where it may be adjacent to the presenting part (occult cord prolapse) or below the presenting part (overt cord prolapse) (Fig 21-12). In occult prolapse, the umbilical cord cannot be palpated during pelvic examination, whereas in funic presentation, which is characterized by prolapse of the umbilical cord below the level of the presenting part before the rupture of membranes occurs, the cord often can be easily palpated through the membranes. Overt cord prolapse is associated with rupture of the membranes and displacement of the umbilical cord into the vagina, often through the introit

Types of prolapsed cords.

Prolapse of the umbilical cord to a level at or below the presenting part exposes the cord to intermittent compression between the presenting part and the pelvic inlet, cervix, or vaginal canal. Compression of the umbilical cord compromises fetal circulation and, depending on the duration and intensity of compression, may lead to fetal hypoxia, brain damage, and death. In overt cord prolapse, exposure of the umbilical cord to air causes irritation and cools the cord, resulting in further vasospasm of the cord vessels.

The incidence of overt umbilical cord prolapse in cephalic presentations is 0.5%, frank breech 0.5%, complete breech 5%, footling breech 15%, and transverse lie 20%. The incidence of occult prolapse is unknown because it can be detected only by fetal heart rate changes characteristic of umbilical cord compression. However, some degree of prolapse appears to be common, given that as many as 50% of monitored labors demonstrate fetal heart rate changes compatible with umbilical cord compression. In most cases, the compression is transient and can be rectified simply by changing the patient's position.

Whether occult or overt, umbilical cord prolapse is associated with significant rates of perinatal morbidity and mortality because of intermittent compression of blood flow and resultant fetal hypoxia. The perinatal mortality rate associated with all cases of overt umbilical cord prolapse approaches 20%. Prematurity, itself a contributor to the incidence of umbilical cord prolapse, accounts for a considerable portion of this perinatal loss.

Causes

Any obstetric condition that predisposes to poor application of the fetal presenting part to the cervix can result in prolapse of the umbilical cord. Cord prolapse is associated with prematurity (< 34 weeks' gestation), abnormal presentations (breech, brow, compound, face, transverse), occiput posterior positions of the head, pelvic tumors, multiparity, placenta previa, low-lying placenta, and cephalopelvic disproportion. In addition, cord prolapse is associated with hydramnios, multiple gestation, or premature rupture of the membranes occurring before engagement of the presenting part. A recent study revealed that obstetric intervention contributes to nearly half of cases of umbilical cord prolapse. Examples cited include amniotomy, scalp electrode application, intrauterine pressure catheter insertion, attempted external cephalic version, and expectant management of premature rupture of membranes.

Clinical Findings

OVERT CORD PROLAPSE

Overt cord prolapse can be diagnosed simply by visualizing the cord protruding from the introitus or by palpating of cord in the vaginal canal.

FUNIC PRESENTATION

The diagnosis of funic presentation is made by pelvic examination if loops of cord are palpated through the membranes. Antepartum detection of funic presentation is discussed below.

OCCULT PROLAPSE

Occult prolapse is rarely palpated during pelvic examination. This condition can be inferred only if fetal heart rate changes (variable decelerations, bradycardia, or both) associated with intermittent compression of the umbilical are detected during monitoring.

FETUS

The fetus in good condition whose well-being is jeopardized by umbilical cord compression may exhibit violent and readily apparent to the patient and the obstetrician. Variable fetal heart rate decelerations will occur during uterine contractions, with prompt return of the heart rate to normal as each contraction subsides. If cord compression is complete and prolonged, fetal bradycardia occurs. Persistent, severe, variable decelerations and bradycardia lead to development of hypoxia, metabolic acidosis, and eventual damage or death. As the fetal status deteriorates, activity lessens and eventually ceases. Meconium staining of the amniotic fluid may be noted at the time of membrane rupture.

Complications

MATERNAL

Cesarean section is a major operative procedure with known anesthetic, hemorrhagic, and operative complications. These risks must be weighed against the real risk to the fetus of continued hypoxia if labor were to continue.

Maternal risks encountered at vaginal delivery include laceration of the cervix, vagina, or perineum resulting from a hastily performed delivery.

NEONATAL

The neonate at delivery may be hypoxic, acidotic, or moribund. A pediatric team should be present to effect immediate resuscitation of the newborn.

Prevention

Patients at risk for umbilical cord prolapse should be treated as high-risk patients. Patients with malpresentation or poorly applied cephalic presentations should be considered for ultrasonographic examination at the onset of labor to determine fetal lie and cord position within the uterine cavity. Because most prolapses occur during labor as the cervix dilates, patients at risk for cord prolapse should be continuously monitored to detect abnormalities of the fetal heart rate. Artificial rupture of membranes should be avoided until the presenting part is well applied to the cervix. At the time of spontaneous membrane rupture, a prompt, careful pelvic examination should be performed to rule out cord prolapse. Should amniotomy be required and the presenting part remains unengaged, careful needling of the membranes and slow release of the amniotic fluid can be performed until the presenting part settles against the cervix.

Management

OVERT CORD PROLAPSE

The diagnosis of overt cord prolapse demands immediate action to preserve the life of the fetus. An immediate pelvic examination should be performed to determine cervical effacement and dilatation, station of the presenting part, and strength and frequency of pulsations within the cord vessels. If the fetus is viable, the patient should be placed in the knee-chest position, and the examiner should apply continuous upward pressure against the presenting part to help maintain the fetus away from the prolapsed cord until preparations for cesarean delivery are complete. Alternatively, 400–700 mL of saline can be instilled into the bladder in order to elevate the presenting part. Oxygen should be administered to the mother until the anesthesiologist is prepared to administer a rapid-acting inhalation anesthetic for delivery.

Successful reduction of the prolapsed umbilical cord has been described, but such an attempt may worsen fetal heart rate changes and should not delay preparation for cesarean delivery. Abdominal delivery should be accomplished rapidly as possible through a generous midline abdominal incision, and a pediatric team should be on standby in event immediate resuscitation of the newborn is necessary.

OCCULT CORD PROLAPSE

If cord compression patterns (variable decelerations) of the fetal heart rate are recognized during labor, an immediate pelvic examination should be performed to rule out overt cord prolapse. If occult cord prolapse is suspected, the patient should be placed in the lateral Sims or Trendelenburg position in an attempt to alleviate cord compression. If the fetal heart rate returns to normal, labor can be allowed to continue, provided no further fetal insult occurs. Oxygen should be administered to the mother, and the fetal heart rate should be continuously monitored electronically. Amnioinfusion can be performed via an intrauterine pressure catheter in order to instill fluid within the uterine cavity and possibly decrease the incidence of variable decelerations. If the cord compression pattern persists or recurs at a point of fetal jeopardy (moderate to severe variable decelerations or bradycardia), a rapid cesarean section should be accomplished.

FUNIC PRESENTATION

The patient at term with funic presentation should be delivered by cesarean section prior to membrane rupture. However, there is no consensus on management if the fetus is premature. The most conservative approach is to hospitalize the patient on bed rest in the Sims or Trendelenburg position in an attempt to reposition the cord within the uterine cavity. Serial ultrasonographic examinations should be performed to ascertain cord position, presentation, and gestational age.

ROUTE OF DELIVERY

Vaginal delivery can be successfully accomplished in cases of overt or occult cord prolapse if, at the time of prolapse, the cervix is fully dilated, cephalopelvic disproportion is not anticipated, and an experienced physician determines that delivery is imminent. Internal podalic version, midforceps rotation, or any other operative technique is generally more hazardous to mother and fetus in this situation than is a judiciously performed cesarean delivery. Cesarean delivery is the preferred route of delivery in most cases. Vaginal delivery is the route of choice for the pre-viable or dead fetus.

Prognosis

MATERNAL

Maternal complications include those related to anesthesia, blood loss, and infection following cesarean section or operative vaginal delivery. Maternal recovery is generally complete.

NEONATAL

Although the prognosis for intrapartum cord prolapse is greatly improved, fetal mortality and morbidity rates still remain high, depending on the degree and duration of umbilical cord compression occurring before the diagnosis is made and neonatal resuscitation is started. If the diagnosis is made early and the duration of complete cord occlusion is less than 5 minutes, the prognosis is good. Gestational age and trauma at delivery also affect the final neonatal outcome. If complete cord occlusion has occurred for longer than 5 minutes or if intermittent partial cord occlusion has occurred over a prolonged period of time, fetal damage or death may occur.

Current OB/GYN > Chapter 22A. Cardiac Disorders in Pregnancy >

CARDIOVASCULAR CHANGES IN NORMAL PREGNANCY

Hemodynamic changes during pregnancy are meant to increase blood flow to the fetoplacental unit. These changes create hemodynamic burden on the maternal heart and may cause symptoms and signs similar to those of heart disease. It is important to be familiar with these cardiovascular adaptations, as women with preexisting cardiovascular disease may exhibit marked clinical deterioration during the course of pregnancy.

Blood volume begins to rise as early as 6 weeks' gestation and continues to increase until midpregnancy. The hormonally mediated increase in plasma volume is disproportionately higher than the red cell mass and, therefore, results in the "physiologic anemia of pregnancy." On average, hematocrit level is reduced to 30–38% by week 30. Increases in blood volume and heart rate result in increased cardiac output. Cardiac output peaks during the second trimester and then remains constant until term. Myocardial contractility improves, left atrial and left ventricular chamber sizes increase, and peripheral vascular resistance falls (as a result of progesterone, circulating prostaglandins, atrial natriuretic peptides, endothelial nitric oxide, and the low-resistance vascular bed of the placenta). The net effect of these changes is an approximately 50% increase in cardiac output.

The overall increment in heart rate by the third trimester averages 10 to 20 bpm. The systemic arterial pressure falls during the first trimester, remains stable during the second trimester, and returns to pregestational levels before term. The reduction in diastolic pressure is more than the reduction in systolic pressure, leading to widening of the pulse pressure. Supine hypotensive or uterocaval syndrome occurs in 0.5–11% of pregnancies and is related to acute occlusion of the inferior vena cava by the gravid uterus in the supine position; and it is characterized by significant decreases in blood pressure and heart rate. This contrasts with the tachycardia seen with hypotension in the nonpregnant state. Patients usually complain of lightheadedness, nausea, dizziness, and syncope in extreme cases. Symptoms are alleviated by changing to a left lateral recumbent position.

Some hemodynamic changes, especially the increases in cardiac output during labor and delivery, are related to the fear, anxiety, and pain experienced by the patient at this stage. Uterine contractions displace 300 to 500 mL of blood with each contraction, augmenting cardiac output by 20%. Oxygen consumption increases 3-fold. The changes in cardiac output are less pronounced if the patient is in the supine position and receives adequate analgesia.

Immediately after delivery, relief of caval compression coupled with autotransfusion from the contracting uterus produces a further increase in cardiac output. This can cause acute decompensation in the immediate postpartum period. Most of the hemodynamic changes revert to prepregnancy levels by 2 weeks postpartum.

HEART DISEASE

Heart disease is quickly becoming one of the leading causes of maternal death. It complicates approximately 1% of all pregnancies. Pregnant patients with significant symptoms on exertion, such as patients in New York Heart Association (NYHA) functional classes III and IV (Table 22A–1), have high event rates and succumb to complications of heart disease, such as heart failure, arrhythmias, and stroke. Patients with stenotic lesions (eg, mitral or aortic stenosis) and minimal baseline symptoms (NYHA class I or II) may deteriorate rapidly. Some other diseases associated with the highest risk of maternal mortality include Eisenmenger's syndrome, primary pulmonary hypertension, fragile aortas as in Marfan's syndrome, left-sided obstructive lesions, and already dilated poorly functioning left ventricles (Table 22A–2).

Table 22A–1. New York Heart Association Functional Classification of Heart Disease.

Class I	No signs or symptoms (chest pain or shortness of breath)
Class II	No symptoms at rest, slight limitation with mild to moderate activity (walking > 2 blocks)
Class III	No symptoms at rest, marked limitation with less than ordinary activity (walking < 2 blocks)
Class IV	Symptoms at rest

Table 22A–2. High-Risk Pregnancy in Women with Heart Disease.

Etiology	Disease
Pump failure	Severe cardiomyopathy
Symptomatic valve narrowing	Mitral stenosis, aortic stenosis, pulmonary stenosis
Cyanotic heart disease	Tetralogy of Fallot, transposition of great arteries
Aortic rupture	Marfan's syndrome with dilated aorta
Artificial prosthesis	Mechanical heart valves
Elevated pulmonary artery pressures	Eisenmenger's syndrome, primary pulmonary hypertension, pulmonary vascular disease

Women of childbearing age are as susceptible to myocarditis, pericarditis, or infective endocarditis as is the general population. Healthy, pregnant women can develop many cardiovascular complications, such as varicose veins, preeclampsia, pulmonary emboli, amniotic fluid emboli, disseminated intravascular coagulation, and shock due to hemorrhage or aortic dissection.

As a result of successful pediatric surgical correction of congenital anomalies, many children are reaching adulthood and subsequently becoming pregnant. Pregnant women with congenital heart disease now outnumber those with rheumatic heart disease in most developing countries. It is important to recognize, however, that subtle clinical clues, such as shortness of breath, may be the only manifestation of conditions such as mitral stenosis or pulmonary hypertension related to rheumatic heart disease. Acquired conditions such as ischemic heart disease are not uncommon today as women are delaying childbearing to the third and fourth decades of life. As the general population becomes more susceptible to diabetes mellitus, morbid obesity, and hypertension, more frequent encounters with ischemic heart disease in pregnant patients are expected.

CARDIOVASCULAR EVALUATION DURING PREGNANCY

Most women with heart disease have successful pregnancies, but complacency in the diagnosis and management of pregnant patients can have dire consequences for both the mother and the fetus. Therefore it is essential to evaluate every pregnant woman with heart disease for her risk of adverse outcomes during pregnancy, labor, delivery, and postpartum. In general, all such women should be referred to a specialist center where their care can be managed jointly by an obstetrician, cardiologist, clinical geneticist, and neonatologist. Ideally, patients with heart disease should consult their physicians prior to their becoming pregnant. Preconception counseling allows for optimal timing for conception, completion of all diagnostic procedures beforehand (especially those involving harmful radiation exposure), discontinuation of teratogenic drugs, and scheduling of corrective/palliative surgery before pregnancy.

The initial evaluation should include a careful medical history, comprehensive physical examination, and noninvasive laboratory testing. Common findings in normal pregnancy are listed in Table 22A–3.

Table 22A–3. Common Findings in Normal Pregnancy.

Symptoms	Fatigue, decreased exercise capacity
	Lightheadedness, syncope
	Palpitations
	Dyspnea, orthopnea
Physical examination	Distended neck veins
	Increased intensity of S ₁ , exaggerated splitting
	Exaggerated splitting of S ₂
	Midsystolic, soft, ejection-type murmurs (lower left sternal border or over the pulmonary area)
	Third heart sound
	Continuous murmurs (cervical venous hum, mammary soufflé)
	Brisk, diffused, displaced left ventricular impulse
	Palpable right ventricular impulse
Electrocardiogram	QRS axis deviation
	Small Q and inverted P in lead III (abolished by inspiration)
	Sinus tachycardia, higher incidence of arrhythmias
Chest radiograph	Horizontal position of heart
	Increased lung markings
Doppler and echocardiography	Slightly increased systolic and diastolic left ventricular dimensions
	Moderate increase in size of right atrium, right ventricle, and left atrium
	Functional pulmonary, tricuspid and mitral regurgitation

Medical History

Most patients admit to reduced exercise tolerance and easy fatigability. This condition is related to both

the weight gained during gestation and the physiologic anemia of pregnancy. Syncopal episodes or lightheadedness occur as a result of mechanical compression of the gravid uterus on the inferior vena cava leading to poor venous return to the heart, especially in the third trimester. Other frequent complaints include hyperventilation and orthopnea (from mechanical pressure of the enlarged uterus on the diaphragm). Palpitations are common and probably are related to the hyperdynamic circulation of pregnancy rather than arrhythmias in most cases.

In patients with an established history of heart disease, it is important to inquire about their functional capacity, prevalence of other associated symptoms, therapeutic regimens, prior diagnostic tests (eg, echocardiogram, exercise testing, and cardiac catheterization), and history of corrective or palliative surgery. In patients with no known heart disease, it is essential to ask about a history of rheumatic heart disease, episodes of cyanosis at birth or early childhood, presence of rheumatologic disorders (eg, systemic lupus erythematosus), episodes of arrhythmias, occurrence of exertional syncope or chest pain, and persistence of lower-extremity edema. In addition, ask about a family history of congenital heart disease, premature coronary artery disease, or sudden death in family members. Signs and symptoms of cardiovascular disease are listed in Table 22A-4.

Table 22A-4. Signs and Symptoms Indicative of Significant Cardiovascular Disease.

Symptoms	Progressively worsening shortness of breath
	Cough with frothy pink sputum
	Paroxysmal nocturnal dyspnea
	Chest pain with exertion
	Syncope preceded by palpitations or exertion
	Hemoptysis
Physical examination	Abnormal venous pulsations
	Rarely audible S ₁
	Single S ₂ or paradoxically split S ₂
	Loud systolic murmurs, any diastolic murmur
	Ejection clicks, late systolic clicks, opening snaps
	Friction rub
	Sustained right or left ventricular heave
	Cyanosis or clubbing
Electrocardiogram	Significant arrhythmias
	Heart blocks
Chest radiograph	Cardiomegaly
	Pulmonary edema

Physical Examination

Hyperventilation is a common phenomenon in pregnancy likely related to the effect of progesterone on

the respiratory center. It is important to differentiate hyperventilation from dyspnea, which is a common finding in congestive heart failure. Bibasilar crackles are commonly heard in normal pregnancy that result from atelectasis that develops from basal compression of the lungs due to uterine enlargement and the subsequent increase in intra-abdominal pressure.

The left ventricular impulse is easily palpated, is brisk, and is nonsustained. The peripheral pulse often is collapsing in character and can be confused with the findings in aortic regurgitation. The jugular veins present a more distended pulse, with prominent a and v peaks with rapid x and y descents. A significant number of pregnant women have leg edema. It develops as a result of a fall in colloid oncotic pressure of the plasma with a concomitant increase in femoral venous pressure as a result of poor venous return.

The physical examination should focus on facial, digital, or skeletal abnormalities that suggest the presence of congenital anomalies. One should observe for clubbing, cyanosis, or pallor. Inspection of the chest can rule out pectus excavatum deformity, precordial bulge, or presence of right or left ventricular heave. The first heart sound usually is widely split (which can be misinterpreted as a fourth heart sound). A loud first heart sound suggests mitral stenosis, whereas a low-intensity first heart sound indicates first-degree heart block. A widely split second heart sound can be interpreted as an atrial septal defect, whereas a paradoxically split sound occurs in severe left ventricular hypertrophy or left bundle branch block. A third heart sound is normal in pregnancy. A fourth heart sound, ejection click, opening snap, or mid to late systolic click suggests heart disease. Innocent systolic murmurs can be heard in most pregnant women and can result from the hyperkinetic circulation of pregnancy. These murmurs are midsystolic and are heard best at the lower left sternal border and over the pulmonic area. Continuous benign murmurs, such as the cervical venous hum and mammary soufflé, also result from increased flow secondary to the hemodynamic changes of pregnancy. The venous hum is best heard over the right supraclavicular fossa, and the mammary soufflé is best auscultated over the breast in late gestation. Diastolic murmurs heard during pregnancy require further investigation by echocardiography and Doppler ultrasound.

Laboratory Examinations

ELECTROCARDIOGRAPHY

The QRS axis in normal pregnancy usually is within normal limits but can shift to the extreme right or left of that range. A small Q wave and an inverted P wave in lead III are abolished by deep inspiration. Greater R-wave amplitude can be seen in leads V_1 and V_2 . The incidences of sinus tachycardia and premature atrial/ventricular beats as well as the susceptibility to paroxysmal supraventricular and ventricular arrhythmias are increased.

CHEST RADIOGRAPH

The radiation exposure from a routine chest radiograph is minimal; however, chest x-ray films still should not be taken casually in pregnancy because of the potential biologic adverse effects of radiation exposure irrespective of the dose used. When chest films are taken, the pelvic area should be shielded with protective lead material. The findings on chest films can mimic abnormal disease conditions. Straightening of the left heart border due to enlargement of the main pulmonary artery can be seen. The heart is more horizontally located, and the lung markings are more prominent due to redistribution secondary to increased pulmonary venous pressure.

ECHOCARDIOGRAPHY

Small pericardial effusions are seen in normal pregnant women late in pregnancy. Dilation of mitral, tricuspid, and pulmonary annuli and enlargement of all the cardiac chambers are seen. Mild physiologic regurgitation of these valves is observed. Transthoracic echocardiography can be used safely on both the mother and the fetus to rule out congenital heart disease, ventricular dilatation, and aortic root disease.

Doppler ultrasound can evaluate the significance of valvular lesions, estimate pulmonary pressures, and rule out intracardiac shunts. Transesophageal echocardiography can improve visualization of posteriorly situated cardiac structures, such as the left atrium and mitral valve.

EXERCISE STRESS TESTING

Stress testing usually is indicated for preconception work-up for estimation of myocardial reserve to determine if a woman can safely carry a pregnancy to term. Some low-level exercise protocols have been developed for implementation during pregnancy to evaluate for ischemic heart disease. These protocols allow the heart rate to go up to only 70% of age-predicted heart rate along with concomitant fetal monitoring.

CARDIAC CATHETERIZATION

Pulmonary artery catheterization without fluoroscopy, at the bedside, is a relatively safe procedure and allows for hemodynamic monitoring during labor and delivery in patients with significant heart disease. Left or right heart catheterization under fluoroscopy should be undertaken only when absolutely essential (eg, for percutaneous coronary intervention or balloon valvuloplasty). Every effort should be taken to shield the abdominal and pelvic areas and to avoid direct irradiation of the fetus.

VALVULAR HEART DISEASE

Mitral Stenosis

Mitral stenosis is the most common valvular lesion seen in pregnancy. It may be congenital or may be caused by rheumatic heart disease, Libman-Sacks endocarditis in lupus, and Lutembacher's syndrome (mitral stenosis in association with an atrial septal defect). Rheumatic heart disease develops after a group A β -hemolytic streptococcal infection of the upper airway. Even though its incidence in developing countries has declined as a result of the prevalent use of antibiotics, rheumatic valvular disease still afflicts a large majority of women of childbearing age in Asia, Central America, and South America. Major Jones criteria for diagnosing rheumatic heart disease include prior evidence of a group A streptococcal infection (elevated antistreptolysin titer, positive throat culture), carditis, polyarthritis, chorea, subcutaneous nodules, and erythema marginatum. Minor criteria consist of fevers, arthralgias, elevated sedimentation rate, and first-degree heart block.

Pregnancy-related complications of mitral stenosis are mostly related to narrowing of the mitral valve in the setting of increasing heart rate and stroke volume. As left atrial pressure rises, the patient begins to develop symptoms of dyspnea, decreased exercise capacity, orthopnea, paroxysmal nocturnal dyspnea, and pulmonary edema. Eventually left atrial outflow obstruction leads to severe pulmonary venous congestion, resulting in pulmonary hypertension and right ventricular failure. Patients can have frank hemoptysis, and the low cardiac output can cause symptoms of dizziness and even syncope. The augmented atrial pressures, increasing atrial irritability, and presence of increasing sympathetic tone predispose the patient to development of atrial fibrillation. This new-onset atrial fibrillation can precipitate acute decompensation of heart disease even in the setting of mild to moderate mitral stenosis due to acceleration of ventricular rate that results in unfavorable hemodynamics.

The normal hemodynamic changes of pregnancy place patients with mitral stenosis at special risk for developing pulmonary congestion. The increased heart rate with consequent shortening of the diastolic filling period, augmented cardiac output and blood volume, and increased pulmonary venous pressure all contribute to raising left atrial pressure. The increased atrial irritability and increased sympathetic tone predispose to atrial fibrillation. The pregnant cardiac patient also is at risk for developing thromboembolic complications because of the hypercoagulable state of the blood during pregnancy as well as venous stasis in the legs. The risk of developing heart failure increases progressively throughout pregnancy and

increases further during labor and delivery and immediately postpartum. Symptoms can be aggravated by associated anemia, thyrotoxicosis, fever, respiratory infections, and tachycardia resulting from anxiety, stress, and unusual physical exertion, as well as a hot, humid environment. The risk of infective endocarditis remains throughout pregnancy, delivery, and early puerperium.

Labor imposes an additional load, and congestive failure may develop for the first time during labor in a previously well-controlled patient with mitral stenosis. The overall mortality rate in women with rheumatic mitral valve disease is 1% overall and reaches 3–4% in women with class III and IV severity.

Clinical Findings

The symptoms of mitral valve disease are similar to those of pulmonary venous congestion: dyspnea on exertion and later at rest, right ventricular failure, atrial arrhythmias, and occasionally hemoptysis. The characteristic findings on physical examination include a right ventricular lift, a loud first heart sound (S_1), an accentuated pulmonic component of the second heart sound (P_2), an opening snap, and a low-frequency diastolic rumble at the apex with presystolic accentuation (if the patient is in sinus rhythm). The murmur is best heard with the bell of the stethoscope in the left lateral decubitus position. The electrocardiogram often is normal but may indicate left atrial enlargement, right-axis deviation, or even right ventricular hypertrophy. The echocardiogram is particularly useful for defining the anatomy of the valvular and intravalvular structures, quantifying the degree of stenosis and associated regurgitation, and identifying the presence of abnormalities in other valves and pulmonary hypertension.

Treatment

The goals of treatment for the patient with mitral stenosis is to prevent/treat tachycardia and atrial fibrillation, prevent fluid overload, and prevent unnecessary increases in oxygen demands that may occur with anxiety or physical activity. Digitalis, quinidine, occasionally β -adrenergic blocking agents, sodium restriction, and diuretics may be necessary to treat congestive failure and atrial arrhythmias. Patients with chronic atrial fibrillation should be anticoagulated with subcutaneous heparin. Anemia, intercurrent infection, and thyrotoxicosis should be corrected. Large fluctuations in hemodynamics due to venous pooling in the legs should be prevented by the use of elastic support hose, especially late in pregnancy.

Medical management remains the first-line therapy in patients with mitral stenosis. In patients with severe mitral stenosis, mitral valvotomy may be performed for symptom relief before they become pregnant. Closed surgical mitral commissurotomy is an option during pregnancy. Balloon valvuloplasty has become a preferred, less invasive procedure, especially for patients with a noncalcified, pliable valve. Occasionally mitral valve placement is necessary as an emergency procedure during pregnancy, for instance, in a patient with prior valve replacement whose valve becomes obstructed by pannus or thrombus. Recent reports indicate a lower mortality rate for both mother and fetus with cardiopulmonary bypass. However, open heart surgery should be deferred until after the pregnancy if possible.

Patients who have a prosthetic valve require anticoagulation and should be switched from warfarin (Coumadin) to heparin during the pregnancy. The teratogenic and fetotoxic effects of warfarin and the risks of bleeding for the mother and fetus during labor and delivery must be balanced against the risks of thromboembolic episodes, especially in patients with earlier-model prosthetic valves. The use of tissue valves obviates the need for anticoagulants, but the life span of bioprosthetic valves is only 8–10 years, and anticoagulation is still required if the patient is in atrial fibrillation.

Patients with mitral stenosis should be delivered vaginally at term unless cesarean section is indicated for obstetric reasons. Narcotic-epidural anesthesia without epinephrine is the preferred option for delivery. Other considerations include maintenance of meticulous fluid balance, oxygen administration, and left lateral decubitus position during labor. The second stage of labor may be shortened with use of outlet

forceps. Careful hemodynamic monitoring during labor and delivery is indicated in patients with compromised circulation. Postpartum uterotonics should be given cautiously and blood loss carefully monitored. Redistribution of fluid from the interstitial to the intravascular space immediately postpartum can precipitate pulmonary edema in compromised patients.

Mitral Regurgitation

Patients with isolated or predominant mitral regurgitation tolerate the physiologic consequences of pregnancy better than do patients with predominant mitral stenosis. The fall in systemic vascular resistance decreases left ventricular afterload and actually reduces the regurgitant fraction, thus reducing the risk of pulmonary congestion. The risks of atrial fibrillation and endocarditis, however, are no less in patients with predominant mitral insufficiency. Although mitral regurgitation frequently is the result of rheumatic disease, other causes include genetic defects in collagen synthesis (as occur in Marfan's syndrome and Ehlers-Danlos syndrome) or following endocarditis of a previously abnormal valve, late complication of mitral valve prolapse, or papillary muscle infarction or rupture. The characteristic finding on physical examination is a long systolic murmur that ends with the second heart sound and is best heard at the apex with radiation into the axilla. An associated third heart sound is often present, and an opening snap may be present with associated mitral valve stenosis.

Rheumatic Disease in Other Valves

The aortic, pulmonary, and tricuspid valves may be involved by the rheumatic process, usually in association with mitral valve disease. Involvement of multiple valves compounds the problems of management in these patients. Patients with aortic or pulmonary stenosis have a fixed ventricular outflow obstruction. The gradient across the valve increases with progressive increase in cardiac output during pregnancy, leading to increased systolic pressure load on the ventricle. Although left ventricular failure is rare, postexertional syncope and angina due to inadequate cardiac output reserve may develop for the first time during pregnancy, especially in the last trimester, when venous return may be abruptly reduced due to compression of the inferior vena cava by the uterus. Patients with severe aortic stenosis should be advised to undergo surgical correction before they become pregnant. Because patients with high-grade aortic stenosis are unable to maintain normal cardiac output, hypotension, hypertension, and increased cardiac work must be prevented by restricting physical activity and carefully replacing intrapartum blood loss.

Patients with aortic insufficiency (eg, those with mitral regurgitation) tolerate pregnancy well because the fall in peripheral resistances favors blood flow and decreases the regurgitant fraction. The risk of endocarditis is present in both stenotic and insufficient valves regardless of severity, and antibiotic prophylaxis during delivery is recommended. Patients with elevated left ventricular end-diastolic pressure, however, are more likely to develop left ventricular failure during pregnancy.

Corrective surgical procedures for rheumatic valve disease include balloon valvuloplasty, surgical commissurotomy, and valve replacement. Two types of valves are available for valve replacement. Tissue valves do not require systemic anticoagulation but tend to deteriorate in 8–10 years. Prosthetic valves, such as the tilting disk or caged ball valves, may last 20 years or longer but always require anticoagulation, complicating the management of pregnancy.

Peripartum Cardiomyopathy

Peripartum cardiomyopathy occurs in 1 in 1500 to 1 in 15,000 pregnancies. It is a dilated cardiomyopathy of an unknown cause. Patients usually present with symptoms of congestive heart failure late in pregnancy or in the early postpartum period. Treatment includes bed rest, fluid and salt restrictions, diuretics, vasodilators, digitalis, and β blockers. In addition, prophylactic anticoagulation

during pregnancy and full anticoagulation for 1–2 weeks after delivery is recommended. Cardiac function normalizes within 6 months of delivery in approximately half of patients with peripartum cardiomyopathy. Because these patients are at risk for developing heart failure and death in subsequent pregnancy, they should be counseled against future pregnancies.

SUMMARY

Most pregnant patients with cardiac disease have successful outcomes with meticulous follow-up. Valvular stenotic lesions pose a high risk to the mother and the fetus, whereas regurgitant lesions are tolerated well by pregnant women. Extremely high-risk patients should be advised against pregnancy and be offered termination if they become pregnant.

Current OB/GYN > Chapter 22B. Pulmonary Disorders in Pregnancy >

ASPIRATION PNEUMONITIS

Pregnant women are at increased risk for aspiration of gastric contents as a result of elevated intra-abdominal pressure, decreased gastroesophageal sphincter tone, delayed gastric emptying, and diminished laryngeal reflexes. Aspiration may be the result of passive regurgitation or active vomiting. Aspiration has been reported to account for 30–50% of maternal deaths related to anesthetic complications. Superimposed bacterial infection following aspiration may occur after 24–72 hours, with mortality rates even higher in these cases. The main determinants of outcome are related to the acidity (pH \leq 2.5) and the volume (\geq 25 mL) of the aspirate and the presence or absence of solid particles in the aspirate.

Clinical Findings

The pathologic mechanism and clinical manifestations depend on the volume and composition of the aspirate. Small volumes of a very acidic aspirate will be highly toxic, whereas relatively large volumes of a buffered aspirate can be tolerated. Aspiration of large, solid particulate matter may occlude portions of the larger bronchi, resulting in hypoxia, pulmonary hypertension, and even death. With smaller particles, bronchial obstruction occurs more distally, resulting in atelectasis, hypoxia, and inflammation of the bronchial mucosal and respiratory distress. Symptoms immediately after aspiration include dyspnea, bronchospasm, cyanosis, tachycardia, and even respiratory arrest. The patient will be hypoxic, hypercapnic, and acidotic. The chest x-ray film may reveal interstitial pulmonary edema.

Prevention

Given the high rate of maternal death associated with aspiration pneumonitis, every effort should be made to prevent this catastrophic condition. General anesthesia is the main risk factor associated with aspiration, and expert airway management during induction and intubation is extremely important.

Oral intake during labor must be avoided. Women undergoing elective cesarean delivery must not be given anything by mouth for at least 6–8 hours prior to the procedure. All anesthetized obstetric patients should be intubated. Laryngeal reflexes will generally prevent aspiration while patients are awake, but the reflexes will be altered in patients who are given excessive sedation, in patients who are under anesthesia, or in patients with seizures. Pain, anxiety, narcotics, and labor itself may cause delayed gastric emptying and increased intragastric pressure. Lowering the volume of gastric contents to < 25 mL and raising the gastric pH to > 2.5 will reduce the risk of pulmonary injury if aspiration occurs. Clear, nonparticulate systemic alkalizers (eg, sodium citrate-Bacitra, or Alka-Seltzer) must be used instead of particulate oral antacids (eg, magnesium trisilicate, Maalox, Riopan). Thirty milliliters of a clear antacid should be routinely given to all women 30 minutes prior to induction of anesthesia.

Gastric acidity may be reduced by histamine-2 (H₂) receptor blockers. Cimetidine and ranitidine have been reported to be safe for use during pregnancy. Metoclopramide may increase lower esophageal sphincter tone and enhance gastric emptying. However, antacids are preferred, particularly in emergency situations, because they are reliable and fast acting. H₂ blockers and metoclopramide are not

recommended for routine use.

Treatment

If aspiration occurs during anesthesia, immediate intubation and suction should be performed, followed by ventilation and adequate oxygenation. Positive end-expiratory pressure may help to better expand areas of fluid-filled collapsed lung. Bronchoscopic suction should be performed as soon as possible if the aspirate contains solid particles. A chest x-ray film should be taken and serial blood gas determinations made. These patients should be managed in the intensive care unit.

If the gastric fluid pH is > 3.0 and the patient appears to be well oxygenated, she can be followed closely with periodic chest x-ray films and blood gas determinations. Use of corticosteroids is not universally agreed upon. Antibiotics should not be given empirically; they should be administered only when clinical evidence and cultures indicate the presence of a superimposed bacterial infection.

ASTHMA DURING PREGNANCY

Frequency

The general prevalence of asthma appears to be increasing. Recent studies report that asthma occurs in 9% of the general U.S. population and in 3.7–8.4% of pregnant women. Therefore, asthma has become one of the most common medical illnesses complicating pregnancy. The most recent government-compiled statistics in 2003 reveal that 20.3 million persons in the United States have asthma; 9 million of these persons are younger than 18 years. There were 1.8 million emergency room visits, half a million hospitalizations, and 5000 deaths in 2003, half of which occurred in those younger than 18 years. The increased prevalence is reported worldwide, particularly in urban areas, and is generally attributed to industrial pollution. However, marked geographic variations occur, and the extent to which genetic predisposition plays a role is under active investigation.

Effect of Asthma on Pregnancy

Childhood-onset asthma affects males more often than females. In contrast, adult-onset asthma reportedly occurs more frequently in women than in men. Overall, the prevalence and severity of asthma are consistently reported to be greater in women than in men. Women also are reported to require more frequent emergency room visits and more hospitalizations. Therefore, sex hormones are believed to play a role in the differences observed in the occurrence of asthma, although the exact mechanisms are not completely elucidated. Asthma shows variations during the menstrual cycle, with premenstrual exacerbation more often reported. Reports on asthma during the menopause are more conflicting, with some studies noting improvement but others reporting more episodes of bronchospasm after 6 months of hormone replacement therapy.

No consistent effect (either worsening or improvement) during pregnancy has been observed, although one-third of women with more severe disease reportedly became worse late in the second trimester or during the third trimester. Others speculate that pregnancy does not have an effect on asthma and that the variations observed are simply part of the natural history of the disease. The responses in subsequent pregnancies are more consistent and tend to be similar to those that occurred during the first pregnancy.

Potential maternal complications include hyperemesis gravidarum, pneumonia (women with asthma account for $> 60\%$ of pneumonia cases in pregnancy), preeclampsia, vaginal bleeding, more complicated labors, and more cesarean deliveries. Fetal complications can include intrauterine growth restriction, preterm birth, low birthweight, neonatal hypoxia, and increased overall perinatal mortality. Women with severe asthma are at the highest risk. However, patients are at little or no increased risk when the

disease is effectively treated and controlled.

Classification

Asthma currently is classified according to severity as (1) mild intermittent, (2) mild persistent, (3) moderate persistent, and (4) severe persistent. In mild intermittent asthma, symptoms do not occur more often than twice per week, and nocturnal symptoms do not occur more often than twice per month. The peak expiratory flow (PEF) or the forced expiratory volume in 1 second (FEV₁) is > 80% of normal, with a variability < 20%. In mild persistent asthma, symptoms occur more often than twice per week but not daily, and nocturnal symptoms occur more often than twice per month. The PEF or FEV₁ still is at least 80% of normal, but the variability is greater at 20–30%. In moderate persistent asthma, symptoms occur daily, and nocturnal symptoms occur more than once per week. The PEF or FEV₁ is < 80% but > 60% of normal, with variability > 30%. In severe persistent asthma, daytime symptoms occur continually, and nocturnal attacks occur frequently. The PEF or FEV₁ is < 60% of normal, with variability > 30%.

Diagnosis

The diagnosis of asthma usually is made on clinical grounds and rarely is difficult if an adequate history and physical examination are obtained. Most patients are diagnosed before pregnancy and already are receiving treatment. Symptoms suggestive of asthma include cough, dyspnea, chest tightness, and wheezing, particularly when episodes occur episodically. Pulmonary function studies are useful to confirm the diagnosis and should be part of the initial investigations. The FEV₁/FVC (forced vital capacity) ratio will be < 70%, and the airway obstruction can be reversed by administration of a short-acting β_2 -agonist preparation. Rarely, bronchospasm is caused by a condition other than asthma. These conditions include acute left ventricular heart failure (also called *cardiac asthma*), pulmonary embolism, exacerbation of chronic bronchitis, carcinoid tumors, upper airway obstruction (laryngeal edema, foreign body), gastroesophageal reflux, and cough caused by some medications.

Common triggers of asthma include upper respiratory infections (more commonly viral); administration of blockers, aspirin, or nonsteroidal anti-inflammatory drugs; sulfites and other food preservatives; allergens such as pollen, animal dander, mites, or molds; smoking; (environmental asthma); gastric reflux; and exercise or other causes of hyperventilation. Both cigarette smoking and other major environmental pollutants are specifically associated with fetal damage.

Treatment

GENERAL MEASURES

The main goal of therapy is to maintain normal or near-normal maternal pulmonary function to allow adequate fetal oxygenation, prevent exacerbations, and allow the patient to maintain her usual activities. In general, pregnant women are receptive to educational interventions that will improve their asthma management, and the benefits are likely to continue after delivery. A good example is learning the proper use of portable peak flow meters to objectively evaluate asthma severity because clinical symptoms and the patient's own perception of the severity of asthma often are inaccurate. The PEF rate correlates well with FEV₁ and allows the detection of worsening at an early stage before serious symptoms appear and the evaluation of response to treatment while the patient is still at home. Avoidance of potential asthma triggers also is extremely important. The general principles of management for pregnant asthmatic women are similar to those for nonpregnant patients and include removing pets if necessary, encasing mattresses and pillows in airtight covers, carefully washing the bedding, keeping ambient humidity < 50%, avoid vacuuming (or at least wear a mask), using air conditioning and air filters, avoiding outdoor activities when allergens and air pollution levels are high, and avoiding nonallergen irritants, such as strong odors, food additives, aspirin, β blockers, and

particularly tobacco smoke. Several recent studies have shown that these measures not only are beneficial but are cost-effective as well.

Patients undergoing immunotherapy may continue doing so during pregnancy but without any further dose increase. Starting immunotherapy de novo during pregnancy is not recommended because uterine contractions are likely to develop if anaphylaxis occurs.

Influenza vaccination is currently recommended for all pregnant women during the flu season. This recommendation is of the utmost importance for pregnant women with asthma. Asthma sufferers also should receive the pneumococcal vaccine but preferably prior to pregnancy.

Treating rhinitis and sinusitis, which often are associated with asthma and may trigger exacerbations, is important. Treatment of rhinitis includes reducing exposure to antigens (environmental control); intranasal cromolyn sodium, antihistamines (tripelennamine or chlorpheniramine), and intranasal steroids are very beneficial. For treatment of sinusitis, amoxicillin (erythromycin if allergic to penicillin), oxymetazoline (nasal spray or drops), and pseudoephedrine are more often used.

PHARMACOLOGIC THERAPY

Many women have the impression that most, if not all, medications might be harmful to the fetus. However, they should be informed that the risk of uncontrolled asthma is far worse than any of the potential side effects of the most common medications used to treat asthma. Most women with asthma can be managed effectively during pregnancy, and complications are generally confined to patients with uncontrolled asthma.

Mild Intermittent Asthma

These patients do not need daily medications. When symptoms occur, 2–4 puffs of a short-acting β_2 agonist can be used as needed. More data are available for use of albuterol than for any other β_2 agonist during pregnancy, and no harm to the fetus has been observed to date. These women may still experience severe exacerbations, which may be separated by long asymptomatic periods, and a short course of systemic corticosteroids may be needed.

Mild Persistent Asthma

The preferred therapy for this group of patients is a low-dose inhaled corticosteroid. More experience is available for budesonide use in pregnancy, and the published data regarding its safety and lack of risk for congenital anomalies are reassuring. Less experience is reported with beclomethasone, but the published data also are reassuring. Inhaled corticosteroids suppress and may even prevent airway inflammation, which plays a critical role in the pathogenesis of asthma and may decrease airway responsiveness as well. Because they may decrease and sometimes even obviate the need for systemic steroids, their use is now recommended at earlier stages of asthma. However, the full benefits may not be seen for 2–4 weeks, so they are not recommended as part of the treatment of acute attacks. Use of a mouth spacer to minimize systemic absorption is strongly recommended. Inhaled corticosteroids are likewise beneficial for rhinitis (2 sprays in each nostril twice daily).

Alternative, but not preferred, therapies for this group include inhaled cromolyn sodium, leukotriene receptor antagonists, or sustained-release theophylline. Cromolyn sodium is also anti-inflammatory drug, but its efficacy is less predictable than that of the inhaled corticosteroids, and the benefits may not be seen for 4–6 weeks. Nevertheless, cromolyn sodium seems to be free of side effects for mother or fetus. Few data on the use of leukotriene receptor modifiers during pregnancy are available, but they are reported to be safe in animals. The extensive experience with theophylline during pregnancy indicates theophylline is safe for the fetus except when maternal levels exceed 12 $\mu\text{g}/\text{mL}$. In these cases, the fetus or newborn may develop jitteriness, tachycardia, and vomiting.

Moderate Persistent Asthma

The preferred treatment is a combination of a low-dose or medium-dose inhaled corticosteroid and a long-acting β_2 agonist. Alternative therapies (but again not preferred) include a low-dose or medium-dose inhaled corticosteroid and either theophylline or a leukotriene receptor antagonist. However, given the scarcity of data on human pregnancy, the use of leukotriene receptor modifiers is reserved for patients who showed a very good response before pregnancy but are not responding well to other medications while pregnant.

Severe Persistent Asthma

The preferred treatment is a high-dose inhaled corticosteroid and a long-acting inhaled β_2 agonist as well as (if needed) a systemic corticosteroid, such as 2 mg/kg/d of prednisone or equivalent steroid not to exceed 60 mg/d, with an attempt to taper to the minimal effective dose. An alternative, but not preferred, treatment includes a high-dose inhaled corticosteroid and sustained-release theophylline (keeping maternal systemic levels at 5–12 $\mu\text{g/mL}$ for the reasons explained above).

Systemic corticosteroids are used when any of the other drug combinations cannot control the asthma. They usually are given first as a short, rapidly tapering course (eg, 40–60 mg/d of prednisone or equivalent steroid for 1 week, tapering off during the second week). If these courses fail to effectively control symptoms for < 2–3 weeks, long-term systemic corticosteroid treatment may be needed. In these cases, the lowest effective dose or alternate-day therapy, if possible, should be used. Potential maternal side effects include impaired glucose tolerance or frank diabetes mellitus, preeclampsia, intrauterine growth restriction, and premature delivery. With prolonged use (1–2 months), maternal adrenal insufficiency may occur, and adequate coverage during periods of stress (including labor and delivery) is mandatory. Use during the first trimester is associated with a higher risk for facial clefts (lip and palate). Pregnant women with asthma who are steroid dependent should be managed by an internist/pulmonologist who is experienced in the treatment of asthma during pregnancy.

OTHER ASTHMA MEDICATIONS

Nonselective β agonists such as epinephrine and isoproterenol are sometimes given subcutaneously during acute asthma attacks. Epinephrine use during pregnancy should be avoided because epinephrine causes vasoconstriction and reduces fetal oxygenation. It is teratogenic in animals as well as in humans. Isoproterenol also is teratogenic in animals. Because many other alternative therapies are available, isoproterenol use in humans is best avoided. Iodine-containing medications should be avoided during pregnancy because the fetus may be at risk for developing a goiter, which may become very large and cause airway obstruction and even asphyxia. Nedocromil sodium is similar to cromolyn sodium. No reports on humans are available, but nedocromil sodium has not been observed to be teratogenic in animal experiments. Anticholinergic medications such as atropine (which block bronchoconstriction by inhaled irritants) may accelerate the fetal heart rate and inhibit breathing. Ipratropium has not been reported to be teratogenic in animals, but data on humans are lacking. Glycopyrrolate has been used safely in humans near term, and no defects have been reported in animal experiments.

Acute Asthmatic Attack

During acute exacerbations, dyspnea, cough, wheezing, and chest tightness increase and expiratory flow decreases. A few, well-educated patients with a relatively mild attacks might be managed at home taking advantage of the judicious use of peak flow measurements. However, any serious exacerbation most likely will require hospitalization. Great care should be exercised to maintain a maternal $\text{Po}_2 > 70$ mm Hg and O_2 saturation > 95%. A maternal $\text{Po}_2 < 60$ mm Hg will result in marked fetal hypoxia.

General measures include reassuring the patient and avoiding sedatives, which may depress respiration. Oxygen can be administered by mask or nasal catheter with the goal of maintaining $\text{Po}_2 > 70$ mm Hg

and O₂ saturation > 90% to ensure adequate fetal oxygenation at all times. A few patients may require endotracheal intubation and mechanical ventilation to maintain an adequate oxygen supply. Blood gas determinations are necessary for this purpose. A chest x-ray film should be part of the initial evaluation. Antibiotics are given only if evidence of bacterial infection is present. Some pregnant women receiving large amounts of intravenous fluids, β₂ agonists, and corticosteroids reportedly develop pulmonary edema, so this risk should be considered under these circumstances.

Initial pharmacologic treatment includes an inhaled β₂ agonist administered by a metered-dose inhaler, 2–4 puffs every 20 minutes to a maximum of 3 doses or less if side effects appear. A subcutaneous β₂ agonist (eg, terbutaline 0.25 mg) is also given and can be repeated once 20 minutes later. Systemic corticosteroids are recommended early in the course of treatment of acute exacerbations. The most frequently used corticosteroid is methylprednisolone intravenously at an initial dose of 1–2 mg/kg/d. At present, intravenous theophylline is used much less frequently for acute exacerbations because of the early use of corticosteroids. When necessary, the recommended initial loading dose is 5–6 mg/kg given intravenously over 20–30 minutes. The loading dose is not given if the patient was receiving adequate oral doses prior to the acute attack, or only half the loading dose is given if the patient was receiving theophylline but only intermittently. Maintenance doses are 0.7 mg/kg/h. Serum levels should be monitored to avoid maternal levels in excess of 12 μg/mL.

After admission to the hospital, administration of β₂ agonists is continued by nebulized aerosol every 4–6 hours; administration of intravenous corticosteroids also is continued (eg, methylprednisolone 0.5–1 mg/kg twice daily). If theophylline was started, it is continued per the maintenance dose protocol, with careful monitoring of maternal serum levels to avoid fetal toxicity. As the patient improves, the β₂-agonist aerosols are continued (2 puffs every 4–6 hours), and at this point the inhaled steroids (high dose, per the protocol for the severe persistent asthma) are resumed or the therapy initiated if the patient was not receiving them prior to the acute attack. If the clinical improvement continues, the systemic steroids can be switched to the oral route (eg, prednisone 0.5 mg/kg/d, with gradual tapering attempted while maximizing inhaled steroid treatment). If theophylline was being given, it also should be changed to the oral route (6 mg/kg), with close monitoring of maternal serum levels.

Management during Labor and Delivery

The medications that were being administered prior to the onset of labor should be continued during labor. Adequate control should be maintained because labor has been reported to trigger an acute attack in approximately 10% of women with asthma. Peak expiratory flow measurements should be obtained at regular intervals to monitor pulmonary status closely. Adequate hydration should be maintained and pain relief provided as necessary. Fentanyl is considered a good analgesic choice for these patients. Analgesics and/or narcotics, which can cause histamine release, should be avoided because of the possibility of respiratory depression and bronchospasm. Continuous O₂ monitoring is mandatory to ensure that O₂ saturation is > 95% at all times.

Medications to avoid include prostaglandin F₂ because it may cause bronchospasm. Prostaglandin E₂, either gel or suppository, is safe for women with asthma and can be used if necessary from the obstetric standpoint. Oxytocin is safe and considered the medication of choice for induction.

Epidural anesthesia is preferred because it reduces O₂ consumption and minute ventilation. General anesthesia may trigger an attack, but the risk may be reduced by pretreatment with atropine (see above for potential fetal effects) and glycopyrrolate, which have a bronchodilatory effect. A low concentration of halogenated anesthetic may provide bronchodilation as well. For induction, ketamine is preferred. An anesthesiologist experienced in the care of pregnant women should be consulted ahead of time when anticipating anesthesia needs.

Ergot derivatives should be avoided because they may precipitate bronchospasm. If postpartum hemorrhage occurs, oxytocin is the best choice. If a prostaglandin is needed, then prostaglandin E₂ is preferred. Aspirin and nonsteroidal anti-inflammatory drugs (eg, indomethacin) may trigger severe bronchospasm as well as ocular, nasal, dermal and gastrointestinal inflammation in 3–8% of asthmatic patients and are best avoided. Magnesium is safe for asthma but with careful monitoring to avoid respiratory depression.

Fetal Monitoring

An ultrasound examination in early pregnancy is useful to confirm dating and to provide a baseline to evaluate future growth assessment. Serial ultrasounds are recommended for women with moderate and severe asthma because they are the most at risk for fetal growth restriction. No specific guidelines have been issued for antepartum fetal surveillance other than very general recommendations such as "when needed in the third trimester to assure fetal well being" and "daily recording of fetal movements is encouraged." Many institutions offer fetal surveillance starting at 32–34 weeks to patients with moderate and severe asthma and at any time during the third trimester when an exacerbation occurs. There is unanimous agreement that all patients with asthma should undergo continuous fetal monitoring during labor and delivery.

Breastfeeding

Inhaled β_2 agonists, cromolyn sodium, steroids (inhaled), and ipratropium are safe while breastfeeding. Systemic (oral or parenterally administered) steroids may enter into breast milk but only in small amounts if the total daily dosage contains less than 40 mg of prednisone (or equivalent steroid).

TUBERCULOSIS

Tuberculosis was one the leading causes of death in the United States for many years until the introduction of effective therapy in the early 1950s. Since then, the number of reported cases declined steadily until recently, when the number of cases has increased. This situation is attributed to increased immigration from countries with a high tuberculosis prevalence and particularly to the human immunodeficiency virus (HIV)/acquired immunodeficiency syndrome (AIDS) epidemic.

Tuberculosis in adults is mainly (> 95%) a disease of the pulmonary parenchyma caused by *Mycobacterium tuberculosis*, a nonmotile, acid-fast aerobic rod. Transmission usually occurs by inhalation of droplets produced by infected individuals when coughing. The droplets can remain suspended in the air for prolonged periods (several hours). The persons most at risk for becoming infected are family members and other close contacts, such as coworkers and roommates (elderly residents and employees in long-term care facilities, correctional institutions), homeless individuals, and intravenous drug users. After the initial inhalation, the bacilli multiply in the alveoli and subsequently spread to the regional lymph nodes and to other organs such as the upper lung regions, kidneys, bones, central nervous system (CNS), and, rarely, during pregnancy, to the placenta. In most people, the infection is contained by cell-mediated immunity, which develops 2–10 weeks after exposure when the infected sites are walled off by granulomatous inflammation and the tuberculin tests then becomes reactive. At this stage, these persons are not infectious and are asymptomatic except for the positive tuberculin skin test. After the initial exposure, the risk of developing active disease during the following 2–5 years is generally given as 5–15%, but the risk later falls to very low levels < 1–2%. However, active disease may ensue if a person is unable to contain the infection when first exposed or if the person subsequently becomes immunocompromised and the infection is reactivated at a time remote from the initial exposure.

Clinical Findings

Most cases of tuberculosis can be diagnosed on the basis of a history of cough, weight loss, positive

tuberculin skin test, and chest x-ray film.

SYMPTOMS AND SIGNS

Typical symptoms include cough, weight loss, fatigue, night sweats, and anorexia. However, some patients may have very few symptoms.

Laboratory Findings

The definitive diagnosis is made after positive identification of the bacilli by Ziehl-Neelsen staining and a positive culture.

TUBERCULIN SKIN TEST

The tuberculin skin test is the most important screening test for tuberculosis. It should be performed early in pregnancy, especially in high-risk populations. An induration of 5 mm or greater is considered positive in individuals with HIV infection, in close contacts of persons with active, infectious tuberculosis, in persons with typical x-ray findings who were never previously treated, and in intravenous drug users. An induration of 10 mm or more is considered positive in persons who have risk factors other than HIV, such as diabetes mellitus, silicosis, chronic use of corticosteroids or other immunosuppressive drugs, cancer (solid tumors as well as leukemias and lymphomas), chronic renal insufficiency, gastrectomy or intestinal bypass, or malabsorption and chronic malnutrition with body weight 10% or less below the ideal.

CHEST X-RAY FILM

With the abdomen shielded and preferably after the first trimester, a chest x-ray film should be taken in patients in whom skin testing is positive after an earlier negative test and in patients with a suggestive history or physical examination even though skin testing is negative.

CONGENITAL TUBERCULOSIS

Congenital tuberculosis is rare. The criteria for diagnosis include positive bacteriologic studies, primary disease complex in the liver, disease occurring within the first few days of life, and exclusion of extrauterine infection. The most common signs are nonspecific and include fever, failure to thrive, lymphadenopathy, hepatomegaly, and splenomegaly. The disease usually is miliary or disseminated. An early diagnosis is necessary for effective treatment.

Treatment

MEDICAL THERAPY

Untreated tuberculosis is far riskier to the mother and fetus than any of the potential medications necessary to treat active disease. A preventive course of isoniazid (isonicotinic acid hydrazide [INH]) is generally recommended for those with a positive skin test and no evidence of active disease if they are at risk for developing active tuberculosis. However, such preventive therapy is withheld in those older than 35 years and during pregnancy and early postpartum because of an increased risk for INH-related hepatitis. In those at high risk (particularly in cases of HIV/AIDS), preventive INH treatment is initiated as soon as evidence of tuberculosis infection (but no active disease) is documented. The recommended dose of INH is 300 mg/d for 9 months as well as pyridoxine (vitamin B₆) to prevent INH-related neuropathy. Periodic evaluation of liver function is recommended to detect hepatotoxicity early if it occurs. Most studies have shown no teratogenic effects of INH.

Active tuberculosis should be treated as soon as the diagnosis is made. Most treatment programs consist of a 3-drug regimen, usually INH 5 mg/kg/d (total 300 mg/d), and ethambutol 15 mg/kg/d, and rifampin 10 mg/kg/d (maximum 600 mg/d) for 8 weeks and the INH and rifampin to complete 9 months.

Pyridoxine should be given along with INH. Local public health departments should be consulted to obtain data about drug resistance. These three medications cross the placenta, but no adverse fetal side effects

have been reported to date. Pyrazinamide has been used in addition to the three medications mentioned in areas of highly drug-resistant tuberculosis but is not recommended during pregnancy because of limited safety data. Because of the risk for fetal (and maternal) ototoxicity, streptomycin, kanamycin, and capreomycin should not be used. Isoniazid has many therapeutic advantages (eg, high efficacy, patient acceptability, and low cost) and appears to be the safest drug for use during pregnancy. The major side effects of INH are hepatitis, hypersensitivity reactions, peripheral neuropathy, and gastrointestinal distress. A baseline liver function test should be obtained and then repeated periodically. *Pyridoxine 50 mg/d should be administered to prevent INH-induced neuritis due to vitamin B6 deficiency.* Optic neuritis is a rare complication reported with ethambutol use. Rifampin may cause hepatitis, hypersensitivity reactions, occasional hematologic toxicity, flulike syndrome, abdominal pain, acute renal failure, and thrombocytopenia. Rifampin may increase the metabolic rate of oral contraceptives through activation of the hepatic P450 enzyme system, so an alternative form of contraception may be necessary after delivery in these patients while they are taking rifampin.

Obstetric Management

Routine antepartum obstetric management includes adequate rest and nutrition, family support, correction of anemia if present, and regular follow-up visits.

Immediate neonatal contact is allowed if the mother has received treatment for inactive disease and no evidence of reactivation is present. In patients with inactive disease in whom prophylactic INH was not given or those with active disease in whom adequate treatment was given, early neonatal contact may be allowed, provided the mother is reliable in continuing therapy. A mother with active disease should receive at least 3 weeks of treatment before coming into contact with her baby, and the baby must also receive prophylactic INH.

There are no absolute contraindications to breastfeeding once the mother is noninfectious. Although antituberculosis drugs are found in breast milk, the concentrations are so low that the risk of toxicity in the infant is minimal. However, each case should be judged individually if the mother wishes to breastfeed her infant. In general, breastfeeding is not contraindicated while the mother is taking antituberculosis medications.

Immunization of the newborn with bacille Calmette-Guérin (BCG) vaccine remains controversial. If prompt use of INH as prophylaxis is unlikely or if the mother has INH-resistant disease, BCG vaccination of the infant should be considered.

Prognosis

If the pregnant patient is adequately treated with antituberculosis chemotherapy for active disease, tuberculosis generally has no deleterious effect either during the course of pregnancy or the puerperium or on the fetus. Pregnant women have the same prognosis as nonpregnant women. Tuberculosis is not a reason for recommending a therapeutic abortion.

Current OB/GYN > Chapter 23. Renal, Urinary Tract, Gastrointestinal, & Dermatologic Disorders in Pregnancy > Renal and Urinary Tract Disorders >

URINARY TRACT INFECTION

Asymptomatic bacteriuria, acute cystitis, and acute pyelonephritis are common renal disorders in pregnancy. For a discussion of normal renal and urinary tract function in pregnancy, see Chapter 7.

Asymptomatic Bacteriuria

Asymptomatic bacteriuria is defined as the presence of actively multiplying bacteria in the urinary tract excluding the distal urethra in a patient without any obvious symptoms. The incidence is the same in nonpregnant and pregnant female and averages 2–10%. Asymptomatic bacteriuria is twice as common in pregnant women with sickle cell trait and 3 times as common in pregnant women with diabetes or with renal transplant as in normal pregnant women. Risk factors for developing asymptomatic bacteriuria include low socioeconomic status, parity, age, sexual practice, and medical conditions such as diabetes and sickle cell trait.

If asymptomatic bacteriuria is left untreated in pregnancy, up to 40% of patients will develop symptoms of urinary tract infection (UTI). Approximately 25–30% of women will develop acute pyelonephritis. With treatment, the rate is only 10%. Asymptomatic bacteriuria has been associated with preterm delivery, fetal loss, and preeclampsia. Approximately 2% percent of pregnant women with a negative urine culture will develop symptomatic cystitis and pyelonephritis. The diagnosis of asymptomatic bacteriuria is based upon isolation of microorganisms with a colony count > 10⁵ organisms per milliliter of urine in a clean-catch specimen. The patient should be instructed to clean the vulvar area from front to back to avoid contamination of the urine sample. *Escherichia coli* is the most common offending organism for asymptomatic bacteriuria (approximately 80% of cases). The *Klebsiella-Enterobacter-Serratia* group, *Staphylococcus aureus*, *Enterococcus*, group B *Streptococcus*, and *Proteus* are responsible for the remainder of cases.

Acute Cystitis

Acute cystitis is uncommon in pregnancy (approximately 1%). The bacteria causing acute cystitis are similar to those in asymptomatic bacteriuria. Clinically, the patient presents with symptoms of urinary frequency, urgency, dysuria, and suprapubic discomfort. The urine often is cloudy and malodorous and should be cultured to confirm the diagnosis and to identify antibiotic sensitivities. The treatment of cystitis is the same as for asymptomatic bacteriuria.

Acute Pyelonephritis

Acute pyelonephritis occurs in 1–2% of all pregnant women (usually, although not invariably, in those with previous asymptomatic bacteriuria) and is associated with risk to the mother and fetus. It is one of the most common causes of hospitalization during pregnancy. Maternal effects include fever, bacterial endotoxemia, endotoxic shock, renal insufficiency, anemia, leukocytosis, thrombocytopenia, and elevated fibrin split product levels. Preterm labor and fetal death may be seen in severe cases. Risk factors for recurrent or severe disease are a history of pyelonephritis, urinary tract malformation, or urinary calculi.

The anemia may be due to marrow suppression, increased erythrocyte destruction, or diminished red cell production. Pulmonary dysfunction has been described in association with acute pyelonephritis. Symptoms and signs may range from minimal (mild cough and slight pulmonary infiltrate) to severe (adult respiratory distress syndrome requiring intensive therapy). Neonatal effects include prematurity and small-for-gestational-age babies.

Clinical manifestations of acute pyelonephritis include fever, shaking chills, flank pain, nausea and vomiting, headache, increased urinary frequency, and dysuria. Urine examination will reveal significant bacteriuria, with pyuria and white blood cell casts in the urinary sediment. A count of 1–2 bacteria per high-power field in unspun urine or > 20 bacteria in the sediment of a centrifuged specimen of urine collected by bladder catheterization helps in the bedside diagnosis. The diagnosis should be confirmed by urine culture. Associated hematuria may indicate urinary calculi.

Treatment

A midstream urine specimen should be collected for culture at the initial prenatal visit and repeated later in pregnancy. At each prenatal visit, dipstick testing should be performed. If proteinuria is present, urinalysis, culture, or both should be done. A pregnant woman with sickle cell trait should have urine culture and sensitivity testing every 4 weeks. The U.S. Preventive Health Task Force states that single urine culture at 12–16 weeks' gestation has 80% sensitivity. Alternatively, regular dipstick testing for leukocyte esterase and nitrites has a negative predictive value > 95% and sensitivity of 50–92%.

Pregnant women should be encouraged to maintain adequate fluid intake and to void frequently.

The initial antibiotic selection should be empiric. Based on the fact that the most common offending pathogen is *E coli*, sulfonamides, nitrofurantoin, or a cephalosporin are reasonable choices. These antibiotics should be safe for the mother and fetus, with minimal side effects. A 5- to 14-day course of one of these agents will effectively eradicate asymptomatic bacteriuria in approximately 65% of pregnant patients. A urine culture should be repeated 1–2 weeks after therapy is started and then monthly for the remainder of pregnancy. Recurrent infections occur in approximately 30% of patients treated once and in approximately 15% of patients who have been treated twice and/or have not responded to initial therapy.

Sulfa drugs must be avoided in mothers with glucose-6-phosphatase deficiency. Additionally, sulfa drugs are best avoided late in pregnancy because of the increased likelihood of neonatal hyperbilirubinemia. Tetracyclines are contraindicated during pregnancy because of dental staining in the exposed child. Trimethoprim is a folic acid antagonist; therefore, trimethoprim-sulfamethoxazole is generally avoided during organogenesis; it may be used when alternatives are limited. A pregnant woman with pyelonephritis initially should be evaluated in the hospital. Antibiotics should be given parenterally and hypovolemia corrected. Acetaminophen can be used as an antipyretic, if indicated. Vital signs, including respiratory rate, and input and output should be closely monitored. Pulse oximetry may be useful. A first-generation cephalosporin such as cefazolin 1 g parenterally every 8 hours usually is effective. However, due to increasing antibiotic resistance, the local susceptibilities should be considered when selecting the initial antibiotic. Ceftriaxone 1 g parenterally every 24 hours often is effective for most *Enterobacteriaceae* in this setting. The urine culture and sensitivities guide therapy thereafter. When the patient is afebrile for 48 hours, parenteral therapy may be changed to an effective oral antibiotic. A total course of 14 days of antibiotic is commonly administered.

If no clinical response is seen in 48–72 hours, a resistant organism can be treated by adding an aminoglycoside such as gentamicin 3–5 mg/kg per 24 hours in 3 divided doses given every 8 hours. Failure to respond may be caused by urolithiasis or a structural urinary tract abnormality. Ultrasound

imaging of the kidneys and urinary tract usually is the next diagnostic test. Perinephric abscess causing persistent pain and fever can be identified by ultrasound. Perinephric abscess usually is due to obstruction complicated by infection. The perinephric abscess must be drained surgically in addition to administration of antibiotic therapy. An intravenous pyelogram is often useful if a lack of response continues. A preliminary "scout" film and a film taken 15 minutes after administration of intravenous contrast often are helpful. In selected cases of persistent infection or obstruction, cystoscopy and retrograde pyelography are needed.

Cunningham (1994) reported that following an episode of pyelonephritis, recurrent bacteriuria occurred in 28% of women, and pyelonephritis recurred in 10% during the same pregnancy. For this reason, antibiotic suppressive therapy with nitrofurantoin 100 mg orally at bedtime, or a similar regimen, is continued during the pregnancy and during the puerperium, often for 6 weeks (Table 23–1). Monthly urine cultures to identify a recurrent UTI may be similar in effectiveness to antibiotic suppression for patients who are allergic or who prefer not to take antibiotics.

Figure 23–1. Antibiotic Regimen for Pyelonephritis.

Antibiotic	Dosage	Route	Frequency
Ampicillin plus gentamicin	1–2 g	IV	q4–6h
	2 mg/kg, then 1.7 mg/kg	IV	q8h
Ampicillin/sulbactam	3 g	IV	q6h
Cefazolin	1–2 g	IV	q6–8h
Ceftriaxone	1–2 g	IV or IM	q24h
Mezlocillin	3 g	IV	q6h
Piperacillin	4 g	IV	q8h

Periodic culture of the urine assists in detection of recurrence. *Relapse* is defined as recurrent infection from the same species and type-specific strain of organism present before treatment; this represents a treatment failure. Most relapses occur < 2 weeks after completion of therapy. *Reinfection* is recurrent infection due to a different strain of bacteria following successful treatment of the initial infection, occurring > 3 weeks after the completion of therapy.

URINARY CALCULI

The incidence of urinary calculi is not altered by pregnancy. The incidence is 0.03–0.35% of pregnancies, and the incidence increases as gestational age advances. Stones cause obstruction, infection, pain, and hematuria. Recurrent hospitalization, preterm labor and delivery, and need for operative intervention are increased. The causes of urinary calculi are the same in pregnant and nonpregnant women: chronic UTI, hyperparathyroidism or other causes of hypercalciuria, gout (uric acid), and obstructive uropathy. Congenital or familial cystinuria and oxaluria are less common causes. Most stones are composed of calcium, usually calcium oxalate.

The physiologic hydroureter of pregnancy is more prominent on the right side; however, stones occur with equal frequency on either side. The physiologic hydroureter of pregnancy increase the likelihood that a pregnant patient will spontaneously pass her stone(s).

Clinical Findings

Patients may present with a variety of symptoms, including typical renal or ureteric colic, vague abdominal or back pain that may radiate into the groin, fever, nausea, and vomiting. The patient may have a history of recurrent UTI or hematuria. Fever, bacteriuria, and flank pain may suggest coexisting pyelonephritis from obstruction. The differential diagnosis includes other acute abdominal conditions unrelated to pregnancy (eg, appendicitis, biliary colic or tract disease, adnexal torsion) and conditions related to pregnancy (eg, abruption placentae, preterm labor, chorioamnionitis). When fever attributed to pyelonephritis persists beyond 48 hours of parenteral antibiotic treatment, then obstruction due to urolithiasis must be evaluated. Hematuria, ranging from microscopic to gross, is usually present, although it is not pathognomonic for urolithiasis. The index of suspicion should be high in the clinical situations described, in patients in whom urine culture is negative in the setting of suspected pyelonephritis, or in cases of persistent hematuria or recurrent UTI.

Clinical diagnosis is confirmed by ultrasound examination of the urinary tract. In selected cases, excretory urography includes a precontrast scout film and another image obtained 20 minutes after contrast injection. This examination exposes the fetus to 0.2 rad. The common indications for intravenous pyelography include microscopic hematuria and recurrent UTI. Sterile urine culture should be performed when pyelonephritis is suspected.

Treatment

Treatment includes hospital admission, adequate hydration, urine culture and Gram stain, appropriate antibiotic therapy, correction of electrolyte imbalances, and systemic analgesia (eg, opioids). Epidural analgesia may be considered for patients with severe pain. Most stones pass spontaneously. The patient should strain her urine so that a stone can be analyzed. Surgical intervention, such as ureteral stenting, transurethral cystoscopic stone extraction, nephrostomy drainage, or open surgery, can be performed by a urologist if indicated for unremitting pain, infection unresponsive to antibiotic therapy, or obstructive uropathy. Lithotripsy is contraindicated during pregnancy.

ACUTE RENAL FAILURE

Acute renal failure is defined as urine output < 400 mL in 24 hours. It occurs infrequently in pregnancy but carries a high mortality rate; therefore it must be prevented where possible and treated aggressively. Most cases result from acute hypovolemia associated with obstetric hemorrhage (placenta previa, placental abruption, or postpartum hemorrhage) or sepsis. Clinically, acute renal failure is a condition in which the kidneys are temporarily unable to perform their excretory and regulatory functions. Blood urea nitrogen and serum creatinine concentrations are increased. Without prompt intervention, the condition may result in abortion, low birthweight, premature labor, and stillbirth. Dialysis may be required.

Although hypotension preterm contractions may occur during dialysis, numerous successful pregnancy outcomes have been reported after dialysis during pregnancy. In these cases renal failure most often is the result of intrinsic renal disease.

Based on the cause, acute renal failure can be classified as prerenal, renal, or postrenal. In the prerenal type, acute renal failure occurs due to renal hypoperfusion secondary to maternal hypovolemia (eg, hemorrhage, dehydration, abruptio placentae, septicemia), circulating nephrotoxins (eg, aminoglycosides), mismatched blood transfusion, preeclampsia–eclampsia, disseminated intravascular coagulation (DIC), and hypoxemia (eg, chronic lung disease and heart failure). In the renal type, a variety of intrinsic renal diseases such as acute glomerulonephritis, acute pyelonephritis, and amyloidosis are responsible for acute renal failure. The postrenal type is caused by urinary obstruction from ureteric stone, retroperitoneal tumor, and other diseases. Bilateral ureteral obstruction due to polyhydramnios is rare.

The state of renal hypoperfusion is reversible within 24–36 hours with volume restoration and treatment of the precipitating factors. Acute tubular necrosis may develop following reduction of the outer cortical blood flow in the absence of such treatment. The most serious condition arising secondary to acute renal failure is acute cortical necrosis in damaged glomerular capillaries and small kidney vessels. Acute cortical necrosis is rare but carries a poor prognosis; partial recovery can be anticipated in patients with patchy lesions.

Clinical Findings

The clinical course has been divided into an oliguric phase, a diuretic phase, and a recovery phase. In the oliguric phase, urine output drops to < 30 mL/h, with accumulation of blood urea nitrogen and potassium. The patient becomes acidotic with the increase in hydrogen ion and loss of bicarbonate. In the diuretic phase, large volumes of dilute urine are passed, with loss of electrolytes due to absence of function of the renal tubules. As tubular function returns to normal in the recovery phase, the volume and composition of urine normalize. Clinical manifestations and complications include anorexia, nausea and vomiting, lethargy, cardiac arrhythmia (secondary to electrolyte disturbance), anemia, renal or extrarenal infection, thrombocytopenia, metabolic acidosis, and electrolyte imbalance (hyperkalemia, hyponatremia, hypermagnesemia, hyperphosphatemia, hypocalcemia).

Treatment

In obstetric practice, prevention of acute renal failure should be the aim, with appropriate volume replacement to maintain adequate urine output. Proper management of high-risk obstetric conditions (eg, preeclampsia–eclampsia, abruptio placentae, chorioamnionitis), ready blood availability, and avoidance of nephrotoxic antibiotics are important.

Specific treatments include the following.

EMERGENCY TREATMENT

Underlying causes of acute renal failure (eg, hemorrhagic shock) may require emergency treatment.

SURGICAL MEASURES

Surgical measures include determination of any obstructive uropathy or sepsis due to infected products of conception. Such problems should be treated appropriately.

ROUTINE MEASURES

Routine measures include achieving fluid and electrolyte balance. Fluid intake can be calculated from urinary output, loss of fluid from other sources (eg, diarrhea, vomiting), and insensible loss of approximately 500 mL/d (correcting for fever may be necessary). Intake and output must be recorded

carefully. The patient should be weighed daily and should maintain a constant weight or lose weight slowly (250 g/d assuming a room temperature of 22–23 °C [71–73 °F]). Hyperkalemia is a significant problem that can be controlled by giving glucose and insulin. The diet should be high in calories and carbohydrates, and low in protein and electrolytes. Parenteral feeding may be given in cases of nausea and vomiting. Prophylactic antibiotics should not be used, but infections can be treated with antibiotics without renal toxicity. Indwelling bladder catheters are to be avoided when possible.

DIALYSIS

Dialysis is indicated if serum potassium levels rise to 7 mEq/L or more, serum sodium levels are 130 mEq/L or less, the serum bicarbonate is 13 mEq/L or less, blood urea nitrogen levels are more than 120 mg/dL or there are daily increments of 30 mg/dL in patients with sepsis, and dialyzable poisons or toxins are present. Different criteria are applied for renal failure in the antepartum period with a continuing pregnancy. In these cases, dialysis is instituted earlier in the process in consideration of fetal well-being. Although specific criteria have not been firmly established, one commonly used figure is a blood urea nitrogen level 60 mg/dL.

GLOMERULONEPHRITIS

Acute glomerulonephritis during pregnancy is rare, with an estimated incidence of 1 in 40,000 pregnancies. The condition is associated with increased perinatal loss. The clinical course is variable during pregnancy and may be easily mistaken for preeclampsia. In some patients, the condition resolves early in pregnancy, with return to normal renal function. Microscopic hematuria with red blood cell casts is a common finding in acute glomerulonephritis. Treatment is similar to that of the nonpregnant patient and consists of controlling blood pressure, preventing congestive heart failure, administering fluids and electrolytes, and close follow-up.

The outcome of pregnancy with chronic glomerulonephritis depends on the degree of functional impairment of the kidneys, blood pressure levels prior to conception, and the exact histology of the glomerulonephritis. For patients with active glomerulonephritis, the principal risk for pregnancy is superimposed preeclampsia. Conditions associated with poor fetal outcome include preexisting hypertension, severe proteinuria during the first trimester, primary focal and segmental hyalinosis, and sclerosis. Successful pregnancy should be anticipated, although renal function is expected to decrease. The incidence of fetal intrauterine growth retardation, premature labor, abruptio placentae, and intrauterine fetal demise is increased. Routine prenatal care must include periodic renal function tests, control of blood pressure, ultrasonic evaluation of fetal growth, and biophysical monitoring of fetal well-being. Hypertension at the time of conception correlates with worsening maternal renal function during pregnancy. Early delivery is indicated after evaluation of pulmonary maturity as appropriate.

SOLITARY KIDNEY

A solitary kidney may be the result of developmental aberration or disease requiring removal of 1 kidney. A single kidney may be abnormally developed or it may be placed low, perhaps even within the true pelvis. A second small, virtually functionless kidney may not be discovered by the usual diagnostic tests. Anatomic and functional hypertrophy of the kidney usually occurs and is augmented by pregnancy. These patients should be evaluated preconceptually for the presence of infection. If renal function is normal, pregnancy is not contraindicated.

During pregnancy, infection in a solitary kidney must be treated aggressively. An increased rate of preeclampsia with a solitary kidney has been reported.

RENAL TRANSPLANTATION

Approximately 0.5% of transplanted women in the reproductive age range become pregnant. A number of large series document successful pregnancy outcomes after renal transplantation. Patients with adequate renal function prior to pregnancy will experience little if any deterioration in graft function during pregnancy. The likelihood of graft rejection during pregnancy remains the same as in nonpregnant graft recipients. For renal transplant patients considering pregnancy, a stable serum creatinine level < 1.4 mg/dL identifies a group more likely to experience an uncomplicated obstetric outcome (97% vs. 75% for patients with a higher serum creatinine level). The spontaneous abortion rate is not increased. In general, prenatal care visits should be made every 2 weeks up to 32 weeks and then weekly from 32 weeks until delivery. Laboratory examination, including complete blood count, electrolyte levels, creatinine clearance, timed protein excretion, and midstream urinalysis, should be obtained every 1–2 months. The risk of infection is considerably higher during pregnancy in renal transplant patients. Primary or reactivated herpesvirus or cytomegalovirus (CMV) infection may be seen. A higher rate of hepatitis B surface antigenemia is seen in dialysis patients as well.

Preterm delivery, both spontaneous and indicated, is common (45–60%). Intrauterine growth restriction and fetal abnormalities caused by immunosuppressive agents taken by the mother may occur. The route of delivery depends primarily on obstetric indications. A transplanted kidney in the false pelvis usually does not cause obstruction leading to dystocia. In patients with aseptic necrosis of the hip joints or other bony dystrophy secondary to long-standing disease, cesarean delivery may be required. Vaginal delivery should be the aim for patients with renal transplant.

PHYSIOLOGIC CHANGES

Many physiologic changes that occur during pregnancy can be noted in the integumentary system and may be confused with disease processes. For example, the impressive vascular changes during pregnancy lead to *erythema* early in gestation, particularly in the midpalmar and thenar areas. Although this sign could be diagnostic of hyperthyroidism, cirrhosis of the liver, or systemic lupus erythematosus, other signs of disease are not present. Palmar erythema usually vanishes postpartum.

Venous congestion and vascular permeability during pregnancy can lead to varicosities and labial edema. Vascular proliferations such as *capillary hemangiomas* are most commonly seen around the gums, tongue, upper lip, and eyelids. Usually patients have a history of preexisting lesions, which in most cases do not recede completely after pregnancy.

Striae are normal findings during pregnancy, but they also may be observed with adrenocortical hyperactivity (eg, Cushing's syndrome, exogenous corticosteroid administration). Increased activity of the adrenal gland during pregnancy may increase their occurrence. Most physicians believe heredity is the most common predictor of the development of these pinkish or purplish lines on the abdomen, buttocks, and breasts. After pregnancy, striae usually become silvery-white and sunken, but they rarely disappear. Many remedies have been proposed (vitamin E oil, lubricants, lotions), but none are effective.

Hyperpigmentation is common in pregnancy and occurs most frequently in the localized areas of hyperpigmentation (eg, nipples, areolae, and axillas). Hyperpigmentation is related to increased levels of melanocyte-stimulating hormone, estrogen, and progesterone. *Melasma gravidarum* ("mask of pregnancy") has a similar cause but usually develops on the forehead and across the cheeks and nose. It tends to recur and worsen with successive pregnancies and oral contraceptive use. There is no effective treatment during pregnancy, although topical application of hydroquinone 2% after delivery may assist in lightening areas of hyperpigmentation. Pigmentation of preexisting nevi or freckles may increase during pregnancy but usually regresses afterward.

Changes in the distribution and amount of *hair* are common during pregnancy. Increased hair growth in facial areas and around the breasts is common, particularly during the second and third trimesters. Importantly, there are no signs of virilization, and hirsutism regresses slightly or remains unchanged postpartum. Postpartum loss of hair is fairly common. During pregnancy, the number of hair follicles in the resting phase (telogen) is decreased by about half and then nearly doubles in the first few weeks postpartum. This increased hair loss usually stops in 2–6 months as the hair follicles enter the growing phase (anagen). Thus, no therapy other than reassurance is required.

POLYMORPHIC ERUPTION OF PREGNANCY (PRURITIC URTICARIAL PAPULES AND PLAQUES OF PREGNANCY)

Polymorphic eruption of pregnancy may be the most common of all the pruritic skin conditions that occur during pregnancy. The lesions usually appear during the third trimester and disappear completely within 2 weeks after delivery.

Clinical Findings

The pruritic papules are generally red, unexcoriated, and found principally on the abdomen. In most lesions a marked halo surrounds the small papules and plaques. Focal lesions are uncommon and rarely appear on the face or distal extremities. The lesions may be indistinguishable from those of herpes gestationis.

Diagnosis

Immunofluorescence reveals no immunoglobulin (Ig) or complement.

Treatment

Symptomatic treatment with antihistamines, topical steroids, and antipruritic medications usually is helpful. Occasionally, oral corticosteroid therapy is necessary.

Complications & Prognosis

This disorder appears to have no ill effect on the mother or the fetus and is self-limiting. It does not tend to recur.

HERPES GESTATIONIS (PEMPHIGOID GESTATIONIS)

Herpes gestationis has an incidence of 1 in 7000 gestations and usually appears in the second and third trimesters. Despite its name, the herpes virus is not the causative agent, and the etiology is unknown. Elevated hormone levels during pregnancy are suspected to be causative because progestins can induce exacerbations.

Clinical Findings

Systemic signs of herpes gestationis may be severe and include malaise, fever, and chills. The lesion appears as erythematous plaques with vesicles that soon form bullae in the periphery of the lesion. The typical blistering eruption has a herpetiform appearance, but the vesicles are not clustered and are more peripheral than herpes. Lesions usually begin on the trunk and spread to the entire body, including the distal extremities. Lesions on mucous membranes are uncommon.

Diagnosis

Most patients with herpes gestationis have circulating IgG that will fix C3 complement.

Immunofluorescence testing of bullous lesions aids in establishing the diagnosis. Pemphigus vulgaris can be differentiated by histologic examination. The pustules, fever, and hypocalcemia of impetigo herpetiformis are not present in herpes gestationis. Dermatitis herpetiformis is excluded because,

although it is pruritic, the clusters of vesicles do not form bullae, and no plaques are present. In herpes gestationis a crust forms, and a hyperpigmented area but little or no scarring occurs after the lesion heals.

Treatment

Oral corticosteroids are the treatment of choice.

Complications & Prognosis

Herpes gestationis is characterized by exacerbations and remissions during pregnancy. Although significant exacerbations can occur postpartum, the condition usually abates by the sixth week postpartum. Recurrence is frequent in subsequent pregnancies, and the disorder may appear earlier in pregnancy than the other disorders discussed. Its effect on maternal and fetal morbidity is not clear because the condition is so rare, but an increase in stillbirths, premature births, and small-for-gestational-age infants has been reported. Five percent of newborns have transient blisters.

IMPETIGO HERPETIFORMIS

Impetigo herpetiformis (also called *pustular psoriasis, von Zumbusch's type*) is a pustular eruption on an erythematous base with total body distribution. It is rare and probably represents an acute form of psoriasis that occurs during pregnancy. Pregnancy may precipitate this acute manifestation, but the disease is not restricted to gestation as it has been documented in nonpregnant women and in males. Most patients with this disease also have chronic psoriasis or a family history of psoriasis.

Clinical Findings

Generalized erythematous patches covered with sterile pustules allow a presumptive diagnosis. Fever, nausea, diarrhea, and malaise often accompany this symptom complex.

Diagnosis

Spongiform pustules noted in the epidermis on biopsy distinguish this disorder from pustular dermatosis or infection. The pustules are usually sterile, but they may become secondarily infected. In addition, pruritus is not a prominent symptom. The disorder is often associated with hypocalcemia and ensuing tetany, seizures, and delirium.

Treatment

Treatment is usually limited to supportive measures, occasional corticosteroids, and appropriate antibiotics for superimposed infection. Methotrexate, vitamin A derivatives, and tetracycline should not be used during pregnancy.

Complications & Prognosis

Data on the fetal effects of this disorder are inadequate. Increased maternal and perinatal mortality have been reported, but these cases may have been related to secondary infection and sepsis.

PEPTIC ULCER DISEASE

Pregnancy usually ameliorates extension of ulceration, and an initial attack rarely occurs during pregnancy. The salutary effect of pregnancy may be related to progesterone's ability to inhibit motility, because acid secretion remains unchanged. The incidence of peptic ulcer disease in pregnancy is rare (1 in 4000 deliveries); it seems to be more common with associated preeclampsia. If activation of previously dormant ulcer disease does occur, it usually is in the puerperium.

Clinical Findings

The classic signs of gastric or duodenal ulcer are related to a burning epigastric pain that is relieved by meals or antacids. Peptic ulcer disease must be differentiated from reflex esophagitis or simple heartburn, which commonly occurs during pregnancy. Patients with a gastric or duodenal ulcer most often report discomfort rather than pain and describe the feeling as "acid" or burning or indigestion.

Diagnosis

The symptoms of peptic ulcer disease are relieved by food but return approximately 1–2 hours later, paralleling gastric acidity. Likewise, antacids may relieve the pain and help confirm the diagnosis. Most commonly, the diagnosis is confirmed by endoscopic visualization of the ulcer crater in the stomach or duodenum. Although gastric carcinoma is rare, many physicians recommend biopsy during the endoscopic procedure. Upper gastrointestinal x-ray films with barium studies usually are avoided because of radiation exposure and because endoscopy is a more direct diagnostic method.

Helicobacter pylori is an organism associated with gastritis, ulcers, and possibly gastric adenocarcinoma and lymphoma. Diagnosis is based on biopsy histology, culture, or urease test. Noninvasive testing includes the C-urea breath test, stool antigen, or serology.

Treatment

Documented peptic ulcer disorders are treated symptomatically during pregnancy by avoiding symptom-provoking foods and using antacids and sucralfate. Supportive advice can be given regarding cessation of smoking, bed rest, and avoidance of stress. For persistent symptoms, an H₂ antagonist such as cimetidine or ranitidine can be given. As a last resort, a proton pump inhibitor such as lansoprazole can be added to the drug regimen. Eradication of *H. pylori* is 90% successful with an antibiotic such as tetracycline or clarithromycin, a bismuth compound, and a proton pump inhibitor.

Complications & Prognosis

In general, the fetus is not adversely affected by peptic ulcer disease unless maternal compromise, such as perforated ulcer with bleeding, occurs. Particular vigilance in the postpartum period is necessary because ulcers become active again during this time and can become penetrating.

INFLAMMATORY BOWEL DISEASE

Inflammatory bowel disease encompasses regional enteritis (Crohn's disease), ulcerative colitis, and granulomatous colitis. In general, inflammatory bowel disease has no effect on fertility unless colonic disease has resulted in pelvic abscesses. Overall, studies show a reduced relapse rate during pregnancy compared to preconception. Relapse shows a predilection for the first trimester and postpartum. Subsequent pregnancies will not necessarily have the same course.

Clinical Findings

In these conditions, cramping, lower abdominal pain, and diarrhea are the main complaints. Weight loss and anorexia, even during pregnancy, may occur. Electrolyte imbalance with severe diarrhea also may occur.

Diagnosis

Infectious disorders that would cause diarrhea and abdominal pain must be ruled out. A personal or family history of inflammatory bowel disease is helpful in confirming the diagnosis. If the lower intestine is involved, proctoscopy or colonoscopy may be helpful. However, in some cases a small bowel series and barium enema are needed to make the diagnosis. Malignancy and infectious disease, such as tuberculosis of the small intestine, also must be considered because they have appearances similar to inflammatory bowel disease on x-ray film. Finally, a response to trials of medication and a change in diet may be helpful in confirming the diagnosis.

Treatment

Treatment of inflammatory bowel disease usually involves dietary management and use of medications. Sulfasalazine inhibits prostaglandin synthesis, which is thought to be important in bowel disease. Although sulfasalazine and corticosteroids cross the placenta, their use during pregnancy may be preferable to acute exacerbations of disease. If sulfasalazine is used, maternal folic acid should be given daily because it inhibits brush border enzymes. Although sulfasalazine is a sulfa drug, no increased risk of neonatal jaundice has been noted. Azathioprine has not been associated with congenital malformations. There is an associated increase in fetal growth restriction and prematurity. Mercaptopurine has shown no fetal toxicity after first-trimester exposure. Methotrexate should be avoided in pregnancy. Short-term use of antibiotics such as metronidazole is allowed. Other immunosuppressant drugs have not been shown to be helpful and should not be used during pregnancy.

Complications & Prognosis

Complications during pregnancy are similar to those in the nonpregnant state: abdominal pain, cramping, and rectal bleeding. The risk of abortion and stillbirth is dependent on disease activity. Pregnancy is not contraindicated with inflammatory bowel disease, but when possible the disorder should be controlled by surgery or medication prior to conception. Pregnancy does not exert an adverse effect on inflammatory bowel disease. In most patients, pregnancy and delivery proceed smoothly. Patients with ileostomies should be followed for complications, most importantly intestinal obstruction (8%). If a patient has undergone a bowel resection, total parenteral nutrition may be required during the pregnancy. Women with active perianal disease should be delivered via cesarean section.

CHOLECYSTITIS

Cholecystitis occurs rarely during pregnancy (0.3%) because the gallbladder and biliary duct smooth muscle are relaxed by progesterone. Acute inflammation during pregnancy is treated with intravenous fluids and limitations of oral intake. If acute cholecystitis does not resolve or if pancreatitis develops, cholecystectomy should be considered. If this operation can be performed in the second trimester, the fetal loss rate probably is not increased. The laparoscopic approach in pregnancy is widely accepted. After 20 weeks' gestation, it should be performed with special care to avoid injury to the uterus. In the third trimester, surgical intervention can cause preterm delivery. Later in gestation, prolonged IV hyperalimentation can be an option to delay surgery until postpartum.

INTRAHEPATIC CHOLESTASIS OF PREGNANCY

Intrahepatic cholestasis of pregnancy is a condition characterized by accumulation of bile acids in the liver with subsequent accumulation in the plasma, causing pruritus and jaundice. It is similar to the cholestasis that occasionally occurs during combined oral contraceptive therapy. Estrogens are considered to play a role in its etiology, probably by slowing the enzymes involved in bile transport. Some cases of intrahepatic cholestasis of pregnancy result from specific mutations in bile transport genes, although common mutations or polymorphisms have not been identified in most cases. The cardinal clinical finding is total body itching involving the palms and soles. The main liver conditions that must be considered in the differential diagnosis are hepatitis and biliary tract disease, in addition to acute fatty liver of pregnancy (AFLP) and the haemolysis, elevated liver enzymes, low platelet count (HELLP) syndrome. Laboratory values show increased levels of alkaline phosphatase, bilirubin, and serum bile acids (chenodeoxycholic acid, deoxycholic acid, cholic acid). Aspartate transaminase (AST) and alanine transaminase (ALT) levels may be mildly elevated. Patients may be symptomatic weeks before the diagnosis laboratory abnormalities are noted.

Symptomatic treatment of pruritus with antihistamines such as diphenhydramine is useful. Ursodeoxycholic acid (10–15 mg/kg/d in 2 divided doses) has been shown to inhibit absorption of toxic bile acids and increase their biliary excretion. In doing so, the medication normalizes bile acids, improves liver function tests, and alleviates pruritus. Oral steroids also have been used to relieve symptoms. Cholestyramine is no longer routinely used because of poor compliance. Symptoms resolve postpartum.

Although controversial, it now is accepted that intrahepatic cholestasis of pregnancy is associated with fetal death, spontaneous preterm birth, and postpartum hemorrhage. The etiology is unclear, but some refer to the fetal toxicity of bile acids as a causative factor. Antenatal testing with a modified biophysical profile twice per week starting at the time of diagnosis is suggested. Because the modified biophysical profile reportedly is less effective in predicting fetal compromise in intrahepatic cholestasis of pregnancy, different strategies have been proposed: amniocentesis at 35–36 weeks, delivery at 37–38 weeks, and delivery at 37–38 weeks only if bile acid concentration is > 40 nmol/L. There is no agreement on whether to induce the pregnancy at 37–38 weeks or to await spontaneous labor.

ACUTE FATTY LIVER OF PREGNANCY

Acute fatty liver of pregnancy is a rare complication (1 in 5000 to 1 in 13,000) that occurs in the third trimester. Early recognition and termination of the pregnancy (delivery) and extensive supportive therapy have reduced the mortality rate to approximately 5–10%. Recurrence in subsequent pregnancies is rare and appears limited to women with mutations in the fatty acid transport and metabolism pathway. A number of studies have shown an association between AFLP and fetal recessive inheritance of long-chain 3-hydroxyacyl-CoA dehydrogenase (LCHAD) deficiency. In all but one reported case, the mother has been a carrier of LCHAD deficiency. AFLP shares clinical and histologic features of the broad family of disorders of fatty acid transport and mitochondrial oxidation, and several disorders of fatty acid metabolism are associated with AFLP. Nevertheless, the specific molecular basis of most cases of AFLP remains unknown.

Symptoms and signs include nausea and vomiting, malaise, epigastric pain, and jaundice. AFLP should be suspected in any patient who presents with new-onset nausea and malaise in the third trimester until the results of liver and chemistry panels are available. Laboratory values show elevated AST and ALT levels (up to 7 times normal) and may show markedly elevated bilirubin level and prolonged prothrombin time. Glucose is low in 30% of cases; levels of platelets and fibrinogen are notably decreased. Almost all women have elevated liver enzyme levels at the time of diagnosis; an elevated serum creatinine level (0.9 mg/dL in pregnancy) is universally present. Liver biopsy, which is rarely needed for diagnosis, reveals microvesicular hepatic steatosis and mitochondrial disruption on electron microscopy. Complications such as acute renal failure, DIC, encephalopathy, and sepsis can be severe. The principles of management are supportive care and prompt delivery. Glucose, blood products, broad-spectrum antibiotic coverage, and pulmonary support are critical. Importantly, the total bilirubin level may continue to rise for up to 10 days after delivery. This process is part of the natural history of recovering AFLP and should not be taken as an indication for liver transplant, which is not required in AFLP.

HELLP SYNDROME

HELLP syndrome is a disorder that in some respects mimics AFLP. This liver derangement is a variant of severe preeclampsia or eclampsia. The disorder occurs in the last trimester of pregnancy and is characterized by nausea and vomiting and right upper quadrant pain. Unlike AFLP, liver function is generally preserved as reflected by the normal prothrombin time. Stillbirth occurs frequently (10–15%) if delivery is not prompt; neonatal loss is high (20–25%), usually because of prematurity (see Chapter 19). Corticosteroids may hasten recovery in HELLP syndrome.

HELLP syndrome occasionally persists beyond 2–3 days postpartum, in which case it takes on the characteristics of other microangiopathic hemolytic disorders, such as thrombotic thrombocytopenic purpura or hemolytic-uremic syndrome. Plasmapheresis may be required with persistent HELLP syndrome.

VIRAL HEPATITIS

Viral hepatitis complicates 0.2% of all pregnancies in the United States. Hepatitis may be caused by numerous viruses, drugs, or toxic chemicals; the clinical manifestations of all forms are similar. The development of specific serologic markers has improved the accuracy of the diagnosis. The most common viral agents causing hepatitis in pregnancy are hepatitis A virus, hepatitis B virus, hepatitis C (formerly termed non-A, non-B hepatitis virus), hepatitis E, hepatitis G, and Epstein-Barr virus. Hepatitis D (Delta) has also received increasing attention as a cause of hepatitis.

Hepatitis A

Hepatitis A may occur sporadically or in epidemics. A generalized viremia occurs with the infection that is predominantly hepatic. The primary mode of transmission is the fecal/oral route. Excretion of the virus in stool normally begins approximately 2 weeks prior to the onset of clinical symptoms and is complete within 3 weeks following onset of clinical symptoms. No known carrier state exists for the virus. Both blood and stool are infectious during the 2- to 6-week incubation period. Perinatal transmission does not occur.

Hepatitis B

Hepatitis B usually is transmitted by inoculation of infected blood or blood products, or sexual intercourse. The virus is contained in most body secretions. Infection by parenteral and sexual contact has been well documented. Groups at risk for hepatitis B infection are injection drug users; male homosexuals (or men who have sex with men [MSM]); medical, hemodialysis, blood bank, and medical laboratory personnel; spouses of hepatitis carriers; prostitutes and others with multiple sexual partners; and Southeast Asian emigrants. Approximately 5–10% of people infected with hepatitis B virus become chronic carriers of the virus. The incubation period of hepatitis B is 6 weeks to 6 months. The clinical features of hepatitis A and B are similar, although hepatitis B is more insidious. Fulminant hepatitis is very rare with hepatitis A but occurs in approximately 1% of patients infected with hepatitis B.

The hepatitis B surface antigen (HBsAg) of the largest of several pleomorphic viral structures is the marker usually measured in blood. The presence of HBsAg is the first manifestation of viral infection; it usually appears before clinical evidence of the disease and lasts throughout the infection. Persistence of HBsAg after the acute phase of hepatitis usually is associated with clinical and laboratory evidence of chronic hepatitis. The hepatitis B core antibody (HBcAb) is produced against the core of the largest viral particle. HBcAb occurs with acute hepatitis B infection at the onset of clinical illness. Hepatitis B e antigen (HBeAg) is a soluble, nonparticulate antigen that is found only when HBsAg is present. Pregnant women who are HBeAg-positive in the third trimester frequently transmit this infection to the offspring (80–90%) in the absence of immunoprophylaxis, whereas those who are negative rarely infect their offspring.

Hepatitis C

Up to 85% of infected individuals become chronic carriers. The incubation period usually is 7–8 weeks but may vary from 3–21 weeks. The course of infection is similar to that of hepatitis B. Hepatitis C antibody is present in approximately 90% of patients. However, the antibody may not be detectable for weeks after infection. Polymerase chain reaction (PCR) for hepatitis C RNA then becomes useful. Vertical transmission occurs in 5–8% of infected pregnancies and is increased with concomitant HIV infection. Risk of vertical transmission is increased with higher hepatitis C viral loads. Although most studies have not demonstrated a decreased risk of vertical transmission with cesarean delivery, some studies suggest cesarean delivery may be protective.

Hepatitis D

Hepatitis D virus is an RNA virus that is smaller than all other known RNA viruses. The agent can cause infection only when HBsAg positivity exists. Hepatitis D is isolated in up to 50% of cases of fulminant hepatitis B infection. Hepatitis D antigen (HDAg) and hepatitis D antibody (HDAb) are serologic markers for the disease.

Hepatitis E

Hepatitis E is transmitted via the oral/fecal route. Hepatitis E is rare in the United States but is endemic in several developing countries. The disease is self-limited and does not result in a chronic carrier state. Pregnant patients who are acutely infected have a 15% risk of fulminant liver failure with a 5% mortality.

rate; the rate is higher in resource-poor settings.

Hepatitis G

Hepatitis G is more likely to be found in people infected with hepatitis B or C or with a history of injection drug use. There is no chronic carrier state. Vertical transmission has been noted.

Clinical Findings

The clinical picture of hepatitis is highly variable. Most patients have asymptomatic infection, but a few may present with fulminating disease and die within a few days. Frequent symptoms include general malaise, myalgia, fatigue, anorexia, nausea and vomiting, right upper quadrant pain, and low-grade fever. Mild hepatomegaly and/or splenomegaly occur in 5–10% of affected patients. The white blood cell count is depressed, and mild proteinuria and bilirubinuria occur early in the course of the disease. The levels of AST, ALT, bilirubin, and alkaline phosphatase usually are elevated. Prothrombin and partial thromboplastin times may be prolonged with severe liver involvement.

Diagnosis

The diagnosis is made using serologic markers—anti-HA IgM, HBsAg, HC PCR, anti-HBc IgM, HD PCR, anti-HE IgM, and anti-HG IgM. Liver biopsy, which should be avoided during pregnancy, shows extensive hepatocellular injury and inflammatory infiltrate. The differential diagnosis of viral hepatitis should include viruses A, B, C, and D; Epstein-Barr virus; CMV infection; cholestasis; preeclampsia; AFLP; toxoplasmosis, other agents, rubella, cytomegalovirus, and herpes simplex (TORCH) infections; secondary syphilis; autoimmune; and toxic or drug-induced hepatitis. Additionally, intrahepatic or extrahepatic bile duct obstruction should be included.

Treatment

Bed rest should be instituted during the acute phase of illness. If nausea, vomiting, or anorexia is prominent, intravenous hydration and general supportive measures are instituted. All hepatotoxic agents should be avoided. Antepartum fetal assessment should be instituted in the third trimester because of the increased risks for premature delivery and stillbirth. Immunoglobulin prophylaxis should be given to pregnant women within 2 weeks of exposure to hepatitis A. Two hepatitis A vaccines using inactivated virus are available and can be used during pregnancy. Hepatitis B Ig can be given to patients parenterally or sexually exposed to blood or secretions from hepatitis B–infected individuals. Hepatitis B vaccine also should be administered to an HBsAg-negative patient. Hepatitis B Ig 0.5 mL intramuscularly and hepatitis B vaccine with a repeat dose at 1 and 6 months should be administered to neonates born of HBsAg-positive mothers, to decrease the risk of vertical transmission. Passive and active immunization of the newborn is 85–95% effective in preventing perinatal transmission of hepatitis B virus. Breastfeeding is not contraindicated with hepatitis B as long as the infant has been immunized.

Complications & Prognosis

The acute illness usually resolves rapidly in 2–3 weeks, with complete recovery usually occurring within 8 weeks. Chronic persistent or chronic active hepatitis develops in 10% of hepatitis B and C cases. Additionally, 1–3% of patients develop acute fulminant hepatitis.

The maternal course of viral hepatitis is generally unaltered by pregnancy, except for hepatitis E in which the pregnant woman may fare worse; prematurity may be increased. In general, infertility results in patients with severe liver disease. Chronic active hepatitis does not mandate therapeutic abortion, but fetal loss is increased. All pregnant women should routinely be tested for HBsAg during an early prenatal visit in each pregnancy. Women with cirrhosis of the liver from other causes have an outcome related to the extent of maternal disease. Perinatal loss rates usually are high with a poor maternal prognosis,

particularly with poor liver function or esophageal varices. Pregnancy in women with liver transplants has been reported and, in general, has an uncomplicated prenatal and delivery course. Treatment with immunosuppressants and corticosteroids is generally well tolerated in pregnancy. Interferon and ribavirin therapy improves the prognosis for chronic active hepatitis (C in particular), but both drugs are relatively contraindicated during pregnancy.

HYPEREMESIS GRAVIDARUM

Hyperemesis gravidarum is persistent, otherwise unexplained vomiting in early pregnancy associated with ketonuria weight loss. It affects 1–2% of pregnant women and is the second most common cause of antenatal hospitalization in the United States. Elevated levels of transaminases, bilirubin, amylase, lipase, and various electrolytes are seen in 15–40% of patients. Biochemical evidence of hyperthyroidism due to the effect of human chorionic gonadotropin on the thyroid-stimulating hormone receptor is seen in 60–70% of patients. The differential diagnosis includes a wide variety of conditions capable of causing persistent nausea and vomiting and must be considered carefully in each patient.

The etiology is not understood. The spectrum of maternal susceptibility to an unknown emetogenic stimulus from the placenta accounts for the variability in the condition and the difficulty in identifying a single etiologic factor. The recurrence rate is approximately 20% in prospective studies but this value probably is an underestimation because the sickest women often limit family size.

Treatment of hyperemesis gravidarum begins with supportive measures including hydration and vitamin supplementation, in particular vitamin B₁, which is needed to prevent Wernicke's encephalopathy. Nonpharmacologic measures, such as vitamin B₆, ginger, and acupressure, appear to be effective with lesser degrees of vomiting but their role in hyperemesis gravidarum is uncertain. Antihistamines as a class have some efficacy and the best record for fetal safety. Other conventional antiemetics can be used in an algorithm that balances safety and efficacy (Fig 23–1).

Figure 23–1.

Nausea or Vomiting Interfering with Daily Routine

Vitamin B₆ 10–30 mg TID–QID PO

Continued symptoms after 48 hours
Add doxylamine 12.5 mg TID–QID PO

Continued symptoms after 48 hours
Substitute doxylamine with other antihistamine:

Promethazine 12.5–25 mg q4h PO or PR

Dimenhydrinate 50–100 mg q4–6h PO or PR

Consider alternative therapies at any point in this sequence:

Acupuncture or acustimulation,
ginger tablets 250 mg QID

Persistent Symptoms, with or without Dehydration

Prochlorperazine 25 mg q12h PR

OR

Metoclopramide 5–10 mg q8h PO or IV

OR

Trimethobenzamide 200 mg q6–8h PR

Dehydration or Weight Loss

Thiamine 100 mg IV daily for 3 days

Continue thiamine in MVI daily

Ondansetron 8 mg q8–12h IV or PO

OR

Methylprednisolone up to 16 mg TID for 3 days

Taper over 2 weeks to lowest effective dose

Total duration of therapy 6 weeks

Unable to Maintain Weight

Institute total enteral or parenteral nutrition

Nausea and vomiting of pregnancy/hyperemesis gravidarum treatment sequence at the University of Southern California. PO = by mouth; PR = by rectum.

Fetal status is generally not adversely affected by vomiting until persistent maternal weight loss occurs. In this setting, the rate of intrauterine growth retardation (IUGR) increases and fetal death appears to increase. Long-term effects of hyperemesis gravidarum on offspring are unknown. If weight loss persists despite therapy, nutritional supplementation by enteral tube feeding or parenteral feeding is necessary.

Current OB/GYN > Chapter 24. Thyroid and Other Endocrine Disorders during Pregnancy >

THYROID DISORDERS

Thyroid diseases are among the most common endocrine disorders encountered during pregnancy. They are challenging because of the potential complications of the disease itself and of the side effects of the medications used to treat mother and fetus.

THYROID FUNCTION DURING NORMAL PREGNANCY: INTRODUCTION

Both total thyroxine (T_4) and triiodothyronine (T_3) levels increase because the level of their carrier, thyroxine-binding globulin (TBG), becomes elevated. Estrogen causes increased TBG synthesis and decreased TBG clearance. The concentrations of free thyroxine (FT_4) and free triiodothyronine (FT_3) fluctuate but are within the normal range. The thyrotropin-stimulating hormone (TSH) level decreases and may even be low in some patients: 13% in the first trimester, 4.5% in the second trimester, and 1.2% in the third trimester. The TSH level is lowest and FT_4 level highest when the human chorionic gonadotropin (hCG) level peaks. Serum thyroglobulin level increases, more toward the end of pregnancy, because of increased thyroid mass. The larger thyroid size is rarely detectable by physical examination, but it has been documented by serial ultrasound measurements. The average increase is 18% but may be much greater in areas of iodine deficiency. Overall, the demand for T_4 increases by an estimated 1–3% above daily nonpregnant needs. The increased demand starts very early, reaching a plateau at 16–20 weeks.

The fetal hypothalamic-pituitary-thyroid axis becomes functional toward the end of the first trimester. Until then, the fetus is dependent on local monodeiodination of transferred maternal T_4 to T_3 . The small but effective transfer of T_4 from mother to fetus seems to be important for fetal growth, particularly early brain development. TSH does not cross the placenta. Thyrotropin-releasing hormone (TRH) crosses the placenta, but it does not have a known effect on fetal thyroid function. Iodine also crosses the placenta, and the fetal thyroid starts concentrating it by weeks 10–12. Excess iodine causes fetal goiter and hypothyroidism. At birth, dramatic changes occur; in the full-term neonate, the thyroid hormone profile reaches normal values after a few hours. Normal thyroid hormones levels in the newborn are crucial for subsequent brain maturation and intellectual development.

HYPERTHYROIDISM

The reported incidence of hyperthyroidism is 0.2–0.9%. Hyperthyroidism rarely starts during pregnancy; in the majority of patients it antedates pregnancy. In most cases (> 85%) the etiology is Graves' disease. Other causes include toxic nodular goiters, iatrogenic (excess exogenous thyroid), iodine induced, subacute thyroiditis, hyperemesis gravidarum, and hydatidiform mole or choriocarcinoma.

Potential complications of hyperthyroidism in the mother include spontaneous abortion, pregnancy-induced hypertension, preterm delivery, anemia, higher susceptibility to infections, placental abruption, and, in severe, untreated cases, cardiac arrhythmias, congestive heart failure, and thyroid storm. In the fetus, possible complications include fetal and neonatal hyperthyroidism, intrauterine growth restriction (IUGR), stillbirth, prematurity, and morbidity related to antithyroid medications. Most maternal and

neonatal complications are seen in cases of uncontrolled or untreated hyperthyroidism.

Graves' disease is caused by thyroid-stimulating antibody (TSAb) belonging to the immunoglobulin (Ig)G class, which binds with high affinity to the TSH receptor. TSAb may cross the placenta, bind to fetal TSH receptors, and cause fetal or neonatal hyperthyroidism. However, the placental acts as a partial barrier, so usually only those with high titers are likely to be affected.

The diagnosis may not be easy, particularly in mild cases, because normal pregnant women may experience symptoms resembling thyrotoxicosis, such as heat intolerance, warm and moist skin, tachycardia, and a systolic flow murmur on cardiac auscultation. More reliable findings include a goiter, a resting pulse > 100 bpm, onycholysis, eye involvement, and weight loss or failure to gain despite a good appetite. The thyroid enlargement usually is diffuse with a firm consistency. A bruit may be audible over the thyroid but disappears after effective treatment. The eyes (Grave's ophthalmopathy) may be affected in up to half of patients, but pretibial myxedema is found in only 6–10% of cases. Hand tremor, proximal muscle weakness, hyperkinesia, and a hyperdynamic cardiovascular system may be present.

Laboratory tests will confirm elevated T_4 , FT_4 , T_3 , and FT_3 levels and a suppressed or undetectable TSH level. TSAb titers will be elevated in a significant number of patients.

Treatment during pregnancy almost always consists of antithyroid medications. Surgery is performed in exceptional situations, such as allergic reactions to all drugs available or lack of response to very large doses ("drug resistance"), which in most cases has been the result of noncompliance. The goals of treatment are to rapidly achieve and maintain euthyroidism with the minimum but effective amount of medication, provide symptomatic relief, and keep FT_4 levels in the upper third of normal. The medications available are propylthiouracil (PTU) and methimazole. Some physicians prefer PTU, but reports of large number of patients indicate that the two drugs are equally effective and have similar side effects. PTU is shorter acting, meaning more pills are required more often; therefore, methimazole may be preferable when compliance is a problem. The initial methimazole dose is 20–40 mg/d and the initial PTU dose is 200–400 mg/d. The dose is gradually reduced as improvement occurs. Most women can be effectively treated on an outpatient basis; however, hospitalization may be considered in severe, uncontrolled cases in the third trimester because of increased risk for complications. Women who have remained euthyroid while taking small amounts of PTU (≤ 100 mg/d) or methimazole (≤ 10 mg/d) for 4 weeks or longer can stop taking the medication altogether by 32–34 weeks' gestation under close surveillance. The purpose is to minimize the risk of fetal/neonatal hypothyroidism, which is otherwise uncommon with PTU doses ≤ 200 mg/d or methimazole ≤ 20 mg/d. The therapy is resumed if symptoms recur. Women with large goiters, long-standing hyperthyroidism, or significant eye involvement should remain on treatment throughout pregnancy. Other potential side effects of antithyroid medications are pruritus, skin rash, urticaria, fever, arthralgias, cholestatic jaundice, lupuslike syndrome, and migratory polyarthritis. Leukopenia may be a medication effect but is also seen in untreated Graves' disease; therefore, a white blood cell (WBC) count should be obtained before treatment is started. Agranulocytosis is the most severe complication, but fortunately it is uncommon.

β Blockers (propranolol 20–40 mg every 6–8 hours) can be used for symptomatic relief in severe cases but only for short periods (few weeks) and before 34–36 weeks' gestation.

Tests of fetal well-being are recommended for poorly controlled cases and for patients with high TSAb titers, even if they are euthyroid. Serial ultrasounds are useful for dating and fetal growth evaluation.

Breastfeeding is allowed if the total daily dose of PTU is ≤ 150 mg or methimazole ≤ 10 mg. The medication should be given immediately after each feeding and the infant monitored periodically.

Fetal and neonatal thyrotoxicosis are rare because placental transfer of IgG is limited. Usually only those

with high titers are at risk. Fetal tachycardia and IUGR are the most common signs. A fetal goiter has occasionally been detected by ultrasound. High levels of fetal thyroid hormone detected by cordocentesis have been confirmed in a few cases. Treatment consists of administering to the mother antithyroid medication, which effectively crosses the placenta. If untreated, the mortality rate may reach 50%. The clinical manifestations of neonatal hyperthyroidism may appear at the time of birth or may be delayed several weeks if the mother was taking antithyroid medication until delivery. The disease will subside after several weeks or months when the maternal T_{SA}b titer disappears, but infants require treatment in the meantime because, if untreated, the mortality rate may reach 30%.

TRANSIENT HYPERTHYROIDISM OF HYPEREMESIS GRAVIDARUM

Biochemical hyperthyroidism is seen in most women (66%) with this condition. Women in early pregnancy with weight loss, tachycardia, vomiting, and laboratory evidence of hyperthyroidism may be difficult to differentiate from early, true thyrotoxicosis. Women with transient hyperthyroidism of hyperemesis gravidarum have no previous history of thyroid disease, no palpable goiter, and, except for tachycardia, no other symptoms or signs of hyperthyroidism. Test results for thyroid antibodies are negative. TSH level may be suppressed and T₄ and T₃ levels elevated, but the T₃ level is lower than in true hyperthyroidism. The degree of thyroid function abnormalities correlates with the severity of vomiting. The time to resolution is widely variable (1–10 weeks). Treatment is symptomatic, and antithyroid medication is not recommended. The most likely etiology is thyroid stimulation by hCG (or perhaps certain hCG subfractions).

HYPOTHYROIDISM

Hypothyroidism was considered rare because of menstrual disturbances and frequent anovulatory cycles in hypothyroid women but recently has been reported to be much more common. Overt hypothyroidism (elevated TSH, low T₄) has been reported in 1 in 1000 to 1 in 1600 deliveries and subclinical hypothyroidism (elevated TSH, normal T₄) in 0.19–2.5% of pregnancies.

The most common cause of hypothyroidism is autoimmune thyroid disease, with the goitrous form more frequent than the atrophic form with nonpalpable thyroid. Most other cases are secondary to previous treatment with radioactive iodine or thyroidectomy. Less common causes are transient hypothyroidism in silent (painless) and subacute thyroiditis, drug induced, high-dose external neck radiation, congenital hypothyroidism, inherited metabolic disorders, and thyroid hormone resistance syndromes. Secondary hypothyroidism may occur in pituitary or hypothalamic disease. Drugs that may cause hypothyroidism by interfering with thyroid hormone synthesis and/or its release include antithyroid drugs (PTU, methimazole), iodine, and lithium. Increased T₄ clearance is caused by carbamazepine, phenytoin, and rifampin. Amiodarone decreases T₄ to T₃ conversion and inhibition of T₃ action. Interference with intestinal absorption is seen with aluminum hydroxide, cholestyramine, ferrous sulfate, calcium, vitamins, soy, and sucralfate. Many pregnant women take ferrous sulfate, and it is important to ensure that thyroxine is taken at least 2 hours before (even 4 hours sometimes recommended) because insoluble ferric–thyroxine complexes may form, resulting in reduced thyroxine absorption.

The clinical diagnosis is difficult and frequently unsuspected except in advanced cases. Symptoms may include fatigue, sleepiness, lethargy, mental slowing, depression, cold intolerance (very unusual in normal pregnancy), decreased perspiration, hair loss, dry skin, deeper voice or frank hoarseness, weight gain despite poor appetite, constipation, arthralgias, muscle aching, stiffness, and paresthesias. Signs include general slowing of speech and movements, dry and pale or yellowish skin, sparse thin hair, hoarseness, bradycardia (also unusual in pregnancy), myxedema, hyporeflexia, prolonged relaxation of reflexes, carpal tunnel syndrome, and a diffuse or a nodular goiter.

The best laboratory test is the TSH level; current sensitive assays allow very early diagnosis and accurate treatment monitoring. Other useful tests include FT₄ and antibody titers. Anemia occurs in 30–40%. It usually results from decreased erythropoiesis, but it may result from vitamin B₁₂, folic acid, or iron deficiency. Levels of lipids and creatine phosphokinase ([CPK] of muscle origin) may be elevated.

Implications of Hypothyroidism during Pregnancy

Some studies have reported a twofold increased rate of spontaneous abortion in women with elevated levels of thyroid antibodies, even if they are euthyroid, but this finding is not universally confirmed. These antibodies (antiperoxidase-TPO, antimicrosomal-AMA, and antithyroglobulin-ATG) may cross the placenta and cause neonatal hypothyroidism, which, if untreated, may lead to serious cognitive deficiencies. Lower IQs in infants of even very mild hypothyroid women have been reported. None of the most recent reports indicate an increased frequency of congenital anomalies. The main complication found in practically all studies is a high risk of preeclampsia, which often leads to premature delivery with its related morbidity, mortality, and high cost. Placental abruption and postpartum hemorrhage may occur. The severity of the hypertension and other perinatal complications is greater in the more severely hypothyroid woman. Early treatment and close monitoring to ensure euthyroidism will prevent or decrease perinatal complications. Hypothyroidism is frequently associated with other illnesses, particularly type 1 diabetes, chronic hypertension, and anemia; these conditions should be properly monitored and treated as well. Why hypertension occurs more frequently in hypothyroidism is unclear. Reduced cardiac output and increased peripheral resistance have been found and attributed to increased sympathetic nervous tone and α -adrenergic response.

There is no consensus on whether or not universal screening for hypothyroidism during pregnancy should be performed. We strongly recommend that certain high-risk women undergo routine screening for hypothyroidism: previous therapy for hyperthyroidism, high-dose neck irradiation, previous postpartum thyroiditis, presence of a goiter, family history of thyroid disease, treatment with amiodarone, suspected hypopituitarism, and type 1 diabetes mellitus. Because thyroxine requirements increase very early in pregnancy, hypothyroid women should be seen early and frequently during the first half of pregnancy and less often afterward in the second half.

L-Thyroxine has long been the treatment drug of choice. The hormonal content of the synthetic drugs is more reliably standardized, and they have replaced desiccated thyroid as the mainstay of therapy. Administration of T₄ alone is recommended. In the normal physiologic process, T₄ is deiodinated to T₃ in the extrathyroidal tissues. In addition, during early pregnancy the fetal brain is unable to use maternal T₃. A combination of T₄ and T₃, approximating the ratio secreted by the thyroid, was sometimes recommended but its usefulness has not been confirmed. The best time to take L-thyroxine is early in the morning, on an empty stomach. Women experiencing nausea and vomiting should be allowed to take it later in the day until they improve. Numerous reports indicate that thyroxine requirements increase during pregnancy. The initial dose should be 2 μ g per kilogram of actual body weight. Further adjustments are made according to the TSH level. If the TSH level is elevated but < 10 μ U/mL, add 25–50 μ g/d; if the TSH level is >10 but < 20, add 50–75 μ g/d; and if the TSH level is > 20, add 75–100 μ g/d. Changes made at less than 4-week intervals may lead to overtreatment. Up to 85% of women receiving thyroxine replacement before pregnancy will require higher doses while they are pregnant. The levels should be checked early in pregnancy and then periodically thereafter to maintain euthyroidism. After delivery, the dosage is reduced to the prepregnancy amount, and a TSH level measured 4–8 weeks postpartum. In women with pituitary disease, the TSH level cannot be used to guide therapy. In these cases, the FT₄ level should be kept in the upper third of normal.

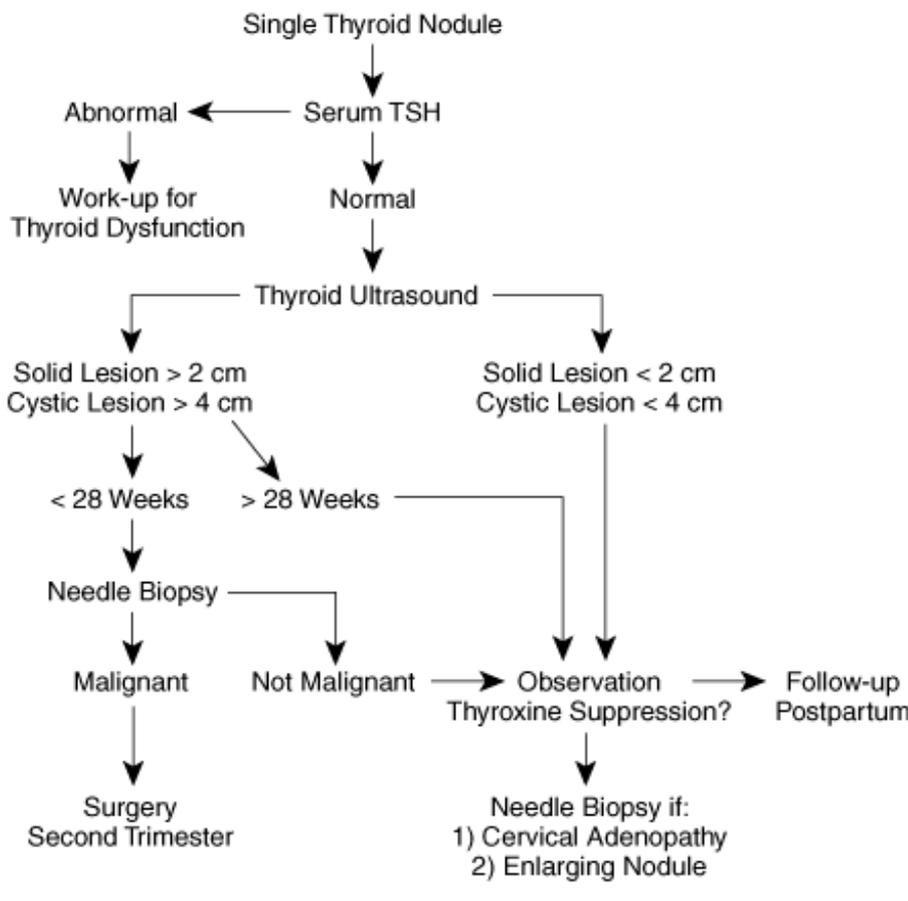

POSTPARTUM THYROID DYSFUNCTION

Postpartum thyroid dysfunction reportedly occurs in between 2% and 5% of all women. It occurs in autoimmune thyroid disease (usually lymphocytic thyroiditis, less frequently in Graves' disease) and often recurs in subsequent pregnancies. In general the condition resolves spontaneously immediately after delivery, but a high rate of hypothyroidism has been observed after long-term follow-up. The clinical course is characterized by mild hyperthyroid symptoms occurring 4–8 weeks postpartum and sometimes later. The TSH level is suppressed, and T_4 , T_3 , and antibody titers are elevated. The thyroid gland may enlarge but is painless to palpation. A needle biopsy, if performed, shows lymphocytic infiltration. A radioactive iodine uptake test, if performed, shows little or no uptake, but the test should not be performed if the patient is breastfeeding. A high uptake would be more consistent with Graves' disease. The symptoms resolve and the results of thyroid tests return to normal after a few weeks or months. However, most patients subsequently develop a hypothyroid phase with clinical symptoms, low T_4 level, elevated TSH level, and further elevation of antibody titers. Spontaneous resolution occurs in most patients after another several weeks or months. The clinical course may vary, with some patients experiencing only the hyperthyroid phase and others only the hypothyroid phase. Treatment in the immediate postpartum is limited to symptomatic patients only (β blockers for the hyperthyroid phase and low-dose levothyroxine or triiodothyronine for the hypothyroid phase, which is enough to alleviate symptoms and allows recovery of thyroid function when discontinued).

SOLITARY THYROID NODULE DURING PREGNANCY

Thyroid nodules are frequently first detected during pregnancy when many women see a doctor for the first time. Little information on the management of these patients is available. The recommended approach in our institution is shown in Figure 24–1. The effect of pregnancy on the natural history of thyroid cancer is not completely known, but the present consensus is that pregnancy does not affect the cancer growth rate or the long-term prognosis. The risk of malignancy for a solitary nodule varies between 5% and 43%, depending on various factors including previous radiation, rate of growth, and patient age. Surgery during pregnancy carries a higher risk if it is performed during the first and the third trimesters (miscarriage, premature delivery, and fetal death); surgery during the second trimester reportedly has a lower complication rate. Radioactive iodine should never be given during pregnancy.

Figure 24–1.

Evaluation of single thyroid nodules in pregnancy.

CALCIUM METABOLISM IN NORMAL PREGNANCY

Both, calcium (Ca) and phosphorus (P) have many metabolic functions, including maintenance of the skeletal system, neuromuscular excitability, cell membrane permeability, high-energy phosphate bonds, and blood coagulation. The daily Ca requirements are 1200 mg (400 mg more than outside of pregnancy) and the total accumulation by term is 30 g (> 25 g in the fetus). It is linearly related to fetal weight, and > 80% accumulates in late pregnancy. Of the circulating Ca, 46% is bound to albumin, 7% to other complexes (phosphate, citrate, and other anions), and 47% is free (or ionized). The protein-bound fraction decreases because of increased extracellular volume, transfer to the fetus, and, perhaps, increased renal clearance. The free fraction remains the same, although some studies have reported a slight decrease leading to increased parathyroid hormone (PTH) levels. Urinary Ca excretion increases early in gestation and decreases in late pregnancy but does not exceed the normal range. The P level falls slightly in early pregnancy and rises to normal by 30 weeks.

The PTH level remains unchanged during the first half of pregnancy and then rises gradually until term, coinciding with the time of greatest fetal skeletal calcification. PTH promotes Ca transport from mother to fetus. The most potent factor affecting PTH secretion is the free Ca level (inverse correlation), but calcitonin, vitamin D, and magnesium (Mg) also play a role. Calcitonin is secreted by C-cells inside the thyroid, but these cells actually are of neural crest origin and migrate to the thyroid. Calcitonin is a Ca-lowering hormone whose secretion is also mainly affected by free Ca levels, but in this case the correlation is direct. Its action is antagonistic to that of PTH, and it plays a role in Ca homeostasis and bone remodeling. Vitamin D increases the efficiency of intestinal Ca absorption, plays a role in the maintenance of Ca and P levels, and has a role in the mineralization of bone matrix. In order to exert its

action, vitamin D must be transformed into active metabolites [1,25-(OH)₂D₃] in the kidney, and PTH is needed for the process. The requirements are 400 IU/d, the same as outside of pregnancy. Vitamin D crosses the placenta readily.

Whether Ca metabolism during pregnancy is influenced by other hormones, such as estrogen, progesterone, or hCG, is not known. The placenta plays a major role in transporting Ca against a gradient. PTH facilitates this transport, although neither PTH nor calcitonin crosses the placenta. The fetal Ca concentration (both total and free) increases gradually from 5.5–11.0 mg/dL from the second trimester to term. In the fetus, the PTH level is suppressed but detectable, and cord levels are 25% lower than in the mother. Calcitonin in cord is higher than in the mother, a combination favoring skeletal growth, which also causes Ca levels in the newborn to fall to normal. Given these findings, all the observed changes in normal pregnancy favor mineralization of the fetal skeleton.

HYPERPARATHYROIDISM

Hyperthyroidism is a frequently occurring disease but has been uncommonly reported to occur during pregnancy. Just over 120 cases have been reported since 1931, with the first successful surgery performed in 1947. The etiology is an adenoma in 89–90% of cases, hyperplasia (of all the glands) in 9%, and carcinoma in 1–2%. The latter should be suspected in severe hyperparathyroidism, particularly if a palpable neck mass is present (palpable neck masses are reported in < 5% of parathyroid adenomas). Rarely it occurs in a familial pattern with or without other endocrine abnormalities (eg, multiple endocrine adenomatosis). Other causes of hypercalcemia during pregnancy are uncommon and include vitamin D toxicity, sarcoidosis, various malignancies, milk-alkali syndrome, thyrotoxicosis, adrenal insufficiency, and secondary hyperparathyroidism in those undergoing chronic hemodialysis or after renal transplantation.

Reported complications include 27.5% fetal mortality and 19% neonatal tetany. Neonatal hypocalcemia is often the initial clue to the presence of maternal hyperparathyroidism. The condition occurs because the high levels of maternal Ca inhibit the activity or the proper development of the infant's parathyroid glands. It develops between days 2 and 14 after delivery, depending on the severity of the maternal hypercalcemia, and usually resolves with appropriate therapy. One case of hypocalcemia persisting for 3 months and another case of hypocalcemia that became permanent have been reported.

Complications in the mother include 36% nephrolithiasis, 19% bone disease, 13% pancreatitis, 13% urinary tract infections and pyelonephritis, 10% hypertension (100% in all cases of carcinoma thus far reported), and 8% hypercalcemic crisis. Maternal deaths have occurred among those with complications of pancreatitis or hypercalcemic crisis. Women who developed hypercalcemic crisis had a 30% maternal death rate and 40% fetal demises. Pancreatitis is reported in only 1.5% of nonpregnant hyperparathyroid patients and in < 1% of normal pregnancies. Most pregnant women with hyperparathyroidism (76%) are symptomatic, whereas 50–80% of nonpregnant hyperparathyroid patients are asymptomatic at the time of diagnosis. Common symptoms include anorexia, nausea and vomiting, thirst, weakness, fatigue, lethargy, headaches, emotional lability, inappropriate behavior, confusion, and even delirium.

A persistently elevated serum Ca level and a normal or elevated PTH level, despite hypercalcemia, confirm the diagnosis. Hypercalciuria is commonly seen. The serum levels of P, Mg, and bicarbonate usually are low, and chloride and citrate levels often are elevated. The chloride/P ratio is sometimes used as a diagnostic clue because the ratio usually is > 30 in hyperparathyroidism but is < 30 in hypercalcemia from other causes. The levels of serum alkaline phosphatase (of bone origin) and urinary hydroxyproline will be elevated in cases with significant bone involvement.

Surgery is the treatment of choice for confirmed hyperparathyroidism. In pregnancy, the optimal time for

surgery is the second trimester, when the complication risks (abortion or premature labor) are reduced. An experienced surgeon performing the neck exploration will be able to proceed appropriately in case of parathyroid hyperplasia (removal of all glands with parathyroid tissue transplantation). In addition, the complication rate should be reduced when an experienced surgeon performs the procedure. Postoperatively, hypocalcemia may occur in patients with significant osteitis fibrosa or if injury occurs to the normal parathyroid glands during surgery. When surgery is not possible, maintaining adequate hydration and administering oral phosphates may be temporary measures until surgery can be safely performed. Preventing hypercalcemic crisis is of utmost importance; if it develops, aggressive treatment is recommended.

HYPOPARATHYROIDISM

The most common cause of hypoparathyroidism is surgical removal or damage to the parathyroid glands, or their vascular supply, during thyroid surgery. Hypoparathyroidism reportedly occurs in 0.2–3.5% of cases after thyroid surgery. Idiopathic hypoparathyroidism is relatively rare and is seldom seen in pregnancy. It may be isolated or occur in association with agenesis of the thymus or as part of a familial disorder, which includes deficiencies of thyroid, adrenal and ovarian function, pernicious anemia, and mucocutaneous candidiasis. Pseudohypoparathyroidism (deficient end-organ response to PTH in bone and kidney) is a rare hereditary disorder infrequently encountered during pregnancy. The severity of symptoms depends on the degree of hypocalcemia and range from clumsiness (fingers), mental changes (mainly depression), muscle stiffness, parkinsonism, acral and perioral paresthesias, to laryngeal stridor, tetany, and convulsions. Clinical signs include dry, scaly skin, brittle nails, coarse hair, and positive Chvostek's (present in 10% of normals) and Trousseau' signs. Ectopic soft tissue calcifications and a prolonged QT interval on the electrocardiogram may be observed. Pseudohypoparathyroidism is more likely if the patient has unusual skeletal or developmental defects and if other family members affected. The diagnosis usually is evident from the history and confirmed by a "normal" or low PTH level in the presence of hypocalcemia, hyperphosphatemia, and normal renal function.

Before the availability of specific therapy, maternal morbidity and mortality rates were high, and termination of pregnancy was frequently recommended. Currently the prognosis is much improved provided the mother is kept eucalcemic. From 1–4 g/d of elemental calcium and 50,000–100,000 U/d of vitamin D usually are recommended. The synthetic vitamin D analogue $1\alpha,25\text{-(OH)}_2\text{D}_3$ at doses of 0.25–2 $\mu\text{g/d}$ is considered safer by some authors. The therapeutic margin is narrow in these patients, who experience frequent episodes of hypercalcemia or hypocalcemia. Hypercalcemia, when it develops, may be long-lasting. The synthetic analogues are more active and shorter-acting, and they might be safer. In hypercalcemia, the vitamin D therapy is stopped, hydration is provided, and a course of corticosteroids is given (prednisone, or equivalent, 40–100 mg/d). If convulsions and tetany result from hypocalcemia, Ca gluconate 10–20 mg is given intravenously, followed by infusion of 15 mg of Ca gluconate per kilogram of actual body weight administered over 4–8 hours, according to the serum Ca level. Replace Mg if the serum level is low. Once the acute episode resolves, the daily oral therapy is readjusted to prevent recurrences.

These patients require frequent serum Ca determinations, and the therapy should be readjusted as often as necessary to prevent acute decompensation. If the mother is hypercalcemic, the newborn may develop hypocalcemia and tetany, the same as when the mother has hyperparathyroidism. If the mother is hypocalcemic, hyperplasia of the fetal parathyroid glands, mobilization of calcium from the skeleton and generalized demineralization, subperiosteal resorption, and even osteitis fibrosa with very high perinatal mortality will occur. With proper treatment, symptoms in surviving infants will subside by age 4–7 months.

After delivery, hypoparathyroid women may develop hypercalcemia with the same dose of calcium and vitamin D that was effective during pregnancy. Hypersensitivity to vitamin D in lactating women may result from the effect of prolactin (PRL) on 1α -hydroxylase vitamin D activity. Serum calcium levels should be monitored closely and the doses readjusted as necessary. Vitamin D travels into breast milk, even when low doses are taken, so many physicians discourage breastfeeding in these women.

ADRENAL DISORDERS: INTRODUCTION

Pregnancy is rarely associated with diseases of the adrenal glands, particularly in those with excessive cortisol secretion, because of the high prevalence of infertility in these women.

CUSHING'S SYNDROME

Up to 75–80% of women with excess cortisol experience menstrual irregularities and infertility. Excess cortisol, either endogenous or exogenous, suppresses gonadotropin secretion. In addition, elevated androgen and PRL levels are contributing factors in some patients. Approximately 70 cases occurring in pregnancy have been reported, usually in the form of single cases based upon a review of the literature. Most cases (70%) of Cushing's syndrome occurring outside of pregnancy are the result of excess adrenocorticotrophic hormone (ACTH) secretion, usually by small pituitary adenomas. However, of the cases reported during pregnancy, only 40% were ACTH-dependent Cushing's syndrome; 60% were adrenal tumors (90% adenomas and 10% carcinomas). Apparently, women with ACTH-dependent Cushing's syndrome have a higher infertility rate.

The clinical diagnosis is difficult because the changes occur insidiously. During pregnancy, diagnosis is even more difficult because weight gain, skin striae (stretch marks), and fatigue are common during normal pregnancy, but all other symptoms and signs will be the same as outside of pregnancy. The laboratory diagnosis also is more difficult during pregnancy. Urinary free cortisol excretion may overlap with that seen in some cases of Cushing's syndrome, and the suppression to exogenous corticosteroids may be incomplete. However, the diurnal variations of both ACTH and cortisol are preserved; therefore, measurement of morning and evening cortisol levels remains very useful. Therefore, the diagnosis may be confirmed by the loss of diurnal variation, elevated levels of urinary free cortisol, particularly if > 250 mg per 24 hours, and lack of cortisol suppression to dexamethasone. Measurements of ACTH may be useful as well ("normal" or high in Cushing's disease and suppressed in adrenal tumors). Magnetic resonance imaging (MRI) may confirm the presence of a pituitary or adrenal tumor. A few cases of "pregnancy-induced" Cushing's syndrome with spontaneous resolution postpartum have been reported and attributed to a placental corticotropin-releasing factor. However, long-term follow-up revealed other causes of Cushing's syndrome in most of the women.

The most common complication (64%) is premature labor resulting in considerable fetal morbidity and mortality. IUGR occurs in 26–37% and fetal losses (spontaneous abortions and stillbirths) in 16%. Little information about the long-term quality of survival of those born premature but alive is available. Hypertension and diabetes mellitus complicate 70% and 32% of these pregnancies, respectively, and unfavorably influence the outcome of these pregnancies if untreated. Other potential maternal complications include congestive heart failure, thromboembolism, osteoporosis and vertebral fractures, proximal muscle weakness, electrolyte disturbances (particularly low potassium), and poor healing with wound breakdown (to be considered in case of cesarean section). Maternal mortality has occurred in 5% of cases.

An attempt at some form of treatment is advocated given the poor outcome. Surgery in the second trimester can be attempted when a pituitary or adrenal tumor is found. Few reports of these procedures performed during pregnancy are documented. Medical therapy is limited, and the potential side effects of

the medications are not well known. Metyrapone, cyproheptadine, aminoglutethimide, and ketoconazole (teratogenic in animals) have been used in a few patients. All efforts should be made to control the hypertension and hyperglycemia so commonly seen with excess cortisol. Early delivery in the third trimester as soon as the fetus is mature is recommended, with postponement of definitive treatment of the mother until after delivery.

ADRENAL INSUFFICIENCY

Primary adrenocortical insufficiency (Addison's disease) more often is the result of autoimmune destruction of the adrenal glands (in the era before antibiotics, tuberculosis was the most common cause). Occasionally, it is associated with other autoimmune endocrine disorders (polyendocrine autoimmune deficiency). Other causes are exceptionally rare in fertile women of childbearing age. Secondary adrenal failure results from reduced or absent ACTH secretion caused by various pituitary disorders or inhibition from chronic exogenous steroid use. Causes of partial or complete anterior pituitary insufficiency in women of reproductive age include tumors, pituitary surgery or radiation, and postpartum infarction (Sheehan's syndrome). Less common causes are acute pituitary hemorrhage, infiltration by granulomatous diseases, thalassemia, necrosis from increased intracranial pressure, and lymphocytic hypophysitis. A few cases of pituitary necrosis in type 1 pregnant diabetic women have been reported.

Since the advent of steroid treatment, most pregnancies have been successfully managed. Even women with anterior pituitary insufficiency may conceive because of advances in infertility treatment and, with proper hormonal replacement, may carry their pregnancies to term. Infants of well-treated mothers with adrenal insufficiency appear to be normal.

The symptoms during pregnancy are similar to those in nonpregnant cases and include weakness, nausea, vomiting, abdominal pain, hyperpigmentation, hyponatremia, and hyperkalemia. The diagnosis may be delayed or missed unless there is a high index of suspicion. Acute adrenal crisis is a more dramatic presentation. If not diagnosed and treated promptly, it will become a catastrophic event resulting in maternal and/or fetal death.

The daily steroid replacement dose is 20–25 mg/m² by mouth (ie, 30–37.5 mg/d of hydrocortisone or equivalent steroid). Two thirds of the daily dose (20–25 mg) is given in the morning and one third (10–12.5 mg) in the late afternoon. Usually the daily dosage does not need to be changed during pregnancy. However, compensation is required for periods of stress and during labor and delivery (up to 300 mg of hydrocortisone or equivalent steroid given intravenously in divided doses the first day and gradual tapering to the maintenance dose over the next several days). In secondary adrenal insufficiency, mineralocorticoid replacement is not necessary, but women with primary adrenal disease also should receive fludrocortisone 0.05–0.1 mg/d by mouth.

CONGENITAL ADRENAL HYPERPLASIA

Of the several inherited enzymatic deficiencies of cortisol synthesis that may cause congenital adrenal hyperplasia, the 21-hydroxylase deficiency accounts for 90–95% of cases. These enzymatic deficiencies are inherited as autosomal recessive traits (25% risk of inheriting the condition and 50% of being a carrier).

The low cortisol level stimulates excessive ACTH secretion, which in turn causes adrenal enlargement ("adrenal hyperplasia"). The excessive secretion of androgens leads to masculinization of the external genitalia (congenital sexual ambiguity) and the low cortisol level to adrenal insufficiency. Untreated, these conditions can be life-threatening. In most cases, the diagnosis is made and treatment initiated after birth when the newborn becomes ill. However, prenatal diagnosis (chorionic villous sampling and DNA testing) now is reported. If the defect is a 21-hydroxylase deficiency and the fetus is female, treatment of the mother with dexamethasone may prevent the development of adrenal hyperplasia and virilization of the external genitalia. Those born with virilization of the external genitalia will require surgical reconstruction to allow vaginal intercourse.

In affected females, the earlier the treatment is initiated, the higher the likelihood that they will be ovulatory and fertile. During pregnancy, glucocorticoid therapy should be continued and adjusted to avoid excessive androgen levels. Otherwise the steroid management is the same as described for adrenal insufficiency. If extensive surgical reconstruction of the genitalia was performed, a cesarean delivery might be necessary. Genetic counseling should be mandatory for these women, before they consider pregnancy, given the high risk of transmission and the severity of the disease.

PHEOCHROMOCYTOMA

Pheochromocytomas are rare in the general population and are the least common cause of hypertension during pregnancy. However, given the severity of the complications (48% maternal mortality and 55% fetal mortality) if untreated, the possibility of its existence must always be considered in the differential diagnosis. The symptoms are similar to those outside of pregnancy and are caused by excess catecholamines. They include sustained or paroxysmal hypertension, headaches, palpitations, diaphoresis, and anxiety. Blurred vision and convulsions are reported more commonly during pregnancy. Higher blood pressure while recumbent and lower when standing may be clues to the diagnosis during pregnancy (pressure from the gravid uterus on the tumor while lying down). Complications include spontaneous abortion, IUGR, placental abruption, and fetal and maternal death. Differentiation from preeclampsia may be difficult when proteinuria is also present. Elevated levels of free catecholamines and their metabolites metanephrine and vanillylmandelic acid (VMA) in a 24-hour urine collection confirm the diagnosis. Urinary metanephrine levels > 1.2 mg/d are considered highly suggestive of pheochromocytoma. A plasma level of total catecholamines > 2000 pg/mL, drawn after the patient has been in the supine position for > 30 minutes, also is highly suggestive. For tumor localization, MRI is the test of choice during pregnancy. Other test and scans are not considered safe during pregnancy. Most pheochromocytomas are benign and are located in the adrenal glands, but approximately 10% are located elsewhere and difficult to find. In a few patients, the pheochromocytoma may be part of a familial disorder and more likely to be bilateral.

Few of the reported cases were diagnosed during pregnancy. However, if the diagnosis is made, surgical removal during the second trimester is recommended. Blood pressure control is attempted first with adequate adrenergic blockade (usually phenoxybenzamine), followed by β -adrenergic blockade if necessary, until surgery can be performed in the second trimester or, if after 26–28 weeks, until the fetus is mature. Phenoxybenzamine is considered safe, but it does cross the placenta and has the potential to cause depression and transient hypotension in the newborn. Laparoscopic removal has been

reported in a few cases, but most surgeons prefer an abdominal approach to ensure adequate adrenal visualization. Vaginal delivery is not recommended because of precipitation of hypertensive crisis by mechanical pressure on the tumor from changes in posture, contractions, and fetal movements. Cesarean delivery followed by tumor removal during the same surgery is generally advised. Adequate medical preparation for surgery is mandatory. Pheochromocytoma removal is a high-risk procedure, and an experienced surgeon and anesthesiologist are strongly recommended.

PITUITARY TUMORS

Prolactinomas are the most common pituitary tumors encountered during pregnancy, particularly since the availability of effective treatments for restoring fertility. The diagnosis usually is made when the PRL level is high enough to cause galactorrhea, oligomenorrhea, or amenorrhea. MRI confirms the diagnosis. The tumors are divided into microadenomas (< 10 mm) or macroadenomas (> 10 mm). The risk of growth during pregnancy is low (1–2%) for microadenomas, in contrast to the 15–25% risk for untreated macroadenomas. Previously treated macroadenomas (bromocriptine, cabergoline, and/or surgery) have a lower risk (4%) of growth during pregnancy. In general, serial PRL measurements do not predict tumor growth and are not recommended. In actuality, pregnant women with prolactinomas tend to have lower PRL levels, a lower response to stimulation (eg, to TRH), and loss of the diurnal PRL variation.

Serial visual field examinations or MRI is not recommended for microadenomas unless symptoms appear. If severe headache occurs, MRI is recommended even if no visual field defects are detected. MRI should always be performed if visual field defects are detected. If the tumor enlarges, medical therapy (bromocriptine or cabergoline) is started and visual field examinations performed daily. If no rapid response occurs, high-dose steroid therapy is added. If still no response occurs, surgery should be strongly considered. Few reports of surgery during pregnancy are documented, but medical therapy, continued until after delivery, generally has been safe and effective. Labor and delivery are generally uncomplicated, but shortening the duration of the second stage in women experiencing tumor growth during pregnancy is recommended in an effort to prevent intracranial pressure elevation during the most active pushing.

In macroprolactinomas, monthly visual field examinations and MRI are recommended if tumor growth is suspected. In addition to headaches and visual changes, pituitary infarction and diabetes insipidus are rarely seen. Complications of tumor growth are more likely to appear during the first trimester.

Most women with prolactinomas are allowed to breastfeed. MRI usually is recommended approximately 3–4 months after delivery to reassess tumor size.

ACROMEGALY

Because menstrual disturbances are very common (up to 75%), few pregnancies during the active phase of the disease have been reported. Hyperprolactinemia, which also is commonly seen (30–40%), adds to fertility difficulties. If conception occurs, spontaneous abortion may occur due to inability to maintain implantation. Diabetes and hypertension are common complications during pregnancy, adding further serious adverse consequences.

The clinical diagnosis is infrequently made early in the disease because changes in shoe or glove size and coarsening of facial features develop slowly. Determination of growth hormone levels during pregnancy requires specific assays able to differentiate growth hormone from pituitary or placental origin. Insulinlike growth factor-I (IGF-I) levels are elevated during normal pregnancy, and their measurement is of limited usefulness in the diagnosis of acromegaly during gestation. Ideally, treatment should be accomplished before pregnancy. In general, medical therapy is stopped when pregnancy is diagnosed. However, bromocriptine administration throughout gestation without untoward effects to mother or infant has been reported. The data for octreotide are limited, so until its safety is determined, octreotide should be stopped when pregnancy is diagnosed. Elective surgery during pregnancy is safer during the second trimester. Emergency surgery is reserved for women with pregnancy-associated tumor enlargement and visual loss.

MRI should be performed in all patients before conception and after delivery. Follow-up for microadenomas during pregnancy include clinical assessments (headaches, visual changes) every trimester and no intervention unless symptoms appear. For macroadenomas, monthly assessments are recommended along with an MRI 4 months into the pregnancy. It appears that women with microadenomas can breastfeed safely.

SHEEHAN'S SYNDROME

H.L. Sheehan described the syndrome bearing his name as partial or complete pituitary insufficiency due to postpartum necrosis of the anterior pituitary gland in women with severe blood loss and hypotension during delivery. Nevertheless, up to 10% cases have no history of bleeding or hypotension. The clinical manifestations depend on the extent of pituitary destruction and hormonal deficiencies. With destruction of 90% or more, symptoms of acute adrenal insufficiency predominate (see Adrenal Insufficiency). If the condition is not treated promptly, serious complications and even death may occur. In most cases, the full-blown picture may take longer, even years, to appear. Failure to lactate, breast involution, and, if untreated, breast atrophy may occur. Loss of pubic and axillary hair (or failure of hair to regrow if it is shaved), oligomenorrhea or amenorrhea, loss of libido, and pale ("waxy") skin with premature wrinkling, especially around the eyes and mouth, are possible. Fatigue, weight loss, and postural hypotension are common complaints. Hyponatremia and anemia (usually normocytic and normochromic) are frequent laboratory abnormalities. Hormonal deficiencies point to a secondary cause, with low thyroxine, TSH, estrogen, gonadotropin, cortisol, and ACTH levels. Provocative hormonal testing may be necessary to confirm the diagnosis. Once the diagnosis of secondary hormonal deficiency is established, MRI of the pituitary and hypothalamus is necessary to exclude a tumor or other pathology.

All deficient hormones must be replaced. However, it is well known that some patients with clear panhypopituitarism may recover TSH and even gonadotropin function after cortisol replacement alone. The mechanism is unknown, but it is speculated that cortisol has a permissive effect on other hypothalamic and pituitary functions. Rare cases of spontaneous recovery have been reported.

The outcome of pregnancy in women with Sheehan's syndrome shows no increased perinatal morbidity or mortality if the mothers are treated properly. Women with persistent amenorrhea and anovulation will

require fertility treatment to become pregnant.

DIABETES INSIPIDUS

Diabetes insipidus (DI) is caused by a deficiency of antidiuretic hormone (ADH), called central DI, or by renal tubule resistance to ADH action, called nephrogenic DI. A transient form of DI during pregnancy has been observed with increasing frequency and has attributed to excessive placental production of vasopressinase, perhaps decreased hepatic clearance, and, because most of the patients reported had abnormal liver function, preeclampsia, fatty liver, or hepatitis. It is possible that some of these cases represent mild preexisting DI unmasked by pregnancy. It usually resolves several weeks after delivery but may recur in subsequent pregnancies, so follow-up is recommended.

A variety of lesions may cause DI, such as pituitary surgery, radiation, trauma, tumors, granulomas, and infections. However, no etiology is found in as many as 50% of patients, and these cases are labeled as "idiopathic." Clinical symptoms include polyuria of 4–15 L/d and intense thirst, particularly for ice-cold fluids. The incidence during pregnancy has been reported as 1 in 50,000 to 1 in 80,000 deliveries. Approximately 60% of women with previously known DI worsen, 20% improve, and 20% do not change during pregnancy. Worsening is attributed to excessive placental vasopressinase production. Some women with DI who also develop placental insufficiency show DI improvement, which is attributed to decreased vasopressinase production by the damaged placenta.

The diagnosis of DI is confirmed by the standard water deprivation test. However, this test may prove hazardous during pregnancy because 3–5% of body weight may be lost during the test. This degree of dehydration, which is required to produce sufficient stimulation for ADH secretion, may lead to uteroplacental insufficiency and fetal distress. Even before fetal distress occurs, uterine contractions and even frank labor may be precipitated, forcing termination of the test before it can be properly interpreted. Uterine contractions respond rapidly to intravenous fluid administration. If the decision is made to perform a water deprivation test, continuous fetal monitoring is recommended. Because of these difficulties, a suggested alternative test is 20 µg of L-deamino-8-D-arginine vasopressin (DDAVP) given intranasal and serial urinary osmolalities determined during the next 12 hours. Any value > 700 mOsm/kg is normal. DDAVP is a synthetic analogue of ADH and is resistant to vasopressinase.

The treatment of choice is intranasal DDAVP. It also can be given subcutaneously when the intranasal route cannot be used. The usual dose is 10 to 25 µg once or twice daily (or 2–4 µg subcutaneously). The dosage is adjusted according to fluid intake, urinary output, osmolality, and plasma electrolytes. Close follow-up is necessary to prevent dehydration or the opposite, water intoxication. Many reports indicate that DDAVP is safe during pregnancy and postpartum, even while the mother is breastfeeding. Oxytocin secretion appears to be normal, and no labor difficulties have been reported. No difficulties with lactation have been reported even in women with central DI.

Current OB/GYN > Chapter 25. Nervous System & Autoimmune Disorders in Pregnancy > Disorders of the Nervous System >

CEREBROVASCULAR DISORDERS

The causes of cerebrovascular disease include insufficiency (*arteriosclerosis, cerebral embolism, vasospasm from hypertensive disease*) and disorders associated with bleeding into the cerebral cortex (*arteriovenous malformation, ruptured aneurysm*). The brain becomes infarcted from lack of blood flow, or intracranial bleeding results in a space-occupying lesion. The severity of such disorders can be affected by blood pressure, oxygen saturation (anemia or polycythemia), hypoglycemia, and adequacy of collateral circulation.

The overall incidence of ischemic cerebrovascular accidents in pregnancy is approximately 1 in 20,000 births, with most occurring in the last trimester or immediately postpartum. Etiologic factors for stroke include cardioembolic disorders, cerebral angiopathies, hematologic disorders, and cerebral vein thrombosis. Causes exclusive to pregnancy are eclampsia, choriocarcinoma, and amniotic fluid embolism. Although cerebral ischemic disease can occur in either the arterial or venous system, approximately 75% of occlusive cerebral disease occurs on the arterial side.

Cerebrovascular accidents involving subarachnoid hemorrhage or intraparenchymal hemorrhage similarly occur at a rate of 1 in 20,000 births. These events usually are the result of aneurysms or arteriovenous malformations. The most common aneurysm is the saccular (berry) variety, which protrudes from the major arteries in the circle of Willis, particularly at its bifurcations. Aneurysms have an increasing tendency to bleed as the pregnancy progresses, likely due to changes in hemodynamic factors. Rupture of arteriovenous malformations have been found to occur evenly throughout gestation. No consensus has been reached regarding the increased frequency of bleeding from either an aneurysm or arteriovenous malformation during pregnancy or the immediate postpartum period. Rupture of the malformation appears to be more frequent during pregnancy. Eclampsia can lead to cerebral hemorrhage when elevated blood pressures lead to vasospasm, loss of autoregulatory function, and rupture of the vessel wall.

Clinical Findings

Headaches, visual disturbances, syncope, and hemiparesis are among the most common presenting findings.

Diagnosis

The pattern of clinical signs and symptoms generally allows recognition of the area of the brain involved. Computed tomography (CT) scan and magnetic resonance imaging (MRI) can be used in pregnancy to increase the delineation of cerebrovascular involvement. Arteriography is considered definitive if surgical intervention is being considered because arteriography can more precisely localize the involved area. Because coagulopathies can also cause intracranial bleeding or may be secondary to the cerebrovascular lesion itself, a coagulation profile should be performed. Additionally, antinuclear antibody (ANA), lupus anticoagulant, factor V Leiden, homocysteine, anticardiolipin, proteins C and S, antithrombin 3, and plasminogen levels should be considered with thrombotic cerebral events.

Treatment

The treatment of ischemic or hemorrhagic cerebrovascular disease is best managed supportively; however, surgery is indicated for treatment of some aneurysms and arteriovenous malformations. Anticoagulation with heparin may be required depending on the etiology of the infarction; tissue plasminogen activator is relatively contraindicated in pregnancy, but it has been used successfully according to several case reports. Normalization of blood pressure, adequate respiratory support, therapy for metabolic complications, and treatment of coagulopathies or cardiac abnormalities are crucial. Dexamethasone 10 mg intravenously initially, followed by 5 mg every 6 hours for 24 hours, may decrease cerebral edema and be of some assistance prior to surgery or in recovery. Additionally, hyperventilation, mannitol infusions, phenobarbital coma, and intracerebral pressure monitoring may be helpful with severe cerebral edema. Once the patient's condition has been stabilized, physical therapy and rehabilitation should begin as soon as possible.

Appropriate surgery for aneurysms and arteriovenous malformations should be performed with the pregnancy undisturbed unless fetal maturity allows for cesarean birth just prior to the neurosurgical procedure. On the other hand, inoperable lesions during pregnancy are managed by pregnancy conservation until fetal maturity is sufficient to allow abdominal birth. Once a lesion has been surgically corrected, vaginal delivery can be attempted depending on the practitioner's comfort level. However, the second stage of labor should be modified by regional anesthesia and forceps delivery to reduce cerebral pressures associated with the Valsalva maneuver.

Complications & Prognosis

The percentage of patients with venous occlusion who recover from the initial episode without neurologic sequelae during rehabilitation equals that of patients with arterial occlusion. Thrombosis of the superior sagittal sinus is a rare complication. Its incidence is increased in pregnancy, and it has a high mortality rate of approximately 55%.

If the cerebral hemorrhagic disorder is operable, the prognosis is favorable, with few long-term neurologic deficits. In inoperable lesions or when severe maternal cerebral hemorrhage has occurred, the prognosis—although unfavorable—is better for those with aneurysms than for those with arteriovenous fistulas. If a neurosurgical procedure is performed during pregnancy, the fetus usually is not adversely affected, despite the induced hypotension that is often necessary. The prognosis for the mother and fetus is the same as that in a normal gestation once the condition has been corrected.

CEREBRAL NEOPLASMS

Cerebral neoplasms occur primarily at the extremes of life; thus primary cancer or even metastatic tumors are uncommon during the childbearing years. Although brain tumors are not specifically related to gestation, meningiomas, angiomas, and neurofibromas are thought to grow more rapidly with pregnancy. Of the primary neoplasms (half of all brain tumors), gliomas are the most common (50%), with meningiomas and pituitary adenomas accounting for 35%. Of the metastatic cerebral tumors, lung and breast tumors account for 50%. *Choriocarcinoma* commonly metastasizes to the cerebrum.

Clinical Findings

The clinical manifestations, although dependent on the type and location of the tumor, are generally characterized by a slow progression of neurologic signs with evidence of increased intracranial pressure. One of the most frequent signs is headache, which must be differentiated from that occurring in tension and in vascular or inflammatory conditions. Pain that is not relieved by analgesics or muscle relaxants (as a tension headache would be), the absence of a history of migraine headaches, and the lack of signs of infection or meningeal inflammation all point to increased intracranial pressure as a possible cause of the headache. Tumors in the pituitary gland or occipital region may be associated with visual deficits. Other presenting signs and symptoms include nausea, vomiting, double vision, vertigo, seizures, and altered mental status.

Diagnosis

CT scan and MRI are of greatest assistance in revealing space-occupying lesions. MRI is generally preferred during pregnancy, although fetal radiation exposure from CT is minimal. If the cerebrospinal fluid glucose and protein levels are normal, inflammation or infection of the central nervous system is unlikely. Similarly, an increase in the cerebrospinal fluid human chorionic gonadotropin (hCG) titer raises the suspicion of metastatic choriocarcinoma. Pleocytosis may be present with cerebral neoplasia, but usually it is lymphocytic or monocytic, without an increase in the number of polymorphonucleocytes. Finally, failure to find blood or xanthochromic fluid in the cerebrospinal fluid helps in differentiating a neoplasm from a hemorrhagic lesion, unless the tumor has undergone hemorrhagic necrosis.

Treatment

The treatment of cerebral neoplasms during pregnancy depends on the type of tumor, its location, and the stage of gestation. Anticonvulsants should be used only if seizures have occurred. Steroids can be used to decrease intracranial pressure causing focal neurologic signs or headaches. Deterioration of the patient's status in early pregnancy should prompt a discussion about the risks of continuing the pregnancy. Nevertheless, most such pregnancies can be carried through successfully. During the second trimester, treatment with surgery, chemotherapy, or directed radiation can be started and the pregnancy allowed to continue. Later in gestation, maternal treatment can be delayed until delivery. Pituitary adenomas can be treated with bromocriptine if visual problems or disabling headaches occur.

Complications & Prognosis

Brain tumors usually do not affect pregnancy or the fetus unless the neoplasm leads to early delivery or maternal death. When diagnosed in the second or third trimester, the outcome for the fetus is excellent, even though therapy may be initiated during the course of the pregnancy.

MIGRAINE HEADACHE

Chronic migraine headaches decrease during pregnancy in 50–80% of affected patients. Women with classic migraine (migraine with aura) may experience their initial onset during pregnancy.

Clinical Findings

Most often, the patient has a history of migraine headaches, which usually are described as "pounding" and may settle in the eyes, the temporal region, or occiput. The pain can be unilateral or bilateral. Frequently, migraines are associated with gastrointestinal complaints (eg, nausea, vomiting, and diarrhea) or with systemic symptoms (eg, vertigo or syncope). Light sensitivity (photophobia) and noise sensitivity (sonophobia) often accompany the pain. An aura may or may not precede the headache, but it is the most common visual phenomenon. Sleep often aborts the attack.

Diagnosis

The diagnosis of migraine headaches usually is made clinically by the characteristics of the pain, associated symptoms, event triggers (see below), and absence of neurologic signs. Tension and caffeine withdrawal headaches typically are associated with bandlike pressure pain. If vertigo is associated with migraine headaches, it is important to rule out Ménière's disease (labyrinthitis). In the latter, vertigo is accompanied by tinnitus, a fluctuating sensorineural hearing loss, and nystagmus. If vertigo is associated with ataxia of gait, it is almost always central in origin, in which case head trauma, brain tumors, seizure disorders, and multiple sclerosis must be excluded. Syncope (fainting) may occur with migraine or vascular headaches and is common during pregnancy. However, when syncope occurs with migraine headache, it usually is associated with vertigo. Rarely, ocular nerve palsy develops in association with migraine headaches; the third cranial nerve is the most commonly involved, and the palsy usually disappears with abatement of the migraine. It is important to visualize the optic disk to ensure that cerebrospinal fluid pressure is not increased. In cases where the disk borders are not sharp, *pseudotumor cerebri* or an intracranial mass lesion should be considered first.

Treatment

Treatment of migraine headaches initially includes identification of any trigger that precipitates attacks, followed by avoidance of those triggers. Common triggers for some migraine patients include missing meals, stress, aged cheeses, sausage or other nitrates, chocolate, citrus fruit, wine and other sulfites, monosodium glutamate, strong odors, lights or glare, and inadequate sleep. When this environmental manipulation fails to control migraines, drug therapy is indicated. Migraine therapy is either abortive or prophylactic depending on the frequency and severity of attacks. Preferred abortive medications during pregnancy include acetaminophen, acetaminophen and codeine or other narcotics, and magnesium. The following are more effective migraine abortive medications but are not preferred during pregnancy: butalbital, isometheptene, caffeine, aspirin, naproxen, ibuprofen, and triptan drugs (eg, sumatriptan). The nonsteroidal anti-inflammatory drugs should not be used for prolonged periods and should be avoided in the third trimester because of possible oligohydramnios or premature closure of the ductus arteriosus. Prophylactic medications should be instituted if abortive therapy is only partially effective and if disabling migraines are occurring more than once per week. Options include beta mimetic blockers, low-dose tricyclic antidepressants, calcium channel blockers, magnesium, riboflavin, and topiramate. Valproic acid or divalproate should be avoided in pregnancy.

Complications & Prognosis

Migraine headaches usually have no deleterious long-term effect on mother or fetus, and treatment of acute exacerbation usually is successful.

EPILEPSY AND SEIZURE DISORDERS

Epilepsy is defined as 2 or more unprovoked seizures and is different from eclamptic seizures sometimes seen during pregnancy. Seizures associated with epilepsy can be generalized convulsive (tonic-clonic or grand mal), complex partial (loss of awareness or staring with mild motor movements), focal motor or sensory (Jacksonian with no loss of awareness, absence or petit mal (brief eye blinking with no postictal confusion), myoclonic jerks, or auras of déjà vu, fear, or abnormal odors). The onset of epilepsy is not increased during pregnancy. More than 95% of patients who have seizures during pregnancy have a history of epilepsy or have been receiving anticonvulsant therapy. Patients whose seizures are adequately controlled are not likely to experience a deterioration of their condition during pregnancy. On the other hand, patients who have experienced frequent and uncontrolled seizures before pregnancy likely will experience the same pattern, particularly during early pregnancy.

Clinical Findings

A detailed history from the patient and observers helps to distinguish true seizures from other forms of loss of consciousness, such as syncopal episodes, hysteric attacks, or hyperventilation. These problems do not commonly involve a postictal confusional state, nor do they usually involve loss of bladder or bowel control or tongue biting. Noncentral nervous system causes, such as hypoxia, hypoglycemia, hypocalcemia, and hyponatremia, also must be excluded. Finally, seizures may result from drug withdrawal, medications, or exposure to toxic substances; thus, appropriate physical examination and screening for toxic substances are important in patients suffering an apparent first seizure during pregnancy.

Diagnosis

Detailed neurologic work-up is required in patients whose first seizure occurs during pregnancy. Electroencephalogram (EEG), CT scan with shielding or MRI, and lumbar puncture are useful for detailing the cause of the seizure and are not contraindicated during pregnancy. In established epilepsy, EEG is useful to confirm the type of epilepsy and therefore provide the appropriate drug therapy.

Treatment

Treatment of epilepsy should consist of the medication that has been most beneficial for the patient and at the lowest possible dose to maintain seizure control with some caveats. Some antiepileptic agents are more likely to cause birth defects than are others, and attempts to change medications should be made prior to conception.

During pregnancy, anticonvulsant levels change as a result of decreased protein binding, increased plasma volume, and alterations in the absorption and excretion of drugs. In addition, lamotrigine, phenytoin, phenobarbital, and carbamazepine have an increased plasma clearance that probably is related to high hepatic metabolism. These factors most often lead to low antiseizure plasma levels. Noncompliance, morning sickness, and hyperemesis gravidarum are other reasons for low drug levels. Therefore, blood level measurements of antiseizure medications are used to monitor and maintain a therapeutic range. Levels should be checked at least each trimester and prior to delivery. More frequent monitoring may be needed. Because of decreased protein binding, serum free drug levels rather than routine serum levels will be more accurate. Breakthrough seizures can result from poor sleep in the third trimester because the patient cannot obtain a comfortable sleeping position. For patients with refractory seizures while taking medication, an attempt should be made to maximize the dosage and the level of 1 medication before switching or adding another agent.

In patients with status epilepticus, control of seizures is mandatory for the safety of the patient and fetus. Lorazepam 2 mg IV push followed by 2 mg IV every minute up to 0.1 mg/kg is first-line treatment. If seizures continue, phenytoin 20 mg/kg slow IV push at a rate of 50 mg/min or fosphenytoin 20

phenytoin equivalents/kg IV at 150 phenytoin equivalents/min can be given intravenously. General anesthesia can be considered if seizures persist. In these cases, cerebral edema almost invariably is present and may be reduced with dexamethasone, mannitol, or hyperventilation. Many cases of status epilepticus in pregnancy are the result of inadequate treatment with antiepileptic drugs, abrupt withdrawal of phenobarbital or benzodiazepines, noncompliance, or failure to monitor serum levels.

Complications & Prognosis

Antiepileptic drugs and seizures can negatively affect a fetus. Seizures can cause maternal and fetal injury, spontaneous abortion, premature labor, and fetal bradycardia. All antiepileptic drugs cross the placenta, equilibrate rapidly in cord blood, and may have teratogenic effects. The risk of anomalies among infants exposed to anticonvulsants is approximately 2-fold greater than in the general population. The previous thinking that women with seizure disorders had an increased risk of fetal malformations even without exposure to anticonvulsant medication has been disproved. The most common defects fall into 2 categories: major and minor malformations. Major malformations include orofacial clefts, neural tube defects, and congenital heart disease. Minor malformations consists of craniofacial anomalies (low-set ears, widely spaced eyes, etc), short neck, and hypoplastic fingernails. The *fetal hydantoin syndrome* (associated with phenytoin) was the first described association between antiepileptic drugs and birth defects. It affects 3–5% of exposed offspring. It is characterized by mental retardation, small-for-gestational-age size, craniofacial anomalies, and limb defects. A milder phenytoin-associated syndrome may be present at a greater frequency (8–15%) but is detectable only by careful assessment during the first 3 years of life. Use of trimethadione in pregnancy has been abandoned given the high rate of anomalies (up to 30%) associated with intrauterine trimethadione exposure.

The teratogenic potential of specific antiepileptic agents has been the subject of much debate. Prospective pregnancy registries have been established around the world to clarify the risks. The older anticonvulsants—ethosuximide, carbamazepine, phenobarbital, valproic acid, primidone, and phenytoin—are all pregnancy category D because of known increased risk of birth defects in exposed fetuses. Neural tube defects are most common with carbamazepine (0.5–1%) and valproic acid (1–2%). The North American AED (antiepileptic drug) Pregnancy Registry has determined that the overall major malformation rate with exposure to valproic acid is 10.7%. Other pregnancy registries and studies have found the teratogenic potential of valproic acid increases with doses higher than 1000 mg/d or levels higher than 70 µg/mL. Besides neural tube defects, hypospadias, polydactyly, and kidney and heart malformation have been associated with valproic acid, so its use during pregnancy should be avoided if possible. Phenobarbital, previously believed to be safe during pregnancy, has a malformation rate of 6.5%, which is slightly higher than the approximately 3% rate of other antiepileptic drugs such as carbamazepine, phenytoin, and lamotrigine. Less human data on the newer antiepileptic drugs are available, with the exception of lamotrigine and oxcarbazepine. All newer antiepileptic drugs are category C, but more data are needed before they can be deemed safe.

Treatment with 2 or more antiseizure medications approximately doubles the risk for malformations.

Women with existing seizure disorders who are contemplating pregnancy should be tested to determine whether they still require anticonvulsant therapy—particularly if anticonvulsants were started during childhood or if the patient has been seizure-free for 2–5 years. If a pregnant woman requires seizure medication, she should be informed of the likelihood of fetal anomalies associated with each drug, and a discussion regarding the risks and benefits of attempting to switch to a different or safer drug, if available, should ensue. The patient should be counseled regarding folic acid supplementation (4 mg/d) starting at least 3 months preconceptionally to possibly reduce the chance of neural tube defects.

If the patient is taking an antiseizure medication metabolized by the P450 liver enzyme system, she

should take vitamin K 10 mg/d from week 36 until delivery to prevent hemorrhage in her baby. This is in addition to the intramuscular vitamin K the infant will receive after delivery.

Antiepileptic drugs pass into the breast milk to varying degrees, depending on protein binding characteristics. The benefits of breast milk usually outweigh the small risk from the medication to the infant. If a breastfed infant is too sedated and not feeding well, presumably from the medication in the breast milk, breastfeeding should be suspended and supplanted with formula.

Mothers with frequent seizures must be counseled on seizure and infant safety. Sponge baths instead of tub baths and use of a strap on the changing table will decrease potential injury to an infant in case of a maternal seizure.

MULTIPLE SCLEROSIS

Multiple sclerosis is an autoimmune demyelinating process in the white matter of the central nervous system. It affects women twice as often as men and usually has its onset between the ages of 20 and 40 years. People in the Northern Hemisphere are more commonly affected. The cause is not known, but possible etiologies include environmental, viral, and genetic.

Clinical Findings

The 2 patterns of disease are relapsing remitting and primary progressive. Findings include weakness in the extremities, sensory loss, difficulty with coordination, and visual problems. Increased reflexes, spasticity, and bladder control problems develop over time. Myasthenia gravis should be ruled out with an anticholinesterase (neostigmine) challenge and acetylcholine receptor antibody testing. Guillain-Barré syndrome should be ruled out if the patient has a history of recent viral infection.

Diagnosis

Laboratory tests and imaging should be performed to rule out other possible etiologies. Serum should be checked for vitamin B₁₂, Lyme and HTLV-1 (human T-cell lymphotropic virus type 1) titers, erythrocyte sedimentation rate (ESR), ANA, and rheumatoid factor. An MRI would reveal lesions (plaques) in the white matter of the brain and spinal cord. Active plaques would enhance with contrast materials. An elevated level of immunoglobulin (Ig)G in the cerebrospinal fluid is virtually diagnostic.

Treatment

Treatment options include interferon beta-1a, interferon beta-1b, and glatiramer. These medications decrease relapse rates, decrease disease activity as measured by serial MRI, and decrease disease progression. The interferon beta-1b and 1a multiple sclerosis trials showed an increased rate of spontaneous abortions of exposed fetuses. Although the increased rate did not reach statistical significance, there is good reason for caution. In patients planning to become pregnant, interferon treatment should be switched to glatiramer until conception then discontinued once pregnancy is established. Symptomatic treatment of spasticity, pain, fatigue, and bowel and bladder dysfunction will be required as well. Intravenous immunoglobulin (IVIg) has been used in the postpartum period to decrease the risk of exacerbation with some success. Short courses of corticosteroids may be helpful if the patient has optic neuritis or other disabling relapse.

Complications & Prognosis

The disease is characterized by exacerbations and remissions, with 70% of patients experiencing slow progression over a number of years. Pregnancy does not appear to exert any deleterious effect on multiple sclerosis and may improve the rate of exacerbation. The risk of exacerbations is increased in the first 3 months postpartum. Family planning should be discussed because of the progressive nature of the disease. If so desired, families should be completed or started as soon as possible.

MYASTHENIA GRAVIS

Myasthenia gravis is a chronic disorder of the neuromuscular junction of striate muscles as result of acetylcholine receptor dysfunction. Antibodies to acetylcholine receptors usually are present. It occurs more commonly in females than in males, and its peak occurrence is in the third decade of life. It is characterized by abnormal voluntary muscle function with muscle weakness after repeated effort. Although some cases of myasthenia gravis appear to be hereditary, most adult cases appear to be acquired.

Clinical Findings

The most common symptom is easily fatigued small muscles, most frequently the ocular muscles, which results in double vision. Weakness usually increases as the muscles are used repeatedly. Patients who may not have noticeable symptoms in the morning may be easily diagnosed in the afternoon. Difficulties with swallowing and speech are not uncommon, and the facial muscles are almost always affected.

Diagnosis

The diagnosis can be confirmed by administering edrophonium (Tensilon; a total of 10 mg, consisting of 2 mg followed by 8 mg 45 seconds later) to assess improvement in muscular weakness. A radioimmunoassay for the acetylcholine receptor antibody can be performed. Repetitive nerve stimulation would show a decrement greater than 15% in a person with the condition.

Treatment

Treatment with anticholinesterases (eg, neostigmine) is the same as in the nonpregnant state, although dosages must be administered more frequently during pregnancy. Other treatment options include thymectomy, steroids, plasma exchange, and IVIG. During labor, anticholinesterases should be administered parenterally rather than orally. Parenteral and regional anesthesia are not contraindicated in labor. Curarelike agents (eg, aminoglycoside antibiotics) and magnesium sulfate, as well as the older general anesthetics such as ether and chloroform, should be avoided. Women taking anticholinesterase drugs are advised not to breastfeed.

Complications & Prognosis

One-third of pregnant patients with myasthenia experience exacerbation, one-third do not change, and one-third have a remission. The disease does not affect uterine activity because the uterus consists of smooth muscle. The length of labor is not affected. However, an assisted second stage might be considered because of maternal fatigue. Exacerbations are most common during the postpartum period. Placental transfer of acetylcholine receptor antibodies can occur, so the fetus should be monitored at frequent intervals during pregnancy with fetal kick counts and ultrasound. A rare finding in neonates is arthrogryposis multiplex congenita, congenital contractures secondary to lack of movement in utero. Antibodies may affect the fetal diaphragm and lead to pulmonary hypoplasia and polyhydramnios. From 12–15% of newborns will be affected with transient myasthenia gravis. The mean duration of neonatal symptoms is 3 weeks.

SPIINAL CORD DISORDERS

Spinal cord lesions that are caused by trauma, tumor, infection, or vascular disorders usually do not prevent conception. Diagnosis and therapy should be performed without regard to pregnancy. In general, pregnancy coexisting with trauma to the spinal cord from any cause, even paraplegia, proceeds unremarkably with the exception of an increased frequency of urinary tract infections and sepsis from pressure necrosis of the skin. Fetal growth usually is unimpeded even though initial maternal weight is frequently < 100 lb because of muscular wasting. Generally labor proceeds without evidence of fetopelvic disproportion. Women whose paraplegia is related to anterior horn cell damage or to cord lesions below the tenth thoracic level have appropriate perception of labor contractions and may require analgesia or anesthesia. In most patients, rapid, painless labors are the rule, with the only abnormality being a prolonged second stage because of decreased muscular effort. Paraplegic patients may develop autonomic hyperreflexia during labor due to loss of central regulation of the sympathetic nervous system below the level of the lesion. This is best managed with an epidural, continuous monitoring of the cardiac rhythm and blood pressures, and an assisted second stage.

DISORDERS OF CRANIAL NERVES

Palsies of the facial nerve due to inflammation are called *Bell's palsy*. Although patients may complain of paresthesia over the area of paralysis, this is strictly a motor disorder involving paralysis of the muscles of facial expression on 1 side that are innervated by the facial nerve. Given that approximately one-fifth of cases of Bell's palsy occur during pregnancy or shortly thereafter, it has been suggested that pregnancy increases the frequency of this disorder, although viral infections also have been causally related. Treatment with corticosteroids (prednisone 40–60 mg/d) and acyclovir is helpful if given within 1 week of onset. However, Bell's palsy usually is self-limited. Because the patient is unable to blink or close her eye on the affected side, corneal damage will occur if frequent eye drops and nighttime closure of the eye with patches and lubrication are not instituted. Rarely is surgical decompression of the nerve indicated.

GUILLAIN-BARRÉ SYNDROME

Guillain-Barré syndrome is an acute inflammatory demyelinating polyneuropathy often related to an upper respiratory or gastrointestinal infection or recent immunization. Rapid onset of weakness occurs, most frequently in an ascending pattern involving the extremities first then respiratory muscles and face. Hospitalization is required and supportive treatment aimed at preventing respiratory failure is mandatory. If the vital respiratory capacity falls to 800 mL or below, tracheostomy should be performed. Plasmapheresis or IVIG is the treatment of choice to shorten the course of illness. Most patients progress normally through pregnancy and deliver at term, so abortion is not mandated. On the other hand, if respiratory paralysis occurs near term, cesarean delivery may be indicated to improve ventilation.

PERIPHERAL NEUROPATHIES

Carpal tunnel syndrome is a neuropathic disorder related to median nerve compression by swelling of the tissue in the synovial sheaths at the wrist. Symptoms usually are limited to paresthesia over the thumb, index, and middle fingers and the medial portion of the ring finger. Most commonly, symptoms are noted at night and usually are best treated conservatively with elevation of the affected wrist and splinting. The syndrome usually abates postpartum. Surgery and corticosteroids are rarely indicated.

Compression of the femoral or obturator nerve can occur from retraction at the time of cesarean delivery or hysterectomy, but it is most commonly related to pressure of the fetus just before and during vaginal delivery.

Femoral nerve palsy results in weakness of the iliopsoas and quadriceps muscles and sensory loss over the anterior thigh. Obturator nerve palsy is characterized by adduction weakness of the thigh and minimal sensory loss over the medial aspect of the affected limb. *Peroneal neuropathy* reveals footdrop and weakness on dorsiflexion of the foot, occasionally with paresthesia in the foot and second toes. This disorder usually appears 1–2 days postpartum and may be related to prolonged episiotomy repair and to pressure on the nerve from knee stirrups. Women at risk include small women with relatively large babies, those who have had midforceps rotations, and those who have had prolonged labor, especially with abnormally large infants (owing to compression of the L4–5 lumbosacral nerve trunk). The prognosis is excellent with conservative therapy, but occasionally a short leg brace is necessary.

Brachialgia or the *thoracic outlet syndrome* occurs when the brachial plexus and subclavian artery are compressed by the clavicle and first rib. Occurrence in pregnancy is increased because of the greater weight of the breasts and abdomen. The pain is referred to the lateral aspect of the hand and forearm, although motor symptoms are rare. Blanching of the fingers and exacerbation of symptoms when the hands are elevated are diagnostic. The syndrome usually is self-limited; posture instruction and strengthening of shoulder suspension muscles are helpful. Surgical removal of the rib is very occasionally necessary (as in the nonpregnant patient).

Herniation of intervertebral disks occurs more commonly in the lumbar than the cervical region. There are both motor and sensory findings along the distribution of the sciatic nerve. It is limited to 1 extremity and must be differentiated from more serious disorders such as spinal cord tumors and hemorrhage. Diagnosis usually can be made by physical examination and history. MRI of the spine is the best diagnostic modality if needed. Conservative management with bedrest and physical therapy is helpful. The process should cause no problems during pregnancy or vaginal delivery unless the patient has cervical disk disease. In that event, cesarean delivery is advised to prevent herniation and paralysis. Surgical correction should be avoided during pregnancy if possible.

RHEUMATOID ARTHRITIS

Rheumatoid arthritis is a chronic autoimmune disease characterized by symmetric inflammatory synovitis. The prevalence in North America is 0.5–3.8%, and it occurs 3 times more frequently in women. Symptoms of rheumatoid arthritis are insidious, with a prodrome of fatigue, weakness, generalized joint stiffness, and myalgias preceding the appearance of joint swelling. The course is variable and unpredictable, with spontaneous remissions and exacerbations. Laboratory findings are mild leukocytosis, elevated ESR (which may not always reflect the activity of the disease), and a positive rheumatoid factor (in the majority of patients).

Treatment consists of rest, anti-inflammatory drugs, splints, physical therapy, a well-balanced diet, and adequate movement of all joints. Cyclooxygenase (COX)-1 and COX-2 inhibitors should be avoided in pregnancy. If they are used, therapy should be limited to short courses prior to 32 weeks' gestation to avoid premature closure of the ductus arteriosus. The amniotic fluid index should be followed for oligohydramnios. Low-dose oral corticosteroid therapy or hydroxychloroquine can be substituted safely for COX inhibitors. Tumor necrosis factor (TNF)- α inhibitors, penicillamine, gold, and methotrexate should be avoided. Symptoms improve during pregnancy in approximately 75% of women. However, many patients relapse within 6 months postpartum. The activity of the disease during pregnancy is best followed by assessment of duration of morning stiffness and the number of joints involved. Levels of Ro/SS_A and La/SS_B antibodies should be obtained to determine the fetal risk for complete heart block. In cases of severe postpartum exacerbation, early termination of breastfeeding may be necessary early in order to allow the full range of pharmacologic therapy, including TNF- α inhibitors.

SYSTEMIC LUPUS ERYTHEMATOSUS

Systemic lupus erythematosus (SLE) is an multisystem autoimmune disorder with a wide spectrum of disease manifestations. It is of interest to obstetricians because it predominantly affects women (10:1) of reproductive age. The diagnosis can be made when 4 of the following criteria are present: malar rash, discoid rash, photosensitivity, oral ulcers, serositis, renal disorders, neurologic disorders, hematologic disorders (hemolytic anemia, leukopenia, thrombocytopenia), immunologic disorders (anti-DNA, anti-SM, false-positive Venereal Disease Research Laboratory [VDRL] test), or an abnormal ANA titer. Common serologic markers of SLE are present 5 years before the diagnosis is made in up to 50% of women. Complications of pregnancy characteristic of SLE may precede the clinical diagnosis by many years as well. The differential diagnosis includes rheumatoid arthritis, drug-induced SLE syndromes, polyarteritis, chronic active hepatitis, and, late in pregnancy, preeclampsia. Common symptoms at presentation in pregnancy are malaise, fever, myalgias, and weight loss.

Management during pregnancy includes a careful history, physical examination, and laboratory evaluation. A history of prior spontaneous abortions or fetal losses should be elicited. The history should note the manifestations of SLE in the past; determination of the severity of disease activity is important in anticipating pregnancy complications. Although the fertility rate of patients with SLE is normal, patients have a higher percentage of total fetal losses. This may be associated with the presence of antiphospholipid antibodies. Physical examination should focus on signs of active disease. Laboratory evaluation should include a complete blood count, serum chemistries, and liver function tests. ANA (if the diagnosis is not previously confirmed), double-stranded DNA, urine protein, C3, C4, and CH₅₀ tests should be obtained. Subsequent changes in these values may herald a flare of lupus nephritis. The results of the SS_A, lupus anticoagulant, anticardiolipin antibody, and anti- β_2 glycoprotein I tests should be known. The presence of SS_A is associated with neonatal lupus, manifested by cutaneous lesions or congenital heart block. Anticardiolipin antibody and lupus anticoagulant anti-beta 2 glycoprotein 1 tests are associated with antiphospholipid antibody syndrome (APS), which predisposes patients to

thromboembolic events, fetal death, fetal growth restriction, and preeclampsia. Prophylactic treatment with daily baby aspirin and heparin is recommended when APS is diagnosed. Diagnostic criteria require a clinical event (as listed above) plus a positive lupus anticoagulant result or moderate- to high-titer anticardiolipin antibody (> 20 GPL or MPL) or a positive anti-beta 2 glycoprotein 1. These tests should be positive on two occasions 12 weeks apart. Most fetal loss in SLE appears to be due to concomitant APS, which occurs in approximately 30% of patients.

Considerable controversy exists about the effects of pregnancy on SLE and vice versa. Most patients who become pregnant while their SLE is not active for at least 6 months seem to have few problems except for a 2-to 3-fold increased risk of superimposed preeclampsia and fetal growth restriction; the risk of a lupus flare is 20%. Women with active SLE are at very high risk for superimposed preeclampsia (60–80%), fetal growth restriction, preterm birth, and lupus flare (50–80%). Women with preexisting renal disease frequently have some deterioration in renal function, but it is irreversible in only 10% of cases.

Distinguishing between superimposed preeclampsia in the third trimester and an SLE flare often is difficult. In fact, it is not possible to say with certainty that preeclampsia is not present, but careful consideration can suggest whether an SLE flare is a contributing factor. In a pregnancy remote from term, aggressive empiric therapy of presumed SLE may allow significant prolongation of pregnancy.

Serial ultrasounds for fetal growth and antenatal testing starting at 32–34 weeks should be instituted to ensure fetal well-being. Delivery is often recommended at 38–39 weeks' gestation. Uterine artery Doppler at midgestation can be used to predict early-onset preeclampsia and fetal growth restriction.

The mainstay of treatment of SLE in pregnancy consists of corticosteroids, hydroxychloroquine, and azathioprine. Corticosteroids appear to be weak teratogens resulting in 1 extra facial cleft for every 1000 first-trimester exposures. Thereafter is a risk of premature rupture of membranes (PROM) and preterm birth, but usually after 34 weeks' gestation. Little information on the use of newer agents, such as mycophenolate, is available. The chance of successful pregnancy outcome for women with SLE has improved dramatically over the years with better understanding of the natural history of the disease and medical therapy in pregnancy.

SCLERODERMA

Pregnancy in patients with scleroderma is rare, as the disorder occurs most frequently in patients beyond reproductive age. Symptoms appear to improve or remain unchanged. One study did show an increase in preterm births. Pregnancy progresses normally in otherwise stable disease. When scleroderma-related renal disease and hypertension are present, pregnancy can be complicated by malignant hypertension.

Current OB/GYN > Chapter 26. Hematologic Disorders in Pregnancy >

ANEMIA

Anemia is a significant maternal problem during pregnancy. The Centers for Disease Control defines anemia as a hemoglobin concentration of less than 11 g/dL (hematocrit of < 33%) in the first or third trimester or a hemoglobin concentration of less than 10.5 g/dL (hematocrit < 32%) in the second trimester. A pregnant woman will lose blood during delivery and the puerperium, and an anemic woman is at increased jeopardy of blood transfusion and its related complications.

During pregnancy, the blood volume increases by approximately 50% and the red blood cell mass by approximately 33%. This relatively greater increase in plasma volume results in a lower hematocrit but does not truly represent anemia.

Anemia in pregnancy most commonly results from a nutritional deficiency in either iron or folate. Pernicious anemia due to vitamin B₁₂ deficiency almost never occurs during pregnancy. Other anemias occurring during pregnancy include anemia of chronic disease; anemia due to hemoglobinopathy; immune, chronic (eg, hereditary spherocytosis or paroxysmal nocturnal hemoglobinuria), or drug-induced hemolytic anemia; and aplastic anemia.

Iron Deficiency Anemia

Iron deficiency is responsible for approximately 95% of the anemias during pregnancy, reflecting the increased demands for iron. The total body iron consists mostly of (1) iron in hemoglobin (approximately 70% of total iron; approximately 1700 mg in a 56-kg woman) and (2) iron stored as ferritin and hemosiderin in reticuloendothelial cells in bone marrow, the spleen, and parenchymal cells of the liver (approximately 300 mg). Small amounts of iron exist in myoglobin, plasma, and various enzymes. The absence of hemosiderin in the bone marrow indicates that iron stores are depleted. This finding is both diagnostic of anemia and an early sign of iron deficiency. Subsequent events are a decrease in serum iron, an increase in serum total iron-binding capacity, and anemia.

During the first half of pregnancy, iron requirements may not be increased significantly, and iron absorbed from food (approximately 1 mg/d) is sufficient to cover the basal loss of 1 mg/d. However, in the second half of pregnancy, iron requirements increase due to expansion of red blood cell mass and rapid growth of the fetus. Increased numbers of red blood cells and a greater hemoglobin mass require approximately 500 mg of iron. The iron needs of the fetus average 300 mg. Thus, the additional amount of iron needed due to the pregnancy is approximately 800 mg. Data published by the Food and Nutrition Board of the National Academy of Sciences show that pregnancy increases a woman's iron requirements to approximately 3.5 mg/d. This need outstrips the 1 mg/d of iron available from the normal diet and must be met by supplementation of at least 40 mg/d of elemental iron (10% of which is absorbed).

Clinical Findings

SYMPTOMS AND SIGNS

The symptoms may be vague and nonspecific, including pallor, easy fatigability, headache, palpitations, tachycardia, and dyspnea. Angular stomatitis, glossitis, and koilonychia (spoon nails) may be present in

long-standing severe anemia.

LABORATORY FINDINGS

The hemoglobin may fall as low as 3 g/dL, but the red cell count is rarely below $2.5 \times 10^6/\text{mm}^3$. The red cells usually are hypochromic and microcytic, with mean corpuscular volumes of less than 79 fL. Serum ferritin concentrations fall to less than 15 $\mu\text{g}/\text{dL}$ and transferrin saturation to less than 16%. Serum iron levels usually are less than 60 $\mu\text{g}/\text{dL}$. The total iron-binding capacity is elevated in both normal pregnancies and pregnancies affected by iron deficiency anemia and therefore is of little diagnostic value by itself. The reticulocyte count is low for the degree of anemia. Platelet counts are frequently increased, but white cell counts are normal. Bone marrow biopsy demonstrates lack of stainable iron in marrow macrophages and erythroid precursors but usually is unnecessary in uncomplicated iron deficiency anemia.

Differential Diagnosis

Anemia due to chronic disease or an inflammatory process (eg, rheumatoid arthritis) may be hypochromic and microcytic. Anemia due to thalassemia trait can be differentiated from iron deficiency anemia by normal serum iron levels, the presence of stainable iron in the marrow, and elevated levels of hemoglobin A₂. Other less common causes of microcytic, hypochromic anemia include sideroblastic anemia and anemia due to lead poisoning.

Complications

Iron deficiency anemia normally does not endanger the pregnancy unless it is severe, in which case intrauterine growth retardation and preterm labor may result.

Angina pectoris or congestive heart failure may develop as a result of marked iron deficiency anemia. Sideropenic dysphagia (Paterson-Kelly syndrome, Plummer-Vinson syndrome) is a rare condition characterized by dysphagia, esophageal web, and atrophic glossitis due to long-standing severe iron deficiency anemia.

Prevention

During the course of pregnancy and the puerperium, at least 60 mg/d of elemental iron should be prescribed to prevent anemia.

Treatment

In an established case of anemia, prompt adequate treatment is necessary.

ORAL IRON THERAPY

Ferrous sulfate 300 mg (containing 60 mg of elemental iron, of which approximately 10% is absorbed) should be given 3 times per day. If this agent is not tolerated, ferrous fumarate or gluconate should be prescribed. Therapy should be continued for approximately 3 months after hemoglobin values return to normal in order to replenish iron stores. Hemoglobin levels should increase by at least 0.3 g/dL/wk if the patient is responding to therapy.

Iron is best absorbed in the ferrous or reduced form from an empty stomach. Administering ascorbic acid at the time of iron supplementation creates a mildly acidic environment that aids the absorption of iron.

PARENTERAL IRON THERAPY

The indication for parenteral iron is intolerance of, or refractoriness to, oral iron. In most cases of moderate iron deficiency anemia, the total iron requirements equal the amount of iron needed to restore hemoglobin levels to normal or near normal plus 50% of that amount to replenish iron stores.

Iron dextran is the most widely available parenteral iron preparation in the United States. Each 2-mL vial

provides 100 mg of elemental iron. After a 0.5-mL test dose, iron dextran can be administered intramuscularly or intravenously at a rate not to exceed 100 mg/d of elemental iron. Intramuscular injection must always be given into the muscle mass of the upper outer quadrant of the buttock with a 2-inch, 20-gauge needle, using the Z technique (ie, pulling the skin and superficial musculature to one side before inserting the needle to prevent leakage of the solution and subsequent tattooing of the skin). Intramuscular iron raises hemoglobin concentration only slightly faster than oral iron administration due to slow and occasionally incomplete mobilization of iron from the muscle. Risks of parenteral iron administration include anaphylactic reaction, muscle necrosis, and phlebitis.

Folic Acid Deficiency Anemia (Megaloblastic Anemia of Pregnancy)

Megaloblastic anemia of pregnancy is almost exclusively caused by folic acid deficiency and is common where nutrition is inadequate. In the United States, access to fresh vegetables and the fortification of grains makes folate deficiency much less common than in the developing world.

In the nonpregnant woman, the minimum daily intake of folate necessary for adequate hematopoiesis and to maintain stores is 50 mg. However, this requirement increases during pregnancy. In order to meet this need and to decrease the neural tube defects associated with folate deficiency, a dietary supplement of at least 400 mg/d of folic acid is recommended.

Additional folic acid may be required in states of heightened DNA synthesis, such as multifetal gestation. Similarly, patients with a chronic hemolytic anemia such as sickle cell anemia require additional folate supplementation in order to meet the demand imposed by increased hematopoiesis. Other hemolytic states are also commonly complicated by folic acid deficiency, including hereditary spherocytosis and malaria.

Folic acid absorption or metabolism may be impaired by the use of oral contraceptives, pyrimethamine, trimethoprim-sulfamethoxazole, primidone, phenytoin, or barbiturates. Alcohol consumption also interferes with folate metabolism. Jejunal bypass surgery for obesity or the malabsorption syndrome (sprue) may impair folic acid absorption.

Clinical Findings

SYMPTOMS AND SIGNS

The symptoms are nonspecific (eg, lassitude, anorexia, nausea and vomiting, diarrhea, and depression). Pallor often is not marked. Rarely, a sore mouth or tongue is present. Occasionally, purpura may be a clinical manifestation. Megaloblastic anemia should be suspected if iron deficiency anemia fails to respond to iron therapy.

LABORATORY FINDINGS

Folic acid deficiency results in a hematologic picture similar to that of true pernicious anemia (due to vitamin B₁₂ deficiency), which is extremely rare in women of childbearing age.

The hemoglobin may be as low as 4–6 g/dL, and the red cell count may be less than 2 million/ μ L in severe cases. Extreme anemia often is associated with leukocytopenia and thrombocytopenia.

The red cells are macrocytic (mean corpuscular volume usually > 100 fL) and appear as macroovalocytes on peripheral blood smear. However, in pregnancy macrocytosis may be concealed by accompanying iron deficiency or thalassemia. Up to 70% of folate-deficient patients also lack iron stores.

Serum folate levels less than 4 ng/mL are suggestive of folic acid depletion in nonpregnant patients. However, in otherwise normal pregnant patients, folate tends to fall slowly to low levels (3–6 ng/mL) with advancing gestation. The red cell folate level in megaloblastic patients is lower, but in 30% of patients the values overlap. The peripheral white blood cells are hypersegmented. Seventy-five percent

of folate-deficient patients have more than 5% neutrophils with 5 or more lobes, but this also may be true for 25% of normal pregnant patients.

The urinary excretion of formiminoglutamic acid (FIGLU) has been used to diagnose folate deficiency, but levels are abnormal only in severe megaloblastic anemia. Bone marrow aspirate demonstrates megaloblastic erythropoiesis but usually is not necessary for diagnosis. Serum iron and vitamin B₁₂ levels should be normal.

Treatment

Folic acid 1–5 mg/d orally is continued for several weeks after delivery or for several weeks in patients diagnosed in the puerperium. This therapy produces the maximum hematologic response, replaces body stores, and provides the minimum daily requirements. The hematocrit should rise approximately 1% each day, beginning on day 5–6 of therapy. The reticulocyte count should become elevated after 3–4 days of therapy and is the earliest morphologic sign of response. Iron supplementation should be administered as indicated.

Prognosis

Megaloblastic anemia due to folate deficiency during pregnancy carries a good prognosis if adequately treated.

The anemia usually is mild unless associated with multifetal pregnancy, systemic infection, or hemolytic disease (eg, sickle cell anemia). Low birthweight as well as fetal neural tube defects are known to be associated with maternal folic acid deficiency. The associations with placental abruption, spontaneous abortion, and preeclampsia–eclampsia are not universally accepted. Even without treatment, anemia due to folate deficiency usually resolves after delivery when folate demands normalize.

Aplastic Anemia

Aplastic anemia with primary bone marrow failure during pregnancy is rare. The anemia may be secondary to exposure to known marrow toxins, such as chloramphenicol, phenylbutazone, mephenytoin, alkylating chemotherapeutic agents, or insecticides. In approximately two-thirds of cases, no obvious cause is detected. Idiopathic aplastic anemia in pregnancy may have a spontaneous remission following delivery or pregnancy termination but may recur in subsequent pregnancies. The condition likely is immunologically mediated.

Clinical Findings

The rapidly developing anemia causes pallor, fatigue, tachycardia, painful ulceration of the throat, and fever. The diagnostic criteria are pancytopenia and empty bone marrow on biopsy examination.

Complications

Aplastic anemia in pregnancy may cause increased fetal wastage, prematurity, or intrauterine fetal demise. Increased maternal morbidity and death usually are due to infection and hemorrhage.

Treatment

The patient must avoid any toxic agents known to cause aplastic anemia. Blood product replacement with packed red blood cells and platelets should be utilized as needed. In some cases, delivery or termination of pregnancy may be necessary. Bone marrow transplantation is performed if remission does not occur following delivery or termination of pregnancy. Other possible treatments include antithymocyte antibody, corticosteroids, or immunosuppressive agents. Infection must be treated aggressively with appropriate antibiotics, but most authorities do not recommend giving prophylactic antibiotics.

Drug-Induced Hemolytic Anemia

Drug-induced hemolytic anemia usually occurs as a result of drug-mediated immunologic red cell injury. For example, a drug can act as a hapten with an erythrocyte protein to which an antidrug antibody attaches. Hemolysis occurs as a result of the subsequent immune response. Many drugs used in pregnancy can have such an effect, including cephalosporins, acetaminophen, and erythromycin.

In African-American women, drug-induced hemolytic anemia is more likely caused by drug-induced oxidative damage rather than a drug-mediated immune mechanism. The most common congenital erythrocyte enzymatic defect to cause this condition is glucose-6-phosphate dehydrogenase (G6PD) deficiency. This X-linked disorder causes a heterozygous state in 10–15% of African-American females, but enzyme activity is variable due to random X-chromosome inactivation.

Decreased G6PD activity in one-third of patients in the third trimester causes an increased risk of hemolytic episodes. More than 40 substances toxic to susceptible people are recognized, including sulfonamides, nitrofurans, antipyretics, some analgesics, sulfones, vitamin K analogues, uncooked fava beans, some antimalarials, naphthalene, and nalidixic acid. Specific laboratory tests to identify susceptible individuals include a glutathione stability test and cresyl blue dye reduction test.

Clinical Findings

The red blood cell count and morphology are normal until hemolysis occurs. Levels of anemia are variable depending on the degree of hemolysis.

Complications

Exposure of the G6PD-deficient fetus to maternally ingested oxidant drugs (eg, sulfonamides) may produce fetal hemolysis, hydrops fetalis, and fetal death. A black pregnant woman probably should be screened for G6PD deficiency before starting sulfonamide therapy for urinary tract infection.

Treatment

Management includes immediate discontinuation of any suspected medications, treatment of intercurrent illness, and blood transfusion where indicated.

SICKLE CELL DISEASE

Sickle cell hemoglobin (hemoglobin S) results from a genetic substitution of valine for glutamic acid at codon 6 of the β -globin chains. Decreased oxygen tension causes hemoglobin S to form insoluble polymers in curvilinear strands. These polymers deform the normal biconcave structure of the erythrocyte. The process is reversible but eventually leads to cell membrane damage and permanent sickling.

Patients homozygous for the hemoglobin S gene have sickle cell anemia (SS disease), and those who are heterozygous have sickle cell trait. Approximately 8–10% of African-Americans carry the sickle cell trait, whereas approximately 1 in 500 has sickle cell anemia.

Other sickling syndromes exist when the gene for hemoglobin S is inherited along with the gene for another abnormal hemoglobin, such as hemoglobin C or thalassemia. Hemoglobin C, also caused by β -globin chain mutation, is less soluble than normal hemoglobin A and has a propensity to form hexagonal crystals. Women who are heterozygous for both the S and C genes have hemoglobin SC disease. Maternal mortality rates are as high as 2–3%. Hemoglobin SC disease is peculiarly associated with embolization of necrotic fat and cellular bone marrow with resultant respiratory insufficiency. Neurologic symptoms from fat embolism have been reported with sickle cell disease.

In hemoglobin S/beta thalassemia disease, the patient is heterozygous for both hemoglobin S and beta thalassemia. The severity of complications during pregnancy is related to hemoglobin S

concentrations in this particular disease.

Prenatal genetic counseling is of great importance. If both partners have the gene for S hemoglobin, their offspring have a 1 in 4 chance of having sickle cell anemia. Fetal DNA isolated from amniotic fluid cells is most useful for prenatal diagnosis of hemoglobinopathy in cases at risk.

Clinical Findings

Sickle cell disease is characterized by chronic hemolytic anemia and intermittent crises of variable frequency and severity. Although persons with sickle cell trait are not anemic and usually are asymptomatic, they have twice as many urinary tract infections as normal women and are at higher risk for preeclampsia. Additionally, their red blood cells tend to sickle when oxygen tension is significantly lowered.

SYMPTOMS AND SIGNS

Chronic Anemia

Chronic anemia results from the shortened survival time of the homozygous S red blood cells due to circulation trauma and intravascular hemolysis or phagocytosis by reticuloendothelial cells in the spleen and liver.

Sickling of Red Blood Cells

Intravascular sickling leads to vasoocclusion and infarction. Small blood vessels supplying various organs and tissues can be partially or completely blocked by sickled erythrocytes, resulting in ischemia, pain, necrosis, and organ damage.

Crises

Crises of variable frequency and severity occur. Pain crises involve the bones and joints. They usually are precipitated by dehydration, acidosis, or infection. An aplastic crisis is characterized by rapidly developing anemia. The hemoglobin may be as low as 2–3 g/dL due to cessation of red blood cell production. An acute splenic sequestration crisis is associated with severe anemia and hypovolemic shock, resulting from sudden massive trapping of red blood cells within the splenic sinusoids.

Other Manifestations

Other manifestations include increased susceptibility to bacterial infection; bacterial pneumonia and pulmonary infarction; myocardial damage and cardiomegaly; and functional and anatomic renal abnormalities in the form of sickle cell nephropathy or papillary renal necrosis, resulting in hematuria. Central nervous system manifestations include headache, convulsions, hemorrhage, or thrombosis (from vasoocclusion). Ophthalmologic abnormalities include anoxic retinal damage, retinal detachments, vitreous hemorrhages, and proliferative retinopathy. Hepatosplenomegaly or cholelithiasis may occur.

LABORATORY FINDINGS

Sickle cell anemia is associated with serious risks for mother and fetus. Screening for abnormal hemoglobin is imperative in the population at risk. Two screening tests are in common use. The sodium metabisulfite test uses 1 drop of fresh 2% reagent mixed on a slide with 1 drop of blood. Sickling of most red cells will occur in a few minutes with both sickle cell trait and sickle cell disease. The Sickledex test is a simple solubility test that uses 20 μ L of blood mixed with 2 mL of sodium dithionite reagent. Clouding of the solution indicates the presence of hemoglobin S. If the test is positive, the homozygous and heterozygous states must be differentiated by hemoglobin electrophoresis.

EFFECTS ON PREGNANCY

Pregnant women with sickle cell disease face increased rates of maternal mortality and morbidity from hemolytic and folic acid deficiency anemias, frequent crises, pulmonary complications, congestive heart failure, infection, and preeclampsia–eclampsia. It is encouraging, however, that maternal mortality has

decreased to 1% since 1972. There is an increased incidence of early fetal wastage, stillbirth, preterm delivery, and fetal growth restriction.

Treatment

Optimal prenatal care, including prevention or rapid treatment of complications, is necessary to increase the chance for a good outcome. Pneumococcal polyvalent vaccine has been shown to reduce the incidence of pneumococcal infection in adults with sickle disease and therefore is highly recommended. This vaccine is not contraindicated in pregnancy. Similarly, influenza vaccine should be administered annually. Folic acid 1 mg/d will prevent megaloblastic anemia, which can result from intense hematopoiesis. Serial ultrasonic evaluations are essential to assess fetal growth. Antepartum testing should begin at 32–34 weeks' gestation. Careful surveillance for asymptomatic bacteruria and demonstration of cure is important for preventing pyelonephritis. Regional anesthesia can be safely administered to patients with sickle cell disease while they are in labor.

In the management of crises, the most common predisposing factors—infection, dehydration, and hypoxia—should be evaluated and treated. Symptomatic treatment of pain crisis consists of intravenous fluid, oxygen supplementation, and adequate analgesics (eg, morphine). Bacterial pneumonia or pyelonephritis must be treated vigorously with intravenous antibiotics. Streptococcal pneumonia is common and is a serious complication. In all cases, adequate oxygenation must be maintained by face mask as necessary.

The concentration of hemoglobin S should be less than 50% of the total hemoglobin to prevent crisis. Blood transfusion should be considered in cases of a fall in hematocrit to less than 25%, but this decision must be guided by the individual patient history and her status during pregnancy. Important considerations are repeated crisis; symptoms of tachycardia, palpitation, dyspnea, or fatigue; and evidence of inadequate or retarded intrauterine growth.

Randomized controlled trials have shown that administration of prophylactic hypertransfusion or exchange transfusion is not necessary to prevent maternal and fetal complications, except in well-defined circumstances. Transfusion carries the risks of allergic reaction, delayed hemolytic reaction, isoimmunization, and transmission of infection.

Bone marrow transplant has been limited by the complications of infection and graft-versus-host disease but shows promise as a potential long-term solution to sickle cell anemia.

Prenatal diagnosis of sickle cell disease is possible using cells obtained from amniocentesis or chorionic villus sampling. Single-blastomere DNA analysis prior to in vitro fertilization has allowed for the successful transfer of unaffected embryos. In utero stem cell therapy with normal hemoglobin stem cells is a potential future treatment for affected fetuses.

THALASSEMIA

The thalassemias are genetically determined disorders of reduced synthesis of 1 or more of the structurally normal globin chains in hemoglobin. Thalassemia is found throughout the world but is concentrated in the Mediterranean coastal areas, central Africa, and parts of Asia. The high incidence in these regions may represent a balanced polymorphism due to heterozygous advantage.

All thalassemias are inherited as an autosomal recessive trait. The two major groups are the alpha and beta thalassemias, both of which affect the synthesis of hemoglobin A, which contains two α and two β chains. The severity of the anemia varies with the type of hemoglobin abnormality.

Pathophysiology

In beta thalassemia, hemoglobin β -chain synthesis is defective, but the α chains are produced normally; in alpha thalassemia, the reverse is true. The unbalanced synthesis results in a relative excess of the normally produced chain. The normal globin chains then form tetramers that precipitate within red blood cell precursors in the bone marrow, resulting in ineffective erythropoiesis, red cell sequestration and destruction, and hypochromic anemia. The most severe forms of this disorder may cause intrauterine or childhood death. A person who is heterozygous, or a carrier, for a thalassemia trait may be asymptomatic.

ALPHA THALASSEMIA

The most severe form of alpha thalassemia compatible with extrauterine life is hemoglobin H (β_4) disease, which results from deletion of 3 of the 4 α -globin genes. In patients with this disease, some normal hemoglobin A ($\alpha_2\beta_2$) is produced because 1 of the α -globin genes is present, but the excess of β -globin changes causes the formation of hemoglobin H (β_4) as well. Anemia of variable levels results that usually is worsened in pregnancy.

In alpha thalassemia minor, 2 α -globin genes are deleted, causing a mild hypochromic, microcytic anemia that must be differentiated from iron deficiency anemia. Women with this condition tolerate pregnancy well.

BETA THALASSEMIA

Beta thalassemia results from impaired β -globin chain production. Beta thalassemia major is the homozygous state, in which there is little or no production of β chains. At birth, the neonate usually is asymptomatic because fetal hemoglobin F ($\alpha_2\gamma_2$) contains no β -globin chain. However, this protection disappears at birth, when fetal hemoglobin production terminates. At approximately 1 year of age, a baby with defective β -globin production usually begins to show signs of thalassemia (anemia, hepatosplenomegaly) and requires frequent blood transfusions. Affected individuals often die in their late teens or early 20s because of congestive heart failure, often related to myocardial hemosiderosis and liver failure. However, improved treatment with transfusion and iron chelation have led to overall improved survival and even to successful pregnancies in women with beta thalassemia major.

Beta thalassemia minor, the heterozygous state, is frequently diagnosed only after the patient fails to respond to iron therapy or delivers a baby with homozygous disease. Such patients usually suffer from mild to moderate hypochromic microcytic anemia, with increased red blood cell count, elevated hemoglobin A₂ ($\alpha_2\delta_2$) concentrations, increased serum iron levels, and iron saturation greater than 20%.

Suspected adult cases of thalassemia are diagnosed by hemoglobin electrophoresis. Antenatal diagnosis of thalassemia is now possible. Molecular hybridization measures the number of intact α -globin structural genes in fetal cells obtained by amniocentesis. Preimplantation genetic diagnosis allows for the transfer of unaffected embryos after in vitro fertilization.

LYMPHOMA & LEUKEMIA

Hodgkin's Disease

The lymphoma of Hodgkin's disease is the most common lymphoma to affect women of childbearing age. Even so, it is uncommon during pregnancy, affecting only approximately 1 in 6000.

Clinical Features

Patients may be asymptomatic or have fever, weight loss, and pruritus. The most common finding is peripheral lymphadenopathy. Histologic evaluation of the affected nodes establishes the diagnosis.

Careful staging is essential prior to the initiation of treatment with radiotherapy or chemotherapy. Modifications of standard staging modalities, such as the use of magnetic resonance imaging (MRI), can allow for adequate staging during pregnancy. However, some procedures, such as staging laparotomy, after the first trimester impose risks to the pregnancy.

Treatment

Treatment is tailored to the individual based on the extent of disease and the gestational age. Radiotherapy is an effective treatment option if radiation scatter to the fetus can be minimized. Chemotherapy is relatively safe later in gestation but best avoided in the first trimester if the clinical situation allows. Pregnancy termination is an alternative if Hodgkin's disease is diagnosed early in gestation. Although pregnancy itself does not appear to adversely affect the lymphoma, pregnancy termination permits the aggressive radiotherapy and chemotherapy often necessary. Conversely, if the diagnosis is made later in gestation and the patient is asymptomatic, delaying therapy until fetal lung maturity is established may be reasonable.

Women with Hodgkin's disease are extremely susceptible to infection and sepsis. Sequelae of treatment include radiation pneumonitis causing restrictive lung disease, pericarditis leading to congestive heart failure, hypothyroidism, and ovarian failure. Given that 85% of relapses in Hodgkin's disease occur within 2 years, it is generally accepted that pregnancy should be deferred for 2 years following remission. The risk of second malignancies, especially leukemia, is dramatically increased.

Non-Hodgkin's Lymphoma

Until recently, non-Hodgkin's lymphomas were encountered infrequently in pregnancy. However, because 5–10% of individuals infected with the human immunodeficiency virus (HIV) will develop a lymphoma, the incidence of non-Hodgkin's lymphomas is rising. Similar to Hodgkin's disease, extensive staging is essential. Treatment with radiotherapy is indicated for localized disease, whereas chemotherapy is used for more extensive disease. Care of the pregnant patient with lymphoma requires a multidisciplinary approach by obstetrician gynecologists, hematologic oncologists, perinatologists, and neonatologists. With careful treatment, the fetuses of affected women appear to tolerate treatment of lymphoma quite well.

Leukemia

Leukemias are malignant proliferations of cells of the hematopoietic system. Acute leukemias are derived from primitive progenitor cells of either the myeloid lineage (acute myelogenous leukemia [AML]) or the lymphocytic lineage (acute lymphocytic leukemia [ALL]). Chronic leukemias are also derived from either myeloid cells (chronic myelogenous leukemia [CML]) or lymphocytic cells (chronic lymphocytic leukemia [CLL]). All leukemias are rare before age 40 years with the exception of ALL, a childhood disease with a median age at diagnosis of 10 years.

Clinical Features

Affected individuals often present with the symptoms of anemia (fatigue, weakness), thrombocytopenia (bleeding, bruising), or neutropenia (infection) caused by the replacement of normal hematopoietic cells with leukemia cells in the bone marrow. White blood cell count in the serum can be low, normal, or extremely elevated. Diagnosis is made by cytochemical, genetic, and immunochemical evaluations of the cells of a bone marrow biopsy or aspirate.

Treatment

Treatment of acute leukemia is based upon immediate initiation of chemotherapy. For example, the median survival time of untreated patients with AML is 3 months or less. Exposure to chemotherapy during organogenesis frequently results in fetal death. However, most authorities consider chemotherapy safe in the second and third trimesters. A period of pancytopenia following chemotherapy can be complicated by infection and hemorrhage. Patients often require erythrocyte and platelet transfusions, as well as antibiotic medications.

Acute leukemia during pregnancy is associated with premature delivery, fetal growth restriction, and fetal loss, but these findings are more likely due to chemotherapy and its complications rather than the leukemia itself.

HEMORRHAGIC DISORDERS

Although hemorrhagic disorders (eg, immune thrombocytopenic purpura [ITP], disseminated intravascular coagulation, circulating anticoagulants) are not common during pregnancy, these conditions could cause significant risks for both mother and fetus.

Gestational Thrombocytopenia

Incidental thrombocytopenia of pregnancy, also termed *gestational thrombocytopenia*, affects 5% of pregnancies. It is characterized by mild, asymptomatic thrombocytopenia with platelet levels usually greater than 70,000/ μ L. It usually occurs late in gestation and resolves spontaneously after delivery. Gestational thrombocytopenia has no association with fetal thrombocytopenia. Its etiology is unclear, although some authorities suspect that gestational thrombocytopenia represents a very mild form of ITP. Antiplatelet antibodies are isolated from patients in both groups and therefore do not aid in diagnosis. Routine obstetric management is appropriate.

Immune Thrombocytopenic Purpura

In ITP, also called idiopathic thrombocytopenic purpura, platelet destruction is secondary to a circulating immunoglobulin (Ig)G antiplatelet antibody that crosses the placenta and may affect fetal platelets.

Clinical Features

The maternal clinical picture varies from asymptomatic to minor bruises or petechiae, bleeding from mucosal sites, or rarely fatal intracranial bleeding. Splenomegaly may be present. In the peripheral circulation, the platelet count often is between 80,000 and 160,000/ μ L, but it may be lower. The bone marrow aspirate demonstrates hyperplasia of megakaryocytes, although this test is rarely indicated. The diagnosis can be made once laboratory evaluation demonstrates an isolated thrombocytopenia and other causes, such as drug-induced or HIV-related thrombocytopenia, have been excluded. Antiplatelet antibody testing is not diagnostic.

Treatment

The standard management is to initiate treatment when the platelet count falls to less than 30,000–50,000/ μ L, although significant bleeding does not begin until platelet levels are less than 10,000/

µL. Glucocorticoids suppress the phagocytic activity in the splenic monocyte-macrophage system, increasing platelet levels in approximately two-thirds of patients. Patients refractory to steroid therapy are candidates for immunoglobulin infusion, which has been a great benefit to most patients who fail glucocorticoid therapy. Splenectomy usually is reserved for patients refractory to prednisone and intravenous immunoglobulin. Immunosuppressive agents should be used with great caution and only in extraordinary cases of ITP in pregnancy. Transfusion of platelets and whole blood may be necessary to restore losses from acute hemorrhage or to normalize low perioperative platelet counts (< 50,000/mL).

Complications

Because maternal IgG antiplatelet antibodies cross the placenta, the fetus is at risk for severe thrombocytopenia. Fortunately, only approximately 10% of infants born to women with ITP have platelet counts less than 50,000/µL at birth. Antepartum identification of severely affected fetuses has proved difficult. Maternal and fetal platelet counts do not correlate well, nor do levels of maternal antiplatelet antibody and fetal platelet levels. Given the low incidence of severe neonatal thrombocytopenia and morbidity, most authorities do not recommend direct fetal platelet determination by fetal scalp sampling or umbilical cord blood sampling.

Circulating Anticoagulants

Circulating anticoagulants, mainly inhibitors of factor VIII, an IgG, can cause minor to severe bleeding from various sites. Bleeding may be spontaneous or due to trauma, surgery, or sometimes delivery. Treatment may include exchange transfusion with replacement of specific factors or use of corticosteroids or immunosuppressive agents.

THROMBOEMBOLISM

Venous thromboembolism (VTE) affects approximately 1 in 1000 pregnancies. Pregnancy and the puerperium are periods of increased risk for these events because they are hypercoagulable states. Indeed, all the elements of Virchow's triad (circulatory stasis, vascular damage, and hypercoagulability of blood) are present. Increased venous capacity during pregnancy coupled with compression of large veins by the gravid uterus causes venous stasis. Endothelial damage occurs at delivery and is more extensive following cesarean delivery, contributing to the increased risk of VTE following cesarean section. Coagulation is favored during pregnancy due to estrogen stimulation of coagulation factors and decreased activity of the fibrinolytic.

Inherited thrombophilias such as activated protein C resistance (most commonly due to the factor V Leiden mutation), prothrombin gene mutation, antithrombin III deficiency, protein C and protein S deficiency, along with acquired thrombophilias such as the antiphospholipid syndrome (APS), have emerged as important risk factors for VTE. Other risk factors include prior VTE, older age, smoking, and immobilization.

Superficial Thrombophlebitis

Patients with thrombosis of the superficial veins of the saphenous system present with tenderness, pain, or erythema along a vein. A palpable cord is sometimes present. Because of the possibility of concurrent deep vein thrombosis (DVT), compression ultrasound is reasonable to confirm the diagnosis and exclude DVT. Treatment consists of compression stockings, ambulation, leg elevation, local heat, and analgesic medications. Of note, the superficial femoral vein belongs to the deep venous system despite its name. A thrombus in this vein requires treatment for DVT.

Deep Vein Thrombosis

Approximately half of DVT in pregnancy occurs antepartum and half occurs postpartum. Previous clinical

practices that contributed to thrombosis, such as prolonged postpartum bed rest, likely falsely elevated the risk of DVT in the puerperium. Greater than 80% of DVT in pregnancy occurs in the left lower extremity rather than the right, a finding attributed to compression of the left iliac vein by the right iliac artery as it branches off the aorta.

Clinical Features

The presentation of DVT is variable but frequently includes lower extremity tenderness, swelling, color changes, and a palpable cord. Homan's sign, pain elicited by passive dorsiflexion of the foot, may be present. Occasionally, the extremity is pale and cool with decreased pulses due to reflex arterial spasm.

Diagnosis

The modality of choice for diagnosis of DVT is real-time ultrasound, used with duplex and color Doppler ultrasound. Venography remains the standard but has been largely replaced by the less invasive diagnostic tests. Magnetic resonance imaging is used when there is a strong clinical suspicion of thrombus not detected by ultrasound or if the ultrasound results are equivocal. With MRI, anatomy above the inguinal ligament can be evaluated as can pelvic blood flow.

Treatment

Anticoagulation, bed rest, and analgesia are the fundamental treatments of DVT. Ambulation with elastic stockings begins once all symptoms have abated, usually in 7–10 days. Patients are initially anticoagulated with unfractionated heparin or low-molecular-weight heparin. Low-molecular-weight heparin has a longer half-life and increased bioavailability, making administration easier and anticoagulant response more predictable. It is associated with fewer bleeding problems than unfractionated heparin and does not require laboratory monitoring. In the postpartum state, the patient can then transition to warfarin. Due to embryopathy and fetal hemorrhage, warfarin is contraindicated during pregnancy. Antepartum DVT is treated with anticoagulation for the rest of pregnancy and then for 6–12 weeks postpartum. Deep vein thrombosis occurring postpartum should be treated with anticoagulation for 3–6 months.

Pulmonary Embolism

Pulmonary embolism accounts for approximately 20% of maternal deaths in the United States. Its antepartum and postpartum prevalence are approximately equal, although postpartum pulmonary embolism is associated with higher mortality rates. Clinical evidence of DVT often precedes pulmonary embolization. However, given the prevalence of thrombosis originating in the iliac veins during pregnancy, antecedent DVT is frequently not clinically apparent.

Clinical Features

The most common presenting symptom of pulmonary embolus is dyspnea, followed by pleuritic chest pain, apprehension, cough, syncope, and hemoptysis. Associated signs include tachypnea and tachycardia.

Diagnosis

Initial evaluation of the symptoms associated with pulmonary embolism usually consists of arterial blood gas measurement, chest radiograph, and electrocardiogram. Ventilation–perfusion scintigraphy is used in most centers to evaluate for perfusion defects and ventilation mismatches that suggest pulmonary embolus. The test has negligible fetal radiation exposure. High-probability scans are indicative of pulmonary embolism in 88% of cases. Conversely, in patients with normal or near-normal scans, pulmonary embolism was detected by angiography only 4% of the time. However, the usefulness of this modality is limited by that fact that the majority of results are reported as intermediate- or low-

probability scans, categories without much diagnostic value. Because of these limitations, spiral computed tomographic (CT) pulmonary angiography is emerging as a useful, noninvasive modality for the detection of pulmonary embolism but is limited in the detection of multiple small emboli. Pulmonary artery catheterization with angiography remains the gold standard but is used less frequently due to its invasive nature.

Treatment

Treatment of pulmonary embolism is anticoagulation. Guidelines such as those published by the American College of Chest Physicians (2004) should be followed. The factors influencing anticoagulant choice (heparin vs. warfarin [Coumadin]) are the same as those for DVT. Therapeutic anticoagulation should be continued for at least 4–6 months to prevent recurrence. Vena caval filter use may be necessary should recurrent embolization occur despite anticoagulation.

Prevention

Prophylactic anticoagulation should be considered for women at high risk for thromboembolism during pregnancy. Women with a prior VTE that was not related to a temporary risk factor (eg, prolonged immobilization after injury) should receive prophylactic anticoagulation with heparin during pregnancy and the puerperium. Women with inherited thrombophilias that confer a high risk for thrombosis during pregnancy, such as antithrombin III deficiency or protein S deficiency, also should be anticoagulated. Recommendations for women with lower risk for thrombophilias, such as activated protein C resistance and the prothrombin gene mutation (G20210A), vary based on the individual woman's past medical and obstetric history. In general, women with these disorders and prior VTE or adverse pregnancy outcome, such as fetal death or severe preeclampsia, are offered anticoagulation.

SEPTIC PELVIC THROMBOPHLEBITIS

Septic pelvic thrombophlebitis is thrombosis in the veins of the pelvis due to infection. The most important risk factor is cesarean section, especially if complicated by infection. In fact, almost 90% of cases occur after cesarean delivery. The overall incidence is low, affecting only approximately 1 in every 2000 pregnancies.

Pathophysiology

Pelvic infection leads to infection of the vein wall and intimal damage. Thrombogenesis occurs at the site of intimal damage. The clot is then invaded by microorganisms. Suppuration follows, with liquefaction, fragmentation, and, finally, septic embolization.

Both the uterine and ovarian veins may be involved, as well as the common iliac, hypogastric, and vaginal veins and the inferior vena cava. The ovarian vein is the most common site of septic thrombosis (40% of cases). The onset of symptoms may be as early as 2–3 days postpartum or as late as 6 weeks following delivery.

Clinical Findings

The condition is suspected when fever persists in the puerperium in spite of adequate antibiotic therapy for aerobic and anaerobic organisms and no other discernible cause of fever. Abdominal pain and back discomfort are common presenting symptoms. A picket-fence fever curve ("hectic" fevers) with wide swings from normal to as high as 41 °C (105.8 °F) is seen in 90% of cases. Tachycardia and tachypnea may be present. Leukocytosis usually is present. Blood cultures drawn during fever spikes yield positive results more than 35% of the time.

Diagnosis

Pelvic examination often is consistent with a normal postpartum examination and therefore not helpful in diagnosing this condition. However, in approximately 30% of cases, hard, tender, wormlike thrombosed veins may be palpable in the vaginal fornices or in one or both parametrial areas. A temperature spike may be noted following examination because of disturbance of infected pelvic veins; this may be considered a diagnostic indication of septic pelvic thrombophlebitis. Chest radiograph often reveals evidence of multiple, small septic emboli. Computed tomography or MRI may eliminate other pelvic causes, such as abscess, and assist in the diagnosis of pelvic vein thrombosis.

Differential Diagnosis

The differential diagnosis includes pyelonephritis, meningitis, systemic lupus erythematosus, tuberculosis, malaria, typhoid, sickle cell crisis, appendicitis, and torsion of the adnexa.

Complications

The serious complications associated with this condition are septic pulmonary emboli, extension of the venous clot in the pelvis, renal vein thrombosis, ureteral obstruction, and death.

Treatment

The mainstays are anticoagulation with heparin and broad-spectrum antibiotics (including coverage for anaerobes and common Enterobacteriaceae). Within 48–72 hours of initiation of heparin therapy, fever should resolve. Treatment usually is empirically continued for 7–10 days.

Current OB/GYN > Chapter 27. Surgical Diseases & Disorders in Pregnancy >

SURGICAL DISEASES & DISORDERS IN PREGNANCY: INTRODUCTION

Surgical interventions other than cesarean section are performed in 1.5–2.0% of all pregnancies. Altered anatomy and physiology and potential risks to the mother and fetus make diagnosis and management of surgical disorders more difficult during pregnancy. Generally, the interests of mother and fetus are best served by the obstetrician's active participation throughout the mother's course of diagnosis and management of a nonobstetric surgical disorder, although usually the responsibility is shared with other specialists. It is imperative that the obstetrician be well informed about the ways in which surgical disorders influence pregnancy and vice versa, the risks of diagnostic and therapeutic procedures to the fetus, and appropriate management of preterm labor in the immediate postoperative period.

Surgical disorders can be either incidental to or directly related to the pregnancy. Diagnostic evaluation requires gentle, sensitive elicitation of physical signs, often without resorting to sophisticated diagnostic aids that involve risk to the developing fetus. Good judgment regarding the timing, methods, and extent of treatment is important. In the absence of peritonitis, visceral perforation, or hemorrhage, surgical disorders during gestation generally have little effect on placental function and fetal development.

MATERNAL CONSIDERATIONS

Pregnancy is accompanied by physiologic and anatomic changes that alter the evaluation and management of the surgical patient. The 30–50% increase in plasma volume during pregnancy affects cardiac output and may alter drug distribution and laboratory test results. Red cell mass increases but not as much as the plasma volume, resulting in a slight physiologic anemia. Colloid osmotic pressure is decreased during pregnancy. Increased interstitial fluid is seen as mild edema, particularly in the lower extremities. Systemic vascular resistance decreases during pregnancy. Systolic and diastolic blood pressures characteristically drop during the early second trimester, with a gradual return to baseline by term. Functional pulmonary residual capacity decreases due to limitation of diaphragmatic excursion. Minute ventilation increases due to increased tidal volume and respiratory rate. A compensated mild respiratory alkalosis exists. Increased renal blood flow is evidenced by increased glomerular filtration rate and decreased serum creatinine and blood urea nitrogen values. Gastrointestinal motility is diminished, resulting in delayed gastric emptying and constipation. The enlarging uterus may alter the anatomic relation among the different organs. When the patient is in the supine position, the enlarged uterus may compress the vena cava and result in the hypotensive vena cava compression syndrome.

FETAL CONSIDERATIONS

Optimal care of the pregnant surgical patient requires that potential hazards to the fetus be minimized. This includes risks associated with the maternal disease, diagnostic radiologic procedures, therapeutic drugs, anesthesia, and surgery. Assessment of the risks and benefits to the mother is relatively easy but less so for the fetus because of its relative inaccessibility.

A number of imaging modalities are available for diagnosis during pregnancy, including ultrasound (US), magnetic resonance imaging (MRI), computed tomography (CT), and x-ray. Although no harmful effects

from the diagnostic use of US and MRI during pregnancy are reported, exposure to radiation is associated with fetal risks. Limited diagnostic CT or x-ray procedures can be undertaken with care in the pregnant patient. The fetus should be shielded whenever possible. The risk of adverse fetal effects associated with radiation exposure changes with gestational age and is related to the radiation dose to the fetus. For example, before 8 weeks the embryo is most susceptible to radiation-induced growth restriction. At 8–15 weeks the embryo is the most susceptible to mental retardation, with an approximately 4% risk upon exposure at 10 rad (radiation absorbed dose) and 60% at 150 rad. The most common fetal defects seen with direct fetal irradiation of 10 rad or more are microcephaly, mental retardation, intrauterine growth restriction, and eye abnormalities. Current evidence suggests no increased structural or developmental fetal risk with radiation doses less than 5 rad. Concern exists regarding in utero radiation exposure associated with an increase in childhood neoplasms. The risk appears dose related. Fetal exposure to 1–2 rad is estimated to translate into a relative risk of 1.5–2.0 for leukemia during childhood. Table 27–1 outlines estimates of fetal radiation exposure with various diagnostic procedures. In summary, routine preoperative x-ray procedures are not justified. However, if a significant alteration in clinical management of the patient would result from the findings of a judiciously performed radiologic procedure, the limited fetal exposure risk is generally warranted.

Table 27–1. Estimated Fetal Radiation Exposure from Common Diagnostic Radiologic Procedures.

Procedure	Fetal Exposure	
	rad	mGY
Chest x-ray (2 views)	$2-7 \times 10^{-5}$	$2-7 \times 10^{-4}$
Mammogram (4 views)	$7-20 \times 10^{-3}$	0.02–0.07
Abdominal x-ray (1 view)	0.1	1
Hip x-ray (1 view)	$1-2 \times 10^{-3}$	0.01–0.02
Ventilation–perfusion scan	0.01–0.04	0.1–0.4
Helical CT chest	$1-10 \times 10^{-3}$	0.01–0.1
CT abdomen	1.7–3.5	17–35

Gray (Gy) is the International System unit for the radiation absorbed dose rad, which is the old but still frequently used unit (1 Gy = 100 rad). Radiographic exposure from a single diagnostic procedure to less than 5 rad (50 mGy) has not been associated with an increase in fetal abnormalities or pregnancy loss. Although concerns about exposure in the range from 5–10 rad (50–100 mGy) have been raised, serious developmental risk to the fetus is not known until the absorbed dose reaches 10 rad (100 mGy).

Fortunately, most women who require surgery during pregnancy are otherwise relatively healthy and undergo an uneventful postoperative course. Generally, the safety of nonobstetric surgery in pregnancy and general anesthesia has been well established. Nevertheless, some increased risks are associated with surgery and anesthesia during pregnancy, and purely elective surgical procedures should be postponed until after pregnancy. A population-based study from Sweden compared 5405 patients who underwent nonobstetric surgery using general anesthesia during pregnancy with 720,000 similar patients who did not receive general anesthesia. Adverse effects including low birth weight, prematurity, intrauterine

growth restriction, and early neonatal death are thought to correlate with the underlying condition that necessitates the surgical procedure. Although several studies have found no increased risk of congenital anomalies with anesthesia and surgery during pregnancy, 1 study of 572 women operated at 4–5 weeks' gestation suggests a possible increase in neural tube defects. Thus, despite the general safety of anesthetic agents in pregnancy, some concern remains regarding teratogenicity in early gestation, and all but truly emergent surgery should be postponed until the second trimester. The second trimester is the preferred surgery time over the third trimester, as the risk of preterm labor is lowest at that time. Whenever possible, regional anesthesia should be performed. No known reproductive toxicity is associated with currently used local anesthetic agents at recommended dose ranges. Short-term postoperative use of narcotic analgesic agents, frequently in combination with acetaminophen or nonsteroidal anti-inflammatory drugs, generally appears to produce no adverse fetal effects.

Because intrauterine asphyxia is a major risk to the fetus consequent to maternal surgery, monitoring and maintaining maternal oxygen-carrying capacity, oxygen affinity, arterial P_{O_2} , and placental blood flow throughout the preoperative, operative, and postoperative periods are important. Attention should be given to providing uterine displacement to prevent venocaval compression when the patient is in the supine position. Supplemental oxygen administration and maintenance of circulating volume also assist fetal oxygenation. A reduction in maternal blood pressure can lead directly to fetal hypoxia. Greater reductions in uteroplacental perfusion by direct vascular constriction and an increase in uterine tonus are noted in association with the use of vasopressors, especially those with predominantly α -adrenergic activity. Ephedrine, with its peripheral β -adrenergic effect, produces much less vasospasm and is the vasopressor of choice in the pregnant patient, especially for treating hypotensive complications of regional anesthesia. To detect fetal hypoxia, continuous electronic fetal heart rate monitoring should be used when maternal surgery is performed in the latter half of gestation as long as the monitoring device can function outside the sterile surgical field.

The severity of the inflammatory response associated with the disease treated by the surgery appears to be more important in determining pregnancy outcome than is the use of anesthesia or the surgical procedure itself. Premature labor does not appear to be a common result of procedures such as exploratory celiotomy unless visceral perforation and peritonitis are encountered or a low pelvic procedure is performed with significant uterine manipulation. Prophylactic use of tocolytics in this setting is controversial. Often, a single dose of a β -adrenergic agent such as terbutaline is sufficient to arrest contraction. Use of indomethacin may be preferred if significant inflammation is present. If possible, uterine activity should be monitored following surgery to detect preterm labor and allow for early intervention.

DIAGNOSTIC CONSIDERATIONS

Pain

Pain is the most prominent symptom encountered with acute abdominal conditions complicating pregnancy. Generalized abdominal pain, guarding, and rebound strongly suggest peritonitis secondary to bleeding, exudation, or leakage of intestinal contents. Cramping with lower central abdominal pain suggests a uterine disorder. Lower abdominal pain on either side suggests torsion, rupture, or hemorrhage of an ovarian cyst or tumor. Right lower or midabdominal pain suggests appendicitis. Disorders of the descending and sigmoid colon with left lower quadrant pain are infrequently encountered because of the relatively young age of obstetric patients. Midabdominal pain early in gestation suggests an intestinal origin. Upper abdominal pain is often related to the liver, spleen, gallbladder, stomach, duodenum, or pancreas. Constipation is a common problem but is rarely associated with other symptoms.

Other Symptoms

Abdominal pain associated with nausea and vomiting after the first trimester usually suggests a gastrointestinal disorder. Nausea and vomiting associated with the inability to pass gas or stool points to an intestinal obstruction. Diarrhea is seldom encountered in association with acute surgical problems except as a symptom of recurrent ulcerative colitis.

Syncope associated with pain and signs of peritoneal irritation usually indicates an acute abdominal emergency with rupture of a viscus, ischemia, or hemorrhage. A temperature of over 38 °C (100 °F) suggests infection, which may be localized by other clinical findings. Vaginal bleeding usually points to an intrauterine problem. Urinary tract infection is often accompanied by urinary frequency and urgency.

History Taking & Examination

Clues to the cause of surgical disorders in pregnancy are often found in a careful review of the medical history. The stage and status of pregnancy are also relevant. The patient with an acute abdomen should undergo careful assessment of the reproductive organs, and her vital signs and general condition should be noted as well as the presence or absence of bowel sounds, abdominal rigidity or rebound tenderness, and the presence or absence of a mass. The fewest possible number of abdominal examinations should be gently performed without haste and with adequate explanation, using the flat part of the hand and starting in an asymptomatic area.

Laboratory Studies

Several laboratory studies routinely used in the evaluation of surgical disease have altered normal values during gestation; they are discussed where appropriate for the specific disease entity. The white blood cell count is considered elevated if the value is above 16,000/ μ L in any trimester. An interval of several hours usually passes between onset of hemorrhage and detection of lowered hematocrit values.

GENERAL VERSUS REGIONAL ANESTHESIA

The type of anesthesia is determined primarily by the planned surgical procedure. As a general rule in pregnancy, it seems prudent to choose the anesthetic technique that requires minimal quantities of drugs and minimizes fetal exposure (eg, regional anesthesia) that is appropriate for the surgical procedure and the patient's condition. Advantages of general anesthesia include optimization of maternal and fetal oxygenation and reduction in intraoperative uterine irritability.

PRINCIPLES OF SURGICAL MANAGEMENT

Delay in diagnosis and performance of surgery is the factor primarily responsible for increased maternal morbidity rates and perinatal loss, especially with maternal abdominal trauma. With unmistakable signs of peritoneal irritation, evidence of strangulating intestinal obstruction with possible gangrene, or intra-abdominal hemorrhage, immediate surgical exploration generally is indicated. In subacute conditions, caution should be used in deciding to proceed with surgery. Surgery that is not urgent and can be delayed is best deferred until the second trimester or puerperium. Surgical techniques usually are not altered because of the pregnancy. Essentials of good preoperative care include adequate hydration, availability of blood for transfusion, and appropriate preoperative medication that will not decrease oxygenation for mother and fetus.

Gestational age, uterine size, the specific surgical disorder, and the anticipated type of surgery to be performed are important factors in the selection of the abdominal incision. At operation, the least extensive procedure necessary should be performed with as little manipulation of the uterus as possible. Unless an obstetric indication is present or the uterus interferes with performance of a procedure, it usually is best not to perform a cesarean delivery during an abdominal operation.

Postoperative care depends on the gestational age and the operation performed. For patients in the second half of gestation, electronic monitoring of fetal heart rate and uterine activity should be continued in the immediate postoperative period. Oversedation and fluid or electrolyte imbalance are to be avoided. Encouragement of early maternal activity and resumption of normal food intake are generally recommended.

LAPAROSCOPY IN PREGNANCY

Over the past decade, laparoscopy has been increasingly used during pregnancy in the management of a variety of surgical disorders, most commonly for the exploration and treatment of adnexal masses, for appendectomy, and for cholecystectomy. The major advantages are decreased postoperative morbidity, less pain, and shorter hospital stay and postoperative recovery time. Possible drawbacks are the risk of injury to the pregnant uterus, technical difficulty with exposure because of the enlarged uterus, increased carbon dioxide absorption, and decreased uterine blood flow secondary to excessive intra-abdominal pressure. Knowledge of the precise effects of laparoscopy on the human fetus is limited. During the first half of pregnancy, the risks inherent to the laparoscopic procedure do not appear to be substantially increased compared to the risks in nonpregnant patients. One population-based study of 2181 laparoscopies during pregnancy and 1522 laparotomies did not find any differential impact of laparoscopy versus laparotomy on perinatal outcome.

UPPER ABDOMINAL DISEASES & DISORDERS: INTRODUCTION

Early accurate diagnosis of serious abdominal surgical disease during pregnancy is more difficult for the following reasons: (1) altered anatomic relationships, (2) impaired palpation and detection of nonuterine masses, (3) depressed symptoms, (4) symptoms that mimic the normal discomforts of pregnancy, and (5) difficulty in differentiating surgical and obstetric disorders. In general, elective surgery should be avoided during pregnancy, but operation should be performed promptly for definite or probable acute disorders. The approach to surgical problems in pregnant or puerperal patients should be the same as in nonpregnant patients, with prompt surgical intervention when indicated. The risk of inducing labor with diagnostic laparoscopy or laparotomy is low, provided unnecessary manipulation of the uterus and adnexa is avoided. Spontaneous abortion is most likely to occur if surgery is performed before 14 weeks' gestation or when peritonitis is present.

APPENDICITIS

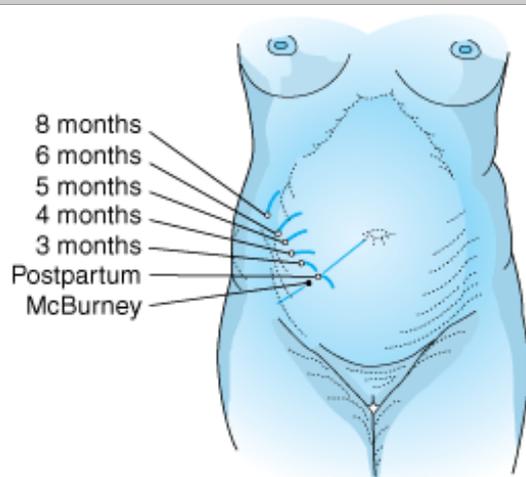

Acute appendicitis is the most common extrauterine complication of pregnancy for which laparotomy is performed. Suspected appendicitis accounts for nearly two-thirds of all nonobstetric exploratory celiotomies performed during pregnancy; most cases occur in the second and third trimesters.

Appendicitis occurs in 0.1–1.4 per 1000 pregnancies. Although the incidence of disease is not increased during gestation, rupture of the appendix occurs 2–3 times more often during pregnancy secondary to delays in diagnosis and operation. Maternal and perinatal morbidity and mortality rates are greatly increased when appendicitis is complicated by peritonitis.

SYMPTOMS AND SIGNS

The diagnosis of appendicitis in pregnancy is challenging. Signs and symptoms often are atypical and not dramatic. Right lower quadrant or middle quadrant pain almost always is present when acute appendicitis occurs in pregnancy but may be ascribed to so-called *round ligament pain* or urinary tract infection. In nonpregnant women, the appendix is located in the right lower quadrant (65%), in the pelvis (30%), or retroceally (5%), but in pregnancy the appendix may be upwardly displaced (Fig 27–1).

Figure 27–1.

All rights reserved.

Changes in position of the appendix as pregnancy advances. After the first trimester and continuing until the 8th month of gestation, the appendix may be gradually displaced above McBurney's point and may rotate upward and toward the right subcostal area.

The most consistent clinical symptom encountered in pregnant women with appendicitis is vague pain on the right side of the abdomen, although atypical pain patterns abound. Muscle guarding and rebound tenderness are much less demonstrable as gestation progresses. Rectal and vaginal tenderness are present in 80% of patients, particularly in early pregnancy. Nausea, vomiting, and anorexia usually are present, as in the nonpregnant patient. During early appendicitis, the temperature and pulse rate are relatively normal. High fever is not characteristic of the disease, and 25% of pregnant women with appendicitis are afebrile.

LABORATORY FINDINGS

The relative leukocytosis of pregnancy (normal 6000–16,000/ μ L) clouds interpretation of infection. Although not all patients with appendicitis have white blood cell counts above 16,000/ μ L, at least 75% show a left shift in the differential. Urinalysis may reveal significant pyuria (20%) as well as microscopic

hematuria. This is particularly true in the latter half of pregnancy, when the appendix migrates closer to the retroperitoneal ureter.

IMAGING

In the nonpregnant patient, CT of the abdomen with and without contrast has become an important tool aiding in the diagnosis of appendicitis. To avoid the risk of radiation to the fetus, US has a distinct role as the first-line imaging modality in pregnancy. Graded compression ultrasonography has been reported in small series to be accurate in the first and second trimesters but technically difficult in the third trimester. MRI has been found helpful in further aiding the diagnosis in patients for whom sonographic findings are nondiagnostic.

DIFFERENTIAL DIAGNOSIS

Pyelonephritis is the most common misdiagnosis in patients with acute appendicitis in pregnancy. The differential diagnosis of appendicitis includes ruptured corpus luteum cyst, adnexal torsion, ectopic pregnancy, abruptio placentae, early labor, round ligament syndrome, chorioamnionitis, degenerating myoma, salpingitis, cholangitis, mesenteric adenitis, neoplasm, diverticulitis, and parasitic infection of the intestine.

TREATMENT

The difficult clinical problem in treating appendicitis during pregnancy is making the decision to operate. Under appropriate conditions, laparoscopic appendectomy can be as safe as open appendectomy. Most large series report a negative surgical exploration rate between 13% and 35%. However, diagnostic accuracy is only approximately 50% at laparotomy or laparoscopy due to the many processes that may mimic appendicitis in pregnancy. When the appendix appears normal at laparotomy, careful exploration for other nonobstetric and obstetric conditions is important.

Treatment of nonperforated acute appendicitis complicating pregnancy is appendectomy. Prophylactic antibiotic therapy is controversial. However, broad-spectrum intravenous antibiotics are appropriate in the presence of perforation, peritonitis, or abscess formation. Induced abortion is rarely indicated. If drainage is necessary for generalized peritonitis, drains should be placed transabdominally and not transvaginally. During the first trimester, a vertical midline or paramedian incision on the right side is generally considered appropriate. Laparoscopy is an alternate surgical approach used with increasing frequency, especially in the first half of pregnancy. In the late second or third trimester, a muscle-splitting incision centered over the point of maximal tenderness usually provides optimal appendiceal exposure. As a rule, appendiceal disease is managed and the pregnancy is left alone. A Smead-Jones closure with secondary wound closure 72 hours later may be advisable when the appendix is gangrenous or perforated or in the presence of peritonitis or abscess formation.

Depending on the gestational age and expert neonatal care available, abdominal delivery occasionally is performed when peritonitis, sepsis, or a large appendiceal or cul-de-sac abscess occurs. Data are limited, so making definitive recommendations regarding the use of prophylactic tocolytics is difficult. It appears unnecessary in uncomplicated appendicitis but may be appropriate with advanced disease. Caution is indicated because of reports that tocolytics are associated with an increased risk of pulmonary edema in women with sepsis. Labor that follows shortly after surgery in the late third trimester should be allowed to progress because it is not associated with a significant risk of wound dehiscence. At times, the large uterus may help wall off an infection, which after delivery may become disrupted, leading to an acute abdomen within hours postpartum.

PROGNOSIS

Better fluid and nutritional support, use of antibiotics, safer anesthesia, prompt surgical intervention, and improved surgical technique have been important elements in the significant reduction of maternal

mortality from appendicitis during pregnancy. Similarly, the fetal mortality rate has significantly improved over the past 50 years. Postoperative preterm labor has been reported to occur in 13–25% of second or third trimester patients. Perinatal loss may occur in association with preterm labor and delivery or with generalized peritonitis and sepsis, occurring in 0–1.5% of uncomplicated appendicitis cases. With appendiceal rupture, fetal loss rates are reportedly as high as 30%. This is of particular concern because appendiceal rupture occurs most frequently in the third trimester. Thus it is imperative to avoid surgical delay. A higher negative laparotomy or laparoscopy rate may be an acceptable trade-off for a lower fetal mortality rate.

CHOLECYSTITIS & CHOLELITHIASIS

Gallbladder disease is one of the most common medical conditions and the second most common surgical disorder during pregnancy. Acute cholecystitis occurs in 1 in 1600 to 1 in 10,000 pregnancies. It has been estimated that at least 3.5% of pregnant women harbor gallstones. Multiparas are at increased risk of gallbladder disease. Both an increase in lithogenicity of the bile and a decrease in gallbladder contractility are seen during pregnancy.

SYMPTOMS AND SIGNS

Signs and symptoms are similar to those seen in the nonpregnant state and include anorexia, nausea, vomiting, dyspepsia, and intolerance of certain foods, particularly those with high fat content. Biliary tract disease may cause right upper quadrant, epigastric, right scapular, and even left upper quadrant or left lower quadrant pain that tends to be episodic. Biliary colic attacks often are of acute onset, seemingly are triggered by meals, and may last from a few minutes to several hours. Fever, right upper quadrant pain, and tenderness under the liver with deep inspiration (Murphy's sign) are often present in patients with acute cholecystitis.

LABORATORY FINDINGS

An elevated white blood cell count with an increase in immature forms is seen with acute cholecystitis. Abnormalities of liver function tests are often encountered, such as increases in aspartate transaminase (AST) and alanine transaminase (ALT) levels. Modest increases in the alkaline phosphatase and bilirubin levels are anticipated very early in cholecystitis or common duct obstruction. However, a more characteristic pattern of relatively normal AST and ALT levels with elevated alkaline phosphatase and bilirubin levels is generally found after the first day of the attack. These changes are not diagnostic and do not signify common bile duct stone or obstruction alone, but when present they serve to support the diagnosis.

ULTRASOUND FINDINGS

US findings of stones in the gallbladder, a thickened gallbladder wall, fluid collection around the gallbladder, a dilated common bile duct, or even swelling in the pancreas are suggestive of cholelithiasis and cholecystitis. The diagnostic accuracy of US for detecting gallstones in pregnancy is 95%, making it the diagnostic test of choice.

DIFFERENTIAL DIAGNOSIS

The major diagnostic difficulty imposed by pregnancy is differentiating between cholecystitis and appendicitis. In addition to gallstones, cholecystitis can be infectious secondary to *Salmonella typhi* or parasites. A number of other lesions of the biliary tract occur rarely during gestation, including choledochal cysts, which are seen as a spherical dilatation of the common bile duct with a very narrow or obstructed distal end. Associated pancreatitis may be present. Severe preeclampsia with associated right upper quadrant abdominal pain and abnormal liver function tests, hemolysis, elevated liver enzymes, and low platelet count (HELLP) syndrome, acute fatty liver of pregnancy, and acute viral hepatitis are in the differential diagnosis. The presence of proteinuria, nondependent edema, hypertension, and sustained

increases in AST and ALT levels compared with alkaline phosphatase level are clinical and laboratory features usually associated with preeclampsia.

COMPLICATIONS

Pancreatitis may frequently accompany cholecystitis during pregnancy. Removal of the gallbladder and gallstones may be preferred over conservative medical therapy when pancreatitis is concurrent. Other uncommon complications of cholecystitis during gestation are retained intraductal stones, cholangitis, and rupture of the cystic duct.

TREATMENT

The initial management of symptomatic cholelithiasis and cholecystitis in pregnancy is nonoperative with bowel rest, intravenous hydration, correction of electrolyte imbalances, intravenous antibiotics, and analgesics. This therapy results in resolution of acute symptoms in most patients. Surgical intervention is indicated if symptoms fail to improve with medical management, for recurrent episodes of biliary colic, and for complications such as recurrent cholecystitis, choledocholithiasis, and gallstone pancreatitis. Because recurrence rates for symptomatic biliary disease during pregnancy may be as high as 60%, active surgical management, especially in the second trimester, has been advocated in recent years. Recent literature has demonstrated the safety of open and laparoscopic cholecystectomy during pregnancy. Endoscopic retrograde cholangiopancreatography (ERCP) with endoscopic sphincterotomy may be an alternative for selected patients with common bile duct stones. Operative therapy for cholecystitis performed during the second and third trimesters does not appear to be associated with an appreciable increase in morbidity and mortality rates or fetal loss.

PROGNOSIS

The outcomes for mother and fetus following uncomplicated gallbladder surgery are excellent. Morbidity and mortality rates increase with maternal age and extent of disease.

ACUTE PANCREATITIS

The incidence of acute pancreatitis in pregnancy reportedly ranges from 1 in 1000 to 1 in 5000 deliveries. Pancreatitis occurs most frequently in the third trimester and puerperium. The mortality rate associated with acute pancreatitis may be higher during pregnancy because of delayed diagnosis. The ultimate cause of pancreatitis is the presence of activated digestive enzymes within the pancreas. Many cases of pancreatitis are idiopathic. As in the nonpregnant state, cholelithiasis is the most commonly identified cause, followed by alcoholism, lipidemia, viral- and drug-induced pancreatitis, familial pancreatitis, structural abnormalities of the pancreas or duodenum, severe abdominal trauma, vascular disease, and preeclampsia-associated pancreatitis.

SYMPTOMS AND SIGNS

Gravidas with pancreatitis usually present with severe, steady epigastric pain that often radiates to the back in general approximation of the retroperitoneal location of the pancreas. Often exacerbated by food intake, its onset may be gradual or acute and is frequently accompanied by nausea and vomiting. During gestation, patients may present primarily with vomiting with little or no abdominal pain. Although physical examination is rarely diagnostic, several findings of note may be present, including a low-grade fever, tachycardia, and orthostatic hypotension. The latter finding may be present with hemorrhagic pancreatitis in addition to Cullen's sign (periumbilical ecchymosis) and Turner's sign (flank ecchymosis). Epigastric tenderness and ileus also may be present.

LABORATORY FINDINGS

The cornerstone of diagnosis is the determination of serum amylase and lipase levels. Interpretation of serum amylase levels in pregnancy is difficult at times because of the physiologic, up to 2-fold rise in

serum amylase level during pregnancy. A laboratory serum amylase level that is more than 2 times above the upper limit of normal suggests pancreatitis. However, an elevated serum amylase level is not specific for pancreatitis because cholecystitis, bowel obstruction, hepatic trauma, or a perforated duodenal ulcer can cause similar serum amylase level elevations. Serum lipase level is a pancreas-specific enzyme and is very helpful in the differential diagnosis. Serum amylase levels usually return to normal within a few days of an attack of uncomplicated acute pancreatitis. In severe pancreatitis, hypocalcemia develops as calcium is complexed by fatty acids liberated by lipase.

ULTRASOUND DIAGNOSIS

Sonographic examination may demonstrate an enlarged pancreas with a blunted contour, peritoneal or peripancreatic fluid, and abscess or pseudocyst formation. Ultrasonography allows for the diagnosis of cholelithiasis, which may be etiologic for pancreatitis. The mere presence of gallstones, however, does not demonstrate etiologic relevance. US also is helpful for evaluating other differential diagnostic considerations.

DIFFERENTIAL DIAGNOSIS

Especially pertinent in the differential diagnosis of pancreatitis in pregnancy are hyperemesis gravidarum, preeclampsia, ruptured ectopic pregnancy (often with elevated serum amylase levels), perforated peptic ulcer, intestinal obstruction, acute cholecystitis, ruptured spleen, liver abscess, and perinephric abscess.

COMPLICATIONS

Although all of the usual complications of pancreatitis can occur in parturients, there is no special predisposition to complications during pregnancy. Acute complications include hemorrhagic pancreatitis with severe hypotension and hypocalcemia, acute respiratory distress syndrome, pleural effusions, pancreatic ascites, abscess formation, and liponecrosis.

TREATMENT

Treatment of acute pancreatitis is primarily medical and supportive, including bowel rest with or without nasogastric suction, intravenous fluid and electrolyte replacement, and parenteral analgesics. Antibiotics are reserved for cases with evidence of an acute infection. Pancreatic enzyme inhibitors have not been successful. Surgical exploration is reserved for patients with pancreatic abscess, ruptured pseudocyst, severe hemorrhagic pancreatitis, or pancreatitis secondary to a lesion that is amenable to surgery. Pregnancy does not influence the course of pancreatitis. Pancreatitis in pregnancy is managed as it is in the nonpregnant state, except that parenteral nutritional supplementation is considered at an earlier point in treatment to protect the fetus. In patients with gallstone pancreatitis, consideration is given to cholecystectomy or ERCP after the acute inflammation subsides.

PROGNOSIS

Maternal mortality rates as high as 37% were reported prior to the era of modern medical and surgical management. Respiratory failure, shock, need for massive fluid replacement, and severe hypocalcemia are predictive of disease severity. Perinatal losses are few, although preterm labor appears to occur in a high proportion of patients with acute pancreatitis in later gestation. Most recent single-institution series reflect a reduced maternal mortality rate of 3.4% and a fetal salvage rate of 89%.

PEPTIC ULCER DISEASE

Pregnancy appears to be somewhat protective against the development of gastrointestinal ulcers, as gastric secretion and motility are reduced and mucus secretion is increased. Close to 90% of women with known peptic ulcer disease experience significant improvement during pregnancy, but more than half will have recurrence of symptoms within 3 months postpartum. Thus, peptic ulcer disease occurring as a complication of pregnancy or diagnosed during gestation is encountered infrequently, although the exact incidence is unknown. Infection with *Helicobacter pylori* is associated with the development of peptic ulcer disease.

CLINICAL FINDINGS

Signs and symptoms of peptic ulcer disease in pregnancy can be mistakenly dismissed as being a normal part of the gravid state. Dyspepsia is the major symptom of ulcers during gestation, although reflux symptoms and nausea are also common. Epigastric discomfort that is temporally unrelated to meals is often reported. Abdominal pain might suggest a perforated ulcer, especially in the presence of peritoneal signs and systemic shock. Endoscopy is the diagnostic method of choice for these patients if empiric clinical therapy, including lifestyle and diet modifications, antacids or sucralfate, and empiric H₂-receptor antagonist therapy, fails to lead to improvement of symptoms.

DIFFERENTIAL DIAGNOSIS

Reflux esophagitis, a common occurrence in pregnancy, and Mallory-Weiss tears may result in symptoms very similar to those of peptic ulcer disease. Gastritis and irritable bowel syndrome must be ruled out. In recent years the diagnosis of persistent hyperemesis gravidarum has been linked to *H. pylori* infection.

TREATMENT

Dyspepsia during pregnancy first should be treated with dietary and lifestyle changes, supplemented with antacids or sucralfate. When symptoms persist, H₂-receptor antagonists or, in severe cases, proton pump inhibitors can be used. A 2-week course of antibiotics for *H. pylori* during pregnancy is controversial. Administration of triple-drug therapy for *H. pylori* often is deferred to the postpartum period because of the low risk of complications from peptic ulcer disease during pregnancy.

COMPLICATIONS

Fewer than 100 parturients with complications of peptic ulcer disease, such as perforation, bleeding, and obstruction, have been reported. Most of these cases have occurred in the third trimester of pregnancy. Gastric perforation during pregnancy has an exceedingly high mortality rate, partly because of the difficulty in establishing the proper diagnosis. Other causes of upper gastrointestinal bleeding in pregnancy are reflux esophagitis and Mallory-Weiss tears. Surgical intervention is indicated for significant bleeding ulcerations. In patients requiring surgery for complicated peptic ulcers late in the third trimester, concurrent cesarean delivery may be indicated to enhance operative exposure of the upper abdomen and to prevent potential fetal death or damage from maternal hypotension and hypoxemia.

ACUTE INTESTINAL OBSTRUCTION

Intestinal obstruction is an infrequently encountered complication of pregnancy that is estimated to occur in approximately 1–3 of every 10,000 pregnancies. However, it is the third most common nonobstetric reason for laparotomy during pregnancy (following appendicitis and biliary tract disease). It occurs most commonly in the third trimester. The most common causes of mechanical obstruction are adhesions (60%) and volvulus (25%), followed by intussusception, hernia, and neoplasm.

CLINICAL FINDINGS

The same classic triad of abdominal pain, vomiting, and obstipation is observed in pregnant and nonpregnant women with intestinal obstruction. Pain may be diffuse, constant, or periodic, occurring

every 4–5 minutes with small-bowel obstruction or every 10–15 minutes with large-bowel obstruction. Bowel sounds are of little value in making an early diagnosis of obstruction, and tenderness to palpation typically is absent with early obstruction. Vomiting occurs early with small-bowel obstruction. Guarding and rebound tenderness are observed in association with strangulation or perforation. Late in the course of disease, fever, oliguria, and shock occur as manifestations of massive fluid loss into the bowel, acidosis, and infection. The classic findings of bowel ischemia include fever, tachycardia, localized abdominal pain, and marked leukocytosis.

The diagnosis usually is confirmed by radiologic studies, which should be obtained when intestinal obstruction is suspected. A single abdominal series (upright and supine abdominal film) is nondiagnostic in up to 50% of early cases, but serial films usually reveal progressive changes that confirm the diagnosis. Volvulus should be suspected when a single, grossly dilated loop of bowel is seen. A volvulus primarily occurs at the cecum but may also be seen at the sigmoid colon. Occasionally, more extensive radiologic imaging is indicated.

DIFFERENTIAL DIAGNOSIS

The diagnosis of hyperemesis gravidarum in the second and third trimesters should be viewed with caution and made only after gastrointestinal causes of the symptoms have been excluded. Adynamic ileus of the colon (Ogilvie's syndrome) and pseudo-obstruction are included in the differential diagnosis but are rarely seen during pregnancy.

TREATMENT

The management of bowel obstruction in pregnancy is essentially no different from treatment of nonpregnant patients. The cornerstones of therapy are bowel decompression, intravenous hydration, correction of electrolyte imbalances, and timely surgery when indicated. The patient's condition must be rapidly stabilized. The amount of fluid loss often is underestimated and may be 1–6 L by the time obstruction is identified on a scout film. Aggressive hydration is needed to support both the mother and the fetus. A nasogastric tube should be placed. Surgery is indicated if perforation or gangrenous bowel is suspected or when the patient's symptoms do not resolve with medical management. A vertical midline incision on the abdomen provides the best operative exposure and can be extended as needed. Surgical principles for intraoperative management apply similarly to pregnant and nonpregnant patients. Cesarean delivery is performed first if the large uterus prevents adequate exposure of the bowel in term pregnancies or if indicated obstetrically. The entire bowel should be examined carefully because there may be more than one area of obstruction or limited bowel viability.

PROGNOSIS

Intestinal obstruction in pregnancy is associated with a maternal mortality rate of 6%, with losses occurring secondary to infection and irreversible shock. Early diagnosis and treatment are essential for an improved outcome. Perinatal mortality is approximately 20% and usually results from maternal hypotension and resultant fetal hypoxia and acidosis.

SPONTANEOUS HEPATIC & SPLENIC RUPTURE

Intra-abdominal hemorrhage during pregnancy has diverse causes, including trauma, preexisting splenic disease, and preeclampsia–eclampsia. Often, the exact cause cannot be determined preoperatively. Spontaneous hepatic rupture associated with severe preeclampsia–eclampsia may be manifested by severe abdominal pain and shock, with thrombocytopenia and low fibrinogen levels. Exploratory celiotomy should be undertaken immediately because early diagnosis, blood transfusion, and prompt operation have been associated with improved survival rates.

Bleeding from a lacerated or ruptured spleen does not cease spontaneously and requires immediate surgical attention. Evidence of a hemoperitoneum on imaging studies or a hemorrhagic peritoneal lavage in association with a falling hematocrit level and abdominal pain establish the presence of a hemoperitoneum.

RUPTURED SPLENIC ARTERY ANEURYSM

Autopsy data suggest that splenic artery aneurysm occurs in 0.1% of adults. It is estimated that 6–10% of lesions will rupture, with portal hypertension and pregnancy being the main risk factors. Twenty-five to 40% of ruptures occur during gestation, especially in the last trimester, and are a major cause of intraperitoneal hemorrhage. Pregnant women who develop ruptured splenic artery aneurysm have a 75% mortality rate, with an even higher fetal mortality rate of up to 95%. Most patients with this condition are thought preoperatively to have placental abruption or uterine rupture.

Prior to rupture, the presenting symptoms may be completely absent or vague. The most common symptom is vague epigastric, left upper quadrant, or left shoulder pain. In approximately 25% of patients a 2-stage rupture is seen, with a smaller primary hemorrhage into the lesser sac, which may allow for temporary tamponade of the bleeding until complete rupture into the peritoneal cavity occurs, causing hemorrhagic shock. A bruit may be audible. A highly diagnostic finding on flat x-ray film of the abdomen is demonstration in the upper left quadrant of an oval calcification with a central lucent area. In stable clinical situations, angiography can provide positive confirmation and is the gold standard for diagnosis. In pregnancy, however, ultrasonography and pulsed-wave Doppler studies are preferred in order to minimize fetal radiation exposure. A splenic artery aneurysm in a woman of childbearing age should be treated electively, even during pregnancy, because of the increased risk of rupture and associated mortality. The elective operative mortality rate reportedly ranges between 0.5% and 1.3%.

OVARIAN MASSES

The incidental finding of an adnexal mass in pregnancy has become more common with the routine use of ultrasonography. As many as 1–4% of pregnant women are diagnosed with an adnexal mass. The majority of the masses are functional or corpus luteum cysts and spontaneously resolve by 16 weeks' gestation. More than 90% of unilateral, noncomplex masses less than 5 cm in diameter that are noticed in the first trimester are functional and resolve spontaneously. Patients who undergo assisted reproduction present a special subgroup as their ovaries frequently have ovarian cysts in the first trimester due to ovarian hyperstimulation. More than 90% of these cysts resolve spontaneously. Pathologic ovarian neoplasms tend not to resolve. The most common pathologic ovarian neoplasms during pregnancy are benign cystic teratoma (21%), serous cystadenoma (21%), cystic corpus luteum (18%), and mucinous cystadenoma. Of the adnexal masses that persist, 1–10% will be malignant.

The three main reasons for advising surgery for an adnexal mass in pregnancy are the risks of rupture, torsion, and malignancy. The risk of malignancy can be further gauged by the ultrasonographic characteristics of the mass. Determination of the actual risk of rupture or torsion of a benign-appearing adnexal mass in pregnancy remains an unsettled issue. It is estimated that only approximately 2% of

such masses will rupture during gestation, and the incidence of torsion in recent published series ranges from 0–7%. The challenge to the clinician is to weigh for each individual patient these risks against the risks of abdominal surgery during pregnancy, including miscarriage, rupture of membranes, and preterm labor. If adnexal masses diagnosed in the first trimester require surgery in pregnancy, it is generally advisable to perform the operation via laparotomy or laparoscopy in the second trimester unless signs or symptoms suggestive of torsion or highly aggressive malignancy indicate the need for more immediate intervention. Similarly, asymptomatic ovarian masses that are initially noted in the third trimester of pregnancy can be followed until the time of delivery or postpartum because the size of the uterus may present problems with access during laparotomy and because preterm labor may be inadvertently induced.

Ultrasonography usually facilitates delineation of the size and consistency of adnexal masses. If the mass is unilateral, mobile, and cystic, anaplastic elements are less likely and operation can be deferred. Ovarian masses must be differentiated from lesions of the colon, pedunculated leiomyomas, pelvic kidneys, and congenital abnormalities of the uterus. Any adnexal lesion that is present after 14 weeks' gestation, is growing in size on serial ultrasonographic evaluations, contains solid and complex components or internal papillae, is fixed, is surrounded by abdominal ascites, or is symptomatic warrants surgical exploration and pathologic diagnosis.

Torsion of the Adnexa

Torsion of the adnexa can involve the ovary, tube, and ancillary structures, either separately or together. The most common time for occurrence of adnexal torsion is between 6 and 14 weeks and in the immediate puerperium. Although torsion of a normal adnexa has been described, it commonly is associated with a cystic neoplasm. Symptoms include abdominal pain and tenderness that usually are sudden in onset and result from occlusion of the vascular supply to the twisted organ. Shock and peritonitis may ensue. Ultrasonography frequently demonstrates an adnexal mass and altered blood flow on Doppler studies. The diagnosis of torsion is ultimately made at surgery. Prompt operation is necessary to prevent tissue necrosis, preterm labor, and potential perinatal death. The right ovary is involved more frequently than is the left ovary. Benign cystic teratomas and cystadenomas are the most common histologic findings in ovaries that have undergone torsion. Traditional thinking has been that ovarian cysts that have undergone torsion must not be untwisted prior to pedicle clamping because of the concern for potential fatal thromboembolic complications. However, recent series on both nonpregnant and pregnant patients demonstrate that adnexa that had undergone torsion can safely be derotated, followed by the appropriate removal of the mass, eg, cystectomy. These adnexa are capable of recovering and being functional. Salpingo-oophorectomy can be reserved for the management of active bleeding or suspicious neoplasms.

Solid Ovarian Tumors

Solid and complex ovarian tumors with significant solid components discovered during pregnancy generally should be treated surgically because of the low but significant incidence of cancer (1–10%).

Carcinoma of Ovary

Carcinoma of the ovary occurs in less than 0.1% of all gestations and has been encountered in all trimesters. Between 1 and 10% of all ovarian tumors complicating pregnancy are malignant. Consistent with the young age of the pregnant patient population, most neoplasms are germ cell tumors (dysgerminoma, endodermal sinus tumor, malignant teratoma, embryonal carcinoma, and choriocarcinoma) and tumors of low malignant potential, but cystadenocarcinomas do occur.

The treatment of gestational ovarian cancer in the pregnant patient is no different from that for the

nonpregnant patient. A generous surgical incision is important not only to remove the tumor but also to properly explore the abdomen and to reduce uterine manipulation until the definitive surgical course of management is determined. Staging is accomplished and adequate tissue obtained for histologic diagnosis. Conservative surgery is appropriate for an encapsulated tumor if no evidence of uterine or contralateral ovarian involvement is seen. In more advanced stages, the extent of surgery, including tumor debulking, will depend upon gestational age and the patient's wishes with regard to the pregnancy. In some cases, optimal surgical cytoreduction of the tumor to < 1-cm residual disease can be accomplished with the uterus and pregnancy left in situ. Neoadjuvant chemotherapy may offer an interim treatment for selected patients diagnosed at midgestation to allow for fetal maturity prior to extensive surgical cytoreduction. Elevated tumor markers, such as α -fetoprotein (AFP), lactate dehydrogenase (LDH), β -human chorionic gonadotropin (β -hCG), and cancer antigen (CA)-125, during the preoperative work-up of an adnexal mass may be misleading because pregnancy itself may cause an increase in these values.

If the tumor is benign, residual ovarian tissue is conserved if possible. The contralateral ovary must always be carefully evaluated to rule out disease. Should surgical extirpation of the corpus luteum be required in the first trimester, progestin support is recommended.

LEIOMYOMAS

Uterine leiomyomas occur in 0.1–3.9% of pregnancies. A large recent cohort study of obstetric outcomes of women diagnosed ultrasonographically with uterine leiomyomas in pregnancy found an increased risk of cesarean delivery, breech presentation, malposition, preterm delivery, placenta previa, and severe postpartum hemorrhage. Uterine leiomyomas may further complicate pregnancy by undergoing degeneration or torsion, or by causing mechanical obstruction of labor. A degenerating leiomyoma or one undergoing torsion is characterized by acute abdominal pain with point tenderness over the site of the leiomyoma. Conservative treatment with analgesia, reassurance, and supportive therapy almost always is adequate. Occasionally, surgery during pregnancy is indicated for torsion of an isolated, pedunculated leiomyoma. With the exception of a pedunculated leiomyoma on a narrow stalk, myomectomy should not be performed during pregnancy because of the risk of uncontrollable hemorrhage.

Ultrasonography is of great value to document the location, size, and consistency of leiomyomas in a pregnant uterus. Cystic changes in leiomyomas are often visualized when clinical signs of degeneration are present.

CANCER IN PREGNANCY: INTRODUCTION

The incidence of cancer in pregnancy is approximately 1 in 1000. The most common malignancies diagnosed during pregnancy are cervical cancer (26%; see Chapter 50), breast cancer (26%), leukemias (15%), lymphomas (10%), and malignant melanomas (8%).

BREAST CANCER

Breast cancer is the most common cancer affecting women in the United States. One of every 5 cases occurs in women younger than 45 years, and 2–5% of women are pregnant when diagnosed with breast cancer. In the United States, the incidence of breast cancer in pregnancy is 3 per 10,000 live births. For this reason, careful breast examination should be performed during prenatal and postnatal care, and a family history should be obtained. Pregnancy- and lactation-related changes in the breast increase the frequency and range of breast problems and make the diagnosis of breast cancer more difficult. A painless lump is the most common presentation of gestational breast cancer. Bloody nipple discharge may be a presenting symptom and requires work-up. Any mass found by the patient or by the obstetrician should be fully evaluated without undue delay. The differential diagnoses is broad and

includes lactating adenoma, galactocele, milk-filled cyst, fibroadenoma, abscess, and cancer.

Initial management of the pregnant patient with a breast mass does not differ significantly from that for nonpregnant women. When a localized lesion is present, breast ultrasonography is the preferred first imaging modality during pregnancy. It is safe and helpful in distinguishing between cystic and solid masses. Although the sensitivity of mammography is diminished by the breast changes in pregnancy, the study still may be helpful for selected patients with inconclusive clinical examinations. With low-dose mammography and appropriate shielding, fetal radiation exposure is minimal. Nonetheless, it is generally recommended that the procedure be avoided during the first trimester. Breast MRI is a promising breast imaging technique and may be indicated in selected patients, although experience with breast MRI in pregnancy is limited. Cystic lesions should be aspirated and the fluid, if bloody, examined cytologically. Malignant cells are rarely found in nonbloody fluid. Fine-needle aspiration, core biopsy, or incisional biopsy can be used in some cases, but surgical excisional biopsy may be most appropriate for clinically suspicious or cytologically equivocal lesions. The increased vascularity of the breasts is associated with a higher rate of bleeding and the lactating breast is prone to infectious complications, but neither pregnancy nor lactation appears to interfere with excisional biopsy in an outpatient setting.

Management of the pregnant woman with breast carcinoma is especially difficult because it requires careful consideration of both mother and fetus. The general approach to treatment of breast cancer in pregnancy should be similar to that in nonpregnant patients and should not be delayed because of pregnancy. Termination of pregnancy has not been shown to improve survival rates. Modified radical mastectomy is the preferred local management of pregnant patients with breast cancer, with the goal of avoiding the need for adjuvant radiation therapy. Breast-conserving surgery, which must be combined with adjuvant radiation, is limited to patients presenting in the third trimester, for whom surgery is performed during late gestation and radiation treatment can be safely postponed until after delivery. Radical mastectomy is well tolerated during pregnancy. Adjuvant chemotherapy is frequently recommended for premenopausal women with breast cancer. The recommendation of chemotherapy to a pregnant woman with breast cancer is a complex decision, but the indications for adjuvant chemotherapy for gestational breast cancer are generally the same as for the nonpregnant patient. Cyclophosphamide, doxorubicin, and 5-fluorouracil have been given successfully during the second and third trimesters, with no measurable increase in congenital malformations. However, the incidences of prematurity and intrauterine growth restriction are increased. Neoadjuvant chemotherapy may be a treatment option in select patients with locally advanced or metastatic gestational breast cancer. Use of tamoxifen in pregnancy is generally discouraged because of reports of teratogenicity and mammary tumorigenicity in rats and ambiguous genitalia in humans. There is no contraindication to breastfeeding after completion of therapy for breast cancer. Breastfeeding should be avoided during chemotherapy, hormone therapy, or radiation. The results of treatment are much the same stage for stage as they are in nonpregnant patients, but pregnancy-associated breast cancers tend to be more advanced at diagnosis (larger tumor size, more frequently involved lymph nodes), resulting in an overall worse prognosis for this group of patients as a whole. Subsequent pregnancies need not necessarily be discouraged after a suitable period of recuperation and observation, as subsequent pregnancy does not increase the risk of recurrence or death from breast cancer. For women who are breast cancer antigen (BRCA)-1 or BRCA-2 mutation carriers, there is no evidence that pregnancy decreases their breast cancer risk.

LYMPHOMAS AND LEUKEMIAS

The incidence of Hodgkin's lymphoma in pregnancy is estimated to be 1 in 1000 to 1 in 6000 pregnancies, with non-Hodgkin's lymphomas being significantly less frequent. The typical presentation is painless adenopathy, and adequate biopsy is essential for diagnosis. Prognosis and stage distribution of pregnancy-associated Hodgkin's lymphoma generally appear comparable to those in the nonpregnant patient. Approximately 70% of patients present with early-stage disease and can be treated with either single-agent chemotherapy or, in selected cases, modified supradiaphragmatic radiation. Patients in early pregnancy presenting with extensive infradiaphragmatic disease, for which radiation therapy would be a significant component of curative therapy, should consider termination of pregnancy because of the associated significant teratogenic risks.

The incidence of leukemia in pregnancy is estimated at 1 in 100,000. The acute leukemias are more frequent. Treatment of acute leukemia should be started immediately after diagnosis. Depending on the gestational age, the management during pregnancy poses many challenges to the patient, her family, and the treating physicians.

MALIGNANT MELANOMA

Of women with melanoma, approximately 30–35% are of childbearing age, and approximately 1% of female melanoma patients are pregnant. The diagnosis is made by excision, allowing for microstaging. Tumor thickness, tumor site, and presence of metastases are the most important prognostic factors. There has been long-standing controversy regarding the prognosis of pregnancy-associated melanoma, but more recent evidence suggests that patients with early primary lesions and wide surgical excision with appropriate margins have a prognosis comparable to that of their nonpregnant counterparts. Data on higher-stage melanoma diagnosed in pregnancy are limited. Malignant melanoma is the tumor that most frequently metastasizes to the placenta or fetus, accounting for more than half of all tumors with fetal involvement.

CARDIAC DISEASE

Cardiac disease complicates 1–4% of all pregnancies in the United States. Rheumatic and congenital heart disease constitute the majority of cases. Patients requiring cardiac surgery should undergo the procedure prior to becoming pregnant. Nevertheless, the rare patient will require cardiac surgery during pregnancy. Most available reports on cardiac surgery during pregnancy involve closed and open mitral valvuloplasties and mitral or aortic valve replacement. Cardiac surgery can be performed with good results in pregnancy, although there is maternal and fetal risk. Operations should generally be performed early in the second trimester when organogenesis is complete and there is comparatively less hemodynamic burden and less risk of preterm labor than later in gestation. Maternal mortality rates average 4–9%, related to the specific procedure performed and the patient's preoperative cardiovascular status. Closed cardiac surgery techniques appear to be associated with better fetal outcome than open cardiac procedures. Fetal or perinatal mortality is expected in 5–10% of percutaneous balloon valvuloplasties and in 20–30% of open valvular or bypass surgery. Fetal risk is substantial because of the nonpulsatile blood flow and hypotension associated with cardiopulmonary bypass. Close fetal surveillance by electronic heart rate and uterine contraction monitoring is essential during any cardiac surgical procedure, whether or not cardiopulmonary bypass is used. During bypass, blood flow to the uterus can be assessed indirectly by changes in the fetal heart rate, and alterations in flow can be made accordingly.

NEUROLOGIC DISEASE

Intracranial hemorrhage during pregnancy is rare (1–5 per 10,000 pregnancies) but is associated with significant maternal and fetal mortality and serious neurologic morbidity in survivors. Rupture of an aneurysm or arteriovenous malformation (AVM) is the most common cause, followed by eclampsia. Other causes include coagulopathy, trauma, and intracranial tumors. During pregnancy the risk of bleeding from an AVM that had not bled previously is 3.5%, which is close to the annual bleeding rate in the nonpregnant patient. However, mortality due to a bleeding AVM in pregnancy is higher (30%) than in the nonpregnant state (10%). Intracranial hemorrhage with associated neurologic damage during pregnancy (limited capacity for decision making, persistent vegetative state, brain death) poses significant medical and ethical challenges in caring for the mother and fetus.

Most commonly, bleeding from an aneurysm occurs in the subarachnoid space, whereas bleeding from an AVM is located within the brain parenchyma. Symptoms and signs of subarachnoid hemorrhage include headache, nausea and vomiting, stiff neck, photophobia, seizures, and a decreasing level of consciousness. The headache usually is very sudden in onset, whereas the headache associated with intraparenchymal bleeding usually is somewhat less severe and is slower in onset. Focal neurologic deficits may be absent in up to 40% of patients. CT or MRI confirm the diagnosis of an intracranial bleed. Cerebral angiography may be needed to identify and characterize an aneurysm or AVM.

Early operative intervention after aneurysmal hemorrhage during pregnancy is associated with reduced maternal and fetal mortality. For patients with AVM, the decision to treat the lesion during pregnancy is less clear but should follow the same guidelines that apply to nonpregnant patients.

HEMORRHOIDS

Pregnancy is the most common cause of symptomatic hemorrhoids. Venous congestion secondary to the enlarging uterus probably is the culprit. The current management approach to hemorrhoid disease is conservative, with simple outpatient treatment preferred, particularly during pregnancy and the puerperium. Medical therapy with dietary changes, avoidance of excessive straining, stool softeners, and hemorrhoidal analgesics often is the only requirement for nonthrombosed hemorrhoids. Rubber-band ligation is a simple, minimally invasive outpatient procedure for the management of hemorrhoids. Hemorrhoidectomy is the best means of definitive therapy for hemorrhoidal disease and should be considered postpartum if the patient continues to fail to respond to conservative measures, if hemorrhoids are severely prolapsed and require manual reduction, or if associated pathology such as ulceration, severe bleeding, fissure, or fistula, is present. Thrombosis or clots in the vein lead to severe symptoms. If thrombosed external hemorrhoids remain tender and resist conservative treatment, they can be infiltrated with 1% lidocaine and a small incision made to extract the clot.

TRAUMA

Approximately 7% of pregnancies are complicated by trauma, such as motor vehicle accidents (40%), falls (30%), direct assaults to the maternal abdomen (20%), and other causes (10%). Automobile accidents are the most common nonobstetric cause of death during pregnancy. The most common cause of fetal death is death of the mother. The second most common cause of fetal death is abruptio placentae. Pregnant women with traumatic injuries may be victims of physical abuse. A pregnancy may increase family stress; therefore, the practitioner should be alert for signs of abuse.

The primary initial goal in treating a pregnant trauma victim is to stabilize the mother's condition. To optimize maternal and fetal outcome, an organized team approach to the pregnant trauma patient is essential. Maternal assessment and management are similar to those for the nonpregnant patient, keeping in mind the goal of protecting the fetus from unnecessary drug and x-ray exposure. The fetus should be evaluated early during trauma assessment, and after fetal viability is reached, continuous fetal heart rate and uterine activity monitoring should be instituted, as long as it does not interfere with maternal resuscitative efforts. Posttraumatic placental abruption usually occurs quite soon after the injury but rarely manifests as late as 5 days post trauma. The fetal heart rate and uterine contractions should be monitored for at least 4 hours after the trauma. Suspicious findings include frequent uterine contractions, vaginal bleeding, abdominouterine tenderness, postural hypotension, and fetal heart rate abnormalities. If any of these signs occur or if the trauma was severe, monitoring should be extended to 24–48 hours. A Kleihauer-Betke test may show evidence of fetomaternal hemorrhage and is recommended for Rh-negative patients. If the results of the Kleihauer-Betke cannot be obtained in a timely fashion, Rh₀ (D) immunoglobulin (RhoGAM) should be given empirically to Rh-negative patients. Routine coagulation profiles are not clinically helpful.

Current OB/GYN > Chapter 28. Complications of Labor & Delivery > Dystocia >

DEFINITION & CLASSIFICATION

Dystocia is defined as difficult labor or childbirth. It can be considered to involve the maternal pelvis (*passage*), the fetus (*passenger*), the expulsive forces (*powers*), or a combination of these factors.

INCIDENCE

The overall incidence of dystocia in women in labor is difficult to determine, in part secondary to ambiguities in definition. In nulliparous patients the incidence of labor disorders is approximately 25%. The clinical diagnosis of dystocia often is retrospective. If the outcome is uneventful and spontaneous vaginal delivery occurs, dystocia may go unreported. Failure to progress and cephalopelvic disproportion are most often diagnosed after clinical identification of abnormal labor patterns.

Over the last quarter of a century, the cesarean section rate in the United States has risen to approximately 25% of deliveries per year. Approximately 50–60% of cesarean deliveries in the United States are directly or indirectly due to dystocia. Dystocia is currently the most common indication for primary cesarean section, approximately 3 times more common than either nonreassuring fetal status or malpresentation. Elective repeat cesarean section is the second most common indication, often following a primary cesarean delivery for dystocia.

ABNORMAL PATTERNS OF LABOR

Labor is a dynamic process characterized by regular uterine contractions that cause progressive dilatation and effacement of the cervix and descent of the fetus through the birth canal. The progress of labor is evaluated primarily through estimates of cervical dilatation and descent of the fetal presenting part. Normal labor patterns in primigravidas and multiparas have been described in detail by Friedman and others.

Friedman described four abnormal patterns of labor: (1) prolonged latent phase, (2) protraction disorders (protracted active-phase dilatation and protracted descent), (3) arrest disorders (arrest of dilatation, arrest of descent, and failure of descent), and (4) precipitate labor disorders.

Prolonged Latent Phase

The latent phase of labor begins with the onset of regular uterine contractions and extends to the beginning of the active phase of cervical dilatation. The duration of the latent phase averages 6.4 hours in nulliparas and 4.8 hours in multiparas. The latent phase is abnormally prolonged if it lasts more than 20 hours in nulliparas or 14 hours in multiparas.

Causes of prolonged latent phase include excessive sedation or sedation given before the end of the latent phase, use of conduction or general anesthesia before labor enters the active phase, labor beginning with an unfavorable cervix, uterine dysfunction characterized by weak, irregular, uncoordinated, and ineffective uterine contractions, and fetopelvic disproportion.

Treatment options in prolonged latent phase primarily consist of therapeutic rest regimens or active management of labor. After 6–12 hours of rest with sedation and hydration, 85% of patients

spontaneously enter the active phase of labor, and further progression in dilatation and effacement may be expected. Ten percent of patients will have been in false labor and can be allowed to return home to await the onset of true labor if no other indications for delivery are present. In the remaining 5% of patients, uterine contractions remain ineffective in producing dilation; in the absence of any contraindication, augmentation with oxytocin infusion may be effective in progression to the active phase of labor.

Some authorities recommend oxytocin infusion as the primary treatment for all patients with prolonged latent phase. If immediate delivery is required for clinical reasons (eg, severe preeclampsia or amnionitis), oxytocin infusion is the treatment of choice.

The prognosis for vaginal delivery after therapeutic measures is excellent. After abnormalities in the latent phase have been corrected, patients are not at any greater risk of developing subsequent labor disorders than are patients who have experienced a normal latent phase.

Protraction Disorders

Protracted cervical dilatation in the active phase of labor and protracted descent of the fetus constitute the protraction disorders. Protracted active-phase dilatation is characterized by an abnormally slow rate of dilatation in the active phase, ie, less than 1.2 cm/h in nulliparas or less than 1.5 cm/h in multiparas. Protracted descent of the fetus is characterized by a rate of descent less than 1 cm/h in nulliparas or less than 2 cm/h in multiparas. The second stage of labor, which normally averages 20 minutes in parous women and 50 minutes in nulliparous women, is protracted when the stage exceeds 2 hours in nulliparas or 1 hour in multiparas, or 3 and 2 hours, respectively, in the presence of conduction anesthesia.

The underlying pathogenesis of protracted labor probably is multifactorial. Fetopelvic disproportion is encountered in approximately one-third of patients. Other factors include minor malpositions such as occiput posterior, improperly administered conduction anesthesia (eg, epidural anesthesia administered above dermatome T10), excessive sedation, and pelvic tumors obstructing the birth canal.

Treatment of protraction disorders depends on the presence or absence of fetopelvic disproportion, the adequacy of uterine contractions, and the fetal status. Cesarean section is indicated in the presence of confirmed fetopelvic disproportion. Patients experiencing protraction disorders generally do not respond to oxytocin infusion if adequate uterine contractions are documented by intrauterine pressure catheter monitoring. Although enhancement of uterine contractility may be possible, progression of dilatation may not improve. In the absence of fetopelvic disproportion, conservative management, consisting of support and close observation, and therapy with oxytocin augmentation both carry a good prognosis for vaginal delivery (approximately two-thirds of patients) if continued cervical dilatation and effacement occur and there is no fetal compromise. Compelling new evidence suggests a link between labor dystocia and nonreassuring fetal heart rate (FHR) patterns, so fetuses should be closely monitored in the presence of protracted labor.

Arrest Disorders

The two patterns of arrest in labor can be characterized as follows: (1) secondary arrest of dilatation, with no progressive cervical dilatation in the active phase of labor for 2 hours or more; and (2) arrest of descent, with descent failing to progress for 1 hour or more.

Approximately 50% of patients with arrest disorders demonstrate fetopelvic disproportion when inadequate uterine contractions have been treated. Other causative factors include various fetal malpositions (eg, occiput posterior, occiput transverse, face, or brow), inappropriately administered anesthesia, and excessive sedation.

When an arrest disorder is diagnosed, thorough evaluation of fetopelvic relationships before initiation of treatment is crucial. Evaluation should include a careful clinical pelvic examination for pelvic adequacy and estimation of fetal weight. If fetopelvic disproportion is established in the context of an arrest disorder, cesarean section is clearly warranted because considerable trauma to both mother and baby could otherwise occur. If fetopelvic disproportion is not present and uterine activity is less than optimal, oxytocin stimulation is generally effective in producing further progress.

Arrest disorders in the presence of adequate uterine contractions carry a poor prognosis for vaginal delivery. If allowed to continue, arrest disorders are associated with increased perinatal morbidity. However, if a postarrest rate of dilatation or descent that is equal to or greater than the prearrest rate can be established, prognosis for vaginal delivery is excellent.

Precipitate Labor Disorders

Precipitate labor has been defined as delivery in less than 3 hours from onset of contractions. *Precipitate dilatation* can be defined as cervical dilatation occurring at a rate of 5 cm or more per hour in a primipara or 10 cm or more per hour in a multipara. Precipitate labor may result from either extremely strong uterine contractions or low birth canal resistance. Although the initiating mechanism for extraordinarily forceful uterine contractions usually is not known, abnormal contractions may be associated with administration of oxytocin. Strong uterine contractions (both in force and increased basal tone) may accompany placental abruption. Little is known about causes of low birth canal resistance.

If oxytocin administration is the cause of abnormal contractions, it may simply be stopped. The problem typically resolves in less than 5 minutes. The patient should be placed in the lateral position to prevent compression of the inferior vena cava. If excessive uterine activity is associated with FHR abnormalities and this pattern persists despite discontinuation of oxytocin, a beta-mimetic such as 125–250 µg of terbutaline or ritodrine can be given by subcutaneous or slow intravenous injection if no contraindications are present. Physical attempts to retard delivery are absolutely contraindicated.

Maternal complications are rare if the cervix and birth canal are relaxed. However, when the birth canal is rigid and extraordinary contractions occur, uterine rupture may result. Lacerations of the birth canal are common. Furthermore, the uterus that has been hypertonic with labor tends to be hypotonic postpartum, thereby predisposing to postpartum hemorrhage.

Perinatal mortality is increased secondary to possible decreased uteroplacental blood flow, possible intracranial hemorrhage, and risks associated with unattended delivery. Persistently increased basal uterine tone can lead to decreased placental perfusion and fetal hypoxemia. Perinatal intracranial hemorrhage may result from trauma to the fetal head pushing against unyielding maternal tissue with contractions. Resuscitation equipment, infant warmers, and other supportive measures may not be readily available in cases of unattended delivery.

ABNORMALITIES OF THE PASSAGE

Abnormalities of the "passage" involve aberrations of pelvic structure and its relationship to the presenting part. Such abnormalities may be related to size or configurational alterations of the bony pelvis, soft-tissue abnormalities of the birth canal, reproductive tract masses or neoplasia, or aberrant placental location. Bony abnormalities are the most common cause of passage dystocia. The etiology and diagnosis of bony abnormalities begin with the shape, classification, and clinical assessment of the adult female pelvis.

Using roentgenographic studies, Caldwell and Moloy classified the 4 major types of adult pelvic types: gynecoid, android, anthropoid, and platypelloid. Pure forms of these pelvic types are rare; mixed

elements are more often present in each type of pelvis. The gynecoid pelvis is considered the most typically "female" type and is the most favorable for uncomplicated vaginal delivery. Found in approximately 50% of all women, the pelvic inlet has an oval configuration with a transverse diameter slightly greater than the anteroposterior diameter. Pelvic side walls are straight, the ischial spines are not prominent, the subpubic arch is wide, and the sacrum is concave. The android, or "male," type of pelvis is found in approximately 33% of white women and approximately 15% of black women. The inlet is wedge-shaped with convergent side walls, the ischial spines are prominent, the subpubic arch is narrowed, and the sacrum is inclined anteriorly in its lower third. The android pelvis is associated with persistent occiput posterior position and deep transverse arrest. The anthropoid pelvis is present in almost half of black women and 20% of white women. The inlet is oval, with an anteroposterior diameter greater than the transverse diameter. Pelvic side walls are divergent, and the sacrum is inclined posteriorly. This pelvic type is most often associated with persistent occiput posterior position. The platypelloid pelvis is present in fewer than 3% of all women. This pelvis is characterized by a transverse diameter that is wide with respect to the anteroposterior diameter. Deep transverse arrest patterns of labor are commonly associated with this pelvic type.

X-ray pelvimetry has now fallen into limited use because accumulating evidence suggests that the measurements obtained do not influence the management of labor and may even increase cesarean section rates. Ultrasound, magnetic resonance imaging (MRI), and x-rays have been used to delineate pelvic size and shape, but clinical pelvimetry usually is sufficient for routine evaluation of obstetric patients. In an era of continuous fetal monitoring and safe protocols for use of dilute oxytocin to induce and augment labor, a trial of labor can be accomplished safely in most patients. The diagnosis of fetopelvic disproportion essentially has become a diagnosis of exclusion, after fetal factors and uterine dysfunction have been ruled out. However, x-ray pelvimetry may retain a role in the evaluation of a pelvis for the feasibility of vaginal breech delivery and in the assessment of gross bony distortion. If abnormal architecture is abnormal based on history and physical examination, imaging studies may be warranted. In this category, traumatic pelvic fractures are the most common abnormalities; other possibilities include rachitic pelves, chondrodystrophic dwarf pelves, kyphotic and scoliotic pelves, exostoses, and bony neoplasms.

Clinical pelvimetry is performed to estimate pelvic dimensions. To assess the pelvic inlet, the diagonal conjugate is obtained by measuring the distance from the lower edge of the symphysis pubis to the sacral promontory. The obstetric conjugate, the distance from the most prominent portion of the symphysis pubis to the sacral promontory, measures 1.5–2.0 cm less than the diagonal conjugate. The obstetric conjugate should measure greater than 10 cm. The pelvic outlet can be assessed by measuring intertuberous diameter and palpating the subpubic arch. Intertuberous diameter greater than 8 cm and a wide subpubic arch characterize an adequate pelvic outlet. The midpelvis is evaluated clinically based on convergence of side walls, prominence of ischial spines, and concavity of the sacrum. Pelvic contractions may present as a floating vertex presentation with no descent during labor, as abnormal presentation, or as a prolapsed cord or extremity. In prolonged labors complicated by pelvic contraction, considerable molding of the fetal head, caput succedaneum formation, and prolonged rupture of the membranes are possible. If allowed to continue, ultimately frank uterine rupture may occur, preceded by abnormal thinning of the lower uterine segment and development of a Bandl's retraction ring. With severely prolonged second stage, vesicovaginal or rectovaginal fistula formation may result with pressure necrosis of the surrounding tissues of the birth canal by the fetal head. Fortunately, these complications are rare in developed countries where cesarean sections are accessible. Other anatomic abnormalities of the reproductive tract may cause dystocia. So-called *soft-tissue dystocia* may be caused by uterine or vaginal congenital anomalies, scarring of the birth canal, pelvic masses, or low implantation of the placenta.

ABNORMALITIES OF THE PASSENGER

Dystocia may be caused by abnormalities of the "passenger," or fetus. Common fetal abnormalities leading to dystocia include excessive fetal size, malpositions, congenital anomalies, and multiple gestation.

Malposition and Malpresentation

Fetal malpresentations are abnormalities of fetal position, presentation, attitude, or lie. They collectively constitute the most common cause of fetal dystocia, occurring in approximately 5% of all labors. Persistent occiput posterior and occiput transverse positions, brow presentation, face presentation, transverse or oblique lies, and breech and compound presentation are included in this category.

VERTEX MALPOSITIONS

Occiput Posterior

The occiput posterior position may be normal in early labor, with approximately 10–20% of fetuses in occiput posterior position at onset of labor. In 87% of cases, the head rotates to the occiput anterior position when it reaches the pelvic floor. If the head does not rotate, persistent occiput anterior position may result in dystocia. Interestingly, approximately two-thirds of cases of occiput posterior presentation at delivery occur through malrotation during the active phase of labor. The mechanism of this fetopelvic disproportion is partial deflexion of the fetal head. This partial deflexion increases the diameter that must engage in the pelvis. Occiput posterior presentation may result from a contracted anthropoid or android pelvis or insufficient uterine action.

The diagnosis of occiput posterior position is generally made by manual vaginal examination of the orientation of the fetal cephalic sutures. If no gross pelvic contraction is documented on clinical pelvimetry and uterine contractions are inadequate, cautious infusion of oxytocin may be tried. A few authorities advocate midforceps rotation from the occiput posterior to the occiput anterior position. This should be attempted only when macrosomia and gross fetopelvic disproportion have been excluded, other criteria for forceps delivery have been met, and the operator is sufficiently skilled. The prognosis for the infant is excellent when these guidelines are followed; however, maternal morbidity, including extension of episiotomies, higher rates of anal sphincter injury, and other birth canal lacerations, occurs more frequently in occiput posterior deliveries.

Occiput Transverse

Occiput transverse is frequently a transient position. In most labors, the fetal head spontaneously rotates to the occiput anterior position. Persistent occiput transverse is associated with pelvic dystocia, uterine dystocia, and platypelloid or android pelvises. Diagnosis, management, and prognosis are similar to those of persistent occiput posterior presentation. When the fetal head engages but for various reasons does not rotate spontaneously in the midpelvis as in normal labor, midpelvic transverse arrest is diagnosed. Deep transverse arrest occasionally occurs at the inlet, with molding and caput succedaneum formation falsely indicating a lower descent. Cesarean section is required.

BROW PRESENTATION

Brow presentations usually are transient fetal presentations with deflexion of the fetal head. During the normal course of labor, conversion to face or vertex presentation generally occurs. If no conversion takes place, dystocia is likely. Brow presentation occurs in approximately 0.06% of deliveries. In approximately 60% of cases, pelvic contraction, prematurity, and grand multiparity are associated findings. The diagnosis is made by vaginal examination. Initial management is expectant, as spontaneous conversion to vertex presentation occurs in more than one-third of all brow presentations. Oxytocin is not recommended, as arrest patterns and uterine inertia are common sequelae because pelvic contraction is often associated with this presentation, and liberal use of cesarean section should be made. Perinatal

mortality rates are low when corrected for congenital anomaly, prematurity, and manipulative vaginal delivery.

FACE PRESENTATION

In face presentation, the fetal head is fully deflexed from the longitudinal axis. Face presentation occurs in approximately 0.2% of all deliveries and has been associated with grand multiparity, advanced maternal age, pelvic masses, pelvic contraction, multiple gestation, polyhydramnios, macrosomia, congenital anomalies including anencephaly and hydrocephaly, prematurity, cornual implantation of the placenta, placenta previa, and premature rupture of the membranes.

Diagnosis of face presentation is most often accomplished by vaginal examination. The prognosis for vaginal delivery is guarded. Complications generally arise with simultaneous pelvic contraction or persistent mentum posterior position. Mentum posterior positions in average-size fetuses are not deliverable vaginally. Arrested labor is typical when spontaneous rotation to the mentum anterior position fails to occur. With mentum anterior presentation, oxytocin augmentation can be considered for arrested labor if cephalopelvic disproportion can be ruled out. Delivery can be accomplished by spontaneous vaginal delivery or cesarean section. There is little or no place for manual flexion of the fetal head or manual rotation from the mentum posterior position to the mentum anterior position.

ABNORMAL FETAL LIE

In transverse or oblique lie, the long axis of the fetus is perpendicular, or at an angle, to the maternal longitudinal axis. Abnormalities in axial lie occur in approximately 0.33% of all deliveries but may occur 6 times more frequently in premature labors. Causative factors include grand multiparity, prematurity, pelvic contraction, and abnormal placental implantation.

When the diagnosis is made in the third trimester prior to labor, external cephalic version (ECV) enables a number of these patients to undergo vaginal delivery. Abnormal axial lies have a 20 times greater incidence of cord prolapse than do vertex presentations. Thus prompt cesarean delivery is mandatory with onset of labor or when the membranes rupture. Increased perinatal mortality is associated mainly with prematurity, cord prolapse, and manipulative vaginal delivery. Increased perinatal mortality rates have been consistently reported secondary to internal podalic version, other birth trauma associated with manipulation, and cord prolapse (11–20% of cases of the latter).

A prolapsed extremity alongside the presenting part constitutes compound presentation. Compound presentation complicates approximately 0.1% of deliveries. Prematurity and a large pelvic inlet are associated clinical findings. Compound presentations are often diagnosed during physical examination and investigation for failure to progress in labor. Most commonly, a hand is palpated beside the vertex. In most of these patients, labor ends in uncomplicated vaginal delivery, but cesarean section should be performed in the presence of dystocia or cord prolapse. Attempts to reposition the fetal extremity are discouraged, except for gentle pinching of the digits to determine whether the fetus will retract the extremity.

BREECH PRESENTATION

Breech presentation is a longitudinal lie with the fetal head occupying the fundus. A frank breech describes a breech presentation with flexed hips and extended knees. A complete breech describes flexion at both hips and knees. An incomplete (footling) breech describes extension of one or both hips. Breech presentation at term occurs in approximately 3–4% of all deliveries. The incidence increases with the degree of prematurity; the incidence at 32 weeks is 7% and at under 28 weeks is 25%. Breech presentation is associated with similar causative factors as face presentation, as well as with previous breech presentation, congenital anomalies, and any anomaly that alters the normal piriform shape of the uterus.

Management options for singleton breech presentation include vaginal breech delivery, ECV with subsequent vaginal cephalic delivery if successful, or elective cesarean section. Recently, a large international multicenter randomized controlled trial clearly demonstrated lower rates of fetal morbidity with planned cesarean section rather than planned vaginal delivery for singleton breech fetuses, with relative risk of 0.33. In light of these findings, the American College of Obstetricians and Gynecologists (ACOG) Committee on Obstetric Practice issued a formal position that planned vaginal breech delivery may no longer be appropriate for singleton pregnancies. ACOG recommends application of ECV to reduce breech presentation or cesarean section for persistent singleton presentation.

ECV performed at 36 completed weeks of gestation or later, usually with tocolysis, may significantly reduce both the incidence of breech presentation in labor and the number of cesarean sections. Success rates range from 35–86%. Predictors of failure include nulliparity, anterior placental location, fetal weight less than 2500 g, advanced cervical dilatation, and low station. Whereas labor after successful ECV demonstrated higher rates of cesarean section for dystocia and FHR abnormalities, overall cesarean section rates for breech can be lowered.

Prospective studies have identified a subgroup of breech presentations that may be safely delivered vaginally, albeit with great caution. This group includes near-term frank breeches weighing between 2500 and 3800 g with flexed head and no concurrent congenital anomalies, maternal pelvis of adequate dimensions, and a normal labor pattern without FHR abnormalities. In addition, women with prior breech deliveries have lower risks of poor perinatal outcome with subsequent breech delivery. Complications of vaginal breech delivery, including maternal or fetal trauma, fetal head entrapment, and cord prolapse, are uncommon when limited to a properly selected group of patients. Piper forceps should be available for delivery of the aftercoming head. Continuous electronic fetal monitoring is essential, and immediate cesarean section should be available.

Fetal Macrosomia

Excessive fetal size encompasses those fetuses that are large for gestational age (LGA) and those with macrosomia. LGA implies a birth weight greater than the 90th percentile, and macrosomia implies growth beyond a certain size, usually 4000–4500 g, regardless of gestational age. It occurs in approximately 5% of deliveries. Associated risk factors include maternal diabetes, maternal obesity (> 70 kg), excessive maternal weight gain (> 20 kg), postdates pregnancy, and previous delivery of a macrosomic infant. However, fewer than 40% of macrosomic infants are born to patients with identifiable risk factors.

Diagnosis by abdominal palpation is notoriously inaccurate. A better estimated weight may be possible with real-time ultrasonography and standard measured parameters, but ultrasound lacks accuracy, particularly with increased fetal size. Whereas morbidities to infant and mother increase with increasing size between 4000 and 4500 g, perinatal mortality for fetuses weighing more than 4500 g is increased over normal weight infants, and the incidence of shoulder dystocia is at least 10% in this group.

Shoulder dystocia, or difficult delivery of the shoulders after delivery of the fetal head, is an obstetric emergency, with approximately 20% risk of fetal brachial plexus injury, hypoxia, or asphyxia. The incidence of shoulder dystocia is 0.6–1.4% of all vaginal deliveries. It may be heralded by the classic turtle sign. After the fetal head delivers, it retracts back on the maternal perineum. The first action is to call for assistance. Then if gentle inferior traction of the fetal head is not successful, the McRoberts' maneuver may be attempted, which causes rotation of the symphysis pubis. The patient's legs are sharply flexed against her abdomen in an attempt to free the anterior shoulder of the fetus. At the same time, suprapubic pressure can be applied. If shoulder dystocia persists, the shoulder can be rotated (Wood's corkscrew or Rubin's maneuver) to a transverse or oblique diameter of the pelvis, or the

posterior arm can be delivered. Episiotomy usually is indicated because it may reduce soft-tissue dystocia and allow the operator to maneuver more easily. Intentional fracture of the clavicle may be required to effect delivery.

If all maneuvers fail and there is a chance for a good fetal outcome, a symphysiotomy or the Zavanelli procedure may be performed. This last maneuver consists of re-placement of the fetal head into the vagina in the flexed position, followed by urgent cesarean section.

Given the morbidity associated with shoulder dystocia and the increasing risk of dystocia with larger fetuses, estimated fetal weights greater than 4500 g in nondiabetic patients and greater than 4250 g in diabetic patients have been suggested by some as thresholds for discussing the option of elective cesarean section for macrosomia. However, because estimations of fetal size frequently are inaccurate, especially in fetuses weighting more than 4000 g, the diagnosis of dystocia secondary to macrosomia requires progression to the active phase of labor and assessment of the adequacy of uterine contractions. In addition, shoulder dystocia cannot be reliably predicted in labor, with more than half of cases occurring without identifiable risk factors. After review of the available evidence, ACOG Practice Bulletin 22 recommends considering elective cesarean section with estimated fetal weight above 5000 g in nondiabetic women or above 4500 g in diabetic women. Prolonged second stage or arrest of descent in macrosomic infants should be delivered by cesarean section rather than operative vaginal delivery, as rates of shoulder dystocia in infants greater than 4500 g delivered with midforceps have been reported to be above 50%.

Fetal Malformation

Fetal malformation may cause dystocia, primarily through fetopelvic disproportion. The most common malformation is hydrocephalus, with an incidence of 0.05%. Management is determined by the severity of the disorder and its prognosis. Other fetal anomalies that may prevent the normal progress of labor include enlargement of the fetal abdomen caused by distended bladder, ascites, or abdominal neoplasms; or other fetal masses, such as meningomyelocele or large omphalocele.

ABNORMALITIES OF THE POWERS

Abnormalities of the "powers" constitute uterine activity that is ineffective in eliciting the normal progress of labor. Ineffective uterine action characteristically falls into one of two categories: hypotonic, with a normal pattern of low-pressure contractions; or hypertonic, with a discoordinated pattern of high-pressure contractions. Studies of normal uterine activity during labor have revealed the following characteristics: (1) the relative intensity of contractions is greater in the fundus than in the midportion or lower uterine segment (fundal dominance); (2) the average value of the intensity of contractions is more than 24 mm Hg (in the active phase of labor, pressures often increase to 40–60 mm Hg); (3) contractions are well synchronized in different parts of the uterus; (4) the basal resting pressure of the uterus is between 12 and 15 mm Hg; (5) the frequency of contractions progresses from 1 every 3–5 minutes to 1 every 2–3 minutes during the active phase; (6) the duration of effective contraction in active labor approaches 60 seconds; and (7) the rhythm and force of contractions are regular.

Quantification of uterine activity during labor uses external tocodynamometry or intrauterine pressure catheter measurement. The external tocodynamometer is a pressure sensor placed over the fundal prominence of the uterus that gives an accurate determination of the frequency and duration of uterine contractions. This technique is not adequate for assessment of the resting tone of the uterus or the intensity of contractions. An internal uterine pressure catheter measures intra-amniotic pressure, which is transmitted through the noncompressible fluid within the catheter to a pressure sensor. This technique shows baseline uterine resting pressure, contraction intensity and duration, and frequency of uterine

activity. It is the most accurate method for diagnosing uterine dysfunction and evaluating treatment. The Montevideo unit is the most widely used measurement of uterine activity. The Montevideo unit is defined as the product of the average intensity of uterine contractions (measured from the baseline resting pressure) multiplied by the number of contractions in a 10-minute interval. Measurements greater than 200 mm Hg should be adequate to produce normal labor progression in most patients.

Uterine dysfunction generally comprises 2 categories: hypotonic dysfunction and uncoordinated hypertonic dysfunction. Hypotonic dysfunction is characterized by contraction of the uterus with insufficient force, irregular or infrequent rhythm, or both. Seen most often in primigravidas in the active phase of labor, hypotonic dysfunction may be caused by excessive sedation, early administration of conduction anesthesia, or overdistension of the uterus (eg, twins, polyhydramnios). Hypotonic dysfunction responds well to oxytocin; however, cephalopelvic disproportion and malpresentation care must be ruled out first. Active management of labor has been shown to decrease perinatal morbidity and cesarean section rates. Less commonly than hypotonic dysfunction, hypertonic uterine contractions and uncoordinated contractions often occur together and are characterized by elevated resting tone of the uterus, dyssynchronous contractions with elevated tone in the lower uterine segment, and frequent intense uterine contractions. It is generally associated with placental abruption, overzealous use of oxytocin, cephalopelvic disproportion, fetal malpresentation, and the latent phase of labor. Treatment may require tocolysis, decrease in oxytocin infusion, or cesarean section as indicated for concomitant malpresentation, cephalopelvic disproportion, or FHR abnormalities. Oxytocin administration is generally of no value. When these patterns occur in the latent phase of labor, sedation may be effective in converting hypertonic contractions to normal labor patterns. Hypertonic labor may cause precipitate labor disorders (see Precipitate Labor Disorders).

Inadequate pushing in the second stage of labor is common and may be caused by conduction anesthesia, oversedation, exhaustion, underlying neurologic dysfunction (eg, paraplegia or hemiplegia), or psychiatric disorders. Mild sedation or a waiting period to permit analgesic or anesthetic agents to wear off may improve expulsive efforts, and outlet forceps or vacuum delivery may be effected in selected cases.

FETAL COMPROMISE: INTRODUCTION

Fetal compromise can be defined as a complex of signs indicating a critical response of the fetus to inadequate oxygenation. It represents a continuum of metabolic derangements ranging from hypoxemia to acidosis that affect the functions of vital organs to the point of temporary or permanent injury or death.

FHR monitoring during labor can be accomplished via continuous electronic monitoring or intermittent auscultation with a DeLee stethoscope. Prompt recognition of the symptoms of fetal compromise and, when necessary, decisive, well-planned interventions are imperative for the reduction of perinatal mortality and morbidity, especially to prevent permanent damage to the central nervous system.

FHR should be regularly evaluated for baseline, presence of variability, presence of accelerations, and presence of periodic or episodic decelerations. Baseline rate is between 110 and 160 bpm. *Variability*, defined as fluctuations in the baseline FHR, is reported as absent (undetectable amplitude range), minimal (range < 5 bpm), moderate (range between 6 and 25 bpm), or marked (range greater than 25 bpm). Lack of FHR variability may be associated with a number of factors (eg, fetal immaturity, effect of drugs) that do not indicate fetal compromise. However, the absence of FHR variability may indicate decreased central nervous system control. FHR accelerations occur frequently in early labor. They usually are caused by fetal movement or fetal stimulation. In the absence of decreased variability or decelerations, accelerations are a favorable sign for fetal well-being. Early FHR decelerations result from

head compression with uterine contractions and are not associated with poor outcome. Variable FHR decelerations are usually due to cord compression and are not worrisome unless they become recurrent, deeper, and longer in duration. Late decelerations are more ominous because they signify fetal hypoxemia due to uteroplacental insufficiency.

Fetal compromise is secondary to decreased oxygen perfusion, which can be classified as maternal, uterine, placental, or cord complications. Maternal hypotension, shock, heart failure, or hypoxia–hypercapnia result in decreased oxygen supply to the uterus. In cases of uterine hypertonia (tachysystole, tetanic contractions) or placental abruption, oxygen cannot cross from the maternal vessels to the placenta. Placental and cord problems include abnormal placentation such as placenta previa, lack of sufficient placental reserve to tolerate labor (postmaturity, placental infarcts), umbilical cord compression (knots, entanglement, occult or frank prolapse), and ruptured vasa previa.

Tachycardia, lack of FHR variability, and late FHR decelerations together signify fetal compromise. Recurrent variable or late decelerations despite attempted therapy and prolonged decelerations are signs of fetal compromise and may represent a fetal pH of less than 7.10, reflecting fetal acidemia. Prompt evaluation and treatment are mandatory.

MANAGEMENT OF FETAL COMPROMISE

It is important to note that although a fetal heart tracing with accelerations carries a high sensitivity and high negative predictive value for a healthy, nonacidotic fetus, the presence of decelerations and decreased variability has a low specificity for acidosis. Thus, except in cases of ominous fetal heart tracing patterns such as refractory bradycardia or a sinusoidal pattern, which mandate immediate delivery, intrauterine resuscitative measures and assessment of fetal status can be accomplished. The presence of FHR accelerations elicited by scalp stimulation or fetal acoustic stimulation strongly correlates with nonacidotic fetal status. Preliminary studies show promise for fetal pulse oximetry as an additional tool in the assessment of fetal status. In the presence of continued signs of fetal well-being, it is possible to allow labor to continue.

Intrauterine resuscitation should be tailored to the likely underlying cause of fetal compromise. In the presence of a concerning fetal tracing, vaginal examination to assess for rapid progression of labor or cord prolapse should be part of the initial assessment. A change of the mother's position may adjust fetal position and decrease compression of the umbilical cord. Variable decelerations can be improved by amnioinfusion, replacement of amniotic fluid with saline via an intrauterine pressure catheter. Maternal venous return, relative hypovolemia, and thus uterine perfusion may be improved with the patient in a lateral position. Supine hypotension, particularly after placement of epidural anesthesia, may be corrected by elevation of the maternal legs, lateral positioning, and rapid administration of fluids intravenously. These actions help to restore the gravida's arterial pressure and increase the blood flow in the intervillous space and perfusion to the fetus. Rarely, cardiotonics (eg, ephedrine) are required. Discontinuing the administration of oxytocin may improve placental perfusion, increasing the oxygenation of the fetus. Administration of high concentrations of oxygen (10 L/min by mask) will raise the maternofetal P_{O_2} gradient and increase maternofetal oxygen transfer, alleviating fetal hypoxia. However, evidence is insufficient to support the use of prophylactic oxygen therapy for women in the second stage of labor or to evaluate its effectiveness in alleviating fetal hypoxemia. In the rare case of maternal acidosis as the cause of fetal acidosis, administering bicarbonate to the mother may benefit both mother and infant. However, if acidosis is severe, the infant should be promptly delivered.

In summary, in cases of possible fetal compromise, vaginal examination should be performed to assess for rapid progression or cord prolapse. Intrauterine resuscitation can be accomplished by changing the position of the mother, amnioinfusion, correcting maternal hypotension by intravenous fluid

administration, decreasing uterine activity by stopping oxytocin or administering tocolytics, and providing oxygen by face mask. Labor can be continued if the FHR tracing is not ominous. If fetal well-being cannot be documented, or if FHR abnormalities do not resolve with these measures, immediate delivery is indicated. Obstetric judgment must dictate how the delivery will be accomplished in accordance with the presentation, station, position, dilatation of the cervix, and presumed fetal status. Cesarean delivery, if chosen, must be accomplished rapidly.

VAGINAL BLEEDING IN LABOR : INTRODUCTION

A small amount of bleeding associated with cervical dilatation is common in labor, but vaginal bleeding must be carefully evaluated to assess for placental abruption or placenta previa.

Placenta previa complicates approximately 0.5% of pregnancies. Diagnosis is frequently made prior to the onset of labor; the hallmark of previa is painless vaginal bleeding during the second or third trimester. Profuse painless bleeding during the course of labor may represent a previously undiagnosed placenta previa. Patients should be evaluated with abdominal ultrasound and, if indicated, vaginal ultrasound. Digital palpation of the cervix should not be done. When diagnosed remote from delivery, previa with bleeding mandates abdominal delivery.

Placental abruption should be suspected in cases of vaginal bleeding with FHR abnormalities. Patients at risk for abruption (see Chapter 20) should be surveilled closely. Abruption also may manifest as bloody fluid at the time of rupture of membranes, abdominal pain, or uterine hypertonicity. If bleeding is severe or the FHR pattern is ominous and vaginal delivery is not imminent, emergent cesarean delivery is necessary.

FETAL BLOOD LOSS IN LABOR

Blood loss occurring in labor and delivery is most commonly of maternal origin, but fetal blood loss may occur from trauma to the placenta or from vasa previa. The fetoplacental vascular volume at term is only 250–500 mL, so what appears to be minor vaginal bleeding could be rapidly fatal to the fetus. Certain FHR patterns on electronic monitoring, particularly fetal tachycardia, recurrent decelerations, prolonged bradycardia, or a sinusoidal pattern, may signify fetal compromise due to anemia. The Apt test and the Kleihauer-Betke test both can detect fetal hemoglobin. However, these tests are performed only when there is clinical suspicion of fetomaternal hemorrhage. When significant fetal bleeding is more certain, delivery must be accomplished expeditiously if the infant is to be saved.

VASA PREVIA

In approximately 1% of pregnancies, the umbilical vessels divide within the amnionic membranes before they reach the placenta. In this condition, known as a *velamentous cord insertion*, the vessels may cross the internal os in advance of the fetal presenting part (vasa previa). During labor, the vessels are likely to be disrupted, with rapid fetal exsanguination occurring in as many as 75% of cases. Diagnosis of vasa previa or velamentous cord insertion is rarely made before rupture of the membranes. The antenatal period is the ideal time for identification of vasa previa, but the discovery of vessels crossing the internal os is rare prior to cervical dilatation.

The diagnosis is often made after the rupture of the membranes by palpation of fetal vessels in the membranes overlying the presenting part through the partially or fully dilated cervix. The usual presentation is sudden-onset bleeding with fetal tachycardia. Fetal tachycardia alone soon after rupture of the membranes may indicate fetal bleeding. Sinusoidal FHR pattern on electronic fetal monitoring may indicate severe anemia. When vasa previa is diagnosed during labor, the infant should be delivered by emergency cesarean section. Even in the most expeditiously performed delivery, infant prognosis is poor when fetal exsanguination occurs.

Current OB/GYN >Chapter 29. Obstetric Analgesia & Anesthesia >

OBSTETRIC ANALGESIA & ANESTHESIA: INTRODUCTION

Analgesia is the loss or modulation of pain perception. It can be (1) local and affect only a small area of the body, (2) regional and affect a larger portion of the body, or (3) systemic. Analgesia is achieved by the use of hypnosis (suggestion), systemic medication, regional agents, or inhalational agents.

Anesthesia is the total loss of sensory perception and may include loss of consciousness. It is induced by various agents and techniques. In obstetrics, regional anesthesia is accomplished with local anesthetic techniques (epidural, spinal) and general anesthesia with systemic medication and endotracheal intubation.

The terms *analgesia* and *anesthesia* are sometimes confused in common usage. Analgesia denotes those states in which only modulation of pain perception is involved. Anesthesia denotes those states in which mental awareness and perception of other sensations are lost. Attempts have been made to divide anesthesia into various components including analgesia, amnesia, relaxation, and loss of reflex response to pain. Analgesia can be regarded as a component of anesthesia if viewed in this way.

The use of techniques and medications to provide pain relief in obstetrics requires an expert understanding of their effects to ensure the safety of both mother and fetus.

ANATOMY OF PAIN

It may be academic to argue that pain should be defined as the parturient's response to the stimuli of labor, but agreement on a definition of pain has eluded scholars for centuries.

Nevertheless, it should be appreciated that the "pain response" is a response of the total personality and cannot be dissected systematically and scientifically. Physicians are obligated to provide a comfortable or at least a tolerable labor and delivery. Many patients are tense and apprehensive at the onset of labor, although they may have little or no discomfort. The physician must be knowledgeable of the options for pain relief and respond to the patient's needs and wishes.

The evolution of pain in the first stage of labor originally was described as involving spinal segments T11 and T12. Subsequent research has determined that segments T10–L1 are involved. Discomfort is associated with ischemia of the uterus during contraction as well as dilatation and effacement of the cervix. Sensory pathways that convey nociceptive impulses of the first stage of labor include the uterine plexus, the inferior hypogastric plexus, the middle hypogastric plexus, the superior hypogastric plexus, the lumbar and lower thoracic sympathetic chain, and the T10–L1 spinal segments.

Pain in the second stage of labor undoubtedly is produced by distention of the vagina and perineum. Sensory pathways from these areas are conveyed by branches of the pudendal nerve via the dorsal nerve of the clitoris, labial nerves, and the inferior hemorrhoidal nerves. These are the major sensory branches to the perineum and are conveyed along nerve roots S2, S3, and S4. Nevertheless, other nerves, such as the ilioinguinal nerves, the genitofemoral nerves, and the perineal branches of the posterior femoral cutaneous nerves, may

play a role in perineal innervation.

Although the major portion of the perineum is innervated by the 3 major branches of the pudendal nerve, innervation by the other nerves mentioned may be important in some patients. The type of pain reported may be a ache in the back or loins (referred pain, perhaps from the cervix), a cramp in the uterus (due to fundal contractions) or a "bursting" or "splitting" sensation in the lower vaginal canal or pudendum (due to dilatation of the cervix and vagina).

Dystocia, which usually is painful, may be due to fetopelvic disproportion; tetanic, prolonged, or dysrhythmic uterine contractions; intrapartum infection; or many other causes (see Chapter 28).

SAFETY OF OBSTETRIC ANESTHESIA

Substantial advances in the quality and safety of obstetric anesthesia have been made in the past 3 decades. Outdated techniques, such as "twilight sleep" and mask anesthesia, have been recognized as ineffective or unsafe and have been replaced by epidural infusion of narcotic/local anesthesia mixtures and patient-controlled analgesia during labor and postoperatively. When required, general anesthesia is provided using short-acting drugs with well-known fetal effects, and careful attention is focused on airway management.

Maternal mortality relating to anesthesia has been reduced 10-fold since the 1950s, largely because of an enhanced appreciation of special maternal risks associated with anesthesia. The overall anesthesia-related death rate in the United States now is as low as 1.3 per million live births, a 5-fold decline in the last decade. Regional anesthesia now is more commonly performed for cesarean delivery, fewer births occur in hospitals performing fewer than 5 deliveries per year, and having both in-house anesthesia and obstetric physician coverage is more common. In the face of these improvements, 2 distressing statistics have recently emerged. First, the case fatality rate for general anesthesia for cesarean delivery has risen from 20 deaths per million general anesthetics administered in the early 1980s to 32.3 deaths per million general anesthetics administered today. This increase occurred during a period when the case fatality rate for regional anesthesia in obstetrics decreased from 8.6 per million to 1.9 per million regional anesthetics administered. The case fatality rate for general anesthesia may have increased because general anesthesia now is reserved for urgent and critical situations, whereas in the past general anesthesia was more commonly used for elective obstetric delivery. Difficulty with intubation, aspiration, and hypoxemia leading to cardiopulmonary arrest are the leading causes of anesthesia-related maternal death.

The second point of concern is the increase in overall maternal mortality (not related specifically to anesthesia) in the United States since 1985. This increase in maternal mortality is most pronounced in older parturients (older than 35 years), particularly in black parturients. Cardiomyopathy, hypertension, and hemorrhage are the principal etiologies associated with these rising mortality rates and are important factors for the anesthesiologist to consider.

TECHNIQUES OF ANALGESIA WITHOUT THE USE OF DRUGS

Psychophysical Methods

Three distinct psychological techniques have been developed as a means of facilitating the birth process and making it a positive emotional experience: "natural childbirth," psychoprophylaxis, and hypnosis. So-called *natural childbirth* was developed by Grantly Dick-Read in the early 1930s and popularized in his book *Childbirth Without Fear*. Dick-Read's approach emphasized the reduction of tension to induce relaxation. The psychoprophylactic technique was developed by Velvovski, who published the results of his work from Russia in 1950. In Russia in the mid-1950s, it became evident that obstetric psychoprophylaxis was a useful substitute for poorly administered or dangerously conducted anesthesia for labor and delivery. This method was later introduced in France by Lamaze. Hypnosis for pain relief has achieved periodic spurts of popularity since the early 1800s and depends on the power of suggestion.

Many obstetricians argue that psychoprophylaxis can largely eliminate the pain of childbirth by diminishing cortical appreciation of pain impulses rather than by depressing cortical function, as occurs with drug-induced analgesia.

Relaxation, suggestion, concentration, and motivation are factors that overlap other methods of preparation for childbirth. Some of them are closely related to hypnosis.

These techniques can significantly reduce anxiety, tension, and fear. They provide the parturient with a valuable understanding of the physiologic changes that occur during labor and delivery. In addition, they provide an opportunity for closer understanding and communication between the patient and her mate, who may be an important source of comfort to her during the stressful process of childbirth. If psychophysical techniques do no more than this, they deserve the obstetrician's support.

Studies undertaken to assess the effectiveness of psychophysical techniques have reported widely divergent results with effectiveness ranging from as low as 10–20% to as high as 70–80%. The overall benefit is best judged by the parturient herself, with validation by the observations of attendants. As is no doubt true in other aspects of medical practice in which emotional overlay and subjective reporting play a role in the evaluation of specific types of therapy, the personality and level of enthusiasm of the doctor can strongly influence the patient's reactions to a given therapy. Practitioners who are skeptical of psychophysical techniques cannot expect to accomplish very much with them.

None of these psychophysical techniques should be forced on a patient, even by a skillful practitioner. The patient must not be made to feel that she will fail if she does not choose to complete her labor and delivery without analgesic medication. It must be made clear to the patient from the outset that she is expected to ask for help if she feels she wants or needs it. All things considered, psychophysical techniques should be viewed as adjuncts to other analgesic methods rather than substitutes for them.

The effectiveness of hypnosis is partially due to the well-known, although incompletely understood, mechanisms by which emotional and other central processes can influence a person's overall responses to the pain experience. Verbal suggestion and somatosensory stimulation may help to alleviate discomfort associated with the first stage of labor. In addition, hypnotic states may provide apparent analgesia and amnesia for distressing, anxiety-provoking experiences. Finally, hypnotic techniques may substantially improve the parturient's outlook and behavior by reducing fear and apprehension. However, certain practical points with regard to hypnosis must be considered because the time needed to establish a suitable relationship between physician and patient often is more than can be made available in the course of a busy medical practice.

ANALGESIC, AMNESTIC, & ANESTHETIC AGENTS

General Comments & Precautions

1. If the patient is prepared psychologically for her experience, she will require less medication. Anticipate and allay her fears during the antenatal period and in early labor. Never promise a painless labor.
2. Individualize the treatment of every patient, because each one reacts differently. Unfavorable reactions to any drug can occur.
3. Know the drug you intend to administer. Be familiar with its limitations, dangers, and contraindications as well as its advantages.
4. All analgesics given to the mother will cross the placenta. Systemic medications produce higher maternal and fetal blood levels than regionally administered drugs. Many drugs have central nervous system depressant effects. Although they may have the desired effect on the mother, they also may exert a mild to severe depressant effect on the fetus or newborn.

The ideal drug will have an optimal beneficial effect on the mother and a minimal depressant effect on the offspring. None of the presently available narcotic and sedative medications used in obstetrics has selective maternal effect. The regional administration of local anesthetics accomplished this goal to a large extent because the low maternal serum levels that are produced expose the fetus to insignificant quantities of drugs.

Pharmacologic Aspects

ROUTE OF ADMINISTRATION

Systemic techniques of analgesia and anesthesia include both oral and parenteral routes of administration. Parenteral administration includes subcutaneous, intramuscular, and intravenous injection. Sedatives, tranquilizers and analgesics usually are given by intramuscular injection. In some cases, the intravenous route is preferred.

The advantages of intravenous administration are (1) avoidance of variable rates of uptake due to poor vascular supply in fat or muscle; (2) prompt onset of effect; (3) titration of effect, avoiding the "peak effect" of an intramuscular bolus; and (4) smaller effective doses because of earlier onset of action.

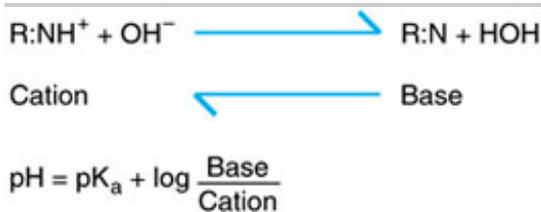

The disadvantages of intravenous injection are inadvertent arterial injection and the depressant effect of overdosage, but the advantage of smaller dosage outweighs the disadvantages.

Always administer the lowest concentration and the smallest dose to obtain the desired effect.

PHYSICAL AND CHEMICAL FACTORS

Anesthetics penetrate body cells by passing through the lipid membrane boundary. This membrane is not permeable to charged (ionized) drugs but is permeable to unionized forms of drugs. Much of the total drug transfer is dependent on the degree of lipid solubility, so local anesthetics are characterized by aromatic rings that are lipophilic, and all are lipid-soluble. The intermediate amine radical of a local anesthetic is a weak base that in aqueous solutions exists partly as undissociated free base and partly as dissociated cation. Figure 29–1 shows the equilibrium for such an existence and the Henderson-Hasselbalch equation, with which the proportion of the anesthetic in the charged and uncharged forms can be determined. The ratio of the cation to the base form of the drug is important, because the base form is responsible for penetration and tissue diffusion of the local anesthetic whereas the cation form is responsible for local analgesia when the drug contacts the site of action within the sodium channel on the axolemma.

Figure 29–1.

Local anesthetics are weak bases coexisting as undissociated free base and dissociated cation. Their proportions can be calculated by means of the Henderson-Hasselbalch equation.

The pK_a of a drug is the pH at which equal proportions of the free base and cation form occur. Most local anesthetics used in obstetric analgesia have pK_a values ranging from 7.7–9.1 (Table 29–1). Because the pH of maternal blood is equal to or greater than 7.4, the pK_a of local anesthetics is so close that significant changes in maternal and fetal acid–base balance may result in fluxes in the base versus the cation forms of the drug. For example, a rising pH shifts a given amount of local anesthetic cation to the base form; conversely, a fall in pH generates more of the cationic form.

Drug	Brand Name	pK _a
------	------------	-----------------

Physical factors are important in drug transfer. Drugs with a molecular weight (MW) under 600 cross the placenta without difficulty, whereas those with MW over 1000 do not. A molecule such as digoxin (MW 780.95) crosses the ovine placenta very poorly. Molecular weights of most local anesthetics are in the 200–300 range. From the physical aspect, most local anesthetics cross the maternal–fetal barrier by simple diffusion according to the principles of Fick's law (Fig 29–2), which states that the rate of diffusion of a drug depends on the concentration gradient of the drug between the maternal and fetal compartments and the relationship of the thickness and total surface available for transfer.

Figure 29–2.

Fick's law. A, surface area available for drug transfer; C_M , maternal drug concentration; C_F , fetal drug concentration; D, membrane thickness; K, diffusion constant of the drug; Q/T, rate of diffusion.

PLACENTAL TRANSFER

Factors other than the physical or chemical properties of a drug may affect its transfer across the placenta. These factors include the rate and route of drug administration and the distribution, metabolism, and excretion of the drug by the mother and fetus. Fick's law may appear to be a simple method of determining drug transfer, but other complexities exist: differential blood flow on either side of the placenta, volume of maternal and fetal blood, and various shunts in the intervillous space that are important determinants of the final amount of drug a fetus may receive. Certain maternal disorders, such as hypertensive cardiovascular disease, diabetes, and preeclampsia-eclampsia, may alter placental blood flow and in some way affect the extent of drug distribution.

As the placenta matures, the thickness of the epithelial trophoblastic layer progressively decreases. This reduction may cause the thickness of the tissue layers between the maternal and fetal compartments to decrease 10-fold (from as much as 25 μm in early gestation to 2 μm at term in some species). As gestation progresses, the surface area of the placenta also increases. At term, these changes in physical structure tend to favor improved transfer of drugs across the placenta.

Placental transfer is affected by the pH of the blood on both sides of the placenta. The pH of the blood on the fetal side of the placenta normally is 0.1–0.2 U lower than that on the maternal side. Therefore, passage of drug to the fetal unit results in a tendency for more of the drug to exist in the ionized state. Because the maternal–fetal

equilibrium is established only between the un-ionized fraction of the drug on either side of the barrier, this physiologic differential will expedite maternal–fetal transfer of drug. With more drug in the ionized form in the fetal unit, the new equilibrium that arises results in a greater total (ionized plus un-ionized) drug load in the fetus. Because the pK_a values of commonly used local anesthetics are closer to the maternal blood pH, these agents tend to accumulate on the fetal side of the placenta. This also is true of other basic drugs such as morphine, meperidol, and propranolol. Further decreases in the fetal pH lead to additional drug entrapment in the fetus. For acidic drugs (eg, thiopental) the shift in total drug concentration is in the opposite direction, that is, toward the maternal side of the placenta.

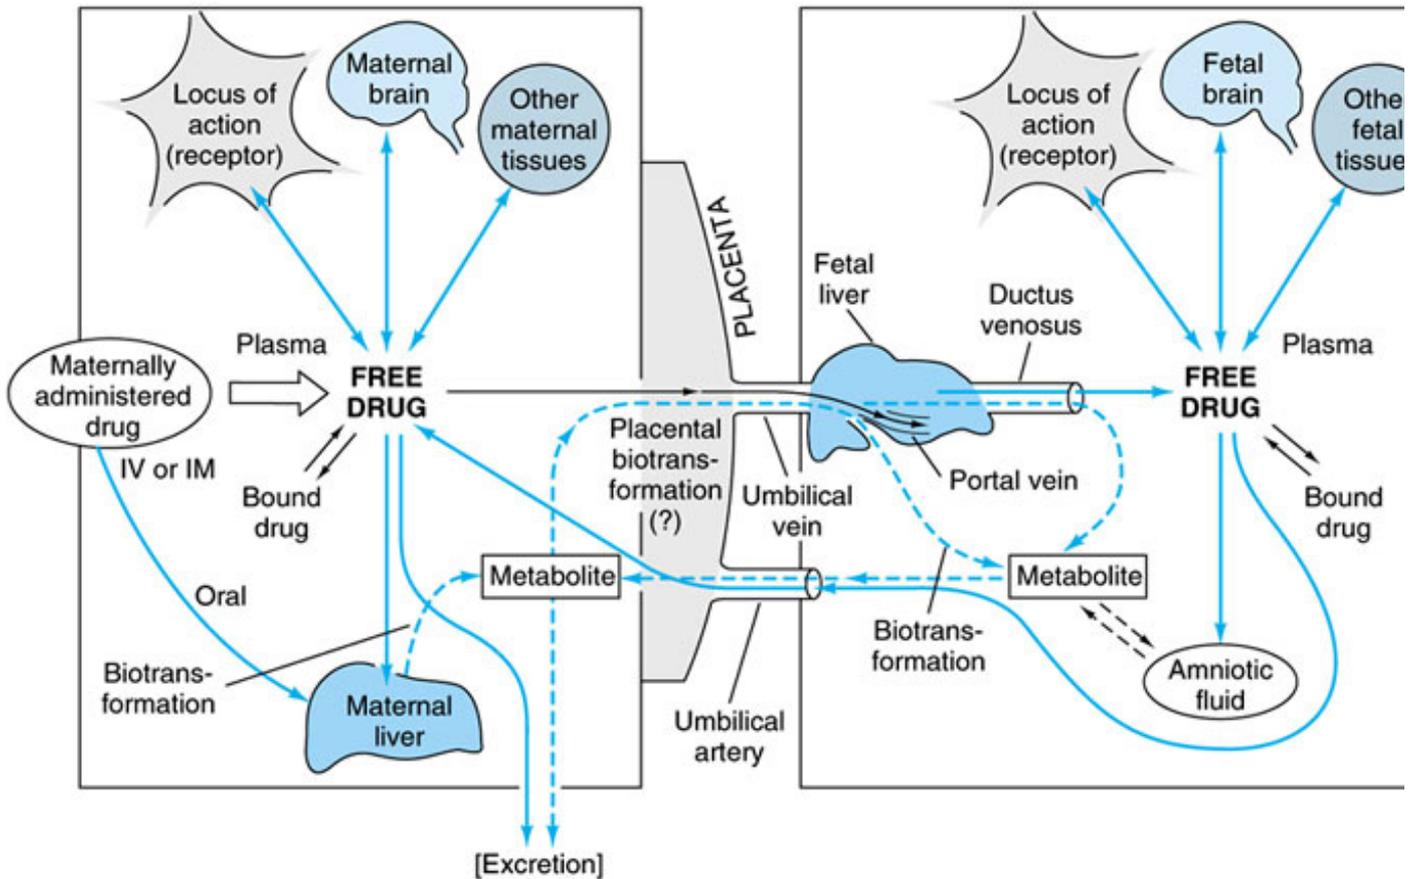

In summary, the rate of transfer of a drug is governed mainly by (1) lipid solubility, (2) degree of drug ionization, (3) placental blood flow, (4) molecular weight, (5) placental metabolism, and (6) protein binding.

FETAL DISTRIBUTION

After a drug deposited in the maternal compartment passes through the maternal–fetal barrier, the drug must reach the fetus and undergo distribution (Fig 29–3). The response of the fetus and newborn depends on drug concentration in vessel-rich organs, such as the brain, heart, and liver. Drugs transferred from the maternal to the fetal compartment of the placenta are then diluted before distribution to the various fetal vital organs.

Approximately 85% of the blood in the umbilical vein, which passes from the placenta to the fetus, passes through the fetal liver and then into the inferior vena cava. The remainder bypasses the liver and enters the vena cava primarily via the ductus venosus. The drug concentration is further reduced by an admixture of blood coming from the lower extremities, the abdominal viscera, the upper extremities, and the thorax. Blood from the right atrium shunts from right to left through the foramen ovale into the left atrium, resulting in a final concentration on the left side of the heart, which is only slightly lower than that in the vena cava.

Figure 29–3.

All rights reserved.

Relationship between maternal and fetal compartments and distribution of drugs between them. Drug is passed the maternal compartment, via the placenta (a partial barrier), to the fetal compartment, where the principles of drug dynamics (ie, distribution, biotransformation, and excretion) determine the eventual specific organ tissue levels. One purely mechanical barrier exists between the maternal and fetal compartments, which attains import in the late first and second stages of labor—the umbilical cord, which is susceptible to partial and total occlusion.

The amount of drug ultimately reaching a vital organ is related to that organ's blood supply. Because the central nervous system is the most highly vascularized fetal organ, it receives the greatest amount of drug. Once the drug reaches the fetal liver, it may either be bound to protein or metabolized.

The uptake of drug by fetal tissues can be very rapid after either intravenous or epidural administration. Measurements of local anesthetics have been found in fetal tissues as early as 1–2 minutes after injection. Lipid solubility of a drug is important in developing concentrations in certain organs with high lipid content, such as the adrenal, ovary, liver, and brain.

Drug metabolism and excretion are the final features of the fetal distribution picture. The fetal liver is able to metabolize drugs and numerous substrates as early as the second trimester, an ability that improves to term. Narcotics and sedatives are metabolized much more slowly by the fetal liver, producing a prolonged effect of the drugs in the newborn who is exposed in utero. Finally, the ability of the fetus to excrete drugs is also reduced by reduced renal function.

Systemic Analgesics & Anesthetics

SEDATIVES (HYPNOTICS)

The principal use of sedative–hypnotic drugs is to produce drowsiness. For many years, these drugs were the or

ones available to reduce anxiety and induce drowsiness. The latent phase of the first stage of labor can be managed by either psychologic support alone or utilization of sedative–hypnotic compounds. Psychologic support may be complemented by the use of sedatives. When properly used, these drugs induce tranquility and an enhanced feeling of well-being. They are poor analgesics and do not raise the pain threshold appreciably in conscious subjects. Amnesia does not occur. Labor may be slowed by large doses of sedatives, especially when given too early in the first stage.

The use of barbiturates alone for obstetric analgesia is not common practice and should be discouraged. The required dosage is dangerous to the fetus, which is extremely sensitive to central nervous system depression by these drugs. Periodic apnea and even abolition of all movements outlast the effects of the barbiturates on the mother.

TRANQUILIZERS AND AMNESTICS

These drugs are used principally to relieve apprehension and anxiety and to produce a calm state. Additionally, they may potentiate the effects of other sedatives. An analgesic-potentiating effect is often claimed for this group of agents but has not been definitely demonstrated. Hydroxyzine and diazepam are popular tranquilizer–amnestics. Scopolamine, which was widely popular in obstetrics in the past, produces no analgesia but has a mild sedative and marked amnestic effect. Scopolamine is no longer used because the amnesia produced is excessive and prolonged. Diazepam should be avoided during labor because it has a long chemical half-life, which is even more prolonged in the neonate. Diazepam readily crosses the placenta and is found in significant concentrations in fetal plasma. At present, diazepam is not recommended if the neonate is premature because of the threat of kernicterus. Other potential side effects related to the use of diazepam are fetal hypotonia, hypothermia, and a loss of beat-to-beat variability in the fetal heart rate.

One of the controversies over diazepam concerns the content of sodium benzoate and benzoic acid buffers. Both compounds are potent uncouplers of the bilirubin–albumin complex, and some investigators have suggested that the neonate may be more susceptible to kernicterus because of an increase in level of free circulating bilirubin. However, because injectable diazepam is effective in the treatment of human newborn seizure disorders, opiate withdrawal, and tetanus and because it is regarded as a useful adjunct in obstetric analgesia, a study was undertaken in which comparable quantities of sodium benzoate were injected to determine whether significant amounts of bilirubin would be made available to the circulation. Midazolam, a short-acting water-soluble benzodiazepine, appears to be devoid of the neonatal effects seen with diazepam and is more rapidly cleared. Midazolam is a relatively new agent with minimal clinical use to date in obstetrics, but in small doses it could conceivably become a useful anxiolytic for the laboring patient. Midazolam is 3–4 times more potent than diazepam, and there is a brief delay in the onset of its sedative effect after intravenous injection. Doses should be kept below 0.075 mg/kg to avoid excessive anterograde amnesia.

NARCOTIC ANALGESICS

Systemic analgesic drugs (including narcotics) are commonly used in the first stage of labor because they produce both a state of analgesia and mood elevation. The favored drugs are codeine 60 mg intramuscularly or meperidine 50–100 mg intramuscularly or 25–50 mg (titrated) intravenously. The combination of morphine and scopolamine was once popular for its "twilight sleep" effect but is rarely used now. Common undesirable effects of this combination of drugs are nausea and vomiting, cough suppression, intestinal stasis, and diminution in frequency, intensity, and duration of uterine contractions in the early first stage of labor. Also, amnesia is excessive for these patients.

Morphine is not used in active laboring patients because of the excessive respiratory depression seen in the neonate compared with equipotent doses of other narcotics. Fetuses who are of young gestational age, are small for date, or have undergone trauma or long labor are more susceptible to narcosis.

Fentanyl is a popular synthetic narcotic that has been used in obstetrics in both the systemic and epidural

compartments. Its use in the epidural compartment has met with good success when combined with small quantities and low concentrations of bupivacaine. Data supporting its use come from both Europe and the United States.

THIOBARBITURATES

Intravenous anesthetics such as thiopental and thiamylal are widely used in general surgery. However, less than minutes after a thiobarbiturate is injected into the mother's vein, the concentrations of the drug in the fetal and maternal blood will be equal. The mother will lose consciousness and airway protective reflexes with a thiopental dose of 1.5–2 mg/kg; therefore, it should be used only in association with general endotracheal anesthesia.

PROPOFOL

Propofol is a newer induction agent that was introduced into practice in the United States in the early 1990s. It is a hydrophobic propylphenol that is formulated as an aqueous emulsion in soybean and egg phosphatide. As an induction agent, it is similar to the barbiturates in mild cardiac depression and loss of peripheral vasomotor tone. It offers the advantages of rapid clearance, short duration of action, antiemetic properties, and reduced risk of airway reactivity. It is an ideal agent for induction of general anesthesia at a dose of 2 mg/kg in parturients. It also can be used in 10- to 20-mg increments during surgery under regional block to treat nausea and vomiting. Neonatal Apgar scores and umbilical gases are similar following induction with propofol or barbiturates.

KETAMINE

The phencyclidine derivative ketamine produces anesthesia by a dissociative interruption of afferent pathways for cortical perception. It has become a useful and widely used adjunctive agent in obstetrics because maternal cardiovascular status and uterine blood flow are well maintained. In low doses of 0.25–0.5 mg/kg intravenously, effective maternal analgesia results but without loss of consciousness or protective reflexes. The margin of safety is narrow, however, so it should be used only by physicians able to easily secure and protect the airway if loss of consciousness occurs. For cesarean section delivery, general anesthetic induction can be produced with 1–2 mg/kg intravenously and is followed in rapid sequence with a muscle relaxant and endotracheal intubation. Ketamine is useful in the setting of major blood loss, when rapid induction of general anesthesia is required. However, it has significant hallucinogenic effects that limit its utility in obstetrics.

Ketamine stimulates the cardiovascular system to maintain heart rate, blood pressure, and cardiac output; therefore, it is useful in complicated situations of maternal hypotension/hemorrhage.

INHALATION ANESTHETICS

Inhaled anesthetics are administered as a component of general anesthesia. In the past, inhaled anesthetics were given during labor in subanesthetic concentrations to treat contraction pain, but they are no longer used for this indication. The mask administration of these gases to the conscious laboring patient can result in airway obstruction, aspiration, and hypoxia. Also, the labor room environment would become unacceptably contaminated by the vaporized gases because effective scavenging of exhaust gases from the room is not possible. Finally, of all the presently used volatile anesthetics, only nitrous oxide has analgesic properties at subanesthetic concentrations.

The most commonly used inhaled anesthetics in pregnancy are nitrous oxide, halothane, and isoflurane. During general anesthesia, 50% nitrous oxide in oxygen is supplemented with either 0.5% halothane or 0.7% isoflurane to provide most of the anesthetic requirements during the maintenance phase of the anesthetic. These drugs all readily cross the placenta and produce significant blood concentrations in the fetus. During the brief exposure to maternally administered anesthetic gases, the fetus is not adversely affected. Fetal cardiac output is slightly reduced by the drugs, but critical organ blood flow is unaffected, and fetal acid–base status is unchanged. Exposure to minimum alveolar concentrations of anesthetic gases for more than 15 minutes is associated with reduced Apgar scores, but other parameters of fetal and newborn well-being are unimpaired.

The term parturient is more sensitive to the anesthetic effects of all inhaled anesthetics, presumably as a result of elevated progesterone levels. This increased sensitivity of 20–30% compared to nonpregnant subjects places the

patient at increased risk for obtundation and aspiration; therefore these drugs should not be administered without preparation for endotracheal intubation. Halothane and isoflurane produce uterine relaxation, and high concentrations should be avoided during delivery to prevent uterine atony and postpartum hemorrhage. At low concentrations (< 1%), they produce amnesia and their tocolytic effects are easily counteracted by standard infusions of oxytocin (Pitocin). These gases are both bronchodilators. Halothane has a more depressant effect on myocardium, and isoflurane produces greater reduction in systemic vascular resistance (SVR).

Newer volatile anesthetics (eg, desflurane, sevoflurane) have not been used widely in the parturient. These anesthetic gases are insoluble in blood and tissue and therefore are very short acting. Whether this property is an advantage or disadvantage during cesarean surgery compared to halothane and isoflurane is not clear.

REGIONAL ANESTHESIA

Regional anesthesia is achieved by injection of a local anesthetic (Table 29–2) around the nerves that pass from spinal segments to the peripheral nerves responsible for sensory innervation of a portion of the body. More recent narcotics have been added to local anesthetics to improve analgesia and reduce some side effects of local anesthetics. Regional nerve blocks used in obstetrics include the following: (1) lumbar epidural and caudal epidural block, (2) subarachnoid (spinal) block, and (3) pudendal block.

Tetracaine (Pontocaine)	Lidocaine (Xylocaine)	Bupivacaine (Marcaine)

Modified and reproduced, with permission, from Guadagni NP, Hamilton WK: Anesthesiology. In: Dunphy JE, Wa LW (editors): *Current Surgical Diagnosis & Treatment*, 4th ed: Lange, 1979.

Infiltration of a local anesthetic drug and pudendal block analgesia carry minimal risks. The hazards increase with the amount of drug used. The safety and suitability of regional anesthesia depend on proper selection of the drug and the patient and the obstetrician–gynecologist's knowledge, experience, and expertise in the diagnosis and treatment of possible complications. Major conductive anesthesia and general anesthesia in obstetrics require specialized knowledge and expertise in conjunction with close maternal and fetal monitoring. This field of expertise has developed as a subspecialty within anesthesia, reflecting the need for specialized understanding of the obstetric patient and her response and of the fetal responses to anesthesia.

Patient Selection

Regional anesthesia is appropriate for labor analgesia, cesarean delivery, and other obstetric operative procedures (eg, postpartum tubal ligation, cervical cerclage). Most patients prefer to remain awake; however, occasionally a choice is made to provide general anesthesia.

The anesthesiologist will assess the patient to determine the relative risks of general versus regional anesthesia. For example, some forms of valvular heart disease may contraindicate regional block, and general anesthesia may be considered more appropriate. Other contraindications to regional anesthesia include infection, coagulopathy, hypovolemia, progressive neurologic disease, and patient refusal.

Patient Preparation

The woman who is well informed and has a good rapport with her physician generally is a calm and cooperative candidate for regional or general anesthesia. The patient and her partner should be well informed early in her pregnancy of the options for labor anesthesia as well as for cesarean section if that circumstance arises. The anesthesiologist can be involved early in pregnancy if the patient has special concerns about anesthesia (family history of anesthetic risk, previous back surgery, coagulation problems). Some hospitals have obstetric anesthesia preassessment clinics that deal with these patient concerns.

Local Anesthetic Agents

A local anesthetic drug blocks the action potential of nerves when their axons are exposed to the medication. Local anesthetic agents act by modifying the ionic permeability of the cell membrane to stabilize its resting potential. The smaller the nerve fiber, the more sensitive it is to local anesthetics because the susceptibility of individual nerve fibers is inversely proportional to the cross-sectional diameter of the fibers. Hence, with regional anesthesia, the patient's perception of light touch, pain, and temperature and her capacity for vasomotor control are obtunded sooner and with a smaller concentration of the drug than is the perception of pressure or the function of motor nerves to striated muscles. The exception to this rule is the sensitivity of autonomic nerve fibers that are blocked at the lowest concentration of local anesthetic despite their being larger than some sensory nerves.

Only anesthetic drugs that are completely reversible and nonirritating and cause minimal toxicity are clinically acceptable. Other desirable properties of regional anesthetic agents include rapidity of onset, predictability of duration, and ease of sterilization. Table 29–2 summarizes the local anesthetics commonly used in obstetrics and gynecology together with their uses and doses.

All local anesthetics have certain undesirable dose-related side effects when absorbed systemically. All these drugs are capable of stimulating the central nervous system and may cause bradycardia, hypertension, or respiratory stimulation at the medullary level. Moreover, they may produce anxiety, excitement, or convulsions at the cortical subcortical level. This response stimulates grand mal seizures because it is followed by depression, loss of vasomotor control, hypotension, respiratory depression, and coma. Such an episode of indirect cardiovascular depression often is accentuated by a direct vasodilatory and myocardial depressant effect. The latter is comparable to the action of quinidine. This effect explains why lidocaine is useful for treatment of certain cardiac arrhythmias.

Chloroprocaine is an ester derivative that was popular in the mid-1960s but fell into disuse clinically. In the 1970s it enjoyed a resurgence in popularity primarily because of its rapid onset and short duration of action and its low toxicity to the fetus. Its physicochemical properties are imparted by the chloro substitution of the 2-position in the benzene ring of procaine. It is metabolized by plasma cholinesterase and therefore does not demand liver enzyme degradation, as do the more complex and longer-acting amide derivatives. Chloroprocaine has a half-life of 21 seconds in adult blood and 43 seconds in neonatal blood. Direct toxic effects on the fetus are minimized because less drug is available for transfer in the maternal compartment.

The potency of chloroprocaine is comparable to that of lidocaine and mepivacaine, and the drug is 3 times more potent than procaine. Its average onset of action ranges from 6–12 minutes and persists for 30–60 minutes, depending on the amount used. Its use has been severely curtailed because of recent reports of toxicity that include arachnoiditis and associated neuropathies. The new 3% chloroprocaine is less acidic and has a reduced concentration of sodium metabisulfate (0.5 mg/mL) and is safe for epidural use.

Bupivacaine, the amide local anesthetic, is related to lidocaine and mepivacaine but has some very different physicochemical properties. It has a much higher lipid solubility, a higher degree of binding to maternal plasma protein, and a much longer duration of action. More than with other local anesthetics, the concentration of bupivacaine can be reduced to produce sensory block with minimal motor block. Because injection of bupivacaine for labor pain relief now is mostly in the form of continuous small-volume and minimal concentration administration by a pump mechanism, the complications previously of concern, such as hypotension and convulsions, are now rare.

A word of caution is needed regarding the administration of bupivacaine for cesarean section delivery. This drug has been implicated in certain cardiovascular catastrophes associated with initial drug injection, such as cardiac arrest that were refractory to full and appropriate resuscitative attempts. Although these catastrophes are rare, the practitioner is well advised to inject no more than 5 mL of the drug at any one time, to wait 4–5 minutes, then to repeat the procedure until the desired volume has been delivered. The maximum concentration of bupivacaine now allowed by the Food and Drug Administration (FDA) for obstetric epidural anesthesia is 0.5%. The toxic dose of bupivacaine now is considered 1–2 mg/kg.

Ropivacaine is a new amide local anesthetic introduced into the United States in the mid-1990s. It is less lipid soluble than bupivacaine, and initial studies suggested that it produced less motor blockade and was less cardiotoxic than its homologue bupivacaine. Later studies have been less convincing in documenting improved efficacy and safety, but ropivacaine has replaced bupivacaine in some institutions. There is ongoing study of the safety and efficacy of levobupivacaine, the levorotatory isomer of bupivacaine, which may also prove less cardiotoxic than its racemic parent molecule. Both of these newer amide local anesthetics are used in doses and concentrations similar to those of bupivacaine.

Local Infiltration Analgesia

Local tissue infiltration of dilute solutions of anesthetic drugs generally yields satisfactory results because the target is the fine nerve fibers. Nevertheless, one must keep in mind the dangers of systemic toxicity when large areas are anesthetized or when reinjection is required. It is good practice, therefore, to calculate in advance the milligram of drug and volume of solution that may be required to keep the total dosage below the accepted toxic dose.

Infiltration in or near an area of inflammation is contraindicated. Injections into these zones may be followed by rapid systemic absorption of the drug as a result of increased vascularity of the inflamed tissues. Moreover, the injection may introduce or aggravate infection.

Regional Analgesia Techniques

LUMBAR EPIDURAL BLOCK

This analgesic technique has become more popular recently because it is well suited to obstetric anesthesia. Either bolus injections or continuous infusion of local anesthetics is used for labor, vaginal delivery, or cesarean surgery. Narcotics are added to supplement the quality of the block.

After the patient is evaluated, an epidural block can be placed once labor is established. Drug dosages can be adjusted as circumstances change. The catheter can be used for surgery and postoperative analgesia if necessary. The second stage of labor is prolonged by epidural anesthesia; however, the duration of the first stage is unaffected. The use of outlet forceps is increased, but fetal outcome is not adversely affected by epidural block.

The epidural block technique must be exact, and inadvertent massive (high) spinal anesthesia occasionally occurs. Other undesirable reactions include the rapid absorption syndrome (hypotension, bradycardia, hallucinations, convulsions), postpartum backache, and paresthesias. Epidural block should eradicate pain between T10 and L1 for the first stage of labor and between T10 and S5 for the second stage of labor.

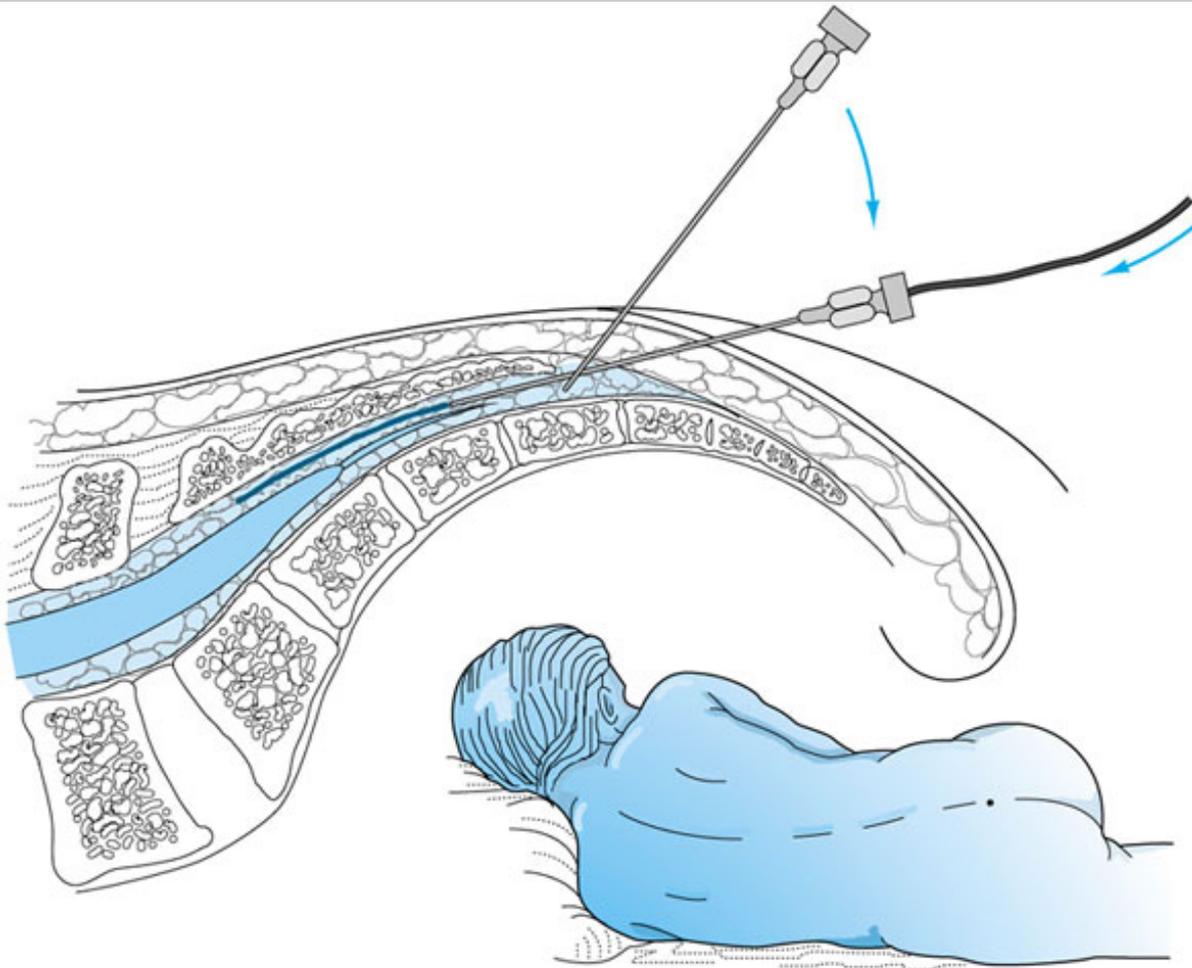

The procedure is as follows. Inject 3 mL of a 1.5% aqueous solution of lidocaine or similar agent into the catheter as a test dose. If spinal anesthesia does not result after 5–10 minutes, inject an additional 5 mL. Inject 10 mL of the anesthetic solution in total to slowly accomplish an adequate degree and suitable level of anesthesia. Once the block is established, a continuous infusion of 10–12 mL/h will maintain the block for labor. Bupivacaine 0.125–0.25% is most often used for an epidural block, with fentanyl 2–5 µg/mL in the epidural mixture.

The mother is nursed in a wedged or lateral position to prevent aortocaval compression. The sympathectomy produced by the block predisposes the patient to venous pooling and reduced venous return. Maternal blood pressure must be measured frequently when the epidural is in effect.

CAUDAL BLOCK

Caudal anesthesia (Fig 29–4) is an epidural block approached through the caudal space. It can provide selective sacral block for the second stage of labor; however, it is rarely used now because of complications specific to the obstetric patient. The descent of the fetal head against the perineum, in addition to the sacral edema at term, obscures the landmarks of the sacral hiatus. This makes the caudal procedure technically challenging, and reports of transfixing the rectum and fetal skull puncture with the epidural needle have led many anesthesiologists to avoid this technique. Lumbar epidural anesthesia is considered a safer alternative.

Caudal catheter in place for continuous caudal anesthesia.

SPIRAL ANESTHESIA

Spinal anesthesia currently is the anesthetic of choice for cesarean delivery. Spinal anesthesia can be performed more quickly than epidural anesthesia and provides ideal operating conditions, including dense sensory and motor block. The onset of sympathectomy is more abrupt than with epidural block, so care must be taken to ensure that the patient is adequately preloaded with 1.5–2 L of saline solution prior to performing the technique. Spinal anesthesia is used less commonly these days to alleviate the pain of delivery and the third stage of labor. The advantages of spinal anesthesia are that the mother remains conscious to witness delivery, no inhalation anesthetic or analgesic drugs are required, the technique is not difficult, and good relaxation of the pelvic floor and lower bony canal is achieved. Prompt anesthesia is achieved within 5–10 minutes. The dosage of spinal anesthetic is small.

Complications are rare and easy to treat. However, spinal headache occurs in 1–2% of patients.

COMBINED SPINAL–EPIDURAL ANESTHESIA

The use of combined spinal–epidural anesthesia (CSE) became popular in the mid 1990s as an alternative to epidural anesthesia for labor. A small dose of local anesthetic and narcotic (2.5 mg bupivacaine and 25 µg fentanyl) is injected through a spinal needle, which is introduced through the epidural needle and advanced into the intrathecal space. The spinal needle is withdrawn and the epidural catheter placed for later use. The spinal medication produces immediate pain relief and minimal motor block and may allow ambulation. Later in labor, the epidural catheter is used for continuous infusion of epidural solution, similar to that described for standard epidural anesthesia in labor.

Detractors of CSE argue that the technique may increase the incidence of post–lumbar puncture headache, and ambulation even after low-dose spinal injection is unsafe for both mother and baby. Finally, because the technique is technically cumbersome, it may be associated with higher complication rates. No data support either a benefit or disadvantage of CSE compared with standard epidural anesthesia for labor.

The most serious consequence of spinal or epidural anesthesia is maternal mortality. Maternal deaths associated with use of 0.75% bupivacaine for cesarean section delivery and labor were reported in the late 1980s, prompting the FDA to outlaw the use of this drug in obstetrics. These deaths were attributed to venous uptake of the drug, resulting in immediate and lasting myocardial depression from the local anesthetic, which did not respond to appropriate cardiac resuscitative efforts. Today maternal mortality associated with regional anesthesia is lower, primarily because bolus dosing of high concentrations of local anesthesia is no longer performed.

Most side effects of spinal or epidural anesthesia are secondary to block of the sympathetic nerve fibers that accompany the anterior roots of the spinal thoracic and upper lumbar nerves (thoracolumbar outflow). Thus, many physiologic regulating mechanisms are disturbed. The blood lumbar pressure falls as a result of loss of arterial resistance and venous pooling—assuming no compensation is made by change of the patient's position (eg, Trendelenburg position). If high thoracic dermatomes (T1–T5) are blocked, alteration of the cardiac sympathetic innervation slows the heart rate and reduces cardiac contractility. Epinephrine secretion by the adrenal medulla is depressed. Concomitantly, the unopposed parasympathetic effect of cardiac slowing alters vagal stimulations. As a result of these and related changes, shock follows promptly, especially in hypotensive or hypovolemic patients. Moreover, a precipitous fall in the blood pressure of the arteriosclerotic hypertensive patient is inevitable.

Fluids, oxygen therapy for adequate tissue perfusion, shock position to encourage venous return, and pressor drugs given intravenously are recommended.

In the past, postdural puncture headache (PDPH) due to leakage of cerebrospinal fluid through the needle hole in the dura was an early postoperative complication in up to 15% of patients. Small-caliber needles (25G) decrease the incidence of headache to 8–10%. With the introduction of pencil-point Whitaker and Sprotte spinal needles, the incidence of PDPH has been reduced to 1–2%. Therapy for PDPH includes recumbent position, hydration, sedation, and, in severe cases, epidural injection of 10–20 mL of the patient's fresh blood to "seal" the defect.

Rarely, spinal or epidural anesthesia caused nerve injury and transient or permanent hypesthesia or paresthesia. Excessive drug concentration, sensitivity, or infection may have been responsible for some of these complications. The incidence of serious complications of spinal or epidural anesthesia is considerably lower than that of cardiac arrest during general anesthesia.

PARACERVICAL BLOCK

Paracervical block is no longer considered a safe technique for the obstetric patient. In the past, paracervical anesthesia was used to relieve the pain of the first stage of labor. Pudendal block was required for pain during the second stage of labor. Sensory nerve fibers from the uterus fuse bilaterally at the 4–6 o'clock and 6–8 o'clock positions around the cervix in the region of the cervical–vaginal junction. Ordinarily, when 5–10 mL of 1% lidocaine

or its equivalent is injected into these areas, interruption of the sensory input from the cervix and uterus prompt follows.

Many now consider paracervical block to be contraindicated in obstetrics because of the potential adverse fetal effects. Many reports in the literature place the incidence of fetal bradycardia at 8–18%. However, recent work with accurate fetal heart rate monitoring associated with continuous uterine contraction patterns suggests that the incidence is closer to 20–25%. Some researchers have attempted to investigate the significance of the bradycardia. One explanation is that an acid–base disturbance in the fetus does not occur unless the bradycardia lasts longer than 10 minutes, and that neonatal depression is rare unless associated with delivery during the period of bradycardia. There seems to be little difference in the incidence and severity of fetal bradycardia by paracervical block between complicated and uncomplicated patients. Other disadvantages of paracervical block include maternal trauma and bleeding, fetal trauma and direct injection, inadvertent intravascular injection with convulsions, and short duration of the block.

PUDENDAL NERVE BLOCK

Pudendal block has been one of the most popular of all nerve block techniques in obstetrics. The infant is not depressed, and blood loss is minimal. The technique is simplified by the fact that the pudendal nerve approaches the spine of the ischium on its course to innervate the perineum. Injection of 10 mL of 1% lidocaine on each side will achieve analgesia for 30–45 minutes approximately 50% of the time.

Both the transvaginal and transcutaneous methods are useful for administering a pudendal block. The transvaginal technique has important practical advantages over the transcutaneous technique. The "Iowa trumpet" needle guide can be used, and the operator's finger should be placed at the end of the needle guide to palpate the sacrospinous ligament, which runs in the same direction and is just anterior to the pudendal nerve and artery. Appreciating the sensation of the needle puncturing the ligament usually is difficult. This facet of the technique (no definite endpoint) may make it difficult for the inexperienced clinician to perform. Aspiration of the syringe for possible inadvertent entry into the pudendal artery should be accomplished, and, if no blood is returned, 10 mL of local anesthetic solution should be injected in a fanlike fashion on the right and left sides. The successful performance of the pudendal block requires injection of the drug at least 10–12 minutes before episiotomy. Often in clinical practice pudendal block is performed within 4–5 minutes of episiotomy, so the local anesthetic may not have adequate time to take effect.

Advantages and Disadvantages

Advantages of pudendal nerve block are its safety, ease of administration, and rapidity of onset of effect.

Disadvantages include maternal trauma, bleeding, and infection; rare maternal convulsions due to drug sensitivity; occasional complete or partial failure; and regional discomfort during administration.

The pudendal perineal block, like any other nerve block, demands some technical experience and knowledge of the innervation of the lower birth canal. Nevertheless, in spite of a well-placed bilateral block, skip areas of perineal analgesia may be noted. The possible reason is that although the pudendal nerve is of S2–S4 derivation and does contribute to the majority of fibers for sensory innervation to the perineum, other sensory fibers also are involved. For example, the inferior hemorrhoidal nerve may have an origin independent from that of the sacral nerve and therefore will not be a component branch of the pudendal nerve. In this case, it must be infiltrated separately. In addition, the posterior femoral cutaneous nerve (S1–S3) origin may contribute an important perineal branch to the anterior fourchette bilaterally. In instances where this nerve plays a major role in innervation, it must be blocked separately by local skin infiltration.

Two other nerves contribute to the sensory innervation of the perineum: the ilioinguinal nerve, of L1 origin, and the genital branch of the genitofemoral nerve, of L1 and L2 origin. Both of these nerves sweep superficially over the mons pubis to innervate the skin over the symphysis of the mons pubis and the labium majus. Occasionally, the nerves must also be separately infiltrated to provide optimal perineal analgesic effect. Thus it should be apparent

that a simple bilateral pudendal nerve block may not be effective in many cases. For maximum analgesic effectiveness, in addition to a bilateral pudendal block, superficial infiltration of the skin from the symphysis mediana to a point halfway between the ischial spines may be necessary. Thus, a true perineal block may be regarded as a regional technique.

Either lumbar epidural or caudal epidural block should eradicate pain between the T10 and S5 levels for the second stage. All of these nerves are denervated because they all are derived from L1–S5 segments.

Procedure

(Fig 29–5)

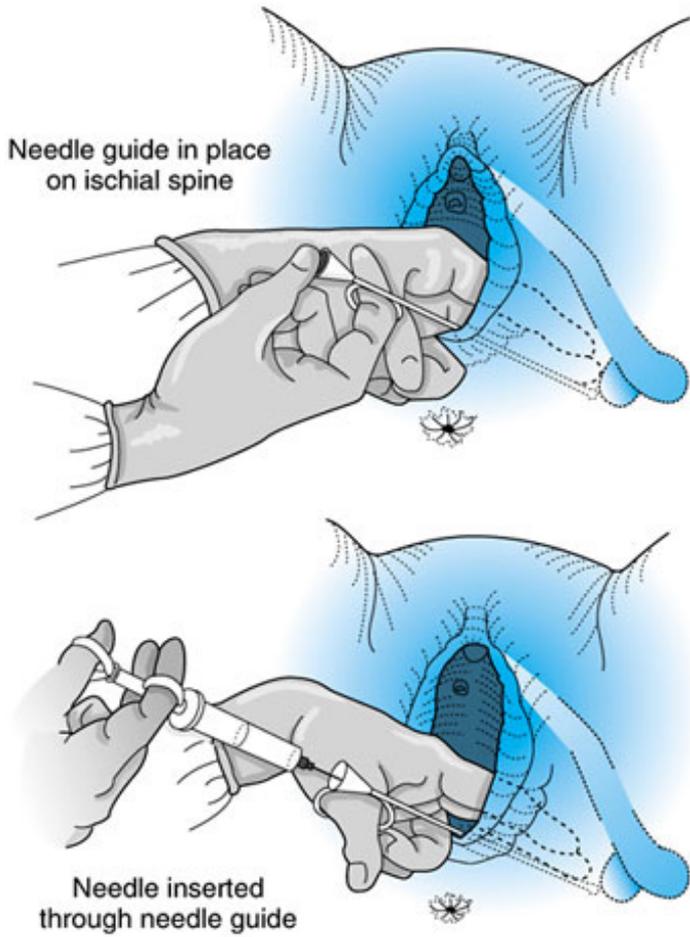

1. Palpate the ischial spines vaginally. Slowly advance the needle guide toward each spine. After placement is achieved, the needle is advanced through the guide to penetrate approximately 0.5 cm. Aspirate and, if the needle is not in a vessel, deposit 5 mL below each spine. This blocks the right and left pudendal nerves. Refill the syringe when necessary, and proceed in a similar manner to anesthetize the other areas specified. Keep the needle moving while injecting and avoid the sensitive vaginal mucosa and periosteum.

2. Withdraw the needle and guide approximately 2 cm and redirect toward an ischial tuberosity. Inject 3 mL near the center of each tuberosity to anesthetize the inferior hemorrhoidal and lateral femoral cutaneous nerves.

3. Withdraw the needle and guide almost entirely and then slowly advance toward the symphysis pubica almost to the clitoris, keeping approximately 2 cm lateral to the labial fold and approximately 1–2 cm beneath the skin. Injection of 5 mL of lidocaine on each side beneath the symphysis will block the ilioinguinal and genitocrural nerves.

If the procedure explained is carefully and skillfully done, only slight discomfort will be felt during the injections. Prompt flaccid relaxation and good anesthesia for 30–60 minutes can be expected. A summary of anesthetic approaches in labor is shown in Figure 29–6.

First-stage management in a primipara can be divided into 3 phases. Phase I (early labor) should be managed by simple reassurance and verbal commentary if the patient has received adequate antepartum education. An epidural may be performed once labor is well established. Phase II can be handled by a segmental epidural block, continued reassurance, a sedative-hypnotic drug, a narcotic, or a tranquilizer. Phase III, the accentuated phase of labor, can be handled by segmental epidural block, a combination tranquilizer and analgesic, or a caudal epidural block. However, use of reassurance and verbal commentary in conjunction with prepared childbirth methods may be adequate for some patients to tolerate the discomfort of phase III labor.

Prevention & Treatment of Local Anesthetic Overdosage

The correct dose of any local anesthetic is the smallest quantity of drug in the greatest dilution that will provide adequate analgesia. The pregnant patient is more likely to have an intravascular drug injection because of venous distention in the epidural space and may be more susceptible to the toxic effects of local anesthetics (Table 29-3). Injection of the drug into a highly vascularized area will result in more rapid systemic absorption than, for example, injection into the skin. To prevent too-rapid absorption, the operator can add epinephrine to produce local vasoconstriction and prolong the anesthetic. A final concentration of 1:200,000 is desirable, especially when a toxic amount is approached. Epinephrine is contraindicated in patients with increased cardiac irritability of medical or surgical origin.

¹ Doses as low as 90 mg have produced cardiac arrest.

Treatment of local anesthetic overdosage manifested by central nervous system toxicity (a convulsion) is generally achieved effectively and without incident. However, the clinician must be aware of certain basic principles. These include the recognition of prodromal signs of a central nervous system toxic reaction and immediate treatment as required. A toxic central nervous system reaction to local anesthetics consists of ringing in the ears, diplopia, perioral numbness, and deep, slurred speech. An adequate airway must be maintained, and the patient should receive 100% oxygen, with respiratory assistance if necessary. Protection of the patient's airway and immediate injection of thiopental 50 mg or midazolam 1–2 mg usually stop the convulsion immediately. Succinylcholine was recommended in the past, but it is a potent neuromuscular relaxant that requires placement of an endotracheal with positive-pressure ventilation. Studies have indicated that cellular metabolism is greatly increased during convulsive episodes so that a definite increase in cellular oxygenation occurs—hence the use of a depressant selective for the hypothalamus and thalamus because these sites are the foci of irritation.

ANESTHESIA FOR CESAREAN SECTION DELIVERY

With few exceptions, all cesarean section deliveries in the United States are performed with spinal, epidural, or general anesthesia. Maternal and neonatal outcomes are good when these techniques are performed effectively. In 1982, more than half of the cesarean births in the United States were performed under general anesthesia. By 1990, the rate had dropped to less than 10% of all cesarean births. Spinal anesthesia has become more common than epidural anesthesia for cesarean delivery in the past few years, primarily as a result of the introduction of newer spinal needles that prevent post-lumbar puncture headaches. Although the majority of anesthesia-related maternal mortality is associated with cesarean birth, the rate has continued to decline dramatically over the last few decades and now is less than 1.5 anesthesia-related deaths per million live births in the United States.

Regional Analgesia

LUMBAR EPIDURAL BLOCK

Lumbar epidural blockade can be used for cesarean section analgesia and adequate analgesia for operative delivery. As mentioned in the discussion of regional anesthesia, the major hazard of the regional analgesic technique is blockade of sympathetic fibers and a decrease in vascular resistance, along with venous pooling and hypotension. However, this can be greatly alleviated by elevating the patient's right hip to prevent compression of the vena cava by the gravid uterus when the patient is lying on the operating table. In addition, the anesthesiologist can rotate the operating table 15–20 degrees to the left to rotate the uterus away from the vena cava.

An epidural catheter can be placed immediately prior to surgery, or a catheter used to provide pain relief for labor can be reinjected for the surgery. After the catheter is suitably placed and taped in position, the patient should be rotated slightly out of the supine position to remove the hazard of vena cava occlusion when local anesthetic is injected as a test dose. Lidocaine 2% with epinephrine 1:200,000 can be used, or lidocaine 2% without epinephrine can be used if cardiovascular instability is present. Bupivacaine 0.5–0.75% or mepivacaine 1.5% with or without epinephrine (as described for lidocaine) also can be used. The total dosage for the therapeutic test is approximately 3 mL, which is an adequate amount to ascertain whether or not inadvertent subarachnoid injection of the drug has occurred. Incremental injections of 5 mL are then titrated to produce a T4–T6 sensory level. Usually a total volume of 18–20 mL of local anesthetic is required.

The blood pressure is monitored every 5 minutes and the dermatome levels examined every 5 minutes for the first 20 minutes to ascertain the height and density of the analgesic block. Usually a waiting period of only 15–20 minutes is needed for adequate analgesic block for incision. During this time, the patient's abdomen is surgically scrubbed and prepared and the patient draped for cesarean section delivery. If a brief episode of hypotension

occurs, the patient is given a rapid infusion of lactated Ringer's solution. In addition, the uterus must be shifted away from the vena cava. If these measures are not sufficient to relieve a brief episode of hypotension, 5–10 mg ephedrine intravenously can be administered for a mild vasopressor effect.

SUBARACHNOID BLOCK

Spinal block is now the most common anesthesia used for elective cesarean delivery in the United States. The advantages are immediate onset of analgesia, so no waiting period is needed for the block to become effective, the absence of drug transmission from the maternal to the fetal compartment because the anesthetic is deposited in the subarachnoid space in such small quantities. In addition, subarachnoid block may be a simpler technique to perform because the endpoint is definite—the identification of fluid from the subarachnoid space. The disadvantages are a more profound and rapid onset of hypotension and more frequent nausea and vomiting due either to unopposed parasympathetic stimulation of the gastrointestinal tract or to hypotension. Subarachnoid block is usually achieved via the paramedian or midline technique, details of which are beyond the scope of this text. The agents most commonly used for subarachnoid analgesia are lidocaine 5% (50–75 mg) and bupivacaine 10–12.5%. As with the lumbar epidural technique, the patient is prehydrated with 500–1000 mL of lactated Ringer's solution.

After the technical aspects of the procedure have been completed, the patient is placed in the supine position with the uterus displaced to the left as described. If hypotension occurs, the uterus should be pushed farther to the left to improve return of blood from the lower extremities into the circulation and increase right atrial pressure and cardiac output, and a bolus of Ringer's lactate should be given. If these measures are not successful, the patient should receive ephedrine 5–10 mg intravenously to sustain a mild vasopressor effect. During a period of hypotension, the mother should receive oxygen by mask to increase oxygen delivery to the uteroplacental bed. Newer spinal needles are associated with a low incidence (1–2%) of spinal headache (PDPH). As a result, spinal anesthesia is becoming more popular for elective cesarean surgery.

General & Local Anesthesia

General anesthesia is indicated for cesarean section delivery when regional techniques cannot be used because of coagulopathy, infection, hypovolemia, or urgency. Some patients prefer to be "put to sleep" and refuse regional techniques.

Ideally, general anesthesia for cesarean section delivery should cause the mother to be unconscious, feel no pain, and have no unpleasant memories of the procedure; the fetus should not be jeopardized, with minimal depression and intact reflex irritability.

General anesthesia for cesarean section delivery is substantially modified from the typical nonobstetric technique. The rapid sequence technique is used with cricoid pressure to prevent aspiration, with recognition that the risks for a term obstetric patient include (1) full stomach (and aspiration), (2) difficulty with laryngoscopy and intubation, and (3) rapid desaturation if intubation is unsuccessful.

PATIENT PREPARATION

Preoperative medication usually is not required when the patient is brought to the cesarean section room. Alert the patient preoperatively that she may have a lucid "window" during the operative procedure when she experiences pain or hears voices. Explain that the condition results from the need to maintain a light analgesic state in order to protect the fetus from large doses of drugs. The patient should be prepared with 30 mL of nonparticulate antacid to offset gastric acidity. The patient is given 100% oxygen with a close-fitting mask for 3 minutes prior to induction.

PROCEDURE

When the surgeon is ready to make the incision, thiopental 2.5 mg/kg should be injected intravenously and cricoid pressure exerted by an assistant. Immediately, succinylcholine 120–140 mg intravenously should be administered and intubation and inflation of the cuff performed. Intubation is confirmed by auscultation and monitoring end-tidal CO_2 before the cricoid pressure is released and the incision made. After 6–8 breaths of 100% oxygen, the patient

should be given nitrous oxide 50% with oxygen 50% until delivery of the fetus. Low concentrations of halothane (0.5%) will reduce the incidence of awareness. Intermediate-acting muscle relaxants maintain paralysis. An attempt must be made to keep the induction-to-delivery time under 10 minutes. Five minutes is required for redistribution of barbiturate back across the placenta into the maternal compartment. After delivery of the fetus nitrous oxide concentration can be increased to 70% if oxygen saturation is more than 98% and intravenous narcotics and benzodiazepines injected for supplemental anesthesia.

The patient should be fully awakened and on her side before extubation. Postoperative analgesia can be provided by patient-controlled administration of morphine or meperidine.

With this approach, good neonatal outcomes are anticipated if induction-to-delivery times and uterine invasion-to-delivery times are kept to a minimum.

SPECIAL PROBLEMS

Midforceps Delivery

Each patient's requirements vary, and every situation must be evaluated on an individual basis. Midforceps delivery often involves both rotation and traction. Therefore, the anesthetic regimen must provide relaxation as well as analgesia for the perineum, lower vagina, and upper birth canal. In order for the obstetrician to perform the procedures necessary for delivery, optimal conditions must be provided so that maternal and fetal trauma can be minimized. Regional analgesia with a lumbar, caudal epidural, or subarachnoid block is preferred because these blocks provide analgesia and optimal relaxation.

The Trapped Head

On the rare occasion when breech delivery is complicated by a trapped head, the application of forceps or other manipulations may be required urgently. If an epidural block is in place, no further analgesia will be required; however, if one is not in place, immediate anesthesia and pelvic relaxation will be required to facilitate rapid delivery and minimize trauma. The best technique for this purpose is general anesthesia with halothane after suitable protection of the patient from the hazards of aspiration. Protection should include use of antacid 30 mL orally and adequate oxygenation, followed by thiopental 200 mg intravenously, succinylcholine 80–100 mg intravenously, and rapid intubation with cricoid pressure. Another approach described in the literature is administration of 50–100 µg intravenous nitroglycerin to relax the lower uterine segment.

Multiple Pregnancy

PSYCHOANALGESIA

The psychoprophylactic technique helps to prepare the patient for the intrapartum experience. When the labor progresses normally, psychoanalgesia can effectively reduce apprehension and enhance the pleasurable aspects of childbirth. It also may prepare the patient for an understanding of some of the complications of multiple pregnancy (uterine inertia in the first stage of labor, uterine atony in the third stage, and possible need for cesarean section delivery) and reduce the total amount of drugs required for analgesia.

PUDENDAL NERVE BLOCK

Pudendal nerve block usually is reserved for cases in which epidural block is not available. Analgesia is more limited and does not provide as effective analgesia should version or breech extractions of the second twin be required.

EPI DURAL BLOCK

This technique is useful as a first-stage analgesic method, but only a segmental type should be used (T10–L2) to prevent the increased hazard of hypotension secondary to a combined large-segment sympathetic block and vertebral venous occlusion. Ideal management entails the use of lumbar epidural block for the first stage of labor and low caudal block for the late second stage of labor. Epidural anesthesia does not affect fetal outcome with twin delivery but the advantage of enabling the obstetrician to intervene more easily if the second twin presents abnormally. The need for a general anesthetic can be avoided if an epidural is in place and a cesarean section is required urgently.

delivery of the second twin.

SPIINAL BLOCK

The low subarachnoid block is rarely used at the end of the second stage for crowning, delivery, and episiotomy. low spinal block does not provide a sufficiently high block for cesarean section should it be required urgently (eg malpresentation or cord prolapse of the second twin). Therefore, an epidural anesthetic is always preferable for labor and delivery of multiple births.

INHALATION ANALGESICS

Nitrous oxide is the only inhalation anesthetic that is analgesic at low concentrations. Experience is needed to use nitrous oxide safely because the pregnant patient is sensitive to the drug's anesthetic effects and she can easily become obtunded. Loss of airway reflexes and aspiration are causes of maternal mortality.

General endotracheal anesthesia can be used for cesarean section delivery of twins. Neonatal depression is more likely if the induction-to-delivery time is long (>8 minutes), especially if the uterine incision-to-delivery time also prolonged (> 3 minutes).

Maternal Complications

PREECLAMPSIA—ECLAMPSIA

This syndrome is classically described as the triad of hypertension, generalized edema, and proteinuria. Other variants are described, the most notable being HELLP syndrome, the constellation of hemolysis, elevated liver enzymes and low platelet count. Preeclampsia— eclampsia accounts for approximately 20% of maternal deaths per year in the United States. The primary pathologic characteristic of this disease process is generalized arterial spasm. As gestation lengthens, there is a tendency toward a fluid shift from the vascular to the extravascular compartment with resultant hypovolemia—in spite of an expanded extracellular fluid space.

It is estimated that nearly 50% of eclamptic patients who die have myocardial hemorrhages or areas of focal necrosis. Major disorders of central nervous system function probably are caused by cerebral vasospasm. Optimal anesthetic management of these patients during the intrapartum period must include a careful preanesthetic evaluation of the cardiovascular and central nervous systems.

The physiologic changes of severe preeclampsia— eclampsia are exaggerated by regional block as a result of restricted intravascular volume, which may lead to considerable depression of blood pressure. A small subgroup of these patients suffer from reduced cardiac output (compared to normal pregnancy), decreased intravascular fluid space, and marked increases in SVR. Patients with severe hemodynamic changes may require direct monitoring of pulmonary artery and wedge pressures to manage labor and the effects of epidural anesthesia. Uterine blood flow increased with epidural block because of the favorable reduction of SVR, as long as central filling pressures and mean arterial pressure are well maintained.

Regional and general anesthesia is used in the management of preeclamptic patients. Contraindications to regional anesthesia include coagulopathy and urgency for nonreassuring fetal testing. The latter may mitigate against taking excessive time for placing a spinal or epidural if the baby requires immediate delivery.

Epidural anesthesia may be preferred to spinal anesthesia in cases of severe hypertension. The more graduated onset of sympathetic block with this technique is thought to produce less hypotension than would occur with spinal block. However, recent evidence suggests that adequate volume preloading of these patients, who by definition are volume depleted intravascularly, results in similar hemodynamic responses to both regional techniques. More study is required to confirm these findings. However, spinal and epidural anesthesia now usually is encouraged for the management of preeclamptic patients. Obstetricians have become aware that epidural anesthesia is a valuable adjunct in the management of hypertension as a result of the pain relief as well as the vasodilation produced by epidural block. In the past, epidural anesthesia was avoided because of an exaggerated concern over hypotension; now epidural anesthesia is encouraged if the patient's volume status is well managed and if coagulopathy does not

complicate the clinical picture.

HEMORRHAGE AND SHOCK

Intrapartum obstetric emergencies demand immediate diagnosis and therapy for a favorable outcome for the mother and fetus. Placenta previa and abruptio placentae are accompanied by serious maternal hemorrhage. Aggressive obstetric management may be indicated, but superior anesthetic management will play a major role in reducing maternal and fetal morbidity and mortality rates. The primary threat to the mother is blood loss, which reduces the effective circulating blood volume and her oxygenation potential. Similarly, the chief hazard to the fetus is diminished uteroplacental perfusion secondary to maternal hypovolemia and hypotension. The perinatal mortality rate associated with placenta previa and abruptio placentae ranges from 15–20% in some studies up to 50–100% in other studies. The overall morbidity and mortality rates for both the fetus and the mother depend on the gestational age and health of the fetus, the extent of the hemorrhage, and the therapy given.

Good anesthetic management demands early consultation. Reliable intravenous lines should be established early. In addition, recommendations for treatment and control of shock must be formulated. Prompt cesarean section delivery often is indicated. Ketamine can support blood pressure for induction. A modified nitrous oxide–oxygen relaxant method of general anesthesia will provide improved oxygenation for both the mother and the fetus and will have minimal effect on maternal blood pressure. As surgery progresses, it may be necessary to administer large volumes of warm blood, intravenous fluids, or even vasopressors when imperative. Regional block is contraindicated in the presence of hypovolemia.

UMBILICAL CORD PROLAPSE

Umbilical cord prolapse is an acute obstetric emergency that is a critical threat to the fetus. Often, because of confusion, irrational behavior by the medical staff may threaten the mother's life. For example, a haphazard rapid induction of anesthesia without attention to many of the essential safety details may be attempted. Naturally, prolapse of the umbilical cord is incompatible with fetal survival unless the fetal presenting part is elevated and maintained in that position to avoid compression of the cord. There then should be adequate time for a methodical, safe induction of anesthesia. General anesthesia is induced as soon as the abdomen is prepped and draped. In the rush of the emergency situation, the anesthesiologist must remain meticulous in his or her assessment and management of the mother's airway. A failed intubation and its consequent cardiorespiratory arrest constitute the leading cause of anesthetic maternal mortality.

BREECH DELIVERY

Epidural anesthesia can be used for the labor patient with a breech presentation. The need for breech extraction is not increased by the use of epidural anesthesia, and a functioning epidural may prevent the need for general anesthesia should an emergency arise at delivery.

If an epidural block is not in place at the time of delivery, the anesthesiologist must be prepared to proceed with immediate endotracheal general anesthesia if the aftercoming fetal head becomes trapped. Drugs, monitors, and anesthetic equipment must be prepared in anticipation of such an event.

Because breech delivery is associated with a high perinatal mortality rate, excellent communication and cooperation between the obstetrician and the anesthesiologist is greatly needed to effect an atraumatic delivery.

ANESTHESIA FOR EMERGENCY CESAREAN SECTION

General anesthesia is the technique most suitable for the urgent cesarean section delivery. It entails placement of an endotracheal tube with an inflated cuff to protect the patient from aspiration of gastric contents into the lung after administration of adequate barbiturate and a muscle relaxant to facilitate endotracheal intubation. Several safety measures must be taken. (1) Give 30 mL of a nonparticulate antacid (sodium citrate) within 15 minutes of induction. (2) Accomplish denitrogenation with 100% oxygen by tight-fitting mask. (3) Inject thiopental 2.5 mg intravenously. (4) Apply cricoid pressure. (5) Give succinylcholine 100–120 mg intravenously. (6) Intubate the

trachea and inflate the cuff. (7) Give 6–8 deep breaths of 100% oxygen. (8) Continue to administer nitrous oxide 50% with oxygen 50%, 0.5% halothane or isoflurane, and maintain relaxation with vecuronium or atracurium. (9) Supplement with short-acting narcotics and midazolam after the baby is delivered.

These steps should be instituted rapidly and with effective communication between the anesthesiologist and the obstetrician, who should be scrubbed and prepared to make the incision. With this technique, anesthesia can be induced and the fetus delivered within 30 minutes from the time cesarean section is ordered. To prevent vena caval occlusion from the gravid uterus, a wedge should be placed under the patient's right hip or the operating table rotated slightly to the left.

ANESTHESIA FOR NONOBSTETRIC COMPLICATIONS

Anesthesiologists use the following classification system developed by the American Society of Anesthesiologists (ASA). It is used in both emergency and nonemergent situations to record physical status and to ascertain that proper materials are available for the anticipated procedure.

Class 1: No organic, physiologic, biochemical, or psychiatric disturbance

Class 2: Mild to moderate systemic disturbance that may or may not be related to the reason for surgery (Examples: Heart disease that only slightly limits physical activity, essential hypertension, anemia, extremes of obesity, chronic bronchitis)

Class 3: Severe systemic disturbance that may or may not be related to the reason for surgery (Examples: Heart disease that limits activity, poorly controlled hypertension, diabetes mellitus with vascular complications, chronic pulmonary disease that limits activity)

Class 4: Severe systemic disturbance that is life-threatening with or without surgery (Examples: Congestive heart failure, crescendo angina pectoris, advanced pulmonary, renal, and hepatic dysfunction)

Class 5: Moribund patient who has little chance of survival but is submitted to surgery as a last resort (resuscitation effort) (Examples: Uncontrolled hemorrhage as from a ruptured abdominal aneurysm, cerebral trauma, pulmonary embolus)

Emergency operation (E): Any patient in whom an emergency operation is required (Example: Otherwise healthy 30-year-old woman who requires dilatation and curettage for moderate but persistent hemorrhage [ASA class 1E])

Hypertension

Preexisting hypertensive cardiovascular disease in a pregnant woman should be differentiated from preeclampsia/eclampsia. Unlike the latter, the manifestations of hypertensive disease usually are present before week 24 of pregnancy and persist after delivery. The untreated disease by itself presents a serious challenge to the obstetrician and increases maternal and fetal risk. Chronic hypertension does not specifically contraindicate any of the anesthetic options, but the anesthesiologist must assess and manage abnormalities of volume and vascular resistance to prevent hypotension. Systemic analgesia with sedatives and tranquilizers may be selected for first-stage pain relief, but a hazard still remains.

Heart Disease

Pregnancy superimposed on heart disease presents serious problems in anesthetic management. Patients with functional class I or II rheumatic or congenital heart disease usually fare well throughout pregnancy. Except for patients with fixed cardiac output (moderate to severe aortic stenosis or mitral stenosis), regional analgesia/epidural block provides ideal management of first- and second-stage pain relief. This avoids undesirable intrapartum problems such as anxiety, tachycardia, increased cardiac output, and the Valsalva maneuver. The lumbar epidural catheter can be activated for first-stage analgesia with sensory levels of T10 through L2 segments. With the restricted epidural technique, wide variations in blood pressure usually will be avoided and adequate analgesia provided.

Patients with valvular heart disease must be thoroughly assessed prior to onset of labor so that the anesthesiologist can determine the risks of regional block, tolerance to volume loading, and sympathectomy and determine the need for invasive monitoring. These patients require thorough physical examination, electrocardiography, echocardiography, and Doppler assessment of valve areas and left ventricular function.

Patients with stenotic lesions may not tolerate fluid loading or sympathetic block. Epidural narcotic anesthesia does not provide complete analgesia for labor but may be an appropriate choice if the patient does not tolerate the autonomic effects of local anesthetics. Patients with regurgitant valve lesions generally do well with this afterload reduction of epidural local anesthesia. Central monitoring of preload is indicated with severe lesions.

Marfan's syndrome and ischemic heart disease require early and aggressive management of labor pain to prevent hypertension and tachycardia. Early lumbar epidural anesthesia with narcotic/local anesthetic mixtures is recommended.

Diabetes Mellitus

Diabetes presents unique problems in anesthetic management because of the hazard to the fetus. The patient with diabetes requires a detailed regimen of antepartum care that extends through the intrapartum and the neonatal period. Moreover, hypotension presents an anesthetic hazard in situations of reduced fetal reserve common to diabetes. The latent phase of labor is best managed with psychological support, mild sedatives, or tranquilizers. The latter part of the first stage can be managed with small intravenous doses of narcotics or epidural block. If labor continues without signs of fetal distress and analgesia for the second stage is desired, either local or pudendal block or epidural or saddle block is appropriate. If a patient is allowed to undergo the stress of labor but fetal decompensation is evident, operative delivery must be performed at once, with emphasis on preventing hypotension. Careful regional block can be used if time permits. If time does not permit placement of a regional block, emergency general endotracheal anesthesia is indicated. Blood glucose levels should be measured intraoperatively because the unconscious patient cannot report hypoglycemia.

Gastrointestinal Difficulties

Gastrointestinal nonstriated muscle has diminished tone and motility during pregnancy. Some medical gastrointestinal difficulties present special problems in management during the intrapartum period. Peptic ulcer disease improves during pregnancy, but in some cases the disease worsens in the last trimester and causes serious problems during labor and the immediate postpartum period. Ulcer perforation and hematemesis are rare in labor. Nonetheless, good management of analgesia during delivery is necessary to decrease anxiety and apprehension.

Ulcerative colitis may worsen during pregnancy. Perinatal and maternal mortality rates are not increased because symptomatic management usually is adequate. Regional ileitis may become more severe during pregnancy.

Chronic pancreatitis may be reactivated during pregnancy. Acute pancreatitis occasionally occurs in the third trimester. The significant laboratory values are elevated serum amylase and reduced serum calcium levels, along with typical symptoms of epigastric pain and nausea and vomiting.

Sympathetic blocking techniques are not contraindicated for anesthetic management of the first and second stages of labor in these gastrointestinal disorders that may coincide with pregnancy. It is clinically desirable to alleviate anxiety and apprehension in the first stage of labor because tension may exacerbate the disease process. There is a tranquilizer–narcotic combination early in the first stage of labor should be considered and then lumbar epidural block for first- and second-stage management. Subarachnoid block can be administered to manage the second stage of labor successfully, with use of a true saddle block obtunding chiefly the sacral fibers.

Psychiatric Disorders

Most patients approaching delivery look upon the experience as one of the happiest times of their lives. However, some patients undergo severe emotional stress during the third trimester and as delivery nears.

The obstetrician and the anesthesiologist should talk openly with a psychiatric patient about the problems of labor and delivery management and offer suggestions for management of discomfort so that she will have minimal emotional stress. The ideal technique is the combined use of lumbar epidural block for the first stage and lumbar caudal epidural block for the second stage. It is best to carefully point out to the patient the reasons for choosing the technique and to review the technical points of the procedure so that she will not be alarmed when the block is attempted. These techniques are preferred because they afford early and continuous analgesia during labor and delivery.

TREATMENT OF COMPLICATIONS OF ANESTHETICS

Resuscitation of the Mother

Anesthesia is responsible for 10% of maternal mortality. The most common cause of maternal death is failure to intubate the trachea at induction of general anesthesia. Less frequently, maternal death results from inadvertent intravascular injection of local anesthetic (toxic reaction) or inadvertent intrathecal injection of anesthetic (total spinal).

When faced with maternal cardiovascular collapse, full cardiopulmonary resuscitation (CPR) is indicated:

1. Establish a patent airway.
2. Aspirate mucus, blood, and vomitus with a tracheal suction apparatus. Use a laryngoscope for direct visualization of air passages and intubate the trachea.
3. Administer oxygen by artificial respiration if respirations are absent or weak. If high spinal anesthesia has occurred, continue to ventilate the patient until paralysis of the diaphragm has dissipated.
4. Give vasopressors intravenously (ephedrine 10–20 mg). Place the patient in the wedged supine position with feet elevated and give transfusions of plasma, plasma expanders, and blood for traumatic or hemorrhagic shock.
5. Specifically treat cardiac arrhythmias in accordance with advanced cardiac life support (ACLS) recommendations.
6. Provide external cardiac massage in the absence of adequate rhythm and blood pressure.
7. Consider immediate cesarean section delivery to salvage fetus and improve venous return if the patient does not immediately respond to efforts.

Full cardiopulmonary arrest can be averted if the prodromal symptoms are recognized and treated immediately. Total spinal block is recognized by excessive and dense sensory and motor block to a test injection of local anesthetic through the epidural catheter. Further injections are avoided, and the patient's blood pressure is supported with fluid, positioning, and vasopressors.

An intravascular injection of local anesthetic is recognized early by symptoms of drowsiness, agitation, tinnitus, perioral tingling, bradycardia, and mild hypotension. The patient should be immediately given 100% oxygen and a small dose of diazepam (5 mg), midazolam (1 mg), or pentothal (50 mg). Further treatment may not be needed. The patient must be watched closely and the epidural catheter removed.

Current OB/GYN >Chapter 30. Operative Delivery>

OPERATIVE DELIVERY: INTRODUCTION

An *operative delivery* refers to an obstetric procedure in which active measures are taken to accomplish delivery. It can be divided into *operative vaginal delivery* and *cesarean delivery*. The last several years have seen a trend toward increasing the operative vaginal delivery rate but a climb in the cesarean section rate. In addition, vacuum-assisted vaginal delivery is increasing while vaginal delivery using forceps has started declining. The success and safety of these procedures depend on operator skill, proper timing, and ensuring that proper indications are met while contraindications are avoided. To ensure the best outcome, how each procedure is performed, the indications and contraindications to the procedure, the potential complications, and how to minimize complications.

FORCEPS OPERATIONS

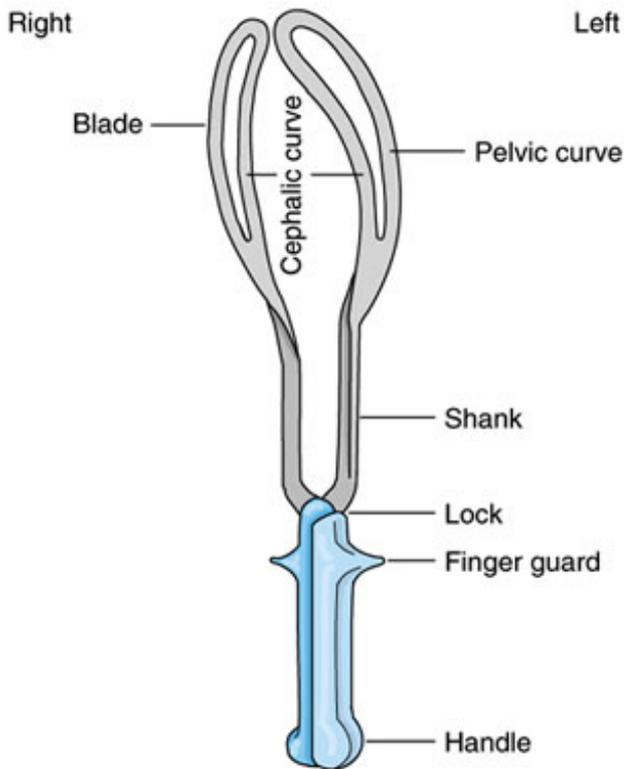

The obstetric forceps is an instrument designed to assist with delivery of the baby's head. It is used either to assist with certain abnormalities in the cephalopelvic relationship that interfere with advancement of the head during labor or to assist with certain primary functions of the forceps are to assist with traction of the fetal head and/or to assist with rotation of the fetal head to a desirable position.

Although forceps-assisted vaginal deliveries once were extremely popular, the most recent data demonstrate that the number of operative vaginal deliveries are performed using forceps. The reverse was true approximately 10 years ago. In fact, many investigators are concerned that the use of forceps is becoming a lost art. The reasons often cited as contributing to the decline in the use of forceps are (1) medicolegal implications and fear of litigation, (2) reliance on cesarean section as a primary mode of labor and delivery and suspected fetal jeopardy, (3) perception that the vacuum is easier to use and less risky to the fetus and (4) decreased number of residency programs that actively train residents in the use of forceps. These factors have led to which less teaching has led to a decrement in technical skills, an increased fear of litigation, and a resultant further decline in the use of forceps.

THE OBSTETRIC FORCEPS

The obstetric forceps (Fig 30–1) consists of 2 matched parts that articulate or "lock." Each part is composed of a blade and handle. Each blade is designed so that it possesses 2 curves: the cephalic curve, which permits the instrument to fit accurately to the sides of the baby's head, and the pelvic curve, which conforms to the curved axis of the maternal pelvis. Each blade is called the *toe*. The front of the forceps is the concave side of the pelvic curve. The blades are referred to as right and left according to the side of the mother's pelvis on which they lie after application. During application, the handle of the right blade is held in the left hand, and the blade is applied to the left side of the mother's pelvis. Conversely, the handle of the left blade is held in the right hand and inserted so as to lie on the right side of the mother's pelvis. When the blades are inserted, the right shank comes to lie atop the left so that the forceps articulate, or lock, as the handles are closed.

DeLee modification of Simpson forceps.

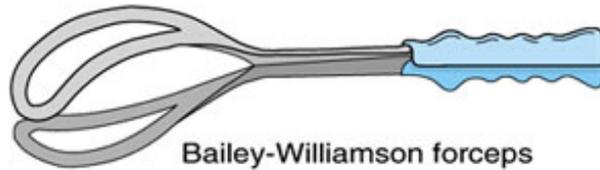

(Reproduced, with permission, from Benson RC: *Handbook of Obstetrics & Gynecology*, 8th ed. Lange, 1983.)

Physicians have been modifying 1 or more of the 4 basic parts since forceps were first invented. Although more forceps have been described, only a few are currently in use (Fig 30–2). Although it is beyond the scope of this chapter, the different varieties of forceps and their indications, a brief comment on the more common types of forceps is warranted. Simpson or Elliot forceps are most often used for outlet vaginal deliveries, whereas Kielland or Tucker-McLane forceps are used for rotational deliveries. Piper forceps are used in the United States for delivery of the aftercoming head. The pelvic shank, blade, lock, and handle are different for each type of forceps. These features determine the type of forceps for the appropriate indication. For example, Piper forceps, which are specifically designed for breech deliveries, have a pelvic curve compared to other forceps. Simpson forceps are suited for application to the molded fetal head, whereas Kielland forceps or Kielland forceps are more appropriate for application to the fetal head with little or no molding.

INDICATIONS AND CONDITIONS FOR FORCEPS DELIVERY

In each of the following indications for forceps delivery, it must be emphasized that cesarean section is an alternative that should be considered depending on the prevailing circumstances. Recognizing the inherent risks of both procedures, the operator must decide which operation (vaginal delivery or cesarean section) will be safer for mother and baby. In modern practice, rarely, if ever, is there a place for the difficult forceps delivery that endangers either mother or child.

The indications for forceps delivery are as follows: (1) nonreassuring fetal heart rate pattern, (2) shortening of labor for fetal or maternal reasons, (3) prolonged second stage of labor not due to dystocia, and (4) delivery of a fetus in a breech presentation. A prolonged second stage of labor has been defined according to parity. In a nulliparous patient, a prolonged second stage is defined as more than 3 hours with a regional anesthetic or more than 2 hours without anesthetic. In a multiparous patient, more than 2 hours with a regional anesthetic or more than 1 hour without anesthetic constitutes a prolonged second stage of labor.

In order for a patient to be considered a candidate for a forceps-assisted vaginal delivery, all of the following prerequisites must be met: (1) complete cervical dilatation, (2) ruptured membranes, (3) vertex presentation, (4) fetal head engaged in a position known, (5) empty bladder, (6) no evidence of cephalopelvic disproportion, (7) adequate analgesia, (8) operator capability, and (9) an experienced operator.

CLASSIFICATION OF FORCEPS DELIVERIES

In 1988 the American College of Obstetricians and Gynecologists redefined the classification of forceps. As discussed, this classification should be applied to vacuum delivery. This classification uses the leading bony point of the fetal skull in relationship to the maternal ischial spines in centimeters as the point of reference. Each station of the fetal head is described by the relationship of the leading bony part of the fetal skull with respect to the ischial spines. The fetal head is said to be at a certain station when the head is at the level of the spines. When the head is above this level, the station is described as -1 through -5, corresponding to the number of centimeters above the level of the ischial spines. When the head is below this level, the station is described as +1 through +5, corresponding to the number of centimeters below the level of the ischial spines.

The classification of forceps is defined as follows:

1. Outlet forceps is the application of forceps when (a) the fetal scalp is visible at the introitus without separation of the fetal skull, (b) the fetal skull has reached the pelvic floor, (c) the sagittal suture is in the anteroposterior diameter or in the right or left oblique position, and (d) the fetal head is at or on the perineum. According to this definition, rotation of the fetal head is equal to or less than 45 degrees.

2. Low forceps is the application of forceps when the leading point of the fetal skull is at station +2 or greater below the pelvic floor. Low forceps have two subdivisions: (a) rotation less than or equal to 45 degrees and (b) rotation greater than 45 degrees.

3. Midforceps is the application of forceps when the head is engaged but the leading point of the fetal skull is at station +3 or greater below the pelvic floor.

Only rarely should an attempt be made at forceps delivery above station +2. Under unusual circumstances, such as severe fetal or maternal compromise or transverse arrest, application of forceps above station +2 can be attempted. However, simultaneous preparation for a cesarean delivery in case the forceps maneuver is unsuccessful. *Under no circumstances should forceps be applied to an unengaged head.*

PREPARATION OF THE PATIENT FOR FORCEPS DELIVERY

The patient must be placed in the dorsal lithotomy position. The legs should be comfortably placed in stirrups with the hips flexed and abducted. The abdomen and legs should be adequately draped, and the vagina and perineum should be prepared in the usual fashion. If general anesthesia is to be used, it must be administered prior to the foregoing. If spinal or epidural anesthesia is to be used, it should be administered after the preliminary examination has been completed and all is in readiness for delivery. An appropriate and effective anesthetic is essential to the performance of any forceps delivery.

The Preliminary Examination

Before the application of forceps, a careful examination is necessary to determine the following:

1. The position of the fetal head, which usually is easily determined by first locating the lambdoid sutures and the direction of the sagittal suture. The posterior fontanelle is readily evident after the 3 sutures running into it. If the most accessible fontanelle is found to have 4 sutures running into it, it is the anterior fontanelle and the position of the fetal head is posterior. In the presence of marked edema of the scalp or caput succedaneum, both sutures and fontanelles may be obscured. In this case the position can be determined only by feeling an ear and noting the direction of the pinna. If the position of the fetal head cannot be adequately determined, then forceps should not be applied.

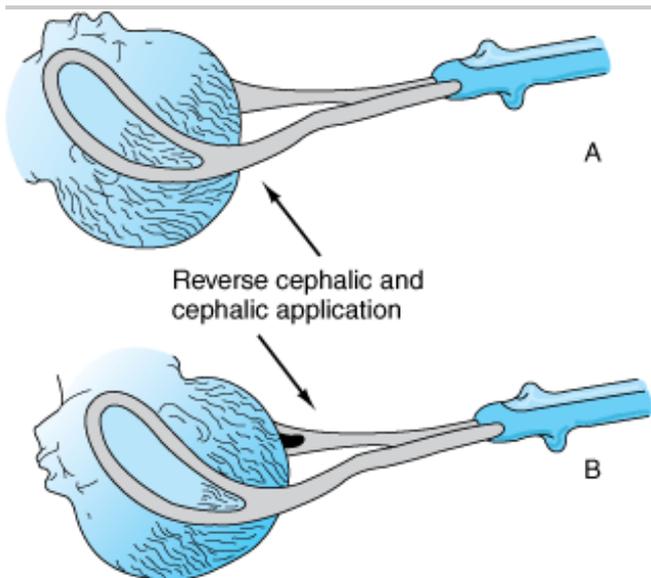

2. The station of the fetal head, which is the relationship of the presenting part to the ischial spines, must be determined. The head should proceed swiftly without complications, such a determination usually is simple and accurate. However, when the second stage of labor is prolonged and is further complicated by marked molding and a heavy caput, the head may suggest a false level of the head in the pelvis. If the head can be felt above the symphysis pubis, forceps should not be applied.

3. The adequacy of the pelvic diameters of the midpelvis and outlet is determined by noting the following: (a) the relationship of the ischial spines, the degree to which they shorten the transverse diameter of the midpelvis, and the amount of molding of the fetal head; (b) the contour of the accessible portion of the sacrum and the amount of molding of the fetal head usually based on the length of the sacrospinous ligament; and (c) the width of the subpubic arch. This kind of examination is neither needed nor feasible for outlet forceps but is essential for indicated low forceps or midforceps.

APPLICATION OF FORCEPS

A major concept to bear in mind is that the application of forceps should use finesse rather than force. Before the forceps are applied to the fetal head, a "phantom application" should be performed first. It is vital to inspect the forceps to ensure that they are a complete and matched set and that they articulate (lock) easily. Forceps should be applied in a delicate fashion to avoid potential injury to the vagina and perineum. The goal is for the blades to fit the fetal head as evenly and symmetrically as possible. The blades should lie evenly against the side of the head, covering the space between the orbits and ears (Fig 30-3) to emphasize that correct application prevents soft tissue and nerve injury, as well as bony injuries to the fetal skull. After the forceps have been applied, they should articulate easily. If the forceps cannot be easily articulated, the forceps should be disarticulated and a second attempt made. Once the forceps articulate, the following checks should be performed for delivery (1) The sagittal suture should be perpendicular to the plane of the blades. (2) The posterior fontanelle should be 1 fingerbreadth away from the plane of the shanks, equidistant from the blades and directly in front of the articulated forceps. (3) If fenestrated (open) blades are used, the amount of fenestration over the fetal head should admit no more than the tip of 1 finger. After these checks have been performed, then traction should be applied to the fetal head. Traction forces should be applied in the plane of least resistance and should follow the curve of the pelvis. This can best be accomplished by applying downward pressure on the shanks with outward pressure exerted upon the blades. Once the fetal head begins to emerge out of the vagina, the forceps are disarticulated, and the head is delivered using a modified Ritgen maneuver. After delivery, it is important to ensure that no vaginal or perineal lacerations go unreported. Particular attention to deep lateral vaginal sidewall (sulcal) lacerations. Lacerations, if present, should be repaired in the same fashion.

Forceps correctly applied along occipitomenal diameter of head in various positions of the occiput. A: Occiput posterior. B: Occiput anterior.

(Reproduced, with permission, from Benson RC: *Handbook of Obstetrics & Gynecology*, 8th ed. Lange, 1983.)

A more detailed step-by-step description of a forceps-assisted vaginal delivery in the occiput anterior position is given in the text (Fig 30-4, 30-5, and 30-6). The left handle is held between the thumb and fingers of the left hand. Using 2 or 3 fingers of the right hand placed into the vagina, the blade is guided to its correct position on the left side of the fetal head (Fig 30-4). This is repeated with the right hand and the right blade, using the fingers of the left hand placed into the vagina to guide the blade.

30-5). The handles are depressed slightly before locking, in order to place the blades properly along the optimal fetal head (Fig 30-6).

Both blades introduced. The 2 handles are brought together and locked. If application is correct, the handles lock and the need for force.

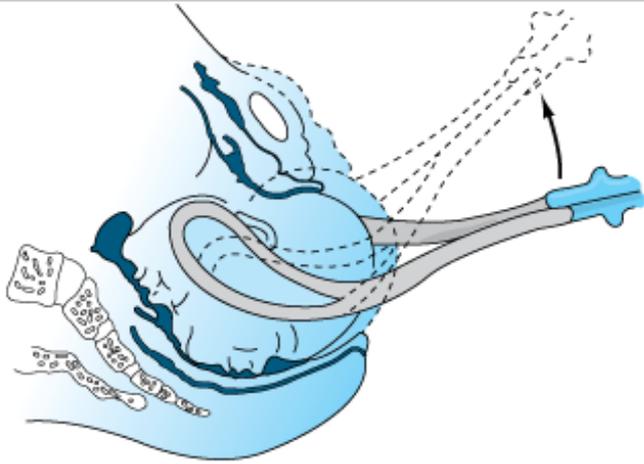

(Reproduced, with permission, from Benson RC: *Handbook of Obstetrics & Gynecology*, 8th ed. Lange, 1983.)

The forceps are designed such that they lock easily as the handles are closed if the application is accurate. If the or if any force is needed to achieve precise articulation, the application is faulty and the position must be rechecked. Manipulation of the blades does not permit easy articulation, the forceps should be removed, the position verified if necessary), and the blades reapplied correctly. After these 3 checks have been adequately performed, traction

Obstetricians hold forceps for traction in different ways. One method is to grasp the crossbar of the handle between middle fingers of the left hand from underneath and to insert the middle and index fingers of the right hand into the instrument from above. Another method is to grasp the handles with the fingers on the top of the handles or shoulders on the bottom. Traction is made only in the axis of the pelvis along the curve of the birth canal. No more force is exerted by the flexed forearms; the muscles of the back must not be used, and the feet must not be braced. If traction is needed, the cause may be cephalopelvic disproportion, asynclitism of the fetal head, or an error in estimated diameters. The obstetrician then should reassess the possibility of successful vaginal delivery.

As the head begins to distend the perineum, both the amount and direction of traction must be altered. The farther the head advances, the less the resistance offered by both the pelvis and the soft parts; hence, only minimal traction should be used. As the head is about to be delivered, the head negotiates the final position of the pelvic curve by extension, and the obstetrician should simulate this movement by elevating the handles of the forceps more and more as the head crowns (Fig 30–7). If the forceps are allowed to remain in place throughout delivery of the fetal head, the handles will have passed the vertical plane as the head is completed. It is preferable to remove the forceps as the head crowns in the reverse order of their application: disarticulating the forceps and raising the right handle until the blade is delivered. The left blade is then removed. Early removal of the forceps reduces the size of the mass that must pass through the introitus and thus reduces the risk of lacerations or extension of episiotomies. After removal of the forceps, the head may recede; however, if the forceps are removed too soon, the head can be delivered readily by the use of the Ritgen maneuver during the next contraction. Rotations with forceps and vaginal breech deliveries are now rarely, if ever, performed, it is beyond the scope of this text to discuss these techniques.

Figure 30–7.

Upward traction with low forceps. As the head extends, the handles are raised until they pass the vertical. Little hand suffices; the other hand may support the perineum.

DANGER AND SAFETY OF FORCEPS

Although use of forceps has fallen into disfavor over the last few years, few studies have prospectively evaluated forceps. A number of injuries to both mother and baby can result from the use of forceps, some serious or even fatal. Complications include lacerations of the vagina and cervix, episiotomy extensions involving third- and fourth-degree pelvic hematomas, urethral and bladder injuries, and uterine rupture. In addition, blood loss and the need for blood transfusion are increased in forceps deliveries. The baby may sustain minor facial lacerations, forceps marks, facial and brachial plexus palsies, skull fractures, intracranial hemorrhage, and seizures.

Many of the serious injuries and many of the minor ones inflicted by obstetric forceps result from errors in judgment or lack of technical skill. Such errors include failure to recognize the essential conditions for forceps delivery and lack of indication for the operation as outlined above. The potential for injury increases in the following settings: (1) intervention too early, before maximal molding and descent have been achieved by the patient's voluntary efforts, (2) continued use in the presence of unrecognized cephalopelvic disproportion, (3) errors in diagnosis of the position of the head, and (4) failure to abandon the procedure and perform cesarean section. Most reports clearly demonstrate that maternal and/or fetal injury is more common with midforceps than with low or outlet forceps. The perception of increased fetal and maternal risk, along with the major driving forces contributing to the widespread decline in the use of forceps.

THE VACUUM EXTRACTOR

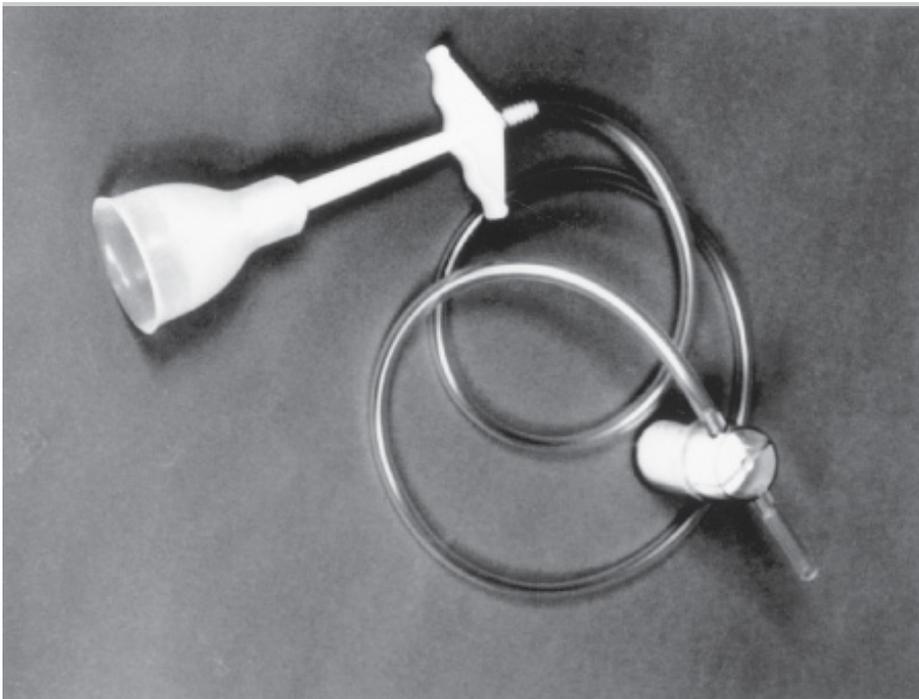

The idea of using a suction device applied to the fetal scalp to help facilitate delivery of the fetal head originated in 1846. The first vacuum cup was not designed until 1890. As one could well imagine, the first types of vacuum devices were made of wood or metal. In fact, the vacuum device did not gain much popularity until Malmstrom introduced a metal vacuum cup. The most common type of vacuum in use today is a pliable, Silastic cup with a handheld pump and gauge that allow the operator to apply the proper amount of suction pressure to the fetal head to effect delivery. Two models are shown in Figures 30-7 and 30-8.

Mityvac obstetrical vacuum delivery system includes extractor cup and pump.

(Photograph reproduced with permission of Prism Enterprises, Inc, Rancho Cucamonga, Calif.)

Figure 30-9.

CMI Tender Touch extractor cup.

(Photograph reproduced with permission of Utah Medical Products.)

The vacuum extractor works by allowing the external traction forces applied to the fetal scalp to be transmitted

The traction on the vacuum apparatus increases the forces of delivery and facilitates passage of the fetus through the birth canal. In order for delivery to be accomplished, both traction on the fetal scalp and compression of the fetal head occur.

INDICATIONS AND CONTRAINDICATIONS FOR VACUUM DELIVERY

With the exception of delivery of the aftercoming head in a breech presentation, the indications for vacuum use are similar to those for forceps. In addition, as mentioned earlier, the classification of forceps deliveries is the same classification used for vacuum deliveries, and the prerequisites are similar. Contraindications for vacuum delivery include the following: face presentation, true cephalopelvic disproportion, congenital anomalies of the fetal head (eg, hydrocephalus), gestational age less than 34 weeks or estimated fetal weight less than 2000 g, estimated fetal weight greater than 4000 g, and an unengaged fetal head.

VACUUM APPLICATION

Before the vacuum is applied to the fetal head, the patient is prepared and the initial patient examination is performed. Application of the vacuum is perceived by many to be much simpler than application of forceps. Before application occurs, the vacuum system should be assembled to ensure that no leaks are present. The suction cup is inserted into the vagina by directing pressure toward the posterior aspect of the vagina. The objective is to place the cup over the sagittal suture at the median flexion point located approximately 3 cm anterior to the posterior fontanelle. Placement should allow for adequate maintenance of flexion of the fetal head during the entire procedure. As with forceps application, 3 checks should be undertaken prior to application of traction to the fetal head. (1) No maternal tissue is included under the cup margin. (2) The cup should be placed in the midline over the sagittal suture and not off to the side of the head. (3) The marker or vacuum port of the suction cup should point toward the occiput.

After the cup has been appropriately placed on the fetal scalp, an initial suction is applied, and the cup edges are held firmly against the fetal scalp to ensure that no maternal tissue is trapped underneath the vacuum cup. While the cup is held firmly against the fetal scalp, the vacuum pressure is increased to approximately 600 mmHg at the beginning of a uterine contraction. As the mother pushes, the pressure is applied along the pelvic axis. If more than 1 contraction is necessary, the vacuum pressure can be decreased to approximately 400 mmHg between contractions. While the fetal head is delivering, the cup should assume a 90-degree orientation to the horizontal plane. Once the head has completely delivered through the vagina, the suction is withdrawn and the cup removed.

EFFECTIVENESS AND SAFETY OF VACUUM

Most reports demonstrate that the vacuum is effective, with a failure rate of approximately 10%. The following factors are implicated in determining the effectiveness of vacuum delivery: cup design, shape, size, and traction site attachment; vacuum pressure and strength of vacuum, strength of maternal expulsive efforts and coordination with traction, fetal size and extent of cephalopelvic disproportion, station and deflection of the fetal head, and angle and technique of traction.

The safety of the vacuum has been called into question. In May 1998, the United States Food and Drug Administration issued a Public Advisory Statement regarding fetal complications associated with vacuum delivery. The purpose of this statement was to advise practitioners that vacuum devices may cause serious or fatal complications when improperly used. As a result of this statement, the following recommendations were made: (1) The vacuum should be used only when a specific obstetric indication is present. (2) The practitioner using the vacuum should be experienced and aware of the indications, contraindications, and precautions. (3) Those who use the vacuum should read and understand the instructions for the particular instrument being used. (4) The neonatal care staff should be informed about the potential complications of vacuum. (5) Individuals responsible for the care of the neonate should be advised of the complications that have been used. (6) All adverse reactions should be reported to the Food and Drug Administration.

Use of the vacuum has been associated with a variety of neonatal injuries ranging from benign superficial scalp lacerations to potentially life-threatening intracranial hemorrhages. The most common neonatal complication is retinal hemorrhage, which occurs in as many as 50% of deliveries. Fortunately, this complication rarely has any clinical significance. Cephalohematoma, or bleeding beneath the periosteum and complicates approximately 6% of all vacuum deliveries. Because the bleeding is beneath the periosteum, significant bleeding rarely results because of the inability of the blood to cross the sutures. Subdural hemorrhage, a more serious complication, occurs in 50 of 10,000 vacuum deliveries. The condition arises when bleeding occurs

subaponeurotic tissues of the scalp. Because bleeding occurs above the periosteum, it is not contained by the skull; therefore, there is the potential for life-threatening hemorrhage. The subgaleal space actually extends from the orbits of the face to the back of the neck. This potential space can occupy over half of a newborn's blood volume. Intracranial hemorrhage occurs in 0.35% of vacuum deliveries. It can be a catastrophic complication that includes subdural, subarachnoid, intraventricular, and intraparenchymal hemorrhage. These complications can be quite severe but fortunately are rare.

Most authorities agree that injury can be significantly decreased or eliminated if the following protocol is used. (1) Vacuum extraction is used only when the patient is actively pushing. (2) Applying torsion or twisting the cup in an attempt to rotate the head is prohibited. (3) The duration of time during which the cup is applied to the head should not exceed 20 minutes. (4) The procedure is abandoned after the cup has dislodged from the fetal head twice. It should not be applied a third time. (5) The procedure is abandoned if there is no fetal descent after a single pull. (6) The vacuum should not be used when the estimated fetal weight is less than 2000 g or greater than 4000 g. (7) Neonatal staff should be present at the time of the vacuum delivery. (8) Neonatal staff (not to forceps deliveries.) (8) Under no circumstances should the operator switch from vacuum to forceps or vice versa. A study examining neonatal injury clearly demonstrated that the greatest incidence of neonatal injury occurred in vacuum and forceps were used. The practitioner must be cognizant of the risk for shoulder dystocia, which is increased with instrumental delivery. Shoulder dystocia occurs more commonly with vacuum deliveries than with forceps deliveries.

A detailed and complete delivery note should accompany each operative vaginal delivery. The medical record must include the indication for the procedure, the fetal station and head position at the time of the application(s) of forceps or vacuum, the device used, the total application time, the number of applications and "pop-offs" if vacuum was used, and, if applicable, the subsequent mode of delivery.

Somewhat surprisingly, relatively few randomized, prospective studies have compared vacuum with forceps. In the medical literature, the following conclusions can be drawn. On the whole, the vacuum extractor is less likely to result in a vaginal delivery than is the forceps. The vacuum is significantly less likely to cause serious maternal injury than the forceps. Although the vacuum is associated with a greater incidence of cephalhematoma, other facial/cranial injuries are less frequent with the vacuum than with forceps. In comparing Apgar scores, the trend is toward more low 5-minute Apgar scores in the vacuum group than in the forceps group. Thus, an overall reduction in severe maternal injuries appears to be the most immediate benefit associated with the vacuum. However, at this time, which instrument results in fewer major adverse neonatal effects remains to be determined.

Although both forceps and vacuum have proved to be useful in assisting with vaginal delivery, the vacuum is the preferred instrument of choice. Both forceps and vacuum have the potential to cause fetal and neonatal injury; however, the incidence of maternal injury is less with the vacuum than with forceps. In order to minimize both maternal and fetal injury, the operator must be familiar with the indications, contraindications, application, and use of the particular instrument. Guidelines similar to those discussed in this chapter should exist in order to facilitate a safe and effective delivery.

CESAREAN SECTION

A *cesarean section* refers to the delivery of a fetus, placenta, and membranes through an abdominal and uterine incision. The first documented cesarean section on a living person was performed in 1610. The patient died 25 days later. Since that time, advances have made cesarean section a safe procedure. In the past 35 years, the rate of cesarean section has increased from 5% to approximately 25%. Over this time, the maternal mortality ratio (maternal deaths per 100,000 births) has decreased from almost 300 to less than 10. The following factors are often cited as contributing to the increasing cesarean section rates: (1) lower vaginal delivery rates, (2) lower rates of vaginal birth after cesarean section (VBAC), and (3) fewer vaginal deliveries. In order for the practitioner to perform this common operation safely, he or she must be aware of the indications, the technique, and potential complications of the procedure.

INDICATIONS

Cesarean section is used in cases where vaginal delivery either is not feasible or would impose undue risks to the mother or fetus. Some of the indications for cesarean section are clear and straightforward, whereas others are relative. In some cases, clinical judgment is necessary to determine whether cesarean section or vaginal delivery would be better. It is not practical to list all the indications for cesarean section.

possible indications; however, hardly any obstetric complication has not been dealt with by cesarean section. The indications are currently the most common.

Repeat Cesarean Section

A prior uterine incision from a myomectomy or previous cesarean section may weaken the uterine wall or predispose to uterine rupture during labor. Labor is permitted. The initial dictum of "once a cesarean, always a cesarean" was held for many years. However, with the publication of articles documenting the safety of VBAC began appearing in the literature, many physicians moved away from that belief. In 2000, a national goal was to lower the rate of repeat cesarean sections to 3% while increasing the VBAC rate to 10%. Major incentives that led to this change in philosophy were fewer delivery risks with vaginal delivery, less need for postpartum morbidity, shorter hospital stay, lower costs, and encouraging earlier and often smoother interaction between mother and infant. As more and more VBACs were performed in less than ideal settings, more complications may be no greater obstetric catastrophe than a uterine rupture resulting in maternal and/or fetal death. In fact, a trend back toward the belief of "once a cesarean, always a cesarean." Suffice it to say, "once a cesarean, always a cesarean."

In general, patients who are the most suitable candidates for trial of labor after cesarean section are those (1) with a transverse cesarean section, (2) who present in labor, (3) with nonrecurring conditions (eg, breech, fetal distress) and (4) with a prior vaginal delivery. Patients who are not candidates for trial of labor include women with a prior uterine incision or prior myomectomy. If a trial of labor is to be conducted, the patient must be placed on continuous fetal heart rate and uterine activity monitoring, and an obstetrician and anesthesiologist must be immediately available to intervene if uterine rupture is suspected. Prostaglandins for cervical ripening must be avoided, and oxytocin must be used in a judicious and conservative fashion, if at all. Current studies cite a maternal mortality rate of close to 1% percent in cases of uterine rupture and a perinatal mortality rate of approximately 50% in association with uterine rupture. Therefore, it is of utmost importance that the patient have appropriate equipment for both maternal and electronic fetal monitoring and appropriate obstetric and neonatal facilities be available. A large bore intravenous catheter must be used, and blood for possible maternal transfusion must be available. Appropriately equipped operating room, and obstetric and neonatal staff experienced in emergency care all must be immediately available.

Cephalopelvic Disproportion/Dystocia

Cases in which the fetal head is too large to traverse the pelvis should be managed by cesarean section. As discussed previously, if the fetal head does not engage during labor and remains at a station higher than 0 station, operative vaginal delivery should not be attempted. Rather, cesarean section must be performed. Inlet disproportion should be suspected in the primigravida who begins labor with the fetal head unengaged. In a significant number of these patients, the head fails to engage at the inlet. Midpelvic disproportion may be suspected if the anteroposterior diameter is short, the ischial spines are close together, the sacrospinous ligament is short, and the fetus is large. Outlet disproportion usually requires a trial of forceps or vacuum extraction. If a trial of vaginal delivery is determined to be impossible, cesarean section is indicated.

Dystocia literally means "difficult labor." This occurs when a patient's labor progresses and then either stops completely or becomes prolonged (*protracted*). When either of these situations occurs during labor, the patient warrants careful evaluation including labor pattern, contraction pattern, evaluation of the estimated fetal weight and fetal presentation, as well as an evaluation of the pelvis.

Malposition and Malpresentation

Transverse lie and breech presentations are common indications for cesarean section. The trend toward cesarean section has been hastened by a large randomized trial comparing breech infants born vaginally versus those born by cesarean section. Better outcomes were achieved after cesarean section. Although some still consider vaginal breech delivery to be an option, experience with the technique is largely disappearing from practice.

External cephalic version is a reasonable alternative for some patients and can be attempted to convert the fetus to a cephalic presentation. However, this procedure is successful in allowing vaginal birth in only 50% of cases.

Fetal Distress

Fetal monitoring before and during labor may disclose fetal problems that otherwise would not be evident. As a result of fetal monitoring, the number of cesarean sections performed for the indication of fetal distress or fetal jeopardy estimates demonstrate that approximately 10% of cesarean sections are performed because of fetal distress.

Other Indications

In addition to the indications discussed, other conditions that can lead to cesarean section are placenta previa, preeclampsia–eclampsia if remote from term, multiple gestations, fetal abnormalities (eg, hydrocephalus), cervical active herpes infection. One other indication that is becoming more prevalent is patient choice. The idea of primary cesarean section continues to increase in popularity and generate controversy.

PREOPERATIVE PREPARATION FOR CESAREAN SECTION

The following steps are generally taken before cesarean section is performed. The patient is made aware of the cesarean section, the alternatives, and the potential risks and complications. She then signs a form indicating that she understands the information and consents to the procedure ("informed consent"). An intravenous 18-gauge needle should be placed in the arm. An appropriate intravenous IV solution running before the operation begins. The patient is given a clear antacid to reduce the likelihood of aspiration during anesthesia. A Foley catheter is placed to allow for continuous bladder drainage before and after surgery. Anesthesia is administered, and the abdomen is prepped and shaved. The patient is covered with a sterile drape. The patient slightly to the left moves the uterus to the left of the midline and minimizes pressure on the inferior vena cava.

OPERATIVE PROCEDURE

Abdominal Incision

Opinions differ regarding the type of abdominal incision that should be performed. Most obstetricians use the transverse (Pfannenstiel) incision with or without transection of the rectus muscles because wound dehiscence and postoperative hernia are rare, and because the cosmetic result usually is better. In cases of fetal distress, especially in patients with abdominal surgery or marked obesity, the midline suprapubic incision is preferred because it is much quicker and allows for an expeditious delivery and resolving uterine bleeding (by hysterectomy, if needed) usually is better. In the presence of a previous abdominal scar, it is important to enter the peritoneal cavity at the upper end of the incision to avoid entering the cavity through the scar, which may have been pulled upward on the abdominal wall at the time of closure of the previous incision.

Uterine Incision

Before the uterine incision is made, laparotomy pads that have been soaked in warm saline and wrung out can be placed on either side of the uterus to catch the spill of amniotic fluid. The degree of dextrorotation should also be determined by palpating the round ligaments so that the uterine incision will be centered. Torsion should not be corrected; instead, access to the uterus should be obtained by retracting the abdominal wall to the patient's right. The different types of uterine incisions are discussed later.

Encountering the Placenta

If the placenta is encountered beneath the uterine incision, the operator should try to avoid cutting through it, as fetal bleeding may result. If the placenta cannot be avoided, an incision can be made through it. However, the placenta should be delivered as quickly as possible and the cord clamped immediately to prevent significant blood loss.

Delivery
