The essence of the nervous system is communication: multifarious, intricate communication between cells. In addition to the well-known neuron-to-neuron communication, there is also communication to and among the so-called supporting cells (i.e., glial or Schwann cells) of the nervous system. Communication between cells involves a variety of biochemical changes, including (but not limited to) ion fluxes, receptor stimulation, generation of second messengers, phosphorylation of proteins, receptor- or voltage-initiated opening of channels, or release of calcium. There is also a less sporadic, slower, communication between nerve cells and their targets in which they continually notify one another through chemical signals or messengers (e.g., trophic factors) that they are still there, that they are still connected. In the developing nervous system, chemical signaling molecules tell neurons when and where to grow, where not to grow, and when to stop growing. In addition to cell-to-cell communication or signaling, there is also communication within a cell, i.e., axonal transport. Moreover, in order for cell-to-cell signaling to occur properly, not only are the chemical signals and messengers integral to proper communication within the nervous system, but the structure of the cells and their connections must be optimal, making biochemical communication and maintenance of structure pivotal to the ideal functioning of the nervous system. Thus, given that the essence of the nervous system is communication, it follows that neurotoxicology may be defined as the disruption of that communication, either through perturbation of biochemical signals or messengers or through perturbation of the structure of the nervous system.

One of the basic tenets of toxicology is that the dosage makes the poison. An extension of that rule is that, in general, if enough of a chemical is administered, there will eventually be an adverse effect. Thus, the discovery that a certain toxicant produces an effect does not warrant concern until the dosage is taken into consideration. One must always be aware of how the dosage level of a chemical compares with the level expected to be encountered in the environment. It is always important to know the absorbed dose or, if possible, the dose at the presumed target site. Furthermore, if a toxic compound causes a loss in body weight or severe liver necrosis, it is possible that there will also be nonspecific alterations in nervous system biochemistry; one must always keep any neurochemical changes in perspective. The goal is to find the mechanism of action of a toxic chemical at a realistic dosage or exposure level, not an effect that is precipitated by an overall toxic response of the organism. This is even more pertinent for an in vitro testing procedure: the careful investigator should always consider the reported in vivo tissue concentration of the toxic compound and how that concentration compares to the effective concentration in any particular in vitro procedure. In all procedures, whether in vivo or in vitro, the strongest, most persuasive experimental design involves using a dose-response paradigm that includes both positive and negative controls. The dose-related response is essential to link the exposure of a toxic compound to a given neurotoxic effect. Moreover, it should be assumed that toxic compounds have multiple effects, not just a single effect. Therefore, the dose-effect assessments allow the investigator to rank order the toxic effects and possibly identify which is the proximal event, i.e., the response that is produced first or at the lowest dosage of the compound.

This unit is not intended to be a comprehensive review of the literature involving biochemical neurotoxicology. Instead, an effort has been made to supply the reader with recent examples of the various approaches to identify neurotoxicants and their modes of action. Moreover, the discussion and the majority of the references will focus on toxic compounds with environmental relevance, not toxins (plant- or animal-derived venoms or poisons) or pharmacologically relevant compounds. There are many reviews published in the last twenty years that address more specific aspects of neurochemical toxicology (e.g., Bondy, 1986; Abou-Donia et al., 1988; Costa et al., 1988; Costa, 1992).

Generally, the nervous system responds to an exposure to a neurotoxicant in a progressive way, much the same way a human responds to an illness. (1) Initially, the cells become abnormal or dysfunctional. One can measure this biochemical malaise through, for example, the induction of stress proteins, changes in second

Current Protocols in Toxicology (2000) 12.1.1-12.1.7

messenger response, increased lipid peroxidation, generation of free radicals, or changes in axonal transport. In some instances, one can tell if the mature nervous system is stressed because adult cells will attempt to repair themselves by adopting a biochemical profile reminiscent of regeneration or development. One approach to studying neurotoxicology is to identify and measure these indicators of a "sick" nervous system either in vivo or in vitro, whether in the neurons themselves or in glia. (2) If the stressed nervous system is unable to repair itself, cell damage occurs. Cytotoxicity may be indicated by increased intracellular calcium concentrations, changes in energy metabolism or glucose utilization, free radical generation, loss of receptors, changes in protein phosphorylation, changes in signal transduction, changes in membrane stability or integrity, and increases in calcium-activated proteases (reviewed in Tymianski, 1996; Verity, 1992). (3) The damaged cells become dead cells, either through necrosis or increased apoptosis. It may seem self-evident, but from a biochemical approach, it is often much easier to measure stressed or damaged cells than dead cells. If a cell is dead, it generates no response at all. This means that the investigator is looking for an absence of response, which is often difficult. With stressed or damaged cells, the investigator is measuring a change in response, which, experimentally, is a more robust endpoint and is easier to detect and quantify. Therefore, in order to determine if a population of cells is dead, measuring the amount of a cell-specific marker would be the choice of tests. For example, decreased amounts of choline acetyltransferase would be a strong indication that cholinergic cells had died. Other cell-specific or region-specific markers could be chosen (see Markers). Another, indirect method for determining cell death would be to look for the "scar tissue" of the nervous system: increases in the amount of glial fibrillary acidic protein.

Although these three stages of neurotoxicity have been delineated above, the distinction between the first two (i.e., stress and damage) is extremely blurred as are the biochemical approaches for detecting these stages. Neuronal cell death, by comparison, is clear cut. Very little regenerative capacity is present in the adult central nervous system (CNS), so neuronal cell death is rarely accompanied by compensatory regeneration. There is a greater capacity for regeneration in the peripheral nervous system (PNS), but that capacity is inversely related to age.

This unit will consider the prominent biochemical approaches that are now being employed to study and identify neurotoxic compounds. All types of studies will be considered: in vivo, in vitro, single-dose, and multiple-dose studies, as well as studies using various routes of administration of the toxic compound, different species, different genders, and different ages. When designing a given study, the choice of route, species, age, gender, and dosing duration is usually made according to the human exposure scenario that the investigator wants to mimic. Below is a compendium of the main approaches in use today by the majority of neurotoxicological biochemists.

NEUROTRANSMITTER DYNAMICS

Historically, one of the most established approaches to studying neurotoxicity is to measure toxicant-induced changes in neurotransmitter dynamics. One may simply measure the level of a given neurotransmitter, but there are other diverse and integral processes surrounding neurotransmitter function in the nervous system which also may be assessed. These include synthesis, packaging, release, breakdown, and reuptake of neurotransmitters. Any of these stages in chemical neurotransmission may be affected by a neurotoxic compound, and many of these processes may be assessed using in vitro or ex vivo methods. Moreover, in an effort to understand the neurotransmitter dynamics in animals treated with a neurotoxic compound, one may isolate the synaptic endings (i.e., synaptosomes) to use as a model for in situ conditions (Lam et al., 1996).

Although the effect of a neurotoxicant on neurotransmission may be multifaceted, there are entire classes of toxic compounds that are "designed" to have an adverse effect on neurotransmission. The accepted mechanism of action of the carbamate and organophosphorus pesticides is inhibition of the enzyme acetylcholinesterase, which breaks down the neurotransmitter acetylcholine. However, even within this class of anticholinesterase pesticides, the picture is becoming much more complicated as evidence mounts that these compounds may interact with other aspects of neurotransmitter dynamics such as receptor binding and reuptake (e.g., Huff et al., 1994; Liu and Pope, 1996; Rocha et al., 1996; Ward and Mundy, 1996). In general, no matter what aspect of neurotransmitter dynamics is under investigation, this biochemical approach is strengthened by the inclusion of other nonbiochemical endpoints, such as behavioral, histo-

logical, or neurophysiological assessment (for example, Boyd et al., 1990; Fredricksson et al., 1993; Kanthasamy et al., 1994). Many good, detailed reviews have been written on the subject of neurotoxicity and neurotransmitter dynamics (Costa, 1988, 1992).

In vivo microdialysis, a method for measuring the presence of any water-soluble biochemical present in the extracellular fluid in the CNS, is often used to study neurotransmitter dynamics. The great advantage of in vivo microdialysis is that the investigator is able to measure the real-time efflux of these endogenous chemicals in freely moving, nonanesthetized experimental animals (Brodie et al., 1990). Basically, the experimenter is only limited by the sensitivity of the analytical method used (usually HPLC). In addition, it is possible to infuse compounds of interest directly into a region of the brain and then measure the response of the cells. Although this is an extremely powerful method because it identifies biochemical changes in the intact experimental animal, one must be cognizant of possible complications due to the insertion of the microdialysis probe (Layton et al., 1997) and of the fact that the basic technique does not allow the investigator to distinguish between pre- and post-synaptic release.

The receptor and the attending transduction of the chemical signaling of the neurotransmitter are key components of the communication network of the nervous system. According to the classical definition of a neurotransmitter, one has to determine or identify the receptor for the putative neurotransmitter or it ceases to have validity as a transmitter, the insinuation being that the neurotransmitter cannot elicit an effect unless there is a receptor for that transmitter. The binding of a neurotransmitter to a receptor elicits a signal, usually either changes in ion fluxes due to an opening of an ion channel or other biochemical changes due to the activation of a second messenger cascade. Showing that a toxic compound perturbs receptor and/or signal transduction is a typical, but very convincing, approach to assessing the neurotoxicity of any toxicant. Moreover, many of the receptors and signal transduction systems are amenable to study either in vivo or in vitro (Nagata et al., 1997). For example, toxic compounds are capable of causing changes in receptor number or sensitivity and perturbing the second messenger cascade (Goldstein, 1993; Costa, 1994; Tandon et al., 1994; Komulainen et al., 1995; Tonner et al., 1997). One must be careful, however, not to equate receptor number with the degree of second messenger response; experimental evidence does not support the generalization that reduced receptor number leads to reduced second messenger response (or that increased receptor number leads to increased response). Beyond the second messenger response is the phosphorylation and dephosphorylation of proteins, often referred to as the "third messenger" of the nervous system. Within the last ten years, there has been a great interest in the effects of various neurotoxicants on the activity of the second messenger–activated kinases, as the kinases are one of the biochemical mechanisms for converting an ephemeral, short-lasting neurotransmitter or ion burst into a longer-lasting, more persistent biochemical change (Kikuchi and Kim, 1993, Chen et al., 1997).

AXONAL TRANSPORT

The circulation of cellular constituents proceeds in every cell, but this circulation is especially exaggerated in neurons given the geometry of these cells. Often, the cell body is located centimeters away from the axon and nerve ending. Because most of the cellular constituents are synthesized and packaged in the cell body, these constituents have to be delivered to the other regions of the axon and dendrite via a complicated system, collectively referred to as axonal transport. This system also removes spent cellular constituents from the distant regions of the neuron and returns trophic factors back to the cell body (Oppenheim, 1996). The disruption of axonal transport is thought to be the basis for many neurotoxic responses, including the majority of peripheral neuropathies (Ochs and Brimijoin, 1993).

Traditionally, the study of axonal transport usually involved performing major surgery on animals in order to inject radiolabeled precursors into the motor roots or sensory ganglia of the sciatic nerve—the nerve that was usually affected first by the toxicant. Within the last ten years, that paradigm has changed, with an increasing usage of in vitro systems for the study of axonal transport (Brat and Brimijoin, 1992; Clarke and Sickles, 1996). More recently, axonal transport studies have also begun to concentrate on studying how neurotoxic compounds interact with the motors of anterograde and retrograde transport (kinesin and dynein, respectively), the reasoning being that if a toxicant interacts with the function of either of these proteins, perturbations in axonal transport would be predicted (Sickles et al., 1996).

IDENTIFICATION OF STRESSED OR DAMAGED CELLS

A stressed cell embarks upon a convoluted biochemical demise that may lead to cell death. There are many hallmarks of a stressed, sick, or dying cell, and not all of these hallmarks need be present (also see *UNITS 2.2 & 2.6*). Interestingly, some cells are much more susceptible to damage and death than are other cells, and, not surprisingly, there is very active research aimed at discovering the bases for this sensitivity. Usually this stress begins with changes in membrane permeability and/or an influx of calcium. This influx could be triggered by activation of glutamate receptors or perturbations in the calcium pumps, and it may activate a cascade of adverse events such as excess nitric oxide release, formation of free radicals, osmotic stress, and lipid peroxidation. All of these biochemical changes happen in normal, healthy cells and, in fact, may be integral to survival of those cells (Huxlin and Bennett, 1995). However, when these changes are generated in excess, or if the cell is unable to repair and restore itself, the cell begins to deteriorate. Therefore, any of these changes may be measured to determine if the cell has become stressed or damaged. Additionally, free radical– or oxidative stress–related injury may be a component of many neurological disorders (Dawson and Dawson, 1996). As an example of how entangled the nervous system is, many of the signal transduction systems also influence the degree of toxicity produced by a given stress response (Maiese et al., 1993).

Another method for determining whether the nervous system has been adversely affected by toxicant treatment is to measure the production of stress proteins, which are synthesized when a cell undergoes chemical or physical stress in order to protect the genome of that cell. Some commonly measured proteins are the heat shock proteins (Opanashuk and Finkelstein, 1995), but recent research indicates that other stress-activated proteins are being identified and used to measure toxic responses in both neurons and glia (Zhang et al., 1996).

MARKERS

"Marker" and "biomarker" are often-used, general terms that signify that a certain biochemical test is a sentinel for exposure to a given toxicant or is a warning that the nervous system has experienced an adverse effect. Accordingly, most biochemical markers may be classified as either markers of exposure or markers of effect, and both human and laboratory animal toxicology strive to identify and validate convenient, easily accessed markers for complicated processes.

Human Studies

Either type of marker is extremely useful in assessing human neurotoxic response to a suspected neurotoxic compound. A human biomarker must be a noninvasive surrogate for either exposure to or effect of a toxic compound. For example, inhibition of blood cholinesterase is an uncontested biomarker of exposure to anticholinesterase pesticides, and hemoglobin adducts are considered markers of exposure to acrylamide (Bergmark et al., 1993). Very few biomarkers have been validated in humans, however, mainly because only blood or urine is available for measurement of markers. One of the emerging, noninvasive methods for studying neurotoxic effects in human is imaging of either the structure or the metabolism of the brain (Brooks et al., 1997). Because detecting human exposure or chemically mediated adverse effects is the ultimate aim of many neurotoxicological studies, emphasis is placed on identifying markers for biomonitoring of humans and validating those markers in animal studies (e.g., Bergamaschi et al., 1996; for a review see Manzo et al., 1996).

Animal Studies

Many of the markers of exposure that are used for humans are also used in animal studies, but the palette of markers of effect available for use in animal studies is more diverse. Cell-specific markers are informative and useful biomarkers of effect that are often employed in animal studies. These markers are biochemical correlates of certain cell types in the brain (for a review of the use of cell- and region-specific markers, see O'Callaghan, 1992). For instance, if the investigator suspects that a certain toxic compound is causing neuronal death, that brain area may be analyzed for levels of a specific synaptic vesicle protein (a marker of synapses and, therefore, a neuronal marker) as well as glial fibrillary acidic protein (GFAP; specific to glial cells). Glial cells tend to form scar tissue in the CNS, so analyzing these two markers allows the investigator to ask two questions: are the synapses gone and has glial tissue filled in the spaces that the synapses vacated? For an example of this approach, see Morse et al. (1996).

Lately, the concept of a marker for susceptibility has arisen. Often times, certain subpopulations of cells or individuals are more sensitive to the toxic effects of a compound.

This approach to neurotoxicity is receiving considerable interest in an effort to facilitate identification of susceptible human populations. For instance, the level of detoxifying enzymes may be correlated with the susceptibility to toxic compounds either in vitro (Rising et al., 1995; Wu and Welsh, 1996) or in vivo (Mortensen et al., 1996; Li et al., 1997). Moreover, in a general sense, age, sex, nutritional status, and species may also be markers of susceptibility.

SENSITIVE SUBPOPULATIONS

One intriguing new area of study concentrates on the identification of sensitive subpopulations, i.e., are there certain individuals that are more (or less) sensitive to a toxicant? All types of sensitive subpopulations are being investigated using both in vivo and in vitro experimental designs that include differences in age, species, genetic makeup (Richter et al., 1995), and prior exposure to other toxicants (Chandler et al., 1993; Sorg et al., 1996). These investigations should provide new information on why some humans are especially debilitated by toxicant exposure, on the mechanism of a toxicant, on how to predict this sensitivity in the future, and on how, ultimately, to design new chemicals that are less toxic to certain individuals. Research on both Alzheimer's disease and multiple chemical sensitivity is expressly involved with the issue of sensitive subpopulations.

EMERGING APPROACHES

The experimental world of molecular biology has just begun to be embraced by biochemical neurotoxicologists. About five to ten years ago, there was a surge in the use of early immediate genes (e.g., *fos* and *jun*) as markers of a toxicological response in a system supposedly stressed by toxicant administration. That approach has become less popular, probably because, although it was a remarkably sensitive approach, it was also an extremely nonspecific response. Right now, only ~10% of neurotoxicological studies incorporate any technique that could be loosely defined as molecular biology. There have been successful and informative uses of various techniques such as subtractive hybridization, mRNA quantitation, in situ hybridization, and the use of transgenic or knockout mice (Toggas et al., 1992; Roberson et al., 1995). Overall, however, the use of these approaches is minimal. One would expect and hope that molecular biological techniques will represent the new wave of neurotoxicological approaches in the future.

Biochemical toxicologists strive to identify the primal or integral biochemical lesion precipitated by exposure to a toxic compound. They should also endeavor to form collaborative relationships with neurotoxicologists of other disciplines, so that the significance of the biochemical lesions may be weighed in the context of behavioral, physiological, or histological changes in the same animal (Costa et al., 1995; Evans et al., 1995; Crofton et al., 1996). This type of multifaceted effort provides a synergy between investigators and adds import and distinction to the research. In addition, when considering the neurotoxicological profile of a specific compound, it is often wise to pause once in a while and summarize the toxicity profile of that compound, taking into consideration all controlled studies from all disciplines in an effort to scrutinize what has been learned and what approaches the future research should take (see, for example, Pahwa and Kalra, 1993; Strong et al., 1996).

Development of an In Vitro Blood-Brain Barrier

The blood-brain interface is constituted by specialized endothelial cells acting as a selective barrier that allows passage of nutrients and metabolic precursors, while isolating the brain from potentially noxious substances. Cell toxicity at the level of the blood-brain barrier causes reduction of this protective shield and may result in chronic neurological disease. Conversely, an intact blood-brain barrier prevents passage of systemically administered chemotherapeutics to the brain.

Cell culture techniques have provided a useful tool to study the physiological correlates of the complex set of functions that any given cell provides to the host organ. Isolation and culturing techniques have developed dramatically in the past decades, and an increasing number of cellular "factors" have been discovered, allowing growth of differentiated cells on plastic substrates or filters. Purified cells exposed to differentiating or otherwise "permissive" factors have been shown to grow and develop a more complex phenotype in the absence of normally occurring cell-to-cell signals. This reductionistic approach to cell biology, however, does not usually provide the natural environment, and aspects of cellular responses to the physiologic environment are frequently bypassed. This is particularly true for a specialized cell type, the blood-brain barrier endothelium, continuously exposed to both cellular (perivascular glia, neurons, and blood cells) and physical (shear stress) stimuli. As a result, cultured brain endothelial cells lose their physiological properties and fail to reproduce the numerous known properties of the blood-brain barrier in vivo. To overcome the limitations of the "purified cell culturing" approach, the authors have developed a quasiphysiological cell culture apparatus that allows for endothelial cell growth and differentiation in the presence of both glia and intralumenal flow.

This unit contains protocols for setting up the model system (see Basic Protocol) and assessing the functions of the model—monitoring glucose consumption and lactate production (see Support Protocol 1), measuring transepithelial permeability (see Support Protocol 2), and assessing blood-brain barrier integrity (see Support Protocol 3).

ESTABLISHING A DYNAMIC BLOOD-BRAIN BARRIER

BASIC PROTOCOL

Cells are co-cultured using hollow fiber tubes (the capillary vessels) inside a sealed chamber (the extralumenal space or ECS) accessible by ports. The cartridge/hollow fiber culturing system (see Fig. 12.2.1) consists of artificial capillaries made from polypropylene and coated with ProNectin F (Protein Polymer Technologies) connected by gas-permeable tubing to a source of growth medium allowing exchange of O_2 and CO_2. A pulsatile pump forces medium through the lumen of the artificial capillaries allowing diffusion of nutrients out to the ECS. Percolation of medium through the 0.5-μm transcapillary pores enables permeation of proteins and solutes into the ECS; this allows nourishment of the cells loaded into the ECS and aids removal of metabolic products at a controllable rate. The pore size used in this example does not allow passage of microbial agents or eukaryotic cells; however, for experiments designed to study passage of viruses or bacteria across the blood-brain barrier, pore size can be increased up to >1 μm. Similar rules apply to the passage of cells or viruses from the ECS into the lumen. The entire apparatus resides in a water-jacketed incubator with 5% CO_2 and can be aseptically sampled by placing it inside a laminar flow hood.

There are at least two types of commercially available hollow fiber apparatuses used for growth of cells into the hollow fiber. The hardware used for these experiments was

Current Protocols in Toxicology (2000) 12.2.1-12.2.11

provided by Spectrum after the original CellMax design by Cellco. Alternative hardware configurations (Genespan) do not require use of an incubator, as the cartridge itself is contained in a benchtop enclosure where oxygenation and pumping of medium is provided. The latter hardware bears promise towards a more rational approach to "benchtop" dynamic cell culturing and is currently being tested in the laboratory of Damir Janigro. Multiple sizes of cartridges are available; selection depends on the desired cell load. The lumenal surface area ranges from 70 to 320 cm^2, while the extracapillary space area ranges from 100 to 420 cm^2 (see Table 12.2.1). The coating of the lumenal artificial capillaries (i.e., fibronectin or nothing) can be customized to the cell type of interest. Cell

Table 12.2.1 Specifications for Cellmax Cartridges[a,b]

	Large cartridge	Small cartridge
Number of fibers	230	50
Lumen volume (ml)	2.7	0.5
Lumen surface (cm^2)	327	70
Endothelial inoculum (lumen)	~3–4 × 10^7 cells	~2–4 × 10^6 cells
ECS volume (ml)	7	1.4
Capillary surface area (cm^2)	423	100
Glial inoclum	~5 × 10^7 cells	~1.2 × 10^7 cells

[a]Available from Spectrum, based on the original design by Cellco.
[b]Cartridges for this purpose are polypropylene, coated cartridges.

numbers required will be specified depending on the size of the hollow fiber system purchased.

This procedure describes the main steps involved in the establishment of endothelial-glial co-culture under dynamic conditions (i.e., intralumenal flow). The initial steps are variable and depend on the cellular source that one desires to study. The first decision to be made by the investigator is whether to rely on cell lines (available commercially) or primary cultures of animal or human origin. The example outlined below refers to the use of commercially available, low-passage human endothelial cells (Cell Systems) and glial cells (Clonetics). However, the references provided at the end of this unit are used to isolate and culture endothelial and glial cells from rat or mouse brain. The following procedures imply good knowledge of aseptic cell culture techniques and access to standard equipment such as incubators and a laminar flow hood (also see *APPENDIX 3B*).

NOTE: All solutions and equipment coming into contact with living cells must be sterile, and aseptic technique should be used accordingly.

NOTE: All culture incubations should be performed in a humidified 37°C, 5% CO_2 incubator unless otherwise specified. Some media (e.g., DMEM) may require altered levels of CO_2 to maintain pH 7.4.

Materials

Human endothelial cells (Cell Systems)
Human glial cells: normal human astrocytes (NHA; Clonetics)
CS-C Complete Medium (Cell Systems) containing 10% (v/v) FBS
Gentamycin (Sigma)
Fungizone (Bio-Whittaker)
AGM BulletKit medium (Clonetics) containing 5% (v/v) FBS
Attachment factor (Cell Systems)
Versene (EDTA) and trypsin/versene (Bio-Whittaker)
DPBS, Ca^{2+}- and Mg^{2+}-free (see recipe)

75-cm^2 tissue culture flasks (Corning Costar), uncoated for glial cells and coated with 50 µg/ml attachment factor for endothelial cells
Cartridge/hollow fiber culturing system (see Fig. 12.2.1; Spectrum)
1-, 3-, 5-, and 10-ml syringes, sterile
18-G needles, blunt ended and sterile
22-G needles, sterile

Additional reagents and equipment for determining glucose levels (see Support Protocol 1)

Prepare cells

1. Grow human endothelial and glial cells to confluence in 75-cm^2 flasks coated with appropriate adhesion molecules (50 μg/ml attachment factor for endothelial cells) or on plastic (glia). Grow endothelial cells in CS-C Complete Medium supplemented with 50 μg/ml gentamicin and 0.25 μg/ml fungizone. Grow glial cells in AGM BulletKit medium, which already contains 5% (v/v) FBS.

   To coat flasks, briefly flood the surface with a solution containing the attachment factor at 50 μg/ml, then aspirate the access.

   Endothelial cells are supplied by the vendor in 25-cm^2 flasks, and each one is initially expanded to one 75-cm^2 flask. This can be further split into two or three more flasks depending on cell needs. Flasks can be expanded several times (see Cell Systems literature; provided by vendor on request).

   Normal human astrocytes (NHA) are purchased frozen with 500,000 cells per ampule, which is used to start one 25-cm^2 flask. This should be expanded first to one 75-cm^2 flask and then further expanded according to needs and speed of growth.

   The choice of substrate, while essential for traditional tissue culturing, is not relevant for the expansion of cells to be used in the dynamic in vitro blood-brain barrier, since final differentiation occurs in the hollow fibers. Another important variable, at least from the practical standpoint, relates to the time spent in traditional culture prior to seeding in the hollow fiber apparatus. If, as in this example, expansion of cell lines or highly purified cell culture is essential, it is useful to grow cells to confluence and then split the cultures until the final cell load is achieved.

2. Wean glial cells from AGM to CS-C Complete Medium by culturing first in 1:2 (v/v) CS-C/AGM for 24 to 48 hr, then in 2:1 CS-C/AGM for 24 to 48 hr, and finally in 100% CS-C.

   Co-cultures must be in the same medium (see Critical Parameters and Troubleshooting). Both cell types should be growing successfully in CS-C Complete Medium before attempting to set up co-culture.

Dissociate endothelial cells

3. Rinse endothelial cells once in 5 to 7 ml Versene (EDTA) or Ca^{2+}- and Mg^{2+}-free DPBS. Dissociate the cells by covering with 4 to 5 ml trypsin/Versene at 37°C or at room temperature until cells begin to round up.

   Dissociation time varies with cell line and stage of development; 1 to 3 min for endothelial cells and 5 to 10 min for glia are usually sufficient when the procedure is performed at room temperature.

4. Pipet detached cells into 1 ml CS-C Complete Medium and centrifuge gently (6 min at $112 \times g$, room temperature).

5. Resuspend the pellet in 5 ml CS-C Complete Medium (ten times the lumen volume) by triturating gently with a pipet bulb until no more clumps are visible.

   The lumen volume is 0.5 ml in the cartridge design used for these experiments.

Load endothelial cells into lumen

6. Detach the capillary bundle/ECS (cartridge) from the flow path and remove medium from the interior of the lumen via 5-ml syringes attached to the endports. Test this medium for glucose level, and also test a sample from the medium source and the ECS (for cell growth monitoring see Support Protocol 1).

7. Aspirate the cells into a 10-ml syringe using an 18-G blunt needle, remove needle and attach syringe to inlet port and flush back and forth with an empty 10-ml syringe attached to the outlet end until all bubbles are forced out and the capillaries are completely filled. Collect excess medium, which is forced out through the pores into the ECS, in a 5-ml syringe via the side ports, and then recap the side ports.

8. Place the cartridge in a 37°C incubator laying on one side and then rotate around its long axis for 4 to 6 hr at 45- to 60-min intervals.

   This allows the cells to settle and begin attaching to the intralumenal surface of the hollow fibers.

9. Detach the syringes and reconnect the cartridge to the flow path. Set the pump responsible for intralumenal perfusion on the lowest speed (i.e., 1 ml/min) and incubate for ≥24 hr at 37°C.

   A low speed is used to avoid pulling cells off the capillary walls. Successful growth of intralumenal endothelial cells may require periods ranging from 24 hr up to 10 days.

10. Take 200-µl samples of the lumen and ECS and analyze for glucose content (see Support Protocol 1).

Load glial cells into ECS

11. Detach glial cells from the flask with trypsin/Versene (see steps 3 and 4).
12. Resuspend the cell pellet in CS-C Complete Medium in a volume equal to the ECS not including the sideport tubing. Collect the cell suspension in a 3-ml syringe with a blunt 18-G needle.
13. Place an empty 3-ml syringe on the downstream side port and attach the cell-filled syringe upstream after removing the needle. Using equal "push-pull" pressure, inject the cells into the space and mix back and forth to chase bubbles back up the side port tubing. Allow a short period of "rest" before the flow is turned back on.
14. Close side ports with serum caps to facilitate future sampling via 22-G needles attached to 1-ml syringes. Incubate 24 to 48 hr.

    It is not necessary to rotate the cartridge after loading the ECS, as these cells are not exposed to pulsatile flow.

15. Decant medium and replace it to remove unattached cells.
16. Monitor the cultures for growth (see Support Protocol 1).

MONITORING CELL GROWTH

SUPPORT PROTOCOL 1

As the cells are not microscopically visible inside the cartridge, indicators of cell metabolism are used to monitor cell expansion. Depletion of the main carbohydrate component of the feeding mix (glucose) and accumulation of metabolically produced lactic acid are used as indicators of cell growth. The calculations for glucose consumption and lactate production rates (mg/day) are detailed elsewhere (Stanness et al., 1996, 1997). The glucose consumption and lactate production formulas are determined based on medium replacement, volume of nonreplaced medium, and previous values.

Glucose levels are measured using a Beckman Glucose Analyzer 2 with Beckman Glucose Standard (150 mg/dl) as a reference; however, any commercially available glucose detector can be used, as long as consistent mg/ml readings can be obtained. Less reliable results are obtained with glucose sticks (such as those commonly found in drug stores), and their use should be avoided. Carbohydrate metabolism produces lactic acid, which can be measured as lactate in an enzymatic assay kit (Sigma) using Sigma lactate standard solution (40 mg/dl) as a reference. Standards and samples are read on a spectrophotometer at 540 nm and converted to mg/ml. Lactate levels are then calculated using the formula lactate (mg/dl) = (A_{540} test/A_{540} standard) × 40.

Glucose consumption rate (mg/day) is calculated based on the concentration of glucose in fresh and unreplaced medium in the system, according to the following equation:

$$\frac{V_n G_n + V_o G_p - V_t G_c}{T_c - T_p}$$

where V represents added volumes of medium (ml), G is the glucose concentration (mg/dl), T is time of sampling (in fractions of days), c and p indicate the immediate and previous samples, respectively, n represents fresh medium added after previous sampling, o represents old, unreplaced medium, and t represents total medium (n + o).

Lactate production rate (mg/day) is calculated similarly:

$$\frac{V_t L_c - V_n L_n + V_o L_p}{T_c - T_p}$$

where L refers to the concentration of lactic acid in mg/ml.

To rapidly determine the mg/day values of glucose consumption and lactate production, it is recommended that a spreadsheet program (e.g., Microsoft Excel) be used to automatically determine the desired values.

SUPPORT PROTOCOL 2

MEASUREMENT OF TRANSENDOTHELIAL PERMEABILITY

The bicameral design of the hollow fiber apparatus, together with the presence of intralumenal flow, allows the measurement of "first-pass" permeability by extrapolation of pharmacokinetic equations derived from in vivo studies.

Additional Materials *(also see Basic Protocol)*

[^{14}C]sucrose (Amersham)
^{3}H-labeled drug under investigation
Additional reagents and equipment for determining glucose consumption and lactate production (see Support Protocol 1)

CAUTION: When working with radioactivity, take appropriate precautions to avoid contamination of the experimenter and the surroundings. Carry out the experiment and dispose of wastes in appropriately designated areas, following the guidelines provided by the local radiation safety officer (also see *APPENDIX 1A*).

1. Before experiments of any kind are undertaken, remove 200-µl samples from the ECS, lumen, and medium source for background levels of the tracer used (radiolabeled compound or molecule under study) and of glucose content.
2. Dilute a known concentration of the ^{3}H-labeled drug under investigation to give 5 to 10 µCi per experiment and 1 µCi [^{14}C]sucrose to a 1-ml volume and inject as a bolus directly into the proximal lumen port (upstream from the pump).

   A number of different compounds can be used as tracers. The choice of the ideal candidate depends on the experimental design and ultimately on availability of radiolabeled compound and an appropriate means of detection. For normal pharmacological studies where the permeability properties of a single molecule are to be studied, the extreme values of permeability in that particular experiment (e.g., $P_{sucrose}$ and $P_{diazepam}$) should be known. The permeability of the experimental drug can then be expressed as a percentage of $P_{sucrose}$ (or $P_{diazepam}$). In the case of high-molecular-weight compounds (e.g., polypeptides, DNA fragments, proteins), it is recommended that the permeability of a comparably sized molecule be determined (e.g., horseradish peroxidase if the experimental compound is a protein). Remember that peptides may be transported across the blood-brain barrier; hence, the reference compound must be of such a nature to exclude active transport (e.g., D-amino acid peptides).

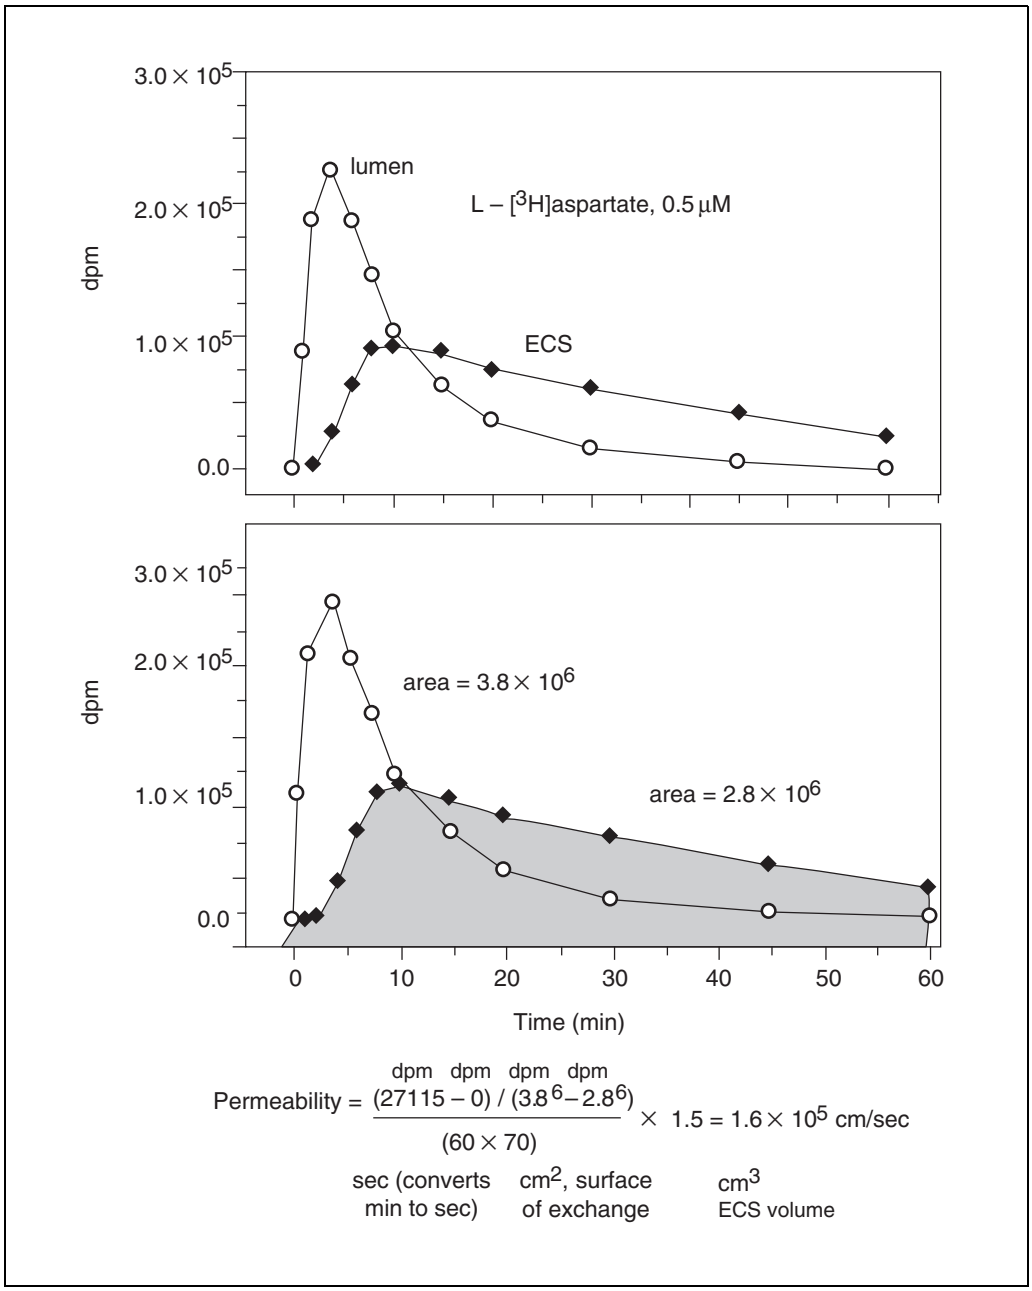

Figure 12.2.2 Testing permeability to L-aspartate.

3. Monitor the diffusion into the ECS over a period of time. Set the capillary flow at 1 dyne/cm^2 (pump setting at 1 ml/min) during the experiment and incubate in a humidified, 5% CO_2 atmosphere maintained at 37°C except during sampling.

   Although it is advisable under most experimental conditions to perform this procedure in a laminar flow hood, it is the authors' experience that, with appropriate care and respect of sterile sampling, cartridges can be sampled directly in the incubator.

4. For short-term permeability measurements, take samples from the ECS and the distal lumen at the following time points: 0, 5, 10, 20, 40, and 60 min. After each extraction (200 µl), refill the ECS content to the original volume with drug-free medium using a "push-pull" system to maintain a constant volume.

   For long-term permeability studies, samples are taken initially as described above; after the initial short-term sampling, samples are collected every 1 to 5 hr for ≥48 hr to allow

distribution to equilibrium of impermeant substances such as [^{14}C]sucrose (permeability ~10^{-7} cm/sec).

5. Analyze radiolabeled samples by liquid scintillographic detection of radioactive tracers (e.g., on a Packard Tri-Carb, 460°C) using a dual-label program to detect both ^{14}C and ^{3}H.
6. Wash excess radioactivity out of both the ECS and flow path by flushing and diluting with medium.

   Without labeled compounds, long-term experiments can be done over a period of days keeping in mind that the medium is being recycled through the system. At the end of any experiment, the medium source should be replaced with fresh medium and a glucose level taken within 24 hr.

7. Calculate the permeability/surface product by graphical integration of the concentration of the drug in the lumen and in the ECS over variable time periods (0 to 60 min; see Fig. 12.2.2). Permeability for a compound "x" is calculated by integrating the area under the ECS and lumen data points according to the following equation describing permeability (P):

$$P = \frac{K([\mathrm{x}]_{\mathrm{ecs,\ final}} - [\mathrm{x}]_{\mathrm{ecs},\ t=0})}{\int_{0 \rightarrow t\,\mathrm{lumen}} [\mathrm{x}] - \int_{0 \rightarrow t\,\mathrm{ecs}} [\mathrm{x}]}$$

   where K is a constant used to normalize rate of efflux for lumenal surface (in cm^2) and ECS volume (in cm^3), and $[\mathrm{x}]_{\mathrm{ecs,\ final}}$ and $[\mathrm{x}]_{\mathrm{ecs,\ t=0}}$ are the ECS concentrations (or dpm, cpm) of x at the extremes of the integration, and $[\mathrm{x}]_{\mathrm{lumen}}$ and $[\mathrm{x}]_{\mathrm{ecs}}$ are the areas under the respective curves.

   Mathematical formulas for the quantification of simple limited integrals are sometimes difficult to use, and graphical integration is preferred. The authors use the commercially available software Origin 6.0 (MicroCal Software) to estimate the areas underlying the profiles of intralumenal and extralumenal drug concentrations.

   Since permeability is normally expressed in cm/sec, the values obtained for P with the above equation have to be divided by 60 to transform from cm/min to cm/sec. The ratio of the concentrations in the equation used to measure P gives a nondimensional quantity. Therefore, as far as the concentrations of drugs are expressed in dimensionally consistent terms, various types of measurement values (e.g., dpm, cpm, mmol/liter) are acceptable. When using radioactive tracers, only minuscule amounts of radiolabeled drugs are used. It is important to remember that transport of drugs depends on the concentrations available for transport (or the K_D of the transporter); thus, when dealing with pharmacological studies, a therapeutic amount of unlabeled drug should be used together with the radioactive tracer. It is also important to note that drugs commonly bind avidly to plasma proteins, reducing their effective free concentrations available for transport or passive permeation.

SUPPORT PROTOCOL 3

FUNCTIONAL ASSESSMENT OF BLOOD-BRAIN BARRIER INTEGRITY

Measurement of drug permeability is time consuming and costly, since radioactive tracers and their disposal are expensive. An alternative approach can be used to indirectly obtain a rough estimate of the degree of endothelial cell differentiation. This technique takes advantages of one of the many quasi-physiological features of the dynamic in vitro blood-brain barrier. Under steady-state conditions, and in the presence of a good barrier, the levels of lumen versus ECS glucose are not equal, owing to the ablumenal-preferring distribution of glucose transporters. Thus, by simply measuring the ECS and lumenal concentrations of glucose, one can detect changes in blood-brain barrier integrity over time. If $\mathrm{glucose}_{\mathrm{lumen}}/\mathrm{glucose}_{\mathrm{ecs}}$ equals 1, there is probably no barrier formed because all the fluxes are paracellular (leak pathway); conversely, when the ratio becomes >1,

blood-brain barrier formation is occurring. An acceptable value is usually ~1.4 (lumenal glucose higher), roughly corresponding to a P_{glu} of 10^{-6} cm/sec.

Using similar considerations, one may decide to use other compounds that are, at steady state, asymmetrically distributed when the blood-brain barrier is endowed with tight junction–dependent exclusion properties. For example, the physiological ion potassium is, like glucose, more concentrated in the plasma. Potassium can be measured by a number of different analytical techniques or, if a department of laboratory medicine is located nearby, by simply treating samples as plasma samples for kalemic determination.

REAGENTS AND SOLUTIONS

Use Milli-Q-purified water or equivalent in all recipes and protocol steps. For common stock solutions, see ***APPENDIX 2A****; for suppliers, see* ***SUPPLIERS APPENDIX****.*

Dulbecco's phosphate-buffered saline (DPBS), Ca^{2+}- and Mg^{2+}-free

0.2 g/liter KCl
0.2 g/liter KH_2PO_4
6.83 g/liter NaCl
2.16 g/liter $Na_2HPO_4 \cdot 7H_2O$
4.76 g/liter HEPES
Adjust pH to 7.2 with NaOH
Sterile filter with a 0.2-µm filter
Store up to 6 months at 4°C

This formulation can be purchased from Bio-Whittaker.

COMMENTARY

Background Information

The cellular basis of the blood-brain barrier is well established and is localized at the level of the brain microvascular endothelial cells. Blood-brain barrier properties are not intrinsic to these cells, however, but are induced by the surrounding brain tissue. In the past, most studies of the blood-brain barrier have been performed in vivo. However, there are limitations to the use of whole animals for the detailed investigation of the modulation of the blood-brain barrier at the cellular level. In vitro models (i.e., isolated microvessel preparations, tissue culture systems) offer a promising alternative for studies of cellular physiology of the blood-brain barrier (Grant et al., 1998; Janigro et al., 1999); however, many of the endothelial cell culture models have been characterized by low transendothelial resistance and relatively high permeability to sucrose. Thus, these models, while versatile and simple, poorly mimic the in vivo blood-brain barrier phenotype. In vitro models of the blood-brain barrier are employed to investigate mechanisms of drug permeation and thus attempt to mimic the salient features of the blood-brain barrier in situ. Static culturing of brain endothelium typically yields low transendothelial electrical resistance and exaggerated permeability, possibly owing to nonphysiological cell growth conditions. The authors developed a dynamic in vitro blood-brain barrier model where near-physiological permeation properties are achieved by growth of endothelial cells in the presence of intralumenal flow and ablumenal glia cells.

There are at least two separate uses for in vitro models of the blood-brain barrier. Depending on the field of study, one may decide to study how drugs cross the blood-brain barrier or whether a particular substance may negatively impact on blood-brain barrier integrity. A brief discussion of these two approaches follows.

Drug permeation across cellular layers constituted by "tight" epithelial or endothelial cells is a common hindrance to effective drug delivery. Since the advent of modern psychopharmacology, it has been understood that the degree of lipophilicity of any given substance is good predictor (under most circumstances) of penetration in the central nervous system. The biological basis for this phenomenon is quite simple since cells are ensheathed by lipid membranes that are amenable for passage of similarly fatty molecules. Another predictor of drug passage is based on the molecular size (molecu-

lar weight) of the drug, with larger drugs being less permeant. It is striking, however, that lipophilicity per se fails to accurately predict passage of numerous therapeutically relevant drugs, including chemotherapeutics and antiretrovirals. It is becoming clear that pathways independent from the cellular integrity of the blood-brain barrier can exclude lipophilic drugs. Specific "reverse transport" molecules have been cloned and studied, including the ubiquitous P-glycoprotein, expressed abundantly in both epithelial and endothelial cells.

Since molecular weight and lipophilicity are not reliable predictors of central nervous system delivery, the use of realistic models has become imperative. To this end, numerous efforts have been made to establish reliable models replicating the cellular properties of the blood-brain barrier in situ. Perhaps surprisingly, and in spite of the availability of modern techniques aimed at permanent cell transformation and genetic manipulations of tissue, in vitro growth of brain endothelial cells has not produced cellular monolayers with the desirable properties (i.e., similar to in vivo). This is partially due to the fact that blood-brain barrier endothelial cells undergo physiological transformations only when exposed to cellular (perivascular glia) and intralumenal (shear stress) influences. To date, only modeling under dynamic conditions has produced results comparable to that obtained in vivo (Grant et al., 1998; Janigro et al., 1999).

Neurotoxicology has heavily relied on isolated organ models to test noxious effects of putative toxins and toxicants. Owing to growing societal concerns over whole-animal testing, and given the obvious obstacles and limitations related to human studies, studies have been routinely performed on cultured neurons or acutely on brain slices. One of the obvious limitations of this approach is the fact that some substances are not neurotoxic in their plasmatic molecular form and become neurotoxic only after passage across the endothelium. Furthermore, it is possible that—in addition to a direct effect on neurons, as estimated in vitro—substances may also affect blood-brain barrier integrity.

Similar consideration applies to studies exclusively performed in vivo. These are commonly done using control subjects, presumably with an intact blood-brain barrier. Under these conditions, a number of potentially neurotoxic compounds are excluded and will not exert central nervous system effects. The issue remains whether the same compound may become neurotoxic in the presence of an "attenuated" or outright leaky barrier. To this end, it is worth remembering that numerous common diseases and conditions negatively impact on blood-brain barrier integrity (Grant et al., 1998).

Critical Parameters and Troubleshooting

Care must be taken to prevent bubbles from forming in the tubing, as they travel to the lumen of the capillaries and strip off cells, leaving bare areas. Bubble formation leads to cell loss and capillary drying. It also decreases the flow rate, depriving cells of adequate nourishment and thus interfering with normal cell growth and differentiation. All connections must be tightened to prevent air leaks. A several-day priming of the system with complete medium allows all spaces to fill; bubbles can then be chased into the bottle before any cells are added. Prewarming medium to 37°C is helpful both for the comfort of the cells and to reduce bubble formation.

Absolute compulsiveness must be used to maintain sterility of the system. Wipe all connections with alcohol swabs before and after disconnection; use sterile syringes for each sample. Perform all sampling in a laminar flow hood, if at all possible. Once contaminated, the cartridge is useless as antibiotics alone are not usually sufficient to kill a bacterial or fungal infection.

Cells need to be monitored frequently for glucose consumption when first set up in order to establish a satisfactory feeding schedule because the cell demands in a cartridge may be very different from those in a flask. Generally the medium source is replaced two to three times per week. Extra glucose may be added to maintain the culture during a time when medium replacement is not possible. Starved cells may begin to die, fall off the capillary walls, and disrupt barrier formation. An acid pH shift (solution turns yellow) provides a visible sign of underfeeding, but hypoglycemia may occur in the absence of any significant pH change.

In co-culture, both cell populations are by design fed the same medium. If one line has been grown in a different medium it must be weaned over to the new formula before it is added to the cartridge. Generally the feed medium of choice is the one in which the more fastidious cell population grows. In this example it is the human endothelial cells lining the lumen that require their own medium formula, so the astrocytes, which are a less demanding population, are weaned over prior to loading in

the extracapillary space. As a rule, feeding the glial flasks first 1:2 (v/v) endothelial/astrocyte medium, then 2:1 endothelial/astrocyte medium, and finally 100% endothelial medium will prepare them to grow in the endothelial medium–fed cartridge.

Barrier formation cannot be hurried. Overly frequent testing with radioactive tracers stresses the cells and may delay barrier formation due to cell loss or disruption. Once the blood-brain barrier is formed, a cartridge may remain healthy up to 6 weeks. Two challenges with radiolabeled tracers per week are usually nondestructive.

Anticipated Results

The endothelial medium CS-C Complete Medium contains 300 mg/dl glucose. A rapidly growing cartridge can deplete this over a few days. It is best to replace medium when glucose levels reach 50 to 75 mg/dl. A level ≤10 mg/dl indicates a starved population of cells and results in massive accumulation of lactic acid in the bathing solution. Examples of glucose consumption and lactate production for a variety of cell types are provided elsewhere (Stanness et al., 1996, 1997; Pekny et al., 1997).

Permeability values are expressed as a velocity, but are measured vectorially since the equation used assumes that passage occurs from blood to brain (i.e., drug added to the lumen). It is possible that a significant permeation from the lumen occurs, due either to a leaky barrier or to use of highly permeant compounds. Under these conditions, the mathematical manipulation may give a negative value for P. Since this is not possible, one must adjust the limit of the integration interval to minimize the quantity of extravasated drug. This is simply achieved by changing the limits of integration to 30 (or even 20) min postinoculation. Remember to also change the values on the numerator. Typical values for poorly permeant substances such as [^{14}C]sucrose are between 2×10^{-6} and 10^{-7} cm/sec. Permeant substances such as diazepam have permeability $>10^{-5}$ cm/sec.

A hollow fiber device can be used for multiple experiments as long as drugs or radioactivity are washed out of the system between each run and background levels are monitored at each testing. The device itself can be stripped of cells by using trypsin and can then be reused in other experiments. It is best to reload with the same combination of cells in subsequent experiments. Needless to say, once sterility has been lost the device is useless. Gas sterilization of the flow path is possible, but the necessary drying of the capillary fibers precludes gas sterilization. The cartridges can be autoclaved under water for 30 min, but care must be taken that they remain wet until reused.

Time Considerations

It may take from 2 to 6 weeks for a human cell–populated cartridge to form a good barrier and be suitable for experiments. A weekly permeability measurement takes about an hour to set up, 40 to 60 min to run, and 2 to 3 hr for washing and refeeding the cartridge. Daily or biweekly samples for glucose need to be taken from the extracapillary space and medium source. At this time notes should be made about the condition of the system—color of medium, debris present, presence of bubbles or leaks. This requires only a few minutes. Glucose samples can be run as taken, can be saved at 4°C for a few days, or frozen for further analysis.

Culturing Rat Hippocampal Neurons

Many toxicants alter the functioning and/or development of the mammalian nervous system. The relative simplicity of neuronal culture techniques and the high degree of control over the conditions under which neurons are grown and exposed to toxicants greatly facilitate investigations into the mechanisms of neurotoxicant action. A wide variety of neuronal cultures has been used in neurotoxicology, including primary cultures from several species (most commonly rats and mice) and from various regions of the brain (including hippocampus, cerebral cortex, cerebellum, and striatum), and immortal cell lines such as PC12 and several neuroblastoma lines. Each of these options may offer advantages for specific studies; for example, site-specific neurotoxicants are probably most suitably studied in cultures from the appropriate brain region. Cultures of embryonic rat hippocampal neurons, however, have found particular favor in basic neurobiology (e.g., in studies of voltage-sensitive and ligand-gated ion channels, synaptic transmission, and neurite development). Therefore, there is a rich background literature on hippocampal neurons that the neurotoxicologist can use to formulate hypotheses, develop experimental protocols, and help understand mechanisms of toxicant action.

This unit describes procedures for isolating hippocampal neurons from embryonic rats and cryopreserving them (see Basic Protocol 1), for culturing the neurons (see Basic Protocol 2), for developing hippocampal astrocyte cultures (see Basic Protocol 3), and for coculturing neurons and astrocytes (see Basic Protocol 4).

NOTE: All protocols using live animals must first be reviewed and approved by an Institutional Animal Care and Use Committee (IACUC) or must conform to governmental regulations regarding the care and use of laboratory animals.

NOTE: All solutions and equipment coming into contact with living cells must be sterile, and aseptic technique should be used accordingly.

NOTE: All culture incubations should be performed in a humidified 37°C, 5% CO_2 incubator unless otherwise specified.

ISOLATING HIPPOCAMPAL NEURONS FROM RAT EMBRYOS

BASIC PROTOCOL 1

This procedure describes the initial isolation of hippocampi from embryonic rats and their dissociation into single neurons. All phases of the dissection must be conducted in a laminar flow hood, using sterilized instruments and surgical gloves. Dissecting tools should be stored with their working surfaces submerged in a vial of 95% ethanol when not in use. Immediately before use, they should be dipped in sterile HBSS to remove the ethanol.

When dissecting, it is best to always have a pair of forceps in one hand and a pair of forceps or scissors in the other. One pair of forceps will always be used to stabilize the head or brain tissue as the other implement is being used. Forearms and hands must be stabilized by resting them on the table and the edges of the dissecting dish, respectively, taking care that fingers aren't dipped in the HBSS.

Even though fetal brains are relatively small and the hippocampi are smaller still, anoxia and cellular damage probably begin as soon as the dam is anesthetized and continue until the neurons are dissociated from the hippocampi. Keeping the brains and hippocampi cold reduces, but does not eliminate, metabolic activity and associated cellular damage.

Contributed by Gerald Audesirk, Teresa Audesirk, and Charles Ferguson
Current Protocols in Toxicology (2000) 12.3.1-12.3.17

The highest number of healthy neurons will be obtained by a well-coordinated dissection team, in which each member of the team is highly proficient at specific tasks, thereby minimizing the total time between anesthesia and dissociation of neurons. It is useful to have one person removing brains from the skulls while a second removes the hippocampi and a third dissociates the hippocampi into a single-cell suspension. Typically, dissection of the hippocampi begins after brains have been removed from about half of a litter. Removal of the brains from the other half of the litter will usually be finished well before hippocampal dissection of the first half is complete; until dissection, these brains may be stored in a refrigerator, in a covered sterile culture dish filled with cold HBSS. Dissociation of the hippocampi from the first half-litter then begins while hippocampi are dissected from the second half. If more than one litter is to be used in a single day, three people can keep up a more-or-less continuous process of brain removal, hippocampal dissection, and hippocampal dissociation until all of the litters are finished.

Each E18 hippocampus typically provides ~0.5 to 1 million cells, almost all of which are neurons. Therefore, depending on the size of the litter, a single litter will provide ~6 to 30 million neurons. Depending on the experimental protocol, this may be far more neurons than can be conveniently used at once. For example, for morphological measurements of neuronal differentiation, neurons are typically plated sparsely (~1,000 to 20,000 cells/cm^2 or ~10,000 to 200,000 per 35-mm culture dish), so a single litter would provide enough neurons for dozens to hundreds of dishes. Further, because of the preparation and setup time, it is often convenient to dissect several litters at once. Cell suspensions may therefore be cryopreserved as described below and used at leisure. Appropriate cryopreservation results in cultures that are virtually indistinguishable from those produced by plating immediately after dissociation (Mattson and Kater, 1988).

Materials

Timed pregnant female rats (e.g., Sprague-Dawley) at gestational day 18 or 19 (E18 or E19)
95% (v/v) ethanol
HBSS (see recipe), sterile, ice cold
CMF-HBSS (see recipe), sterile, ice cold
2 mg/ml trypsin (Life Technologies) in CMF-HBSS, prewarmed (37°C)
2 mg/ml trypsin inhibitor (Sigma) in CMF-HBSS, prewarmed (37°C)
Complete EMEM (see recipe; optional) or equivalent
Cryopreservation medium (see recipe; optional), cold
Propanol (optional)

Laminar flow hood
Dissecting microscope, total magnification of ~14×
Fiber optic illuminator (e.g., Fiber-Lite, Dolan Jenner Industries)
Large magnifying glass on stand (Edmund Scientific)
CO_2 tank and tubing
Anesthetizing chamber
Dissecting pans of various sizes, all with autoclavable rubber of silicone filling for pinning tissue
~24 × 32–nm
18 × 20–nm
10-cm dia., 4-cm deep
10-cm tissue culture dish

Dissection tools (Roboz Surgical Instruments or Fine Science Tools), sterile:
Bone cutters or strong, short-bladed scissors
Rat-tooth forceps
Large and small dissecting scissors (~4- and 2-cm blades)
Microdissecting forceps (Dumont no. 5 or equivalent; old or deliberately blunted forceps work best for pinning tissues, sharpened forceps for actual dissection)
Blunt forceps
Fine dissecting pins (e.g., Minuten insect pins, Carolina Biological Supply)
Large and small spring-handled microdissecting scissors (10- and 3-mm blades, respectively)
5-ml disposable plastic tubes (e.g., Falcon), sterile
Fire-polished Pasteur pipet, sterile
Hemacytometer and coverslip
Upright compound microscope (400× total magnification)
Freezing vials (e.g., 2-ml vials from Nalgene; optional)
Vial-freezing containers (e.g., Nalgene cryo 1° freezing containers; optional)

Remove uterine horns

1. Prepare the dissection area. Ensure that all dissecting equipment is sterile and place it in a sterile laminar flow hood with a dissecting microscope and fiber optic illuminator. Ensure that all solutions are filter sterilized and place them in the hood.

   All procedures after the initial removal of the uterus from the anesthetized dam should be carried out in a sterile, laminar flow hood. A laminar flow hood with a dissecting microscope built into the front glass would be ideal, but is not necessary. A clean dissecting microscope and illuminator placed in the hood and carefully wiped down with ethanol should suffice. A large adjustable magnifying glass will facilitate removal of the fetal brains from the skulls.

2. Insert tubing connected to a CO_2 tank through the hole in the lid of an anesthetizing chamber. Allow the chamber to fill with CO_2 for 10 to 20 sec.

   The chamber can be easily constructed from a plastic cage bottom and a piece of plastic large enough to completely cover the cage top. Drill a hole in the plastic just large enough to accommodate tubing connected to a CO_2 tank.

3. Remove the lid, rapidly place a timed pregnant female rat in the chamber, and replace the lid. Wait until the rat has stopped breathing for a few seconds.

   Hippocampal neurons are usually taken from rats at day 18 or 19 of pregnancy (E18 to E19). At this stage, most of the pyramidal neurons have formed, but there are very few glial cells. If it is not desirable to keep a rat colony or to maintain pregnant rats, pregnant rats may be obtained from several companies, timed to arrive in the laboratory at E18 (or earlier).

   Longer anesthesia is unnecessary and may result in damage to fetal neurons caused by anoxia and/or pH changes.

4. Remove the dam from the anesthetizing chamber and rapidly transfer it to a large (~24 × 32-cm) dissecting pan, dorsal side up. While immobilizing the head, rapidly pull the tail so that the neck is broken. Using bone cutters or strong, short-bladed scissors, crush or sever the cervical spinal cord.

   Dissecting pans can be made from dishes filled 2 to 4 cm deep with Sylgard (Dow Corning) or similar material into which pins may be inserted during dissection. The addition of carbon black to the Sylgard before polymerization provides a black background, which greatly assists visualization of the brain during dissection.

5. Turn the dam ventral side up and sterilize the abdomen by pouring 95% ethanol over it.

6. Rinse rat-tooth forceps and short-bladed scissors in ethanol, grasp the abdominal skin with the forceps, and cut the abdomen completely open, from near the vagina to the thoracic cavity. Rinse the forceps and scissors in ethanol again.

7. Identify the uterine horns by their dark red color, with ~2-cm-long fetuses separated by constrictions. Gently grasp a horn at one of the constrictions and lift up. Remove the horns by cutting their attachments to the abdominal cavity and place in a sterile 14×20-cm dissecting dish.

   The uterine horns should be removed as rapidly as possible, because the fetuses are no longer receiving oxygen from the dam. At this stage, blood samples may be taken from the dam by cardiac puncture and/or other body parts may be removed from the dam.

   The uterine horns may come out in one or two pieces. Typical litters have six to fifteen fetuses (Sprague-Dawley rat litters average eleven fetuses).

Isolate fetal heads

8. Transfer the dissecting pan with the uterine horns to the laminar flow hood.

   Although not necessary during the removal of the uterine horns from the dams, surgical gloves should be worn during all other procedures.

9. Remove the fetuses from the uterine horns and place in cold, sterile HBSS. Using microdissecting forceps and small dissecting scissors, decapitate the fetuses and place the heads in fresh, cold HBSS in a 10-cm dissecting dish.

   For larger litters, or if the dissecting process is slow, some of the heads can be stored in HBSS in a covered sterile culture dish in the refrigerator (up to 15 min).

Dissect out fetal brains

10. Place a 10-cm circular dissecting dish in a larger dish of crushed ice and fill to ~2 cm deep with fresh, ice-cold HBSS. Orient a fetal head in the dish, with the neck down and the snout facing away. Using blunt forceps, place a dissecting pin through the snout to anchor the head.

11. Insert the tip of a pair of large spring-handled microdissecting scissors under the nearest cut edge of the skin and skull. Orient the scissor blades along the longitudinal fissure separating the hemispheres. Anchoring the head with the forceps, lift upward with the scissor blades while cutting through the skull, in order to avoid slicing the underlying brain tissue. Slice forward almost to the pin anchoring the snout.

    Initially, it may be easier to cut through the skin first, then through the transparent skull, but these steps can be combined after skill is achieved.

    It is important that the scissors be positioned exactly along the longitudinal fissure in order to avoid cutting the cerebral cortex.

12. Using two pairs of microdissecting forceps, grasp the cut edges of both skull and skin on either side of the incision and separate them, exposing the brain. Anchor each flap to the side with a dissecting pin.

13. Using the scissors held horizontally, place the blades beneath the brain, and use a few snips moving toward the snout to sever the cerebral hemispheres and cerebellum from the spinal cord.

    The scissors can now serve as a platform to lift the brain upward out of the skull.

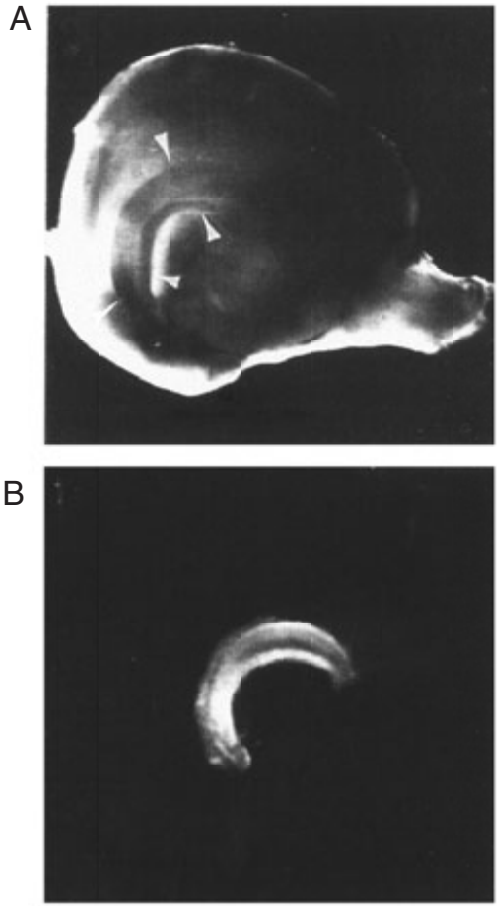

Figure 12.3.1 Hippocampal dissection. (**A**) A view of the medial surface of the left cerebral hemisphere. The arrows indicate the boundaries of the hippocampus, as described in the text. (**B**) The hippocampus after removal from the cerebral hemisphere. From Goslin and Banker (1991). Reprinted by permission of MIT Press.

14. Remove brains from all heads before continuing. Remove HBSS contaminated with blood by slowly and gently pouring it off the dissected brains, leaving them behind in the dissecting pan. Replace with fresh, ice-cold HBSS.

Dissect out hippocampi

15. Orient the brain dorsal side up with the cerebellum toward you. Insert the blades of the large spring-handled scissors between the junction of one hemisphere and cerebellum, with the blade extending along the longitudinal fissure and angled toward the midline, and use a single cut to isolate the cerebral hemisphere from the cerebellum and the brainstem. Repeat on the other side of the brain and for all the brains before removing any hippocampi.

16. Place cerebral hemispheres in a small dissecting dish that is sitting in ice. Orient one hemisphere with the medial surface upwards (Fig. 12.3.1). Anchor it with a single microdissecting pin through the severed corpus callosum just below the center of the hemisphere, allowing rotation of the tissue around the pin as needed.

A remnant of thalamus may remain attached to the medial cortex, obscuring the hippocampus (Goslin and Banker, 1991). This is easily cut away with forceps or scissors, leaving the smooth, flat medial surface of the cortex exposed. When orienting the cerebral hemisphere, the olfactory bulb, a nubbin of tissue that projects anteriorly, is a good landmark. Note in Figure 12.3.1 that the dorsal cerebral hemisphere is much more rounded than the ventral surface. The cortex is surrounded by semitransparent tissue, the meninges, in which blood vessels are embedded.

The hippocampus, located in the medial and posterior half the cerebral cortex, is a C-shaped structure whose concave portion faces the olfactory bulb. The hippocampal fissure, which forms the dorsal border of the hippocampus, is a shallow depression sometimes highlighted by a blood vessel, as seen in Figure 12.3.1. The fissure separates the dorsal margin of the hippocampus from the adjoining subicular and entorhinal cortex (Banker and Cowan, 1977). The ventral margin of the hippocampus is free, bordered by a translucent band of tissue, a developing fiber tract called the fimbria (Goslin and Banker, 1991). Immediately behind the hippocampus is the lateral ventricle.

Because the cerebral tissue is delicate and easily torn when grasped with forceps, the authors leave the meninges attached so that the tissue can be lifted by grasping the meninges. However, some researchers prefer to remove the meninges before dissecting the hippocampus. This must be done slowly and gently, stabilizing the underlying cerebral tissue with forceps to avoid tearing it.

17. Make a single cut with small microdissecting scissors from the dorsal-most part of the cerebral hemisphere (the top of the head) down through the fimbria (toward the central pin).

    This cut will define the approximate anterior boundary of the hippocampus.

18. Make a curving incision just dorsal to the hippocampal fissure, parallel to the ventral free border of the hippocampus, and extending posteriorly and ventrally. Use a final snip at the end of the curved incision to release a fingernail paring–shaped piece of tissue containing the hippocampus (see Fig. 12.3.1).

    If the meninges are still attached, remove them at this time by pulling them off gently with a pair of forceps, while stabilizing the hippocampal tissue with another pair.

19. Transfer the hippocampus to a 5-ml sterile disposable plastic tube containing 4 ml ice-cold CMF-HBSS.

    The tube may be embedded upright in crushed ice or stored in a tube rack (such as Kryorack VI) in which the tube slots are surrounded by a frozen solution.

20. Remove remaining hippocampi and add to the tube.

    Typically, the hippocampi from one litter can be processed in a single tube.

Dissociate hippocampi

21. Remove hippocampi and combine them in a 5-ml tube containing 2 ml of 2 mg/ml trypsin solution, prewarmed to 37°C. Place in 37°C water bath for 15 min.

22. Gently aspirate off the trypsin solution with a sterile pipet and add 2 ml of 2 mg/ml trypsin inhibitor solution, prewarmed. Incubate 5 min at 37°C.

23. Gently aspirate off the trypsin inhibitor solution and add prewarmed (37°C) complete EMEM (to plate the neurons immediately) or ice-cold cryopreservation medium (to preserve the neurons for later use) at 100 µl per hippocampus. Dissociate the hippocampi into a (mostly) single-cell suspension by gently pipetting through a fire-polished, sterile Pasteur pipet.

    Vigorous or excessive pipetting will result in significant cell death. It is probably better to pipet less and leave a few cell clumps than to overpipet and risk damaging many of the cells. The authors usually pipet the hippocampi only eight to ten times. Care should be taken to avoid aspirating air and causing foaming of the medium, as cell viability will be severely compromised. Finally, when fire polishing the pipets, the pipet tips should be heated just enough to smooth the opening without greatly reducing its diameter. Very small tip openings caused by excessive fire-polishing result in too much shear stress upon the cells during pipetting.

24. Place a small drop of cell suspension in a hemacytometer, apply a coverslip, and determine the cell density using an upright microscope with 400× total magnification (*APPENDIX 3B*). Add the appropriate amount of complete EMEM or cryopreservation medium to adjust the suspension to the desired cell density.

    For immediate culture (see Basic Protocol 2), there is no optimal cell density. For most applications, it is probably simplest to adjust the suspension to a fairly high density (e.g., 5–10 × 10^6 cells/ml) and dilute the resulting suspension in culture medium when the cells are plated, to obtain the density required by the experimental protocol. For cryopreservation, adjust cell density to 8 × 10^6 cells/ml.

    Some investigators use trypan blue staining (APPENDIX 3B) to distinguish live from dead cells when determining density. In the authors' experience, there is no need for trypan blue staining. Most living cells are round (possibly with a small stump of a process remaining attached to the cell body) and bright, and most dead or dying cells are clearly ragged. Counting only the round bright cells agrees very closely with results from trypan blue staining.

25. *Optional:* To cryopreserve cells, place 250-µl aliquots of cell suspension (2 × 10^6 cells) in freezing vials. Place the freezing vials in a Nalgene vial-freezing container filled with room-temperature propanol. Place the freezing container in a −70° or −80°C freezer and store for up to 1 month.

    Cryopreservation works best when a cryopreservative is added to the medium to reduce ice crystal formation and when freezing is done slowly (~1°C per min). Commercial cryopreservative media are available (e.g., Life Technologies), but simply adding dimethyl sulfoxide (DMSO) and 10% (v/v) fetal bovine serum to EMEM produces excellent results. Slow freezing may be accomplished manually, for example, by sequential cooling of the vials in a refrigerator (4 hr), a −20°C freezer (4 hr), and then a −70°C freezer. However, freezing containers greatly simplify the process.

CULTURING HIPPOCAMPAL NEURONS

BASIC PROTOCOL 2

There is no generally acknowledged optimal set of culture conditions for hippocampal neurons, in part because the appropriate plating substrate, culture medium, additives, and neuronal density may vary depending on the experimental design and aims. This protocol describes sparse plating of neurons on polylysine-coated plastic culture dishes in fairly typical Eagle's minimal essential medium containing fetal bovine serum and other supplements. See Background Information for a brief description of a few alternative media and additives that may be appropriate for certain types of experiments.

Materials

0.1 mg/ml poly-D-lysine (mol. wt. 350,000; Sigma), filter sterilized (cellulose acetate, 0.2-µm pore size)
Dissociated hippocampal cell suspension (see Basic Protocol 1)
Complete EMEM (see recipe)
10× cytosine arabinoside (typically, 10 to 100 µM) in complete EMEM, filter sterilized (optional)
Laminar flow hood
35-mm plastic cell culture dishes (Corning or Nunc)

1. Open a package of 35-mm plastic cell culture dishes in a laminar flow hood.
2. Pipet ~0.5 ml of 0.1 mg/ml poly-D-lysine solution into each dish, replace lids, and leave in the hood for 30 min.

    Many other substrates are in common use, including poly-L-lysine, polyornithine, laminin, fibronectin, collagen, and combinations of these. Several companies also sell precoated

dishes with any of several treatments (e.g., Biocoat markets dishes coated with collagen, fibronectin, laminin, poly-D-lysine, and other substrates). Poly-D-lysine and poly-L-lysine are probably the most commonly used, but the investigator should be aware that coatings, particularly protein coatings, may interact with attachment receptors on the neurons and significantly affect neuronal differentiation in culture.

3. Rinse each dish three times for 30 min each with 2 ml sterile deionized or distilled water. Aspirate off the last rinse and leave the lids ajar in the hood until the dishes are dry.

   Dishes may be used for ≥2 weeks after coating, if they are kept dry at room temperature.

4. Determine the desired number of cells per dish and calculate the volume of dissociated hippocampal cell suspension needed to contain this number. In the laminar flow hood, using sterile pipet tips, pipet the appropriate volume into 2 ml complete EMEM in each coated 35-mm culture dish. Place the culture dishes in a 37°C, 5% CO_2 incubator.

   In relatively high-density cultures (e.g., >200,000 cells plated in 2 ml medium), it may be useful to replace the medium after 2 to 4 hr to remove debris produced during trypsin digestion and cell dissociation.

   The dissociated cells will settle to the bottom of the tube if they are not used shortly after dissociation. If necessary, gently resuspend the cells with one pass through a fire-polished, sterile Pasteur pipet.

   If cryopreserved cells are used, thaw cells rapidly by filtering ~750 µl warm complete medium directly into the freezing vial (about three times the volume of the frozen cell suspension) and gently agitating in a 37°C water bath. Resuspend the cells with two or three passes through a fire-polished Pasteur pipet before dispensing into culture dishes. Replace the medium after 2 to 4 hr to remove debris and reduce the concentration of DMSO or other cryoprotectants in the culture medium. However, do not attempt to remove all of the medium during the change. A thin layer of medium should be left on the dish at all times.

5. If neurons are to be maintained more than a few days, feed once every 4 to 7 days by replacing about one-fourth to one-half of the medium with fresh complete medium.

   Probably the single greatest cause of neuronal death, other than contamination, is feeding. By the time the culture is a few days old, it becomes susceptible to glutamate-induced excitotoxicity. Most sera contain considerable amounts of glutamate, so complete replacement of medium with 10% or even 2% serum will probably cause excitotoxic cell death in relatively mature cultures. In reduced-serum or serum-free medium, this is less of a problem.

6. Reduce or eliminate proliferating glial cells to avoid astrocyte dominance of the culture. On about the second to fourth day of culture (sooner with high-serum medium, later or possibly not at all in serum-free medium), add 250 µl of 10× cytosine arabinoside to each culture.

   Neurons do not multiply in culture, but glial cells, particularly astrocytes, do. Although there are very few astrocytes in cell suspensions from E18 fetuses, they will eventually dominate the culture. This step can substitute for the first feeding.

   Although cytosine arabinoside is primarily toxic to dividing cells, in the authors' experience, it is also toxic to neurons if the concentration is too high. Further, the availability and/or toxicity of cytosine arabinoside appears to be inversely proportional to the serum concentration. Typical effective concentrations are ~10 µM in medium with 10% serum, decreasing to 1 µM in low-serum or serum-free media. It may be useful to change the medium after 1 or 2 days to remove the cytosine arabinoside.

OBTAINING HIPPOCAMPAL ASTROCYTE CULTURES

There are very few glial cells in E18 rat fetal hippocampi, but there are a few astrocytes or astrocyte progenitors (see Fig. 12.3.2B). Although it is much more efficient to obtain astrocyte cultures (or cultures of other types of glial cells) from early postnatal brain tissue, hippocampal astrocyte cultures can be produced from the neuronal cultures described above.

Because astrocytes foster neuronal survival, there will be varying numbers of neurons remaining in the initial astrocyte culture, even after the astrocytes reach confluency. Elimination of neurons can be accomplished in one of two ways: initial plating on uncoated dishes or subculturing. Astrocyte purity can be estimated by immunostaining representative dishes for the astrocyte-specific protein glial fibrillary acidic protein (GFAP). Either of the neuron-eliminating protocols usually results in astrocyte purity of 98% or better.

Materials

Dissociated hippocampal cell suspension (see Basic Protocol 1)
Complete EMEM (see recipe)

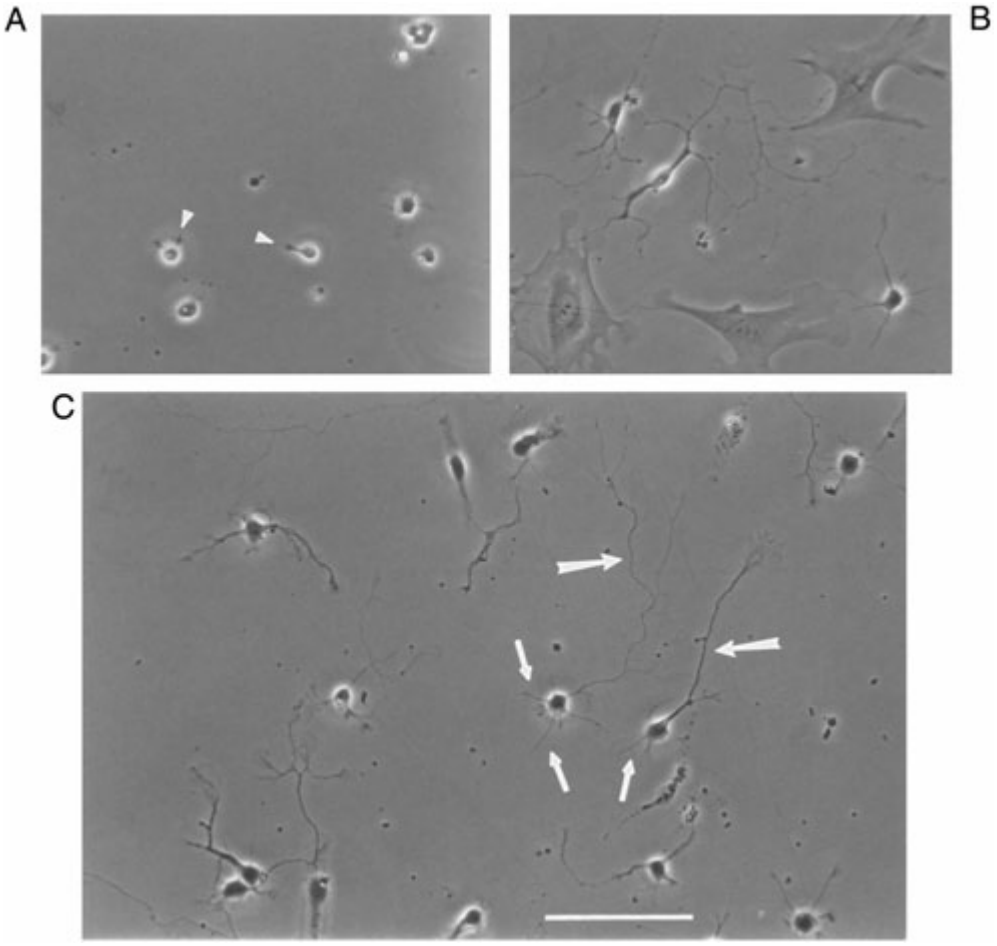

Figure 12.3.2 Typical sparse hippocampal cultures in which 100,000 E18 cryopreserved cells were plated in 35-mm plastic culture dishes coated with poly-D-lysine, using EMEM with 2% fetal bovine serum. (**A**) At 4 hr, most neurons are phase bright, and many already possess one or more short processes (arrowheads). (**B**) Occasional astrocytes (large, polygonal cells) are also found in E18 hippocampal cultures. In serum-containing medium, these will multiply over time. (**C**) At 3 days, most neurons have developed a single, long axon (large arrow) and several much shorter dendrites (small arrows), although in some neurons (e.g., upper left) there is no clear morphological distinction between axons and dendrites. Scale bar = 100 μm.

CMF-HBSS (see recipe)
2 mg/ml trypsin (Life Technologies) in CMF-HBSS

Laminar flow hood
35-mm plastic cell culture dishes, uncoated or poly-D-lysine coated (see Basic Protocol 2)
Rotary shaker (optional)
Fire-polished Pasteur pipet, sterile

To purify astrocytes at time of plating:

1a. In a laminar flow hood, plate dissociated hippocampal cell suspension at a high density in 2 ml complete EMEM/10% to 20% FBS on uncoated tissue culture dishes (≥500,000 cells per 35-mm culture dish). Incubate 24 to 48 hr in a 37°C, 5% CO_2 incubator.

See Basic Protocol 2 (step 4 annotations) for additional information on plating cells.

Neurons do not adhere well to uncoated dishes, but astrocytes do. Thus, astrocytes can be purified by washing away the unadhered neurons (below). In the authors' hands, it appears that astrocyte cultures grow more rapidly on coated dishes. Therefore, confluency may be delayed with this method.

2a. Gently shake dishes for 1 min (manually or on a rotary shaker) and remove the medium to remove most of the neurons.

3a. Immediately replace with 2 ml fresh medium containing ≥10% fetal bovine serum and return to incubator.

4a. Completely change medium once a week until astrocytes are nearly confluent.

When the neuronal suspension is initially plated at 500,000 cells/plate, it takes approximately 7 to 10 days to obtain nearly confluent astrocyte cultures. Higher plating densities will, of course, result in more rapid development of confluent astrocyte cultures.

To purify astrocytes by subcloning:

1b. In a laminar flow hood, plate the dissociated hippocampal cell suspension on poly-D-lysine-coated 35-mm culture dishes in 2 ml complete EMEM containing ≥10% fetal bovine serum. Place in a 37°C, 5% CO_2 incubator and change the medium once a week until astrocytes are nearly confluent.

See Basic Protocol 2 (step 4 annotations) for additional information on plating cells.

An initial plating density of 500,000 hippocampal cells per 35-mm plate will yield nearly confluent astrocytes in approximately 7 to 10 days.

2b. Remove medium from confluent cultures, rinse once briefly with 2 ml 37°C CMF-HBSS, and add 0.5 ml of 2 mg/ml 37°C trypsin solution to each dish. Incubate until cells have mostly detached from the dish (5 to 15 min), checking every 5 min.

The astrocytes will round up, detach from the bottom of the dish, and usually adhere to one another. Neurons do not tolerate trypsinization very well, so the subculturing both propagates astrocytes and quite effectively eliminates neurons from the secondary cultures, which should have «1% neurons.

3b. Add 1 ml complete EMEM with 10% fetal bovine serum (or other suitable serum-containing medium) and triturate the cells a few times with a fire-polished Pasteur pipet.

4b. Replate aliquots of cell suspension in new coated dishes with serum-containing medium.

Cells may be diluted if increased numbers of astrocytes are desired (e.g., plate 2 to 5 new dishes with the cells from one confluent dish).

To plate reasonably precise numbers of astrocytes in the subcultures, the cells will need to be dissociated into a (mostly) single-cell suspension and counted in a hemocytometer (APPENDIX 3B). This may require prolonged trypsinization and vigorous pipetting. Astrocytes are usually quite robust and can withstand such treatment. On the other hand, for many uses, the subcultures will be grown to confluency after replating. The authors have found that, within reason, widely varying numbers of astrocytes per dish will nevertheless reach confluency at about the same time and result in about the same number of cells per dish at confluency (as estimated by protein determinations). Therefore, depending on the experimental protocols for which the astrocytes will be used, precise cell counting may be unnecessary.

In principle, subculturing can be continued indefinitely. However, it is probably best to limit the number of times that a given astrocyte culture is divided in this way. Selection for rapidly reproducing cells, mutation, and possible spontaneous transformation may significantly alter the characteristics of astrocyte cultures after repeated subculturing. The authors usually do not subculture more than once.

COCULTURING HIPPOCAMPAL NEURONS AND ASTROCYTES

BASIC PROTOCOL 4

In the intact brain, neurons are in close association with astrocytes. In culture, neurons usually survive longer and grow better in the presence of astrocytes. Therefore, it may seem obvious that neurons should always be cocultured with astrocytes. For toxicologists, however, the decision to coculture neurons with astrocytes must be made with an awareness of the possible effects of astrocytes on the toxicant, the neurons, and the surrounding medium. For example, release of (usually unidentified) growth substances by the astrocytes will make the culture medium less defined. Further, astrocytes will remove glutamate from the medium and may sequester some toxicants. Substances released by astrocytes into the medium may bind to toxicants and alter their availability to neurons. The oxidant status of both the medium and the neuronal cytoplasm may be altered. These factors may make mechanistic experiments more difficult to interpret and dose-response curves more uncertain. Nevertheless, coculturing can be a valuable tool for in vitro neurotoxicology.

There are three fundamentally different ways to "assist" neurons with astrocytes: using astrocyte-conditioned medium, plating neurons directly on the surface of a confluent astrocyte layer, and plating astrocytes and neurons on separate surfaces so that they are in the same culture dish but not physically in contact. Although astrocyte-conditioned medium provides some assistance to neuronal survival and growth, it is not as beneficial as the other techniques (Goslin and Banker, 1991). However, using astrocyte-conditioned medium is simple and does not require any special techniques. Simply incubate the desired medium for 24 to 48 hr in dishes or flasks containing confluent astrocyte layers, and then use this medium for neuronal culturing.

Plating hippocampal neurons directly on an astrocyte layer probably provides the greatest similarity to the in vivo condition. It also has disadvantages for many experiments, because the astrocytes may visually obscure parts of the neurons, particularly fine neurites, and because the mass of the astrocytes is usually much larger than that of the neurons. To plate neurons (10,000 to 200,000 depending on the experiment) on an astrocyte layer, grow astrocytes to confluency in serum-containing medium and then add the neurons. If desired, change the medium to one that is more compatible with neuronal growth or that is optimal for a particular experimental protocol. Astrocytes typically will not overgrow neurons.

Plating neurons and astrocytes on separate surfaces may be done with two very different procedures, which might be loosely called the "closed" and "open-face" sandwich methods. In the closed sandwich method, the surfaces upon which the neurons and astrocytes are growing face each other but are kept separate by small "feet" attached to one of the surfaces. This method is somewhat complicated and will not be described here; the interested reader is referred to a complete description by Goslin and Banker (1991). The open-face sandwich method is simple yet effective. Prepare glass coverslips by soaking in concentrated nitric acid overnight to remove any contamination and to etch the surface slightly. It is convenient to use 12-mm round coverslips, which may be used for electrophysiology or imaging experiments in temperature-controlled perfusion chambers available from Warner Instrument. Rinse the coverslips with deionized water six times for 30 min each, and sterilize by autoclaving. Coat the coverslips with poly-D-lysine by placing up to five coverslips in a 35-mm culture dish and following the procedure for coating culture dishes (see Basic Protocol 2). Using sterile forceps, move the coverslips around at the beginning of each rinse to prevent them from adhering to the culture dish (if they do adhere, a short incubation in culture medium will loosen them). To coculture the neurons and astrocytes, gently place up to three coated coverslips atop a confluent layer of astrocytes in a 35-mm culture dish containing 2 ml of the medium normally used to plate neurons. Plate neurons onto the coverslips by gently pipetting them into the medium directly above each coverslip. Leave the culture dishes undisturbed in the laminar flow hood for 30 to 60 min after plating the neurons, allowing the neurons to drift down onto the coverslips and adhere. Cultures will be fine at room temperature for this length of time in HEPES-buffered medium. Then move the dishes to the incubator for a few more hours. Replace the medium as with ordinary neuronal cell cultures.

REAGENTS AND SOLUTIONS

*Use Milli-Q-purified distilled or deionized water in all recipes and protocol steps. For common solutions, see **APPENDIX 2A**; for suppliers, see **SUPPLIERS APPENDIX**.*

Ca^{2+}- and Mg^{2+}-free Hank's balance salt solution (CMF-HBSS)

Ca^{2+}- and Mg^{2+}-free HBSS (Sigma) containing:
350 mg/liter $NaHCO_3$
10 ml/liter antibiotic/antimycotic solution (Life Technologies)
10 mM HEPES buffer
Adjust to pH 7.3
Store up to 2 weeks at 4°C

Cryopreservation medium

EMEM (see recipe) containing:
19 g/liter glucose
On the day of use, add:
8% (v/v) dimethyl sulfoxide
10% (v/v) fetal bovine serum (final)

Complete Eagle's minimum essential medium (EMEM)

Phenol red–free EMEM (Sigma) containing:
1 g/liter glucose
10 ml/liter antibiotic/antimycotic solution (Life Technologies)
1 mM pyruvic acid (Sigma)
2 mM glutamine (Sigma)
25 mM $NaHCO_3$
25 mM HEPES buffer (optional)
Adjust to pH 7.3

continued

Filter sterilize into 500-ml borosilicate glass bottles (preferably with Teflon-lined bottle caps) using bottle-cap filters (cellulose acetate, 0.2-μm pore diameter; e.g., Corning)
Store up to 2 weeks at 4°C
Just before use, add 2% to 10% (v/v) fetal bovine serum (Hyclone) and warm to 37°C

Other supplements appropriate for the experimental design (e.g., B27, N2; see Commentary) can also be added.

The water must be of extremely high quality. Barnstead and Millipore, among others, manufacture deionizing systems that will produce 17 to 18 megohm tissue culture–quality water. Water may also be purchased from cell culture supply companies.

Most media are buffered principally with bicarbonate, with pH ~7.3 measured at 37°C in an incubator containing 5% CO_2/95% air. The pH may be very different at room temperature and atmospheric CO_2 concentrations (e.g., during culture setup and manipulations, such as addition of toxicants or photographing neuronal growth). The pH may also change during prolonged culturing in the incubator. For these reasons, many investigators buffer their media with 25 mM HEPES. Several companies manufacture media containing HEPES, usually adjusting the bicarbonate concentration and/or sodium chloride concentration to keep the osmotic strength similar to normal medium. If medium is made up from powders, then supplements can be added without changing the concentration of its other components.

During neuronal culturing, the importance of sterility cannot be overemphasized. Carry out all manipulations in a laminar flow hood. It is probably best to sterilize the complete medium just before use by filtering it directly into the culture dishes through a syringe filter. It is typical to use 2 ml for a 35-mm dish. If cells are not to be placed in the dishes immediately, keep the dishes in the incubator until used.

Hank's balanced salt solution (HBSS)

HBSS (Sigma) containing:
350 mg/liter $NaHCO_3$
10 ml/liter antibiotic/antimycotic solution (Life Technologies)
10 mM HEPES buffer
Adjust to pH 7.3
Store up to 2 months at 4°C

COMMENTARY

Background Information

Uses of hippocampal cultures in neurotoxicology

Hippocampal neuron cultures are favored in vitro preparations in neurobiology for studies of such diverse phenomena as neuronal differentiation, formation and functioning of synapses, electrophysiology of voltage-sensitive and ligand-gated ion channels, and calcium homeostasis. In culture, hippocampal neurons develop axonal and dendritic trees with considerable biochemical and morphological similarity to the in vivo condition. These cultures readily lend themselves to highly quantitative analyses of neurite development, including growth cone movement, differentiation of neurites into axons or dendrites, cytoskeletal involvement in neurite development, and axonal and dendritic elongation and branching. Hippocampal cultures contain a large complement of voltage-sensitive ion channels (including several types of sodium, calcium, and potassium channels) and a variety of ionotropic and metabotropic receptors (including receptors responsive to glutamate, γ-aminobutyric acid [GABA], and acetylcholine). Finally, the roles of transmembrane Ca^{2+} fluxes, Ca^{2+} release from intracellular stores, and free Ca^{2+} ion concentrations in neurite development, gene expression, synaptic plasticity, and excitotoxicity have been extensively studied in hippocampal cultures.

Hippocampal cultures have found considerable use in neurotoxicology, although probably not as much as some other systems, particularly PC12 cells. The following examples illustrate the variety of effects of toxicants that have been studied in cultured hippocampal neurons. Several toxicants, including lindane, inorganic

lead, aluminum, and ethanol, perturb specific aspects of neurite development. Inorganic lead reduces current flow through voltage-sensitive calcium and potassium channels, the *N*-methyl-D-aspartate (NMDA) subtype of ionotropic glutamate receptors, and some types of nicotinic acetylcholine receptors. Lead also increases spontaneous transmitter release. Ethanol alters current flow through NMDA and $GABA_A$ receptors. Aluminum, inorganic lead, and ethanol all cause oxidative stress. Lead and ethanol alter Ca^{2+} homeostasis. For a more extensive discussion of the uses of neuronal cultures in neurotoxicology, with some references to hippocampal cultures, see Audesirk (1997).

Alternative culture conditions

There is a bewildering array of basic media used to culture hippocampal neurons and other cell types. Many of these media, with suitable additives, enable hippocampal neurons to attach, grow extensive networks of morphologically and biochemically identifiable axons and dendrites, make effective synaptic contacts, express many intracellular molecules (e.g., cytoskeletal proteins, protein kinases, gene transcription factors), and live for many days. Probably the three most common media for hippocampal culture are the traditional Eagle's minimum essential medium (EMEM), Dulbecco's modification of MEM (DMEM), and Neurobasal. EMEM and DMEM are available from many vendors and are manufactured with many modifications, including formulations with HEPES buffer and additions or deletions of various nutrients. For radioactive labeling experiments, the ready availability of leucine- and methionine-deficient EMEM may make this the medium of choice. The investigator should consult reference texts on cell culturing for details on each of these media. In essence, however, EMEM, as its name implies, is a minimal medium, with fairly low concentrations of many nutrients and lacking several potential nutrients, including several amino acids. DMEM is much richer, with higher concentrations of many nutrients (often double) and with several additional nutrients. Neurobasal is available only from Life Technologies. It is similar to DMEM with reduced sodium chloride, rendering it quite hypoosmotic to most mammalian extracellular fluids. All of these are suitable for hippocampal cultures. Most investigators add pyruvate and glutamine (or the proprietary Glutamax from Life Technologies), which can be important energy sources for cultured cells.

Neurons need growth factors (e.g., hormones, attachment factors) for survival and development. Traditionally, these have been provided in unknown types and amounts by adding serum, usually fetal bovine serum, to the basic culture medium. More recently, several defined medium supplements have been developed. The most prevalent of these for hippocampal culture is the B27 mixture of Brewer et al. (1993), commercially available from Life Technologies. Most investigators who use B27 still plate the neurons in serum-containing medium, but then change medium after several hours or a day to B27. Brewer and Life Technologies recommend B27 in Neurobasal, but B27 in EMEM or DMEM works equally well in the authors' hands.

There are several advantages of serum-free media for neurotoxicology. First, the ingredients are defined. Although "defined" should not be confused with "physiological," at least the investigator knows what is in the medium. Second, the reduced protein levels more closely resemble the low protein content of cerebrospinal fluid and presumably brain extracellular fluid. For toxicants that may bind to proteins, this may be important. Third, potential excitotoxic effects of changing serum-containing medium are reduced or eliminated, because neither the basic medium nor the supplements usually contain glutamate. Fourth, some serum-free supplements, such as B27, do not support astrocyte proliferation very well and thus help to keep neuronal cultures relatively pure even in the absence of cytosine arabinoside.

Finally, researchers should carefully investigate the ingredients in any culture medium or supplement to ensure that they do not mimic or antagonize the actions of the toxicant under study. For example, most media contain the pH indicator phenol red. Some lots of phenol red contain a by-product introduced during manufacturing that mimics some of the actions of estrogen. Therefore, these would be unsuitable for studies of any substance thought to have estrogenic or antiestrogenic effects. Even in studies that are not directly concerned with estrogenic effects, lot-to-lot variability in estrogenicity may introduce variability in neuronal survival and development. B27 contains triiodothyronine, and would be unsuitable for studies with toxicants that may mimic or antagonize thyroid hormone effects. B27 also contains antioxidants such as superoxide dismutase, vitamin E, and glutathione. Therefore, a recent change of medium containing B27 would protect neurons against oxidative stress and prob-

ably also against glutamate excitotoxicity, as reactive oxygen species apparently contribute to excitotoxic cell death.

Critical Parameters and Troubleshooting

Even the most experienced cell culture laboratory has occasional times when cultures fail, because there are so many steps that are critical to producing healthy, contamination-free cultures (see Goslin and Banker, 1991).

Contamination

Laminar flow hoods are essential to cell culturing. Horizontal laminar flow hoods (in which the filtered air blows toward the person using the hood) typically produce the most sterile conditions toward the back of the hood and lose sterility near the front. A useful monitoring procedure is to place a series of culture dishes with complete medium at various locations in the hood, remove the lids for a few minutes, replace the lids and then incubate the dishes for a few days. The hood can then be marked at the location where the dishes begin to show contamination, and all work can be performed behind this line. Vertical laminar flow hoods (in which filtered air blows down from the top and flows out slots at the lower back and front of the hood) are less susceptible to contamination and protect the user from airborne particles. This is especially important when working with pathogens or highly toxic compounds. However, the slot at the front of the hood draws air both from the inside of the hood and from the room. It is therefore probably the most contaminated location in the laboratory. Users must consciously train themselves to work deep in the hood, away from the front slot. Conversations with hood users should be prohibited. Because hoods are typically noisy, users will automatically lean back when spoken to in order to hear better, often pulling their hands and whatever items they are holding out into the contaminated front part of the hood.

A laminar flow hood cannot maintain sterility if the solutions, pipet tips, and other items used in the hood are already contaminated. All reusable containers, glass pipet tips, and so on must be sterilized before each use, usually by autoclaving. Disposable items such as syringes, syringe filters, and culture dishes, should be opened only in the hood. Disposable plastic pipet tips can be purchased sterile or can be autoclaved. The tip box must be opened only in the hood. Even though all solutions and apparatuses are presumably sterile before they are brought into the hood, it is routine practice in the authors' laboratory to sterilize medium through a syringe filter as it is added to the culture dishes. Finally, human skin constantly sheds large numbers of microbes and dead epidermal cells (usually contaminated with microbes). Well-fitting latex gloves minimize the possibility of contamination from the user's hands without significantly affecting dexterity.

Culture viability and development

Neurons, even in uncontaminated cultures, sometimes fail to survive (acutely or after several days in culture) or develop robust neurites. This may, of course, be caused by lack of suitable attachment factors on the culture surface, by inappropriate medium (e.g., simple medium without serum or growth factors), or by errors in preparation (e.g., forgetting to add serum). Assuming that these types of problems have not occurred, there are a few likely suspects to investigate if your cultures do not grow well.

Water. Most labs use deioinized water for cell culture. If the deionizing and organic-removal cartridges are too old (or the feedstock water is too impure), the water may no longer be of suitable quality. The water from the deionizing setup usually flows through a hose; if the hose is old, algae and bacteria may be growing in it, contaminating the water with both microbes and/or toxic organics.

Cell isolation and plating. As mentioned earlier, cell damage and death probably begin as soon as the dam is anesthesized. Therefore, speed of dissection and dissociation of cells is helpful in obtaining healthy cells. To minimize cell damage and death, keep fetuses, heads, and brains cold during dissection. In dissociating cells, do not pipet too long or too vigorously, or through a very narrow-bore pipet. As the members of the dissection team become more experienced, speed, sterility, and gentleness usually improve, as does the health of the cultures. When plating cells from a relatively high-density suspension (e.g., from cryopreserved neurons), remember that the cells metabolize and may alter the medium (for example, by acidification or depletion of oxygen) if left too long at high density at warm temperatures. Finally, there is some evidence that free polylysine may be toxic to neurons, so the dishes must be adequately rinsed after coating and before use.

Culture maintenance. Be sure that the medium and supplements are maintained properly

before use. Check with the manufacturer about shelf-lives, especially in solution, and optimal storage conditions (e.g., 4° versus −20° versus −70°C). Find out if any of the medium components in use are light sensitive, and treat them accordingly. Feed the cells as seldom, and with as small a volume, as is consistent with maintaining the health of the culture. This reduces the chance of contamination and excitotoxic cell death. It is also likely that the cells "condition" the medium as they grow, and soluble conditioning factors will be removed during feeding. This is probably particularly important if astrocytes are part of the culture, as conditioned medium from astrocytes is well known to facilitate the growth of neurons. There is no golden rule about feeding, but one fourth of the culture volume exchanged twice a week is probably a good starting point.

Anticipated Results

Number of cultures

The density of neurons and therefore the number of cultures that will be obtained from a single litter depend on the purpose of the experiment. For detailed morphological examination of neurite development, neurons are generally plated quite sparsely, between 10,000 and 200,000 cells per 35-mm culture dish or equivalent surface area of coverslips or wells. For studies of intracellular signaling or gene expression, in which mRNA or proteins may be extracted from the cultures or relatively low-efficiency gene transfection may be used, 500,000 or even 1 million neurons per culture may be necessary, depending, for example, on the abundance of the mRNA or protein of interest and the sensitivity of the assay employed. Assuming 500,000 to 1 million neurons per hippocampus and 6 to 15 fetuses per litter, the number of cultures that can be plated from one litter will therefore vary from fewer than twenty to several hundred.

Culture development

Examine the cells with an inverted phase-contrast or differential interference contrast microscope, using a green filter between the light source and the cells. Although the time required for cells to settle depends on the concentration of serum and other proteins in the culture medium, healthy hippocampal neurons, either freshly dissociated or cryopreserved, should attach firmly to the bottom of the culture dish within a couple of hours of plating. Within 4 hr or so, at least some of the neurons should already extend short processes (Fig. 12.3.2A). By 24 hr, probably all of the neurons that will ever grow neurites will have done so. There may already be some differentiation of axons and dendrites, at least in length. The rate of differentiation into axons and dendrites, and the markers of differentiation that are present (e.g., long versus short length, tau versus MAP2 microtubule-associated proteins; see Goslin and Banker, 1991) varies with the culture conditions. Usually, by 2 or 3 days, most neurons display a characteristic morphology consisting of a single process (the presumed axon) that is several times longer than any of the other processes (the presumed dendrites; see Fig. 12.3.2C). By this stage, biochemical markers of axons and dendrites (e.g., tau versus MAP2) should be more abundant in the appropriate neurites. There may also be a few astrocytes in the culture (Fig. 12.3.2B).

In simple culture conditions, such as EMEM with fetal bovine serum and no astrocytes, many neurons will continue to survive and elaborate neurites for at least a few days, although by 4 or 5 days some death is usually evident. In more complete culture conditions, such as medium with B27, many neurons will thrive for ≥2 weeks, although some cell death will gradually occur. The most robust neurite growth and longest survival occur when densely plated neurons are cocultured with astrocytes (Goslin and Banker, 1991) in complex medium, particularly B27-containing medium (Brewer et al., 1993). Under these conditions, a large percentage of neurons remain vigorous for several weeks, and can be used for a variety of purposes, including studies of excitotoxicity, synaptic transmission, ion channel function, and gene expression. How closely the responses of neurons in such "mature" cultures resemble those of neurons of similar age in vivo remains largely unknown.

Time Considerations

With experience, dissociation of neurons from a single litter of fetuses takes ~2 hr from sacrifice of the dam to placement of the dissociated neurons into culture dishes or cryopreservation vials. With an efficient team of three people, tasks can overlap in time, so that neurons from as many as six litters can be obtained in 4 to 6 hr. Of course, once begun, the entire dissociation and plating or cryopreservation protocol must be completed without interruption.

Plating neurons from dissociated neuronal suspensions takes only a few minutes, once the

culture dishes have been prepared and filled with medium. Plating from cryopreserved stocks requires only 1 or 2 min longer, for rapid thawing of the cell suspension.

Isolation of Neonatal Rat Cortical Astrocytes for Primary Cultures

The central nervous system (CNS) is comprised of two major cell types, the electrically excitable neurons, and the nonelectrically excitable glia. The glial cells, also known as neuroglia, can be further divided into the macroglia, consisting of astrocytes and oligodendrocytes, and the microglia. Although the term glia is sometimes used to describe a specific cell type, most often astrocytes, its proper use is to describe the entire class of nonneuronal cells. The functions of these cells are distinct. Oligodendrocytes are the myelin-producing cells in the CNS, analogous to Schwann cells in the peripheral nervous system (PNS). Microglia are similar to macrophages; they remain silent until activated, when they remove cellular debris. Astrocytes serve multiple functions within the CNS including production of growth factors, maintenance of the extracellular environment, and modulation of synaptic transmission.

Over the past two decades there has been increased focus on the role of astrocytes, not only in the normal physiology of the central nervous system, but also on their potential role as mediators of neurotoxicity (Fedoroff and Verndakis, 1986; Kimelberg and Norenberg, 1989; Murphy, 1992; Kettenmann and Ransom, 1995; Aschner and Kimelberg, 1997). It is now apparent that astrocytes are much more than just connective or structural tissue filling the space between neurons as originally envisioned—they are intimately and actively involved in maintaining the proper functioning of the CNS. Indeed, astrocytes are integral in the removal of neurotransmitters such as glutamate, and they also contain a large complement of receptors, enabling them to respond to and modulate neuronal function. These revelations have come about, in large part, due to the ability to produce high-purity primary cultures of rodent astrocytes. These cultures have led to great advances in the understanding of these often underappreciated cells (Kimelberg, 1983; Aschner and Vitarella, 1995).

The culture technique described here (see Basic Protocol) is based largely on the method first published by Frangakis and Kimelberg (1984), and has undergone minor refinement in this laboratory. The authors have recently found this technique to also work well with cells from transgenic knockout mice (Yao et al., 2000). Given the ever-increasing importance of transgenic mice to the field of toxicology, the ability to produce high-yield astrocytic cultures from these animals will allow further elucidation of the role of astrocytes in the mechanisms of neurotoxic substances. In addition, the authors have successfully obtained viable cortical astrocytes from neonatal rat brains stored at 4°C for up to 24 hr (Aschner et al., 1997).

NOTE: All steps including cell isolation and, when possible, preparation of solutions should be performed in a laminar flow hood.

NOTE: The authors recommend the use of cell culture-tested water in all steps and for preparation of all solutions. This can be obtained from Life Technologies.

NOTE: All solutions and equipment coming into contact with living cells must be sterile, and aseptic technique should be used accordingly. All nondisposable materials should be reserved for cell culture use only and cleaned thoroughly immediately after use.

NOTE: All culture incubations should be performed in a humidified 37°C, 95% air/5% CO_2, 95% relative humidity incubator unless otherwise specified.

NOTE: All protocols using live animals must first be reviewed and approved by an Institutional Animal Care and Use Committee (IACUC) or must conform to governmental regulations regarding the care and use of laboratory animals.

BASIC PROTOCOL

ISOLATION AND CULTURE OF NEONATAL RAT ASTROGLIA

The astrocyte isolation method described involves enzymatic dissociation of tissue with a bacterial neutral protease (dispase). Astrocytes are recovered by repeated removal of dissociated cells from nondissociated sedimenting tissue. This method is less traumatic than techniques based on mechanical isolation, and therefore produces a greater cellular yield. Dissociation by trypsin is more rapid and produces a cellular yield similar to dispase, but dispase digestion results in higher astrocyte viability. From one litter of 1-day-old rat pups (eight to twelve pups), the authors routinely obtain a sufficient number of cells (10^8) for approximately one hundred 100-mm culture dishes. These cells reach confluency in ~3 weeks and are >95% positive for glial fibrillary acid protein (GFAP), a cytoskeletal intermediate protein localized within the CNS only in astrocytes (Eng et al., 1971). The remaining cell types within the cultures are largely oligodendrocytes, neurons, microglia, and O-2A progenitor cells. Just as astrocytes can be identified by immunoreactivity for GFAP, the other cells types can be characterized with specific antibodies (see Critical Parameters and Troubleshooting).

See Table 12.4.1 for a suggested preparation schedule for astrocyte isolation.

Materials

1-day-old Sprague-Dawley rat pups from pathogen-free time-dated pregnant dams, timed to arrive at animal facility ~1 week prior to delivery date (rat gestation is 21 days)
Halothane or other approved anesthetic
70% (v/v) ethanol
Complete S-MEM (see recipe)
Dissociation medium (see recipe), prewarmed to 37°C
Astrocyte growth medium (see recipe)
8000 U/ml DNase I solution (see recipe)
0.08% (w/v) trypan blue staining solution: 1:4 (v/v) 0.4% trypan blue (Life Technologies) in PBS (*APPENDIX 2A*)

Table 12.4.1 Timetable for Preparation of Solutions and Instruments

Time	Preparation procedure
1 or 2 days prior to isolation	Fire polish and Sigmacote Pasteur pipets
	Prepare gelatin solution for coverslips
	Prepare borate buffer, stock DNase I, and poly-L-lysine solutions
	Autoclave glass pipets, surgical instruments, 50-ml beakers with stir-bars, coverslips, and gelatin solution
1 day prior to isolation	Check for birth of pups and determine number of pups
	Treat coverslips with gelatin and poly-L-lysine; store in refrigerator overnight
Day of isolation	Check number of 1-day-old pups (i.e., to determine number of extractions)
	Prepare complete S-MEM and place 25 ml plus 10 ml/extraction on ice in 50-ml conical centrifuge tubes
	Prepare dissociation medium and place in the incubator to warm for 1 hr
	Retrieve rat pups from mother and bring to laboratory
	Proceed with dissection and dissociation

Dissecting tools, sterile:
Mayo scissors, 7-in. (17.8-mm) length, 50-mm curved blade
Fine-angled microdissecting scissors, 4-inch length, 25-mm blade
Curved forceps, 4-inch length, full curve, 0.8-mm tip width
Curved forceps, 4-inch length, full curve, 0.4-mm tip width
Dumont forceps, pattern no. 5, 110-mm length, 0.1 × 0.06–mm tip
Sterile gauze pads
Dissecting microscope or 4× to 8× lighted magnifying lamp
50-ml conical polypropylene tubes, sterile
9-in. Pasteur pipets:
Cotton plugged and sterile
Cotton plugged, fire polished, Sigmacote treated, sterile (see Support Protocol 1)
50-ml beaker and 25-mm stir bar, sterile (cover with foil prior to autoclaving)
10-ml glass serological pipets, cotton plugged and Sigmacote treated (see Support Protocol 1)
Laminar flow hood
15-ml conical polystyrene centrifuge tubes, sterile
Low-speed centrifuge with swinging bucket rotor and adapters for 50-ml conical tubes
Inverted phase-contrast microscope
Tissue culture plates of desired size for culturing astrocytes
Coated 18 × 18–mm coverslips (optional; see Support Protocol 2, up to step 6)
Vacuum source

Additional reagents and equipment for counting cells with a hemacytometer (*APPENDIX 3B*)

Dissect out fetal brain

1. Anesthetize 1-day-old Sprague-Dawley pups with halothane or other approved anesthetic.

   To anesthetize pups, place a small ball of cotton in a 50-ml tube and add a few drops of halothane. Place the pup's head into the tube until it is anesthetized. Be sure to cap the tube between uses and replenish the halothane as necessary.

   The number of pups from Sprague-Dawley rats usually varies between 8 and 15. The optimum number of pups to process at one time is 10 to 12. Use of more pups does not appreciably increase cell yield. The arrival of pregnant rats prior to delivery allows acclimatization of the animals and helps prevent delayed parturition due to transport stress. The use of time-dated rats allows scheduling of cultures on a consistent day. The authors typically prepare cultures every other Thursday from ~1-day-old pups, and therefore purchase rats that will deliver pups on Wednesday.

   Neonatal rats can very quickly become hypothermic. Placing the pups in a nest of cotton in a small open box helps the pups to stay warm when they are being transported from their cage to the laboratory. They should be kept covered as much as possible to help them maintain their body temperature.

2. Gently hold pup with thumb and forefinger around thorax and rinse head and neck of pup with 70% ethanol.

3. Using 7-in. curved Mayo scissors, decapitate a pup and place the head on a sterile gauze pad. Place body in a plastic bag for disposal.

   Scissors and forceps should be placed either on a sterile gauze pad or in a beaker of 70% ethanol between decapitations.

4. Secure the head by holding down the snout. With fine-angled microdissecting scissors, cut the skin along the midline from base of the skull to the eyes. Use 0.8-mm forceps to separate the skin and expose the skull as necessary.

5. Use a similar technique to expose the brain by cutting along the midline of the skull with the microdissecting scissors. If desired, cut away the skull flaps to ease removal of the brain.

   Placing the scissors at a slight upward angle helps prevent inadvertent damage to the underlying brain tissue.

6. With 0.8-mm-tip curved forceps, sever the olfactory bulbs at the anterior end of the brain and the spinal cord at the posterior end. Sever the cerebellum.

Isolate cortices

7. Gently slip the two sides of 0.4-mm-tip curved forceps under the cortices on either side of the brain so that the forceps are straddling the brain.

8. Gently move forceps from side to side and, with a slight back angle, pull up the cortices.

   This will separate the cortices from the rest of the brain, which remains in the head, but care should be taken not to separate the cortices from each other.

Dissect cortices

9. Place the cortices on a sterile gauze pad under a dissecting microscope with the dorsal side up and the anterior (rostral) side facing away.

10. Unfold the cortices and remove any extraneous tissue.

11. With Dumont forceps, gently tease away the meningial coverings on the cortical surface.

    Take care not to destroy the tissue by pressing the cortices into the gauze pad.

12. Turn the gauze 180° from its original orientation and gently place curved forceps under the cortices. Flip the cortices up and slightly back to expose the underside of the tissue.

    This can sometimes be difficult due to adherence of the tissue to the gauze pad. The tissue can be dislodged by gently running the forceps under the cortices.

13. Gently remove the darker hippocampal crescents with the curved 0.4-mm forceps.

14. Remove any remaining meninges with Dumont forceps.

    The total time spent removing meninges should be ~10 min per brain.

15. Place cortices in a sterile 50-ml conical polypropylene tube containing 10 ml complete S-MEM on ice.

16. Repeat steps 1 to 15 with remaining pups, placing all cortices in a single 50-ml tube on ice.

    Generally, processing more than 12 pups does not substantially increase the final number of cells obtained.

Dissociate cells

17. Carefully remove as much S-MEM as possible with a sterile, cotton-plugged, 9-in. Pasteur pipet, taking care to retain all of the cortices.

18. Add 12 ml prewarmed (37°C) dissociation medium to a 50-ml beaker with stirbar and carefully pour cortices into the beaker. Gently triturate the cortices seven to eight times using a Sigmacote-treated 10-ml glass serological pipet.

19. Stir 10 min at low speed (60 rpm) on a stir plate in a laminar flow hood.

20. While this is stirring, prepare two 15-ml conical polystyrene centrifuge tubes for each extraction to be performed. Add 5 ml room temperature astrocyte growth medium to each tube. Also thaw DNase I solution and place it on ice.

    The number of extractions is usually equal to the number of dissected brains.

21. After 10 min of gentle stirring, remove the beaker from the stir plate and place at a 45° angle for 2 to 3 min to allow the nondissociated tissue to collect at the bottom of the beaker.

    Resting the edge of the beaker on a lid from a culture dish works well.

22. Carefully aspirate 10 ml dissociated cells with a Sigmacote-treated 10-ml glass serological pipet.

    Take care not to remove the undissociated tissue pieces.

23. Place 5 ml suspension into each of the first two 15-ml centrifuge tubes containing astrocyte growth medium. Invert the mixture two to three times to mix and then allow tubes to sit undisturbed during the continuing extractions.

    The serum in the growth medium acts to inhibit dispase and prevents overdigestion of the dissociated cells.

    During this time, undissociated tissue will settle to the bottom of the 15-ml tube. This undissociated tissue will be placed back into the 50-ml beaker for further dissociation during the final two extractions.

24. Add another 10 ml prewarmed dissociation medium to the 50-ml beaker and add 100 µl of 8000 U/ml DNase I solution. Continue to stir for another 10 min.

    The removal of dissociated cells and replacement with 10 ml dissociation medium is called an extraction.

    DNase I is added after the first extraction to prevent the genomic DNA released by damaged cells from making the dissociation medium too viscous during the on-going digestion. Note that it is added only after the first extraction and is not added again.

    DNase I from pancreas is vulnerable to inactivation by physical damage. Mix all DNase I solutions carefully and do not vortex.

25. Place the 50-ml beaker at an angle for 2 to 3 min, remove 10 ml dissociated cells, and place 5-ml aliquots into a second pair of 15-ml tubes containing astrocyte growth medium.

26. Repeat extractions until there is only fibrous tissue remaining in the 50-ml beaker.

27. To remove undissociated tissue from the 15-ml tubes, insert a sterile, fire-polished, cotton-plugged, Sigmacote-treated 9-in. Pasteur pipet to the bottom of the tube and carefully aspirate the undissociated tissue. Place this tissue back into the 50-ml beaker and perform two final extractions.

    This is done only during the final two extractions because serum carried over from the completed extractions can inactivate the dispase.

Table 12.4.2 Approximate Surface Area, Plating Density, and Growth Medium Volume for Plates Used in the Production of Primary Astrocyte Cultures

Plate type	Surface area (cm^2)	Seeding density[a]	Growth medium (ml)
35-mm	9.40	1×10^5	2
60-mm	28.27	3×10^5	3
100-mm	78.54	7.5×10^5	7
150-mm	176.71	1.8×10^6	15
96-well	0.32	3.2×10^3	0.1
24-well	1.88	2×10^4	0.5
12-well	3.83	4×10^4	1
6-well	9.40	1×10^5	2

[a]Given as cells per plate or well.

Pellet cells

28. Pool dissociated cells and medium from the 15-ml centrifuge tubes into 50-ml conical tubes (one 50-ml tube for each five 15-ml tubes). Centrifuge 10 min at 400 to 1000 × *g*, 4°C, in a swinging bucket rotor to pellet the suspended cells.

    Centrifugation at room temperature is acceptable if necessary.

    If astrocytes are to be seeded on coverslips, the coverslips should have been incubating overnight in poly-L-lysine up until this point (see Support Protocol 2). This is a good time to finish their preparation.

29. Carefully aspirate medium from the cell pellets.

30. Resuspend in ~20 ml astrocyte growth medium per 50-ml tube by gentle pipetting with a Sigmacote-treated 10-ml glass serological pipet.

31. Allow cells to sit for an additional 5 min and remove any sedimented tissue as above (step 27). Discard this undissociated tissue.

32. Pool the suspended cells into 50-ml tubes on ice.

Assess cell number and viability

33. Gently mix 100 µl cell suspension with 100 µl of 0.08% trypan blue staining solution. Allow the cells to take up the trypan blue for 2 to 5 min.

    Trypan blue is used determine cell viability. Intact cells are able to exclude trypan blue while dead or damaged cells retain the dye.

34. Determine total cell number and cell viability with a hemacytometer and an inverted phase-contrast microscope (see *APPENDIX 3B*).

Plate and grow cells

35. Dilute cell suspension to 10,000 viable cells/ml with astrocyte growth medium.

36. Pipet 10,000 to 20,000 viable cells/cm^2 into tissue culture dishes and then add astrocyte growth medium to the final volume given in Table 12.4.2. To plate cells on coverslips, place a coated 18 × 18–mm coverslip in a 35-mm tissue culture dish (or 6-well plates) before adding cells and medium.

37. Incubate cells in a 37°C, 95% air/5% CO_2, 95% relative humidity incubator.

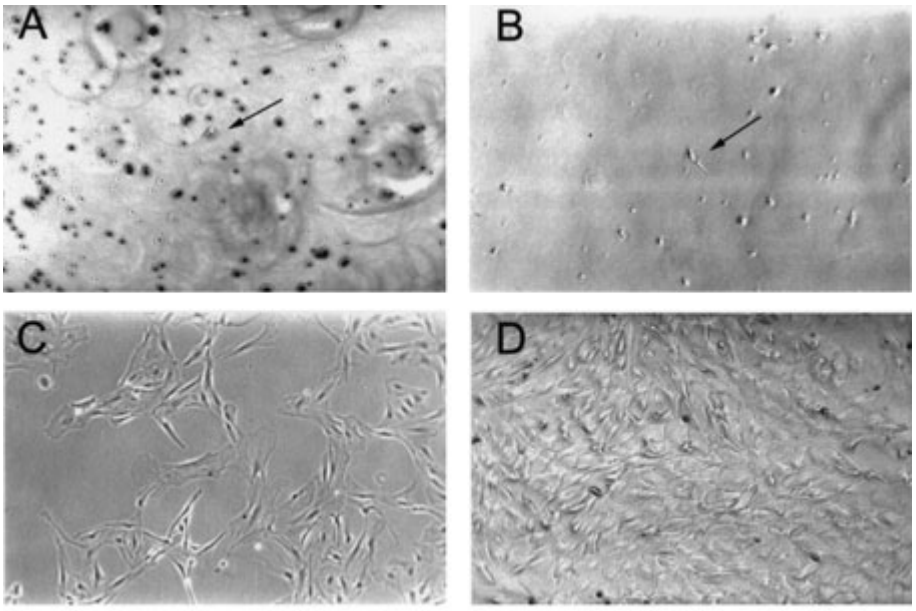

Figure 12.4.1 Primary cultures of neonatal rat astrocytes at various stages of growth (bright-field photomicrographs, 100× magnification). (**A**) 24 hr postisolation but prior to initial medium change. Note the large amount of floating debris. The arrow shows a single attached astrocyte. (**B**) 24 hr postisolation following medium change. Note only a single astrocyte (shown by the arrow) has attached to the cell culture plate in this microscopic field. (**C**) 1 week postisolation. (**D**) At 3 weeks postisolation, the astrocytes are fully confluent.

38. At 18 to 24 hr after plating, remove old growth medium with a sterile 5-in. Pasteur pipet attached to a vacuum source, and add fresh medium to the volumes as listed in Table 12.4.2 using a large disposable pipet.

    This is vital in minimizing neuronal, microglial, and oligodendrocyte contamination of cultures.

    Duplicate 2-liter heavy-walled vacuum flasks arranged in series with a hydrophobic filter (Gelman Vacushield or equivalent) between the last flask and the vacuum source should be used to prevent accidental contamination of vacuum lines. If no vacuum source is available, a peristaltic pump may be used.

    When changing medium, do not completely remove the lid of the culture plates. Instead, use one hand to hold the plate at a slight angle toward you and raise the lid ~45°. Change the Pasteur pipet frequently and any time it may have touched anything other than the inside of the culture dishes. A pipet contaminated during medium changes can easily infect the entire culture if it is not changed.

    It is not necessary to replace the medium immediately; cells may sit for a few minutes, allowing one to remove and replace medium in batches of ~20 plates. This is much more convenient than removing and then immediately replacing medium on each plate individually.

    When adding fresh medium, pipets should only be placed in the bottle of growth medium once, to prevent possible contamination from the culture plates.

39. Change medium twice per week (e.g., on Tuesday and Friday).

    Approximately 2% to 3% of the astrocytes should attach and reach confluence between 2.5 and 3.5 weeks after plating. Astrocytes at different stages of growth are represented in Figure 12.4.1. If cells do not reach confluence or begin detaching from the culture plates, the cells should be discarded and the possibility of contamination should be considered.

SUPPORT PROTOCOL 1

FIRE POLISHING AND SIGMACOTE TREATMENT OF PIPETS FOR CELL ISOLATION

Sigmacote is a prediluted silane-based coating for glass surfaces. It bonds with the uneven surface of glass pipets and provides a smooth hydrophobic barrier. The adherence of cells to the glass surface is greatly reduced, and this minimizes physical damage to the cells. Only pipets used for cell isolation, not routine changing of medium, need to be fire polished and Sigmacote treated. This is most conveniently done in batches of 30 to 50 pipets.

Materials

Sigmacote (Sigma)
9-in. Pasteur pipets
Cotton-tipped swabs
10-ml glass serological pipets, cotton-plugged

1. Fire polish the tip of a 9-in. Pasteur pipet by placing the small end in an open flame from a Bunsen burner for a few seconds. Take care not to make the diameter of the opening too small.

   This will slightly melt the borosilicate glass and will produce a smooth tip to the pipet, which helps prevent damage to the cells. However, if the opening becomes too small, increased shear forces during trituration may lead to increased cell damage.

2. Plug the large end of the Pasteur pipet with cotton removed from a cotton-tipped swab. Use the stick from the swab to push the cotton down to the notch in the neck of the pipet.

   The amount of cotton obtained from a single swab is sufficient for one pipet. With a slight pulling and twisting motion, the cotton is easily removed from the swab.

3. Treat fire-polished Pasteur pipets and 10-ml glass, cotton-plugged serological pipets with Sigmacote by drawing the viscous solution up into the pipet with a portable power pipetter. Do not allow the solution to touch the cotton plug.

   It is not necessary to fire polish or plug the glass serological pipets.

4. Allow the Sigmacote to drain back into the bottle, and allow the pipets to drain and dry completely in a beaker lined with paper towels.

5. Place coated pipets in a metal container and autoclave.

SUPPORT PROTOCOL 2

COATING COVERSLIPS FOR ASTROCYTE CULTURE

As a general rule, cultured cells do not adhere well to glass, and thus cell growth on glass coverslips can be difficult. However, many microscopic, histological, or other procedures are necessarily performed on glass, and therefore a procedure for promoting attachment of astrocytes by coating coverslips with gelatin followed by poly-L-lysine is given below.

Materials

2.5% (w/v) gelatin solution (see recipe)
1× poly-L-lysine solution (see recipe)
70% ethanol
H_2O, sterile

18 × 18–mm (no. 2) glass coverslips
Laminar flow hood with ultraviolet light
Sterile forceps
6-well tissue culture plates

1. Rinse 18 × 18–mm (no. 2) coverslips with 70% ethanol and place in an autoclavable container in multiple layers between Kimwipe tissues. Do not crowd coverslips.

   Coverslips must not overlap during autoclaving.

2. Autoclave coverslips.
3. In a laminar flow hood, use sterile forceps to remove coverslips and place them into individual wells of a 6-well tissue culture plate.
4. Add 1.5 ml sterile, room-temperature 2.5% gelatin solution to the surface of each coverslip. Allow gelatin to coat the coverslips for 30 min at room temperature.
5. Aspirate gelatin solution and add 1.5 ml of 1× poly-L-lysine solution to the surface of each coverslip.
6. Incubate plates containing coverslips at 4°C overnight to allow adherence between poly-L-lysine and the gelatin coating.
7. After isolation of cells the following day and ~1 hr before seeding cells, aspirate poly-L-lysine and wash three times with 1.5 ml sterile water.
8. After removing all water, place dishes with coverslips under the ultraviolet light of the laminar flow hood for 30 min to dry the coverslip and to crosslink the poly-L-lysine and gelatin.

   Coverslips are ready for immediate use for culturing astrocytes.

REAGENTS AND SOLUTIONS

Use Milli-Q-purified water or equivalent in all recipes and protocol steps. For common stock solutions, see ***APPENDIX 2A****; for suppliers, see* ***SUPPLIERS APPENDIX****.*

Astrocyte growth medium

900 ml minimal essential medium with Earle's salts (MEM; Life Technologies)
10 ml penicillin/streptomycin (Life Technologies; 100 U/ml penicillin, 100 µg/-liter streptomycin final)
100 ml heat-inactivated horse serum (see recipe; 10% v/v final)
1 ml Fungizone (optional)
Sterilize with a 1-liter sterile filter flask (0.2-µm pore size, cellulose acetate)
Store up to 1 month at 4°C

Penicillin/streptomycin from Life Technologies contains 10,000 U/ml penicillin G and 10,000 µg/ml streptomycin sulfate. Storing penicillin/streptomycin in 10-ml aliquots at −20°C is suggested to avoid repeated freeze-thaw cycles and because it provides the correct amount for 1 liter of medium. (See manufacturer's expiration date.)

Borate buffer

1.24 g boric acid
1.9 g borax
400 ml H_2O
Adjust pH to 8.4 with NaOH
Store at 4°C (stable for many months)

Complete S-MEM

500 ml minimal essential medium with Earle's salts, modified for suspension cultures (S-MEM; Life Technologies)
5 ml penicillin/streptomycin (Life Technologies; 100 U/ml penicillin, 100 µg/l streptomycin final)

continued

Store up to 2 months at 4°C

S-MEM has been modified to contain no Ca^{+2} which can produce cell clumping due to interactions of extracellular matrix proteins.

Penicillin/streptomycin from Life Technologies contains 10,000 U/ml penicillin G and 10,000 µg/ml streptomycin sulfate. Storing penicillin/streptomycin in 10-ml aliquots at −20°C is suggested to avoid repeated freeze-thaw cycles. (See the manufacturer's expiration date.) The use of Fungizone is not recommended.

Filter sterilization of S-MEM is optional.

Deoxyribonuclease I (DNase I) solution, 8000 U/ml

Dilute 15,000 U DNase I from bovine pancreas (type IV; Sigma) in 1.875 ml water. Mix gently; do not vortex. Sterilize with a 0.2-µm syringe filter (cellulose acetate). Store in 100-µl aliquots at −20°C for many months (see manufacturer's expiration date).

DNase I from pancreas is vulnerable to inactivation by physical damage and should not be vortexed.

Dissociation medium

Complete S-MEM (see recipe)
3 U/ml dispase (Life Technologies)

On the day of isolation, prepare 10 ml per brain plus an additional 25 ml (e.g., for 10 brains, add 375 U dispase to 125 ml complete S-MEM). Sterilize with a 150-ml sterile filter flask (0.2-µm pore size, cellulose acetate). Prewarm in a 37°C incubator for 1 hr before use. Discard any unused dissociation medium.

Gelatin solution, 2.5% (w/v)

25 mg gelatin (type A from porcine skin, bloom 300)
100 ml water
Autoclave
Store up to 6 months at room temperature

Heat-inactivated horse serum

Avoid repeated freeze-thaw cycles of horse serum (Life Technologies). To thaw frozen serum, place the bottle in a refrigerator for ~24 to 48 hr. If rapid thawing is needed, place in a water bath that is no warmer than 40°C. Dispense into aliquots in 50-ml tubes and store up to 1 year at −20°C. Thaw at room temperature over a few as hours as necessary.

Thawed serum can be stored for up to 1 week at 4°C, but freezing of aliquots is recommended.

Purchase of horse serum that has been heat inactivated by the vendor is highly recommended.

Poly-L-lysine solution, 1× and 10×

10× stock solution: Dissolve 25 mg poly-L-lysine (Sigma) in 25 ml borate buffer (see recipe). Store up to 2 months at 4°C.

1× working solution: Dilute 5 ml of 10× stock solution into 45 ml borate buffer. Filter sterilize with a 0.2-µm cellulose acetate filter. Prepare fresh each day and keep at 4°C.

Poly-D-lysine is an acceptable substitution for poly-L-lysine and may be preferred due to decreased of digestion of the D isomer by cells (Higgins and Banker, 1998). Regardless of the isomer, the large molecular weight (>300 kDa) preparations should always be used.

COMMENTARY

Background Information

Prior to the development of simple and reliable culture techniques in the late 1970s and early 1980s, the majority of studies on astrocytes dealt mainly with their morphological and developmental properties. With the advancement of cell culture techniques, investigations into the biochemical, physiological, pharmacological, and molecular aspects of astrocyte function are now possible. These cultures provide a model to study astrocytic function under controlled and reproducible conditions.

Given the wide array of functions performed by astrocytes, the range of possible uses for primary cultures is vast. A brief list includes intracellular signaling with Ca^{2+}-sensitive fluorescent dyes (*UNIT 12.5*), electrophysiological examination of ion channels and receptor function, production and secretion of growth factors, toxicant-induced astrocyte swelling, and production of free-radicals, just to name a few. The use of cell culture systems consisting of neurons grown in wells with astrocytes grown above them on inserts allows studies on the influence on neuronal function of factors released by astrocytes.

The use of primary astrocyte cell cultures rather than tumor cell lines such as the human U373 or rat C6 gliomas has both advantages and disadvantages. Tumor cell lines are less expensive and less time consuming to prepare and maintain. In addition, there should be little culture-to-culture variation in these cells. However, since the cell lines are derived from abnormal tissue, their physiology must be carefully examined. Given that the ultimate goal of most studies is to understand the function of normal astrocytes in vivo, the role of cell lines is perhaps questionable.

Of course, one must similarly be cautious when relating processes seen in culture to the in vivo situation whether the cells are primary cultures or cell lines. Indeed, there are multiple cell types within the CNS (neurons, astrocytes, oligodendrocytes, and microglia), and the complex interactions between them are not easily modeled using cell culture without losing one of the most attractive features of cell culture, the ability to study a distinct cell population. In an attempt to address some of these issues of reciprocity between neurons and astrocytes, a technique of producing astrocyte-neuron cocultures has recently been described (Aschner and Bennett, 1998; see *UNIT 12.3*).

There are multiple techniques for the isolation of astrocytes from neonatal rodents. The most common of these methods is either mechanical dissociation (McCarthy and de Vellis, 1980) through increasingly smaller-diameter nylon sieves (Cole and de Vellis, 1992), or enzymatic dissociation using either trypsin (Eng et al., 1971) or dispase (Frangakis and Kimelberg, 1984). The selection of an isolation method depends upon a number of factors, including the number and the purity of astrocyte cultures required.

To shake or not to shake? This is a common methodological question encountered in preparing primary cultures of astrocytes. The mechanical dissociation method (McCarthy and de Vellis, 1980; Cole and de Vellis, 1992) includes vigorous shaking (200 to 250 rpm for up to 24 hr at 37°C) of 7- to 8-day-old cultures grown in 75-cm^2 flasks plated at a density of at least one brain per flask. During this shaking, the astrocytes remain attached to the culture dishes, while the other cell types (neurons, microglia, oligodendrocytes, and O-2A progenitor cells) detach from the astrocytic layer and are removed by replacing the medium. The remaining astrocytes are then collected by trypsinization, replated in new culture dishes, and again allowed to grow until confluent. This procedure produces astrocytes of slightly higher purity than the procedure described here (98% versus 95%); however, it is well accepted that passage of cells changes their biochemical and immunological phenotypes (Cole and de Vellis, 1992), and thus the authors prefer a method that does not involve any passage of astrocytes.

Regardless of the method used for production of astrocytes, an important variable to consider when performing neurotoxicological studies in cultured cells is verifying that effects are not simply due to cell death following treatment. The use of standard toxicological assay such as lactate dehydrogenase (LDH) release or neutral red uptake (*UNIT 2.6*) should be performed to differentiate alterations in function from cell death.

Critical Parameters and Troubleshooting

Several critical parameters in astrocyte culture are discussed below. Table 12.4.3 presents a number of potential problems associated with production of primary astrocyte cultures, along with possible causes and solutions.

Table 12.4.3 Problems Commonly Encountered During Cell Isolation

Problem	Possible cause	Possible remedy
Clumping of cells during extractions (not to be confused with sedimentation of tissue)	Ca^{2+} present in medium	Use only S-MEM, which is Ca^{2+}-free, to prepare dissociation medium
Medium becomes viscous during extractions	No DNase I	Add DNase I (mix DNase I solutions gently; do not vortex)
Low cell yield/viability	Cell death due to excessive trituration	Use Sigmacote-treated glass pipets; do not allow air bubbles to enter cell suspension during trituration
	Prolonged dissection time	Limit dissection to 10 min per brain
	Ca^{2+} present in medium, causing cellular aggregation	Use S-MEM during cell isolation
Floating cells in cultures after initial isolation	Contaminated cultures	See Critical Parameters and Troubleshooting
	Cultures are too old	Use cultures within 3 to 4 weeks
	Loss of poly-L-lysine on coverslips	Treat coverslips with poly-L-lysine only 1 day prior to plating cells

Tissue dissection

The rapid dissection of the brain area of interest and meticulous removal of meninges is vital for the successful isolation of primary astrocytes. If the meningial removal is incomplete, fibroblast contamination can overwhelm cultures due to the faster propagation of fibroblasts compared to astrocytes. Although removal of meninges must be complete, it is recommended that no more than 10 min per brain be spent on this task. The speed and accuracy of removing the meninges will likely improve with experience.

Dissociated cell extraction

There can be lot-to-lot variability with even the highest-quality enzymes. Thus, if a rapid and continuing decrease in cell number or viability is seen, careful attention should be paid to both the age and lot number of the dispase. In general, it is good to record lot numbers of all reagents used in preparing and maintaining the cultures. Successive disappointing cell isolations may be traced to an unsatisfactory lot of enzyme or serum.

In addition, the importance of handling the dissociated cells gently cannot be over emphasized. The use of Sigmacote-treated glass pipets greatly reduces the trauma to cells during the isolation process. It is also vital to not dissociate the tissue by forceful triturations or excessively rapid mixing on the stir plate. If air bubbles are introduced into the suspension, the trituration is too harsh and will lead to a large reduction in cell viability.

Purity of cultures

The purity of the cultures can be determined by immunohistochemistry using markers for astrocytes (GFAP) and neurons (microtuble associated protein 2, MAP-2) as described previously (Aschner and Bennett, 1998). Additionally, markers for oligodendrocytes (2′,3′-cyclic-3′-phosphohydrolase, CNP; Promega; Cammer, 1990) and microglia (OX-42; Harlan Bioproducts for Science; Castellano et al., 1991) are also available.

Astrocyte cultures obtained by dispase dissociation are routinely >95% positive for GFAP by immunohistochemistry (see Fig. 12.4.2). However, this can vary between cultures, with some producing a greater degree of neuronal, oligodendrocyte, and microglial contamination. It has been suggested that using 24- to 48-hr-old rat pups may decrease the number of contaminating neurons (McCarthy and de Vellis, 1980).

Time in culture

Important variables to consider when performing studies with primary astrocyte cultures are the effects of confluency and time in culture. Unlike tumor cells, these astrocyte cultures stop growing and dividing once confluent, due to cell-cell interactions. It is strongly recommended that the effects of confluency be deter-

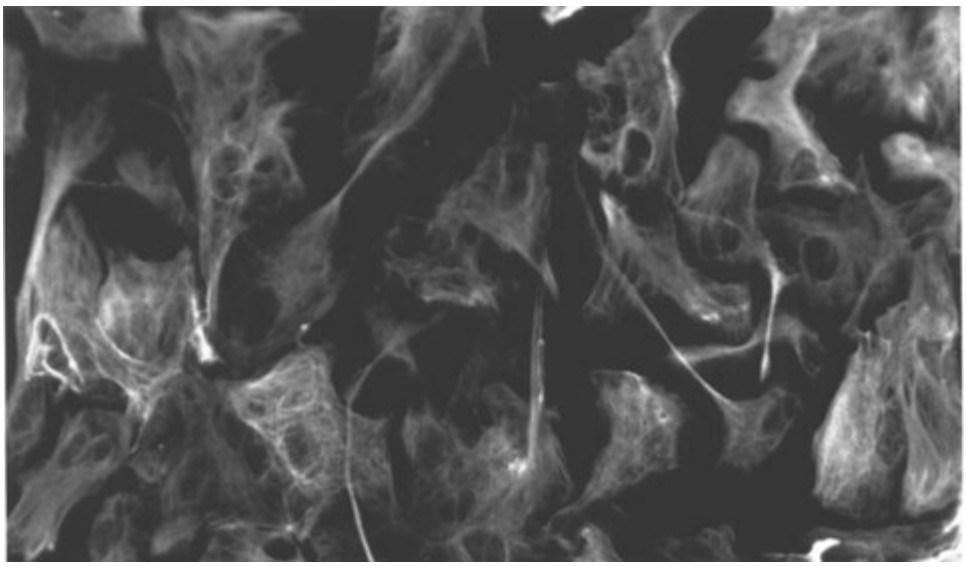

Figure 12.4.2 GFAP immunofluorescence of cultures (fluorescent photomicrograph, 400× magnification) of confluent astrocytes processed for the astrocytic marker as described previously (Aschner and Bennett, 1998). The cells are routinely >95% positive for GFAP, attesting to the purity of the cultures.

mined by treating cells at various states of confluency. In a related issue, the time in culture can have profound effects on the genotype and phenotype of the astrocytes. Thus, preliminary studies should examine temporal changes in expression of the product of interest, and subsequent studies must contain appropriate controls to account for temporal changes in expression during treatments.

Contamination

Microbial contamination of primary cell culture is probably the most common problem encountered once the initial cell isolation is successful. Contamination may be due to invasion by bacteria, yeast, fungi, molds, mycoplasma, viruses, or any combination of the above. Although isolated contamination of an individual culture plate or two is not uncommon, widespread or continual contaminations (in more than two separate isolations) requires investigation of the source of the microbes. Once contamination is suspected, the rapid and accurate identification of the offending class of microbe can aid in determining the source of contamination. If contamination of cells is suspected, the authors highly recommend that a sample be sent to a certified microbiological laboratory for identification of the class of microbe.

Any infected culture plates must be disposed of immediately. All surfaces, including microscopes, pipettors, incubators, and refrigerator door handles, should be cleaned with 70% ethanol.

Since the growth medium contains antibiotics (penicillin and streptomycin), bacterial contamination is uncommon. The addition of gentamicin sulfate may be beneficial in controlling bacterial and also mycoplasma contamination. When adding new antibiotics, begin with the lowest recommended concentrations (available in Life Technologies catalog) and perform a dose-toxicity curve in a few noninfected plates to assess effects on growth rate and cytotoxicity. In general, the highest concentration of antibiotic that doesn't adversely inhibit cell growth should be used.

In the authors' experience, the most common sources of contamination are yeast and fungi. The addition of 0.25 μg/ml Fungizone (Amphotericin B; Life Technologies) effectively halts both yeast and fungal infections. The authors do not routinely add Fungizone to the growth medium, but use it only as necessary to control sporadic infections that seem to occur mainly during spring and summer.

Cultures with yeast contamination can usually be readily identified by examination of the medium. The growth medium appears cloudy and, if phenol red is present, usually turns yellow due to acidification. The rapidly growing yeast consume the available glucose and then convert to anaerobic metabolism, which produces large quantities of lactic acid. It is this lactic acids that alters the pH (and thus the

color) of the growth medium. Microscopic examination of yeast-contaminated cultures reveals small round spores floating throughout the medium. The source of yeast is often hard to identify and thus the list of possible suspects is long. Any item to be placed in the laminar flow hood should be cleaned with 70% ethanol, but special care must be taken when laboratory water baths are used to thaw or warm reagents for cell culture.

The use of disposable plastic pipets can greatly reduce the possibility of contamination. The pipets should only be placed in the growth medium once and used to feed one stack of culture plates. This prevents transfer of contaminants from a single plate to the growth medium, which can then infect the entire culture. The Pasteur pipets used for removal of medium should similarly be changed frequently.

Fungus is often found growing directly on the astrocyte cell layers or even on the walls of culture plates. It grows rapidly to form green to yellow sponge-like circles and rapidly absorbs much of the growth medium. When a fungal infection is discovered, careful examination of the incubator is necessary, as this is often a reservoir of fungal spores. A thorough disinfection of the incubator with 70% ethanol is suggested.

Mycoplasma contamination cannot be easily detected by visual inspection of the cultures. If cultures die prior to reaching confluency or are growing slowly, mycoplasma contamination may be suspected. Once again, the authors recommend sending samples to a certified microbiological laboratory for testing of mycoplasma. Alternatively, kits designed for mycoplasma detection are commercially available (MycoTest, Life Technologies; Mycoplasma Detection Kit, Roche).

Anticipated Results

Cultured astrocytes produced by dispase digestion have a flat polygonal appearance (Fig. 12.4.1) and are >95% positive for GFAP (Fig. 12.4.2). Cell yields should be ~10^7 cells per brain, with viability ~95%. Only 2% to 3 % of seeded astrocytes actually adhere to culture plates after changing the medium at 24 hr. The development of cultures at various stages is presented in Figure 12.4.1.

A 100-mm culture plate of confluent astrocytes routinely provides a minimum of 15 µg total RNA or 150 µg cellular protein. Therefore, a single plate provides ample RNA or protein for most northern or immunoblotting procedures.

Time Considerations

The total time for the preparation of astrocyte cultures is ~6 to 8 hr depending on the number of extractions performed and the number of rat pups used for the dissections. The twice weekly change of medium (feeding) usually requires ~1 to 2 hr, but will, of course, vary with the number of plates.

Analytical Cytology: Applications to Neurotoxicology

The protocols described in this unit provide examples of analytical cytology applied to two fundamental areas in neurotoxicology: cell-cycle regulation and cell signaling. The first protocol explains the use of dual-parameter flow cytometry to determine the effects of a toxicant on cell cycling (see Basic Protocol 1). While dual-parameter flow cytometry is only one of several available methods for detecting cell proliferation (e.g., tritiated thymidine incorporation, anti-BrdU antibody detection), it provides additional quantitative information regarding the number of completed mitotic divisions and cell-cycle phase length (i.e., G1, S, G2/M), thus giving important information on potential mechanisms of agent toxicity not easily obtained by alternative methods. Support Protocol 1 describes preparation of primary astrocytes for the flow experiment. The second protocol details the steps involved in the quantification of intracellular calcium concentrations within individual cells using scanning confocal laser microscopy (SCLM; see Basic Protocol 2). Along with the protocols describing the method that uses the fluorescent calcium probe Indo-1, a protocol for the generation of a calcium calibration curve (see Support Protocol 2) and a protocol for measuring intracellular calcium using the fluorescent calcium probe Fluo-3 (see Alternate Protocol) are provided.

The rationale behind presenting the two basic protocols, one using flow cytometry, the other SCLM, is to demonstrate how these fluorescence-based methods, both of which are widely used in analytical cytology, can be applied to neurotoxicology (also see *UNIT 2.5*).

NOTE: All solutions and equipment coming into contact with living cells must be sterile, and aseptic technique should be used accordingly.

NOTE: All incubations should be performed in a humidified 37°C, 5% CO_2 incubator unless otherwise specified.

NOTE: Fluorescent dyes are photolabile, and all manipulations with these compounds or cells loaded with these compounds should be carried out in a darkened room.

CELL-CYCLE ANALYSIS OF GLIAL CELLS BY BrdU/HOECHST FLOW CYTOMETRY

BASIC PROTOCOL 1

Flow cytometry is a well-established procedure for quantitative cell cycle analysis, and application of this technique to glial cells for use in neurotoxicological studies is described in the following protocol. Basic tissue culture techniques are described in *APPENDIX 3B* and basic flow cytometry techniques are described in the manufacturer's literature. Primary rat astrocytes are prepared as in Support Protocol 1 (also see *UNIT 12.4*). Following reseeding, astrocytes are grown for 2 days, then rinsed with phosphate-buffered saline and serum deprived for 2 days to obtain quiescence. Once the monolayer of cells is quiescent, the cells are then continuously incubated with 5-bromodeoxyuridine (BrdU), in the presence or absence of mitogen(s) and/or toxicant(s). After the desired treatment period, cells are harvested and resuspended in buffer containing Hoechst 33258. Because Hoechst cannot bind to regions of DNA that have incorporated BrdU, its fluorescence will be reduced in cells that have incorporated BrdU into DNA during DNA synthesis; used in this way, Hoechst fluorescence can provide information on the number of completed cell cycles. Prior to flow cytometric analysis, the cells are further stained with ethidium bromide, providing the second fluorescence parameter with which one can distinguish cell-cycle phases (i.e., G0, G1, S, G2/M) and cell-cycle phase transition times.

Current Protocols in Toxicology (2000) 12.5.1-12.5.16

Materials

Monolayer cultures of primary rat astrocytes (see Support Protocol 1)
Complete DMEM medium/5% and 10% (v/v) FBS (see recipe)
Ca^{2+}, Mg^{2+}-free Dulbecco's phosphate-buffered saline (CMF-DPBS; *APPENDIX 2A*)
Serum-free medium (see recipe)
Agent to be tested for mitogenic potential
15 mM BrdU (see recipe)
Hoechst buffer (see recipe)
100× ethidium bromide (see recipe)
0.1% (v/v) trypsin in CMF-DPBS

24-well tissue culture plates
12 × 75–mm polystyrene tubes
Flow cytometer equipped with UV-excitation (351 to 362 nm lines of argon-ion laser, or 365 nm line of a mercury arc lamp)
MPLUS AV program (Phoenix Flow Systems) or equivalent flow cytometry software program for data analysis

Additional reagents and equipment for tissue culture and trypsinization of cells (*APPENDIX 3B*) and flow cytometry (*UNIT 2.5*)

1. Plate cells in 24-well plates at 5×10^5 cells/well and maintain them in complete DMEM medium/10% FBS for 2 days (*APPENDIX 3B*). Rinse cells with 37°C CMF-DPBS. Serum-deprive cells for 48 hr to bring them to quiescence by incubating in 1 ml serum-free medium.

   Depending upon the toxicant exposure conditions and the experimental outcome measurements desired, quiescent cells can be treated to determine the mitogenic, and therefore possible oncogenic, effects of a chemical or physical agent. Alternatively, the effect of treatment on the proliferative effects of known mitogens can be investigated to determine toxicant-induced effects on normal proliferative responses. The protocol described here is to assess the proliferative effect of a treatment.

2. Replace the medium with 1 ml of fresh serum-free medium in the absence or presence of chemicals or physical agents to be tested for their mitogenic potential.

   Each well is one treatment and each treatment should be carried out in triplicate.

3. At the end of the treatment, add 10 µl of 15 mM BrdU (150 µM final concentration) to each well. Incubate 48 hr.

   BrdU is photosensitive; do not expose to light. Wrap the plates in aluminum foil during the period of BrdU incubation, as exposure of cells that have incorporated BrdU to light will result in DNA strand breaks. Avoid exposing the samples to direct light from this point until flow cytometric analysis.

4. After incubation, remove the supernatant from each well, and harvest the cells from each well by adding 200 µl/well of 0.1% trypsin solution for 5 min. Neutralize trypsin by adding 200 µl of complete DMEM/10% FBS and pipet repeatedly up and down to obtain a single-cell suspension (*APPENDIX 3B*).

5. Transfer the cells from each well into an individual 1.5-ml tube and microcentrifuge 10 min at 1000 × *g*, 4°C. Remove the supernatant by aspiration and resuspend the cells in 500 µl Hoechst buffer.

   Single-cell suspensions should be checked under a microscope to ensure that there is no clumping, as this would clog the flow cytometer and result in spurious analyses.

   Cells resuspended in Hoechst must be analyzed within 8 hr. If cells will not be analyzed within that time frame, add DMSO to the Hoechst buffer to give 10% (v/v) DMSO (final

concentration) and store the cells in this solution at −20°C. Samples can be stored in this way up to 1 week. Thaw samples 15 min before flow cytometric analysis.

6. Transfer the samples to 12 × 75–mm polystyrene tubes. Add 5 µl of 100× ethidium bromide stock solution for a final concentration of 5 µg/ml, and thoroughly mix each sample.

   CAUTION: *Ethidium bromide is an animal carcinogen. Use extreme care while handling.*

   The samples are now ready for immediate flow cytometric analysis.

7. Carry out flow cytometric analysis by exciting both the stains at 351 to 362 nm (argon-ion laser) or 365 nm (mercury arc lamp). Collect Hoechst emission at 420 to 490 nm and ethidium bromide emission at wavelengths >610 nm. Collect data from 10,000 or more cells per sample for sufficient for data analysis.

PREPARATION OF PRIMARY RAT ASTROCYTES

SUPPORT PROTOCOL 1

Primary rat astrocytes are prepared as described in Guizzetti et al. (1996; also see *UNIT 12.4*).

Materials

Day-21 rat fetuses
Complete DMEM medium/10% FBS (see recipe)
75-cm^2 tissue culture flasks, poly-D-lysine coated

Additional reagents and equipment for tissue culture (*APPENDIX 3B*)

1. Mince and trypsinize cortices from day-21 fetuses (0.2% w/v trypsin in PBS for 10 min at 37°C) and wash 3 times by centrifugation at 225 × *g*, 4°C, with complete DMEM medium/10% FBS.

2. With a narrow-bore pipet, triturate tissue, filter, and plate in 75-cm^2 flasks previously coated with poly-D-lysine (10 µg/ml), at 1.5×10^5 cells/cm^2.

   To coat flasks with poly-D-lysine, cover the surface of the flask with sterile 10 µg/ml poly-D-lysine and incubate 10 min at 37°C. Aspirate the solution and rinse the flask with sterile, room temperature, double-distilled water. Let dry overnight.

3. Within 24 hours of plating, shake flasks, and add fresh medium.

4. Incubate flasks for 9 days and feed every 2 to 3 days. On day 9 of culture, shake flasks overnight, trypsinize, and reseed for experiments (see Basic Protocol 1).

ANALYSIS OF INTRACELLULAR CALCIUM IN INDIVIDUAL GLIAL CELLS USING INDO-1/AM

BASIC PROTOCOL 2

Outlined here is a protocol for the quantification of intracellular calcium concentration ($[Ca^{2+}]_i$) within individual, attached glial cells to determine the effect of a toxicant on both basal $[Ca^{2+}]_i$ and stimulus-induced $[Ca^{2+}]_i$ changes. This basic protocol describes the technique used to examine human 132 1N1 astrocytoma cells (provided by Dr. J. Heller-Brown, University of California at San Diego) using the ratiometric calcium probe Indo-1/AM. Kinetic analysis allows determination of the effect of acute or chronic incubation with a toxicant on stimulus-evoked responses, as well as any effects of the toxicant on basal calcium by scanning prior to the addition of the stimulus. For generation of a calcium calibration curve, see Support Protocol 2. An Alternate Protocol describing the measurement of $[Ca^{2+}]_i$ using Fluo-3/AM, a non-ratiometric calcium-sensitive dye, is also provided. In both this and the Alternate Protocol, 132 1N1 astrocytoma cells are loaded with a calcium-sensitive probe in Krebs'-bicarbonate buffer and rinsed; fluorescence is then measured using an SCLM (also see *UNIT 2.5*).

Materials

132 1N1 astrocytoma cells (available from Dr. J. Heller-Brown, University of California at San Diego)
Complete DMEM medium/5% FBS (see recipe)
Serum-free medium (see recipe)
Toxicant of interest
Krebs' bicarbonate buffer (see recipe)
Loading buffer (see recipe)
2 µM Indo-1/AM in loading buffer
Stimuli (e.g., serum, mitogens, glutamate)

2-well coverglass chamber slides (Nunc)
Inverted, scanning confocal microscope equipped with a mercury arc lamp or argon ion laser capable of an emission wavelength of 351 to 363 nm
445-nm long-pass dichroic filters (Omega Optical)
Neutral density filters (Omega Optical)
Two photomultiplier tubes or other fluorescent detectors (capable of quantifying fluorescence in the range of 400 to 410 nm and 500 to 530 nm simultaneously)
Data acquisition system for collecting and storing digital images
Spreadsheet software

Additional reagents and equipment for generation of a calcium calibration curve (see Support Protocol 2)

Prepare cells and reagents

1. Plate 2×10^4 cells/cm^2 (2 ml at 5×10^4 cells/ml) in a coverglass chamber slide in complete DMEM medium/5% FBS. Allow cells to grow in the incubator for 2 days in complete DMEM medium/5% FBS (or until desired confluency is reached), then serum-deprive the cells for 2 days by substituting serum-free medium. Treat with toxicant in the appropriate manner.

   Depending upon the toxicant exposure conditions and the experimental outcome measurements desired, cells can be treated chronically prior to assay, treated acutely before assay, treated and removed during an assay, or added following basal $[Ca^{2+}]_i$ determinations. The protocol described here assumes that cells have been pretreated with a toxicant for the time period of interest.

   Coverglass chamber slides are fragile; hold the chamber by the flanges to avoid leakage and breakage. It is advisable to keep them on a tray in the incubator in case of leakage. Different cell types may require special tissue culture conditions, such as precoating the coverglass chambers with poly-D-lysine or collagen to allow attachment.

2. Warm up and align laser/mercury lamp.

   Once one is comfortable with the technique, the microscope can be set up during the loading period to preserve laser or arc lamp life.

3. Tune the laser to excite in the range of 351 to 363 nm with at least 60 mW of illumination. Insert filters so that the fluorescence emission is split (e.g., 445-nm long-pass dichroic filter) and can be read simultaneously by one detector at 405 nm and the other detector at 530 nm.

   Use of an oil-immersion, 100× objective will allow for optimal resolution and is compatible with the coverslip thickness of a 2-well chamber slide.

4. Create a directory on the computer to save images and data.

   Multiple image files are generated which require a large amount of storage space. High-capacity magnetic storage devices (e.g., a ZIP drive or WORM drive) work well as a data-storage medium.

Load cells with Indo-1/AM

5. Rinse cells once with 2 ml Krebs' bicarbonate buffer and once with 2 ml loading buffer.

   If more than 2 wells are being assayed, the loading of each plate should be appropriately timed (i.e., for a 5-min scan, stagger loading by ≥20 min).

6. Incubate the cells for 1 hr at 37°C in 2 ml per well of the Indo-1/AM solution (2 μM final concentration).

   Indo-1 is light sensitive and steps involving the dye or loaded cells should be carried out in a darkened room.

7. Remove the Indo-1 AM solution and replace with loading buffer. Leave cells in loading buffer for 15 to 30 min at 37°C to allow further cleavage of the AM ester.

8. Remove loading buffer. Rinse once with 37°C Krebs' bicarbonate buffer, and add 1 ml Krebs' bicarbonate for fluorescence measurements.

Measure intracellular fluorescence

9. Secure the coverglass chamber slide on the microscope stage and prefocus under normal light. Conduct a preview scan with the laser to determine if the data acquisition settings are optimal, and adjust the focus to ensure that fluorescence from cells is maximally captured.

   If one is expecting to see an increase in calcium levels following treatment, adjust baseline fluorescence such that signals from the detector measuring 405 nm (emission of Indo-1 when bound to calcium) can increase without overshooting the range of fluorescence detection of the system. Similarly, the detector measuring 530 nm (emission of Indo-1 when not bound to calcium) should be adjusted to accommodate a stimulus-induced decrease in fluorescence.

   Different parameters may be desired for different experiments. The photomultiplier tube (PMT) percentages can be changed initially, but must be kept constant to compare ratio values between experiments and must be the same as those used for generating the standard curve. Use a UV-corrected objective of the desired magnification. Set the number of scans and scan delay depending upon the data desired (the delay will depend upon the scan speed and field size). The step (pixel) size determines the resolution and the number of pixels in the X and Y dimensions determines the field size. The scan strength can be adjusted between experiments and neutral-density filters can be used to keep fluorescence within quantifiable ranges.

10. Begin scanning/collecting data, scanning at least three times to determine the baseline level of $[Ca^{2+}]_i$. Add stimulus (e.g., serum, mitogens, glutamate), made up in Krebs' bicarbonate buffer, manually using a pipet. Collect as many time points as desired (determined by parameters).

    Be careful not to disrupt the focus when adding stimulus (i.e., don't touch the chamber slide with the pipet), and, to ensure adequate mixing of stimuli, add solutions of stimuli in a large volume (e.g., 1 ml into 1 ml in well) or mix well with a pipet.

    Care must be exercised so as not to photobleach the Indo-1 by scanning too frequently with excessive excitation power.

Analyze fluorescence data

11. With an initial (baseline) image displayed on the computer monitor, encompass individual cells with an "area" tool (e.g., polygon or circle), and save the area as a template to apply to subsequent images. Use the computer software to integrate fluorescence within each area over time. Generate a standard curve (see Support Protocol 2) to calculate the absolute $[Ca^{2+}]_i$ from the ratios. Save these values and export to a spreadsheet program for subsequent analyses as desired.

    Data analysis can be conducted any time after the experiment is finished.

SUPPORT PROTOCOL 2

GENERATION OF CALCIUM CALIBRATION CURVE

A calcium calibration curve can be generated in order to determine the absolute (nM) concentration of $[Ca^{2+}]_i$ that corresponds to a given ratio of Indo-1 dye fluorescence in the bound and unbound states.

Additional Materials *(also see Basic Protocol 2)*

Calcium Calibration Buffer Kit 1 (Molecular Probes)
Ethanol
Indo-1 free acid

1. Set up the SCL microscope and data acquisition system (Basic Protocol 2, steps 2 to 4).

   It is important that the PMT settings for the two detectors be the same as those used in the experiment. Changes in these will alter the ratio for a given concentration of calcium. The excitation intensity may differ (by use of neutral density filters and adjusting the scan strength) from that used in experiments.

2. Carefully scratch the internal surface of a 2-well coverglass chamber (use a sharp metal object) to focus on the Indo-1 solution/glass interface.

3. Adjust the pH of both the zero and high-calcium calibration buffers to 7.4 with either HCl and NaOH.

   It is important to use deionized water and plastic containers for any solutions to avoid the addition or leaching of calcium.

4. To both the zero and high calcium calibration buffers, add ethanol to a final concentration of 20% (v/v) and Indo-1 free acid to a final concentration of 10 μM.

   Ethanol helps control for differences in the viscosity between cells and the buffers (Poenie, 1990). A higher concentration of Indo-1 is used for curve generation as compared to experiments with cells, since the dye does not become concentrated in solution as it does in the cells.

5. Place the chamber securely on the microscope stage and focus on the internal surface using the scratch to focus on the plane of the solution. Move the stage such that the scratch is no longer in the field of view, add the zero calcium solution, and conduct a preview scan to focus for maximal fluorescence. Adjust the parameters to stay within the range of fluorescence detection of the system.

6. Following the directions provided with the calcium calibration buffer kit, remove the volumes of zero calcium concentration buffer and add the calculated volumes of zero and high calcium concentration buffers to determine fluorescence ratios that correspond to known concentrations of free calcium.

   Additional points on the curve can be added by using the equations shown in the kit instructions and by calculating the volumes to be removed and added.

7. Using the K_d^{EGTA} for a pH of 7.4 at 37°C (K_d^{EGTA} = 43.7 μM) and the calculation instructions provided in the kit, calculate the concentration of free calcium corresponding to each addition of high concentration calcium solution, remembering to account for the change due to the presence of ethanol.

   The calibration curve generated can be used to determine the absolute calcium concentration corresponding to the Indo-1 fluorescence ratio in a cell.

ANALYSIS OF INTRACELLULAR CALCIUM IN INDIVIDUAL GLIAL CELLS USING FLUO-3/AM

ALTERNATE PROTOCOL

When a laser with UV excitation capability is not available, or the imaging equipment does not have the ability to detect fluorescence simultaneously at two different wavelengths, Fluo-3 can be used as a calcium probe. This probe displays an increase in fluorescence quantum yield, and therefore an increase in fluorescence, when bound to calcium. With this method, the calcium measurements are highly dependent upon the dye loading, in contrast to methods that use ratiometric dyes, such as Indo-1 and Fura-2.

Additional Materials *(also see Basic Protocol 2)*

2 μM Fluo-3/AM solution, in loading buffer
35-mm plastic tissue culture dishes
Inverted, scanning confocal microscope equipped with mercury arc lamp or argon ion laser capable of emission wavelength of 488 nm
530/20-nm band pass filters

Prepare and load cells

1. Prepare and treat cells (Basic Protocol 2, step 1), substituting 35-mm dishes for coverslip chambers and Fluo-3/AM for Indo-1/AM.
2. Tune the laser to excite at 488 nm and insert filters (530/20-nm band pass filters) such that the emission intensity at 530 nm can be quantitated.
3. Load cells with Fluo-3/AM solution (see Basic Protocol 2, steps 5 to 8, but substituting Fluo-3/AM solution for the Indo-1/AM solution).

Measure intracellular fluorescence

4. Secure the tissue culture dish on the microscope stage and focus under normal light. Conduct a preview scan to determine if the data acquisition settings are appropriate and adjust the focus such that fluorescence from cells is optimal.

   If expecting to see an increase in calcium levels following treatment, set parameters (see Basic Protocol 2) such that an increase in emission intensity can be detected.

Analyze fluorescence data

5. With an initial (baseline) image displayed on the computer monitor, encompass individual cells with an "area" tool (e.g., polygon or circle), and save the area as a template to apply to subsequent images. Use the computer software to integrate fluorescence within each area over time. Express the data as relative fluorescence intensity versus time. Save these values and export them to a spreadsheet program for subsequent analyses as desired.

   Data analysis can be done any time after experiment is finished.

REAGENTS AND SOLUTIONS

Use nanopure water or equivalent in all recipes and protocol steps. For common stock solutions, see ***APPENDIX 2A****; for suppliers, see* ***SUPPLIERS APPENDIX****.*

5-Bromodeoxyuridine (BrdU), 15 mM

Dissolve 46 mg BrdU in 10 ml water; freeze in 1-ml aliquots and store up to 2 weeks at −20°C in the dark.

Complete DMEM/5% and 10% FBS medium

Dulbecco's modified Eagle medium (DMEM; low-glucose, with HEPES) containing:

continued

5% or 10% (v/v) fetal bovine serum (FBS)
1% (v/v) penicillin/streptomycin solution (10,000 U penicillin/10 mg streptomycin/ml/0.9% NaCl)
Store up to 1 month at 4°C

Ethidium bromide staining solution, 100×

On the day of the experiment, dilute the 10 mg/ml ethidium bromide (Molecular Probes) 1:20 in water for a stock solution of 500 µg/ml. Protect from light until use.

Hoechst buffer

Dissolve in <1 liter :
8.53 g NaCl (0.146 M final)
12.11 Tris base (0.1 M final)
Adjust pH to 7.4 with HCl
Add:
1 ml of 500 mM (10.165 g/100 ml) $MgCl_2$ stock solution
2.0 g bovine serum albumin (BSA; 0.2% w/v final)
1 ml Igepal CA-630 (0.1% w/v final)
5.9 mg Hoechst 33258 (5.9 µg/ml final)
Bring up to 1 liter with H_2O and store up to 1 month in a light-shielding container at 4°C

Krebs' bicarbonate buffer

To prepare 10× stock solution combine the following:
70.14 g NaCl
3.5 g KCl
1.91 g $CaCl_2$
1.63 g KH_2PO_4
2.96 g $MgSO_4 \cdot 7H_2O$
21.08 g glucose
Bring up to 1 liter with H_2O

This 10× stock solution can be made in advance and refrigerated (4°C) for a few months.

Working solution: On day of experiment, dilute 1 part 10× stock solution with 9 parts water, add 2.1 g/liter of $NaHCO_3$ and adjust the pH to 7.4 with HCl.

This will give a buffer solution that is 120 mM NaCl, 4.7 mM KCl, 1.3 mM $CaCl_2$, 1.2 mM KH_2PO_4, 1.2 mM $MgSO_4 \cdot 7H_2O$, 11.7 mM glucose, and 25 mM $NaHCO_3$.

Loading buffer

100 ml 1× Krebs' bicarbonate buffer (working solution; see recipe) containing $NaHCO_3$
1.0 g fraction V bovine serum albumin (BSA; 1% w/v final)
Adjust pH to 7.4 with HCl
Store in aliquots up to 1 year at −20°C protected from light

The volume required depends upon the number of wells assayed. 100 ml each of the Krebs' bicarbonate buffer and the loading buffer is more than sufficient for 4 wells.

Serum-free medium

Dulbecco's modified Eagle medium (DMEM; low glucose, with HEPES)
1% (w/v) fatty acid–free, fraction V bovine serum albumin (BSA)
1% (v/v) penicillin/streptomycin solution (10,000 U penicillin/10 mg streptomycin/ml/0.9% NaCl)
Store up to 1 month at 4°C.

COMMENTARY

Background Information

This unit presents several methods in analytical cytology useful for evaluating the effects of toxicants on nervous system cells. Like spectrofluorimetry, flow cytometry and attached cell scanning confocal laser microscopy (SCLM) can make use of changes in dye fluorescence properties to indicate cellular responses to toxicant exposures. However, unlike spectrofluorimetry, which generates a single value for an entire population of cells, flow cytometry and SCLM allow for examination of the responses in individual cells. Although they require complex and expensive equipment, flow cytometry and SCLM are valuable tools to investigate the effects of toxicants on CNS cellular subtypes either temporally or spatially. The nature of the question being asked will dictate whether SCLM or flow cytometry is the appropriate methodological tool.

Cell-cycle analysis

Flow cytometric analysis of cell cycling by the BrdU/Hoechst method provides quantitative information on cell proliferation, including data on the fraction of cycling cells, the number of cycles any given cell has completed, and cell-cycle phase distribution. Glial cells are incubated with BrdU, a thymidine analog that is incorporated into DNA during DNA synthesis, and are exposed to both Hoechst 33258, a fluorescent DNA stain that binds preferentially to AT base pairs, and ethidium bromide, a DNA-intercalating flurochrome. Because Hoechst fluorescence is quenched by BrdU, cells that have undergone one or more rounds of DNA replication during BrdU incubation can be distinguished from nonproliferating cells by their diminished Hoechst fluorescence. However, ethidium bromide fluorescence is not quenched by BrdU and is proportional to the amount of DNA present in the cell. Its fluorescence is minimal when cells are in the G0/G1 phase, increases during the S phase, and is maximal in the G2 phase, while it is independent of the number of mitotic cell divisions. Therefore, the use of BrdU/Hoechst and ethidium bromide in combination allows for the separation of G0, G1, S, and G2/M phases of the cell cycle for three complete cell cycles, and also allows the determination of the length of time in each phase (Rabinovitch, 1983).

The method described here is a useful tool in toxicology as it is able to reveal chemically or physically induced alterations or blocks in the cell cycle of synchronized cells. Neurooncology (M. Wei, M. Guizzetti, and L.G. Costa, unpub. observ.) and developmental neurotoxicology (Guizzetti and Costa, 1996) are two fields where this method has been applied to toxicology with positive results. With flow cytometry it is possible to test environmental exposures (either chemical or physical) for their ability to induce cell proliferation, and consequently, to be "tumor promoters" through an epigenetic mechanism. In addition, exposure to chemicals that have the ability to interfere with the cell cycle during brain development could lead to severe, long-lasting consequences for the neurobehavioral abilities of individuals, and the techniques described in this unit can be used to identify such chemicals.

This technique is also useful with unsynchronized cells. However, these flow cytograms are more difficult to interpret (Ormerod and Kubbies, 1992). Asynchronous Hoechst–ethidium bromide flow cytometric analysis has been applied in developmental neurotoxicology to examine the cell cycle kinetics of proliferating rat midbrain neuroepithelial cells exposed to either methylmercury or colchicine (Ponce et al., 1994). Use of flow cytometric Hoechst–ethidium bromide analysis is rapidly performed and provides greater information than radioactive [^{3}H]thymidine incorporation or single-parameter flow cytometry (Rabinovitch et al., 1988; Poot et al., 1990). Nevertheless, [^{3}H]thymidine incorporation, with its sensitivity in detecting DNA synthesis and its simplicity and relatively low cost, may be a better method for "routine" experiments (i.e., when information about cell cycle phase distribution or the length of cell cycle phases are not required).

To aid in the analysis and interpretation of the flow cytometric results, a positive control should be employed to monitor for variation between primary cell preparations and to ensure that the cells are responding as expected. Potential agents for use as positive controls for inhibiting cell cycling are the antimitotics, i.e., colchicine or benzimidazole analogs, or 5-azacytidine, an inhibitor of DNA synthesis. Fetal bovine serum (10%) added to the medium acts as a strong mitogen and can be used as a positive control for inducing a high percentage of cells to exit quiescence (see Fig. 12.5.1).

In addition to the protocol described here, other protocols can be designed to evaluate the time course of stimulation and provide temporal information about cell cycle characteristics fol-

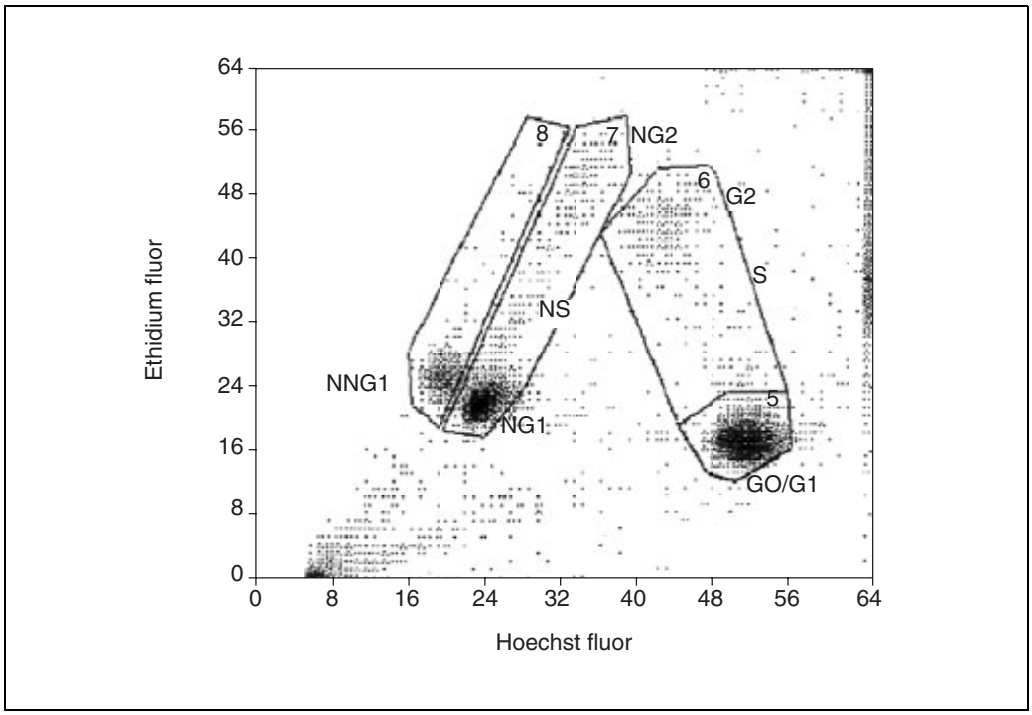

Figure 12.5.1 Flow cytometry plot for bivariate cell cycle analysis. Rat astrocytes in primary culture were stimulated with 10% FBS in the presence of BrdU for 48 hr. On the abscissa: Hoechst fluorescence emission. On the ordinate: ethidium bromide emission. G1: cells in Gap 1 phase; S: cells in synthesis phase; G2: cells in Gap 2/mitosis phases; NG1, NS, NG2: cells that have completed the first mitosis and are now in the second cell cycle (N = new); NNG1, NNS, NNG2: cells that have duplicated twice and are now in the third cell cycle.

lowing toxicant exposure. For example, it is possible to obtain information about the length of each phase of the cell cycle and to reveal abnormalities in these following toxicant exposure by incubating cells in the presence of BrdU for different lengths of time (Vogel et al., 1986).

Intracellular calcium measurement

The use of analytical cytology to measure intracellular calcium concentration allows the quantification of both basal and stimulant-mediated calcium content within individual subtypes of neural cells following toxicant exposure. The use of scanning confocal laser microscopy (SCLM) enables the researcher to distinguish between effects on the basis of the number of cells responding and the size of the maximal response, and to observe subtle effects on spatial and temporal changes in normal calcium responses following stimulation. Although the Alternate Protocol is useful, especially when the necessary excitation wavelengths for Indo-1 are not available, Basic Protocol 2 provides much more accurate quantitative data on absolute calcium levels, with few problems associated with photobleaching and interference from other ions and chemicals present. In the case of both Indo-1 and Fluo-3, the basic chemistry underlying their ability to act as calcium probes is their ability to chelate calcium. The principal difference between the two, however, is that the binding of calcium to Indo-1 results in a shift in the emission wavelength of the dye, whereas the binding of calcium to Fluo-3 increases the fluorescence intensity.

The protocols for measuring calcium provided here are only examples of many applications of SCLM as a tool in neurotoxicological research. Similar techniques, using different fluorescent probes, have investigated the levels of other ions, intracellular pH, levels of messenger RNA, cellular glutathione levels, and intercellular communication. Any of these techniques could be applied to the study of neurotoxicology using modifications to the basic protocols outlined here. Similarly, flow cytometric analysis is a useful tool in neurotoxicology beyond cell-cycle analysis; by use of various fluorescent probes and antibodies the effects of toxicants on various cellular aspects can be assessed at the single-cell or cell-population level. The techniques described in these protocols have been used in glial cells; however, they can also be used for other cell types, and in the case of SCLM, organotypic brain slices.

Some of the considerations in applying these techniques to other experimental systems are discussed below.

Critical Parameters and Troubleshooting

Many of the stains and probes used in these fluorescence assays are photolabile or cytotoxic when exposed to light. Therefore, precautions must be taken when carrying out these types of experiments to protect these compounds from light, and to protect the cells from excessive light exposure when they have been loaded or stained with the fluorescent dyes.

Flow cytometry

The method described for cell-cycle analysis is designed for primary cultures of rat astrocytes (Guizzetti et al., 1996). A similar protocol has been followed for flow cytometric analysis of the human astrocytoma 132 1N1 cell line. In this case, cells are reseeded at 5×10^4 cells/well, cultured in a complete 5% medium for 4 days, and then serum deprived. Astrocytoma cells are harvested using 0.05% trypsin. This method can be modified for use in other cell types. However, certain considerations must be made when doing so. For example, the optimal concentration of BrdU for continuous labeling is dependent on the cell type, and therefore experimental range-finding, with analysis of cytotoxicity, will be necessary to determine the optimal BrdU concentration. The extent of cell quiescence is also dependent upon the cell type studied. Although only 92% to 93% of primary rat astrocytes reach quiescence after 48 hr in serum-free medium, under the same conditions, almost all (>98%) 132 1N1 astrocytoma cells are in the G0/G1 phase, a difference that can be explained by the fact that astrocytes are usually able to produce autocrine growth factors.

A further concern for other cell types is the long duration of serum deprivation (48 hr prior to and 48 hr during BrdU incubation). If this extensive serum deprivation induces an unacceptable level of cell death (often seen as an increase in the number of nuclei with fluorescence intensity less than that of G0/G1 nuclei), it is possible to use a low serum concentration (i.e. 0.1% FBS) to induce quiescence in the cells. However, this problem can be avoided by studying asynchronous cultures. If it is not possible or desirable to artificially synchronize the cell cultures under investigation, single-parameter analysis (to determine cell cycle phase distribution) combined with dual-parameter analysis, to examine successful completion of cell division, can be used to obtain information on cell-cycle kinetics (Ponce et al., 1994).

The density of cells in suspension should be adjusted so as to provide an optimal sampling rate for the flow cytometer. In this case, the authors use $1–2 \times 10^6$ cells/ml with a sampling rate of ~300 cells/sec, which requires a minimum of 0.5 ml of cellular suspension. If the cell density is lower than this, analyzing each sample will take more time (because of slower sampling rate) or require a higher pressure to achieve the same sampling rate (which can decrease the quality of the results). In contrast, a very high cell density can result in clogging of the machine and poor reproducibility; dilution of cells in dye-containing buffer can correct for this situation. If the experimental conditions under investigation either inhibit cell proliferation or cause cytotoxicity, additional cells should be plated and harvested in order to obtain the volume and density of cells required for analysis.

Although sample preparation for cell cycle analysis is relatively straightforward, some precautions must be taken in this preparation. It is advisable to prepare each treatment in triplicate in case problems arise and samples are lost. It is also important to ensure that trypsinization is complete in order to obtain a good cell yield and avoid cell clumping, as this can give spurious flow cytometric results and clog the machine. Incomplete trypsinization is especially a problem when using primary cultures as these cells tend to have stronger cell-cell adhesion than is typical with transformed cells. Should clumping be a problem, repeated passage of the cells through a 26- to 28-G needle prior to flow cytometric analysis or slightly longer trypsinization time during harvest (e.g., 10 min) should be attempted.

Care must also be taken to avoid aspirating the pellet following centrifugation. Both harvest and centrifugation are made more difficult by the need to carry them out in the absence of direct light, although sodium lamp illumination will not cause BrdU-induced cytotoxicity and may facilitate these procedures.

Another problem that can occur during sample preparation is insufficient entry of the Hoechst stain into the cells due to an inadequate concentration of detergent (Igepal CA-630). If this occurs there will be no detection of Hoechst-associated fluorescence during flow cytometric analysis. Slightly increasing the amount of detergent, or staining the cell suspension for a longer period of time before analysis (e.g., by freezing the sample in the presence of 10%

Table 12.5.1 Affinity Constants (K_d) for Indo-1 at Varying pH

	pH = 5.5	pH = 6.0	pH = 6.5	pH = 7.0	pH = 7.4

DMSO in Hoechst buffer) can solve this problem.

A caution regarding the use of agents that are incorporated into DNA during DNA synthesis, including both BrdU or [^{3}H]thymidine, is warranted if the toxicant or exposure conditions under investigation cause or promote DNA repair or unscheduled DNA synthesis. Because DNA is synthesized for other reasons besides cell division, exposure conditions that lead to such incorporation of either BrdU or [^{3}H]thymidine into DNA can cause spurious results upon cell-cycle analysis (with either scintillation counting, autoradiography, or flow cytometry).

Scanning confocal laser microscopy

Indo-1 has a peak emission in the calcium-free form of 475 nm. As Indo-1 binds calcium, this peak shifts towards lower wavelengths. The calcium-independent emission wavelength (i.e., the isosbestic point) is ~450 nm. However, rather than monitor changes in peak fluorescence intensity at 475 nm, the dynamic range may be increased for this dye by examining changes in emission at 530 nm, because the fluorescence diminishes at a proportionately greater rate with small increases in calcium at this wavelength as compared to 475 nm (Rabinovitch and June, 1990).

Several issues regarding Indo-1 loading should be raised. First, excessive loading of Indo-1 may lead to calcium buffering and underestimation of response following signaling. Moreover, excessive Indo-1 loading may lead to incomplete intracellular hydrolysis of Indo-1/AM (Lückoff, 1986). Because the Indo-1/AM also exhibits fluorescence properties (that are not responsive to changes in intracellular calcium), excessive incomplete hydrolysis can lead to spurious results. Second, loading of Indo-1 for long-periods of time can lead to Indo-1 intracellular compartmentalization. However, Indo-1/AM loading times may vary among different cells depending upon the activities of nonspecific esterases in the cells that cleave the acetoxymethylester (AM) group and release the active calcium probe.

Under optimal circumstances, Indo-1, Fura-2, Fluo-3, and other fluorochromes undergo fluorescence property changes upon binding calcium. However, the fluorescence properties and the calcium affinity of these dyes may be affected by such factors as temperature, pH (Table 12.5.1), viscosity, and the presence of other factors in the incubation medium (Table 12.5.2), including other divalent cations (Tsien, 1989; Owen et al., 1991; Bancel et al., 1992). Because of the sensitivity of Indo-1 cation affinities and emission spectral properties to their environment, cell-free analyses to evaluate the interaction of Indo-1 with experimental medium components are advised. Such evaluations can be conducted using spectrophotometric analysis

of Indo-1 or Fluo-3 free acids over the full spectral range of fluorescence emission in the presence and absence of medium components.

There has been criticism of the use of a cell-free method for construction of a calcium calibration curve, with some concern over the differences in viscosity between buffer and cells, which could affect the responsiveness of Indo-1 to changes in calcium concentration. To address this issue it has been suggested that 20% ethanol be used during calibration, as some of the viscosity problems have been shown to be corrected for by the addition of ethanol to buffers during calibration curve generation (Popov et al., 1988).

While Indo-1 and other calcium-sensitive fluorochromes have a relatively high specificity for calcium, they can also bind a number of other divalent cations (Table 12.5.1). Because the spectral properties of Indo-1 are affected by both the cation species present and dye concentration, evaluation of changes in the Indo-1 405 nm/530 nm emission ratio alone may not allow evaluation of the relative impact other divalent cations may have on the measured fluorescence. To determine whether other divalent cations may be affecting Indo-1 fluorescence (independent of calcium), one may monitor fluorescence changes at the Indo-1 isosbestic point (~450 nm), as changes in Indo-1 fluorescence intensity at this point cannot be attributed to calcium and may indicate interference due to other cations. Specific chelators can also be used to avoid confounding of the calcium signal by other cations. For example, tetrakis-(2-pyridylmethyl)ethylenediamine (TPEN), a relatively selective zinc chelator (Table 12.5.2), can be used in moderate zinc levels to prevent its interference with the Indo-1 fluorescence. Cell-free analyses demonstrate no direct effect of TPEN on Indo-1 fluorescence (Owen et al., 1991; Ponce, R.A. and Kavanagh, T.J., unpub. observ.).

A cell-type dependent problem that may be encountered when working with calcium probes is dye extrusion. For example, 132 1N1 astrocytoma cells do not extrude Indo-1, whereas primary rat astrocytes cultured in this laboratory required coincubation with probenecid to avoid extrusion of this dye from the cells (Gafni et al., 1997). In some cases, this efflux is mediated by organic anion transporters and can be prevented by the addition of inhibitors of this pump, such as probenecid or sulphinopyrazone (DiVirgilio et al., 1988, 1990; Arkhammar et al., 1990). In other cell types, P-glycoprotein is responsible for the extrusion of calcium probes; in these cases, this extrusion can be inhibited by addition of verapamil or cyclosporin (Brezden et al., 1994).

In addition to cell-type specific Indo-1 efflux, membrane damage may lead to dye release from cells or allow influx of non-calcium extracellular cations. To examine the role of membrane damage on intracellular Indo-1 fluorescence, Mn^{2+} addition to extracellular medium has been used as this ion will only enter the cell if the membrane is damaged. Because Mn^{2+} quenches Indo-1 fluorescence across all wavelengths, examination of cellular Indo-1 fluorescence in the absence and presence of Mn^{2+} can be used as an indicator of nonspecific membrane damage.

When performing kinetic analyses of intracellular calcium, the focus of the microscope may change or the field of observation may be shifted; such effects are especially likely to occur at the time when a stimulus is added and can confound the interpretation of Indo-1 fluorescence data. Successive fluorescence images should be watched throughout the collection period to ensure that the fluorescence intensity displayed by both detectors does not abruptly decrease, indicating a loss of focus, in which case the experiment must be repeated. It is also useful to look at the fluorescence data from individual detectors over the entire time course of the experiment to establish that any change in fluorescence seen is due to the treatment and not due to photobleaching or dye loss. One must be careful not to scan too long or with excessive excitation intensity, either during preview scans or during the experiment, as this may cause photobleaching of the dye. Under the conditions described here, this is usually not a problem with Indo-1, as it is fairly resistant to photobleaching.

One must ensure that the tissue culture dishes being used do not interfere with passage of exciting or emitted light. If the cells have a substantially higher-than-expected basal calcium level, this may be due to cellular autofluorescence. This can be corrected for by subtracting the average autofluorescence readings obtained from cells which have not been loaded with Indo-1 or Fluo-3.

Anticipated Results

The protocols described in this unit will provide the researcher with data at the individual cell level. All the protocols will qualitatively assess the effects of compounds on various aspects of cellular activity and generate figures that can indicate visually the effects of the treatments. In addition, the two basic protocols can

Table 12.5.3 Distribution of Cells in the Cell Cycles[a]

	Cell number	% of total (raw data)	% of total (adjusted data)
First cell cycle	4913	50.1	68.5
Second cell cycle	4155	42.3	28.9
Third cell cycle	744	7.6	2.6

[a]The data are expressed both as proportions of the cells present at the time of analysis ("raw data") and as "adjusted data" obtained by accounting for the number of cell divisions undergone by cells (reflecting the proportion of cells originally placed in culture).

be analyzed quantitatively to determine absolute numbers of cells in particular cell-cycle stages and absolute calcium levels and changes, in the flow cytometric experiments and SCLM experiments respectively. Details of the expected results from these two protocols are given below.

Flow cytometry

In a typical experiment, cell-cycle compartments are analyzed by plotting the Hoechst-associated fluorescence (abscissa) against ethidium bromide–associated fluorescence (ordinate). Figure 12.5.1 shows an example of cell cycle flow cytogram using bivariate (Hoechst/ethidium bromide) analysis. During DNA synthesis (S-phase), the nuclear DNA content increases; this can be observed as an increase in ethidium bromide fluorescence and a decrease in Hoechst-associated fluorescence due to the incorporation of BrdU into DNA. The G2/M phase, when all the DNA is duplicated and the cells undergo cell division, can be observed as the maximal ethidium bromide/Hoechst fluorescence (because both G2 and M have 2× DNA, they cannot be distinguished with the flow cytometric technique). Division of the cells corresponds to a drop in ethidium bromide fluorescence, a further decrease in Hoechst fluorescence (new G1 phase), and a consequent shift of the cell population to the left and down on the graph.

G0, G1, S, and G2/M phases of each of three successive cell cycles can be quantified by analysis of the respective regions of the two-parameter flow cytograms. The correct number of proliferating cells is obtained by dividing the number of cells in the second or third cycle by two and four, respectively, because in these cases the cell number is the result of one mitosis (second cycle) or two mitoses (third cycle) occurring from the beginning of BrdU incubation (Table 12.5.3). The number of noncycling G0-phase cells can be obtained by quantifying the number of G0/G1 cells that have failed to incorporate BrdU.

Scanning confocal laser microscopy

Kinetic analysis of intracellular calcium with confocal microscopy generates data from which a number of endpoints can be quantified. The scans prior to addition of the stimulant can be used to compare basal calcium levels between treated and untreated cells. The initial calcium spike can be assessed for the percentage of cells responding to the stimulus, the rate of the calcium increase, and the maximal response; these endpoints can be used to compare the control and toxicant-treated cells. It is important to assess the effect of the toxicant on the basal calcium level to properly interpret any effects on the maximal response. In addition, the effect of the toxicant on the total calcium present across time (area under the time-versus-fluorescence-intensity/calcium concentration curve), and on intracellular calcium oscillations, if present, can be determined (Barhoumi et al., 1995). An example of expected results is provided in Table 12.5.4. These calcium measurements were obtained in 132 1N1 human astrocytoma cells, using 0.01 mM carbachol as a stimulant, under control conditions or following a 24-hr incubation with the specified concentration of ethanol. Note that results, including the basal calcium concentration, will vary depending upon cell type.

The absolute $[Ca^{2+}]_i$ can be calculated using Basic Protocol 2 for calcium measurement and Support Protocol 2 for generation of a calibration curve. While the Alternate Protocol with Fluo-3 as a probe is not as quantitative, relative changes in $[Ca^{2+}]_i$ over time can be determined. Whether one uses Indo-1 or Fluo-3, pseudocolor images can be generated by most software packages, and this provides a visually interpretable assessment of the spatial/temporal effects of substances on normal calcium homeostasis.

Table 12.5.4 Expected Calcium Measurements[a]

[Ethanol] (mM)	Basal [calcium] (nM)	% cells responding	Average amplitude of response (% of basal)	Area under curve
0	67	92	498	22
25	71	43	257	17
250	83	53	236	7

[a]Measurements are made following stimulation with 0.01 mM carbachol in human 132 1N1 astrocytoma cells, under control conditions, or following a 24-hr incubation with ethanol. Experiments were carried out in calcium-free Krebs' buffer. Ethanol was present at the time of addition of carbachol. Results were analyzed to determine the basal calcium concentration, the percentage of cells responding to carbachol, the average amplitude of the response, and the area under the curve.

To study the role of extracellular calcium in the intracellular calcium response to stimuli, incubations with EGTA, EDTA, or other membrane-impermeable cation chelators are often useful. However, as these chelators may also deplete intracellular calcium over time, baseline studies should be conducted to determine whether use of the chelator is depleting intracellular stores of calcium over the experimental observation period. In cases where extracellular calcium is required to maintain steady-state intracellular calcium concentrations, special calcium-buffering systems may be applied (Denny and Atchison, 1996).

Using the protocols outlined here, kinetic analysis can be carried out to allow investigation of acute toxicant effects on intracellular calcium levels. In this case, no pretreatment is done, and the toxicant is added after establishing a baseline calcium level. With this protocol, analyses may be made of the percentage of cells affected, the rate of $[Ca^{2+}]_i$ increase/decrease, the maximal response, total calcium changes integrated over time, and any oscillatory effects that the compound causes. In addition, calcium changes within specific intracellular compartments and in specific areas within the cytosol can be assessed using confocal microscopy and calcium-sensitive dyes. If the researcher is not interested in temporal changes in calcium or the effect of a toxicant on calcium responses, but is simply interested in effects on resting calcium levels, a kinetic analysis is not necessary, and scans of multiple fields can be carried out to determine the effects of the toxicant on basal $[Ca^{2+}]_i$ in many cells.

Time Considerations

Flow cytometry

The total time for the flow cytometric procedure will vary depending on experimental and culture conditions. Treating the cells with mitogens and BrdU will take ~10 min for 24 samples (each treatment in triplicate). Harvesting, centrifuging, and resuspending cells in buffer will take 30 min. Staining the cells with ethidium bromide will take 15 min. Flow cytometric analysis of each sample will take 2 to 10 min of actual machine time per sample to collect data from 10,000 cells (depending on sampling rate and cell density). Data analysis will take ~1 hr.

Scanning confocal laser microscopy

The total time for SCLM is also dependent upon the culture conditions and experimental design being studied. Once cells have been serum deprived and pretreated (if desired) with toxicant, the experiment should take from 3 to 6 hr, depending upon loading conditions required for the cell type and the number of treatments studied. Preparation of the stock solutions can be done in advance to save time. Once cells have been loaded with dye, quantification of the fluorescence on the microscope can take 5 min, or longer if many time points are desired. It is important to remember to stagger experiments in different plates; thus the more plates that are to be examined, the longer the experiment. Due to the many solution changes and the need to stagger incubations, scanning many wells may become logistically difficult; it is not recommended that >10 wells be scanned in a given experiment.

Estimating Cell Number in the Central Nervous System by Stereological Methods: The Optical Disector and Fractionator

Recent advances in stereology methods allow truly unbiased estimates of the total cell and synapse number within discrete structures of the central nervous system (CNS). These new advances, based upon the disector and fractionator tools, combine unbiased counting frames, unbiased systematic random sampling, and unbiased estimates of the structure (reference) volume to produce the final estimate of total number. The estimates are unbiased because the experimental methods employed are design-based as opposed to the previously available model–based methodologies. No assumptions inherent in model-based procedures are employed. Hence the final estimates are not biased by any known or unknown assumptions about the model.

The methods are also very efficient. Proper sampling design, featuring systematic random sampling, requires that only between 100 and 300 particles (e.g., cells or synapses) per structure actually be counted. Additional effort (counting) will usually not significantly improve the results because inherent biological interanimal variation begins to predominate over the observed variation within a treatment group, once these initial 100 to 300 particles have been counted. This type of biological interanimal variation cannot be reduced by additional sampling.

Previously, the only unbiased method available for determining total cell or synapse number required complete serial reconstruction of the region of interest. This method involves no sampling or estimation. Cells or synapses are directly counted during reconstruction. Although capable of being performed in an unbiased and accurate manner, serial reconstruction is decidedly inefficient because of the enormous amount of labor required. All other previously available methods, including profile counting, profile densities, profile ratios, and the model-based methods of Abercrombie or Konigsmark, are recognized as producing either estimates with unknown amounts of bias or inaccurate results (Williams and Rakic, 1988; Coggeshall and Lekan, 1996). This unit contains protocols for estimating total cell number by optical fractionation (see Basic Protocol), N_v,V_{ref} (see Alternate Protocol 1), and physical disector (see Alternate Protocol 2), as well as glycolmethacrylate embedding (see Support Protocol 1) and Giemsa staining (see Support Protocol 2).

The stereology methods that are featured in this unit entail several concepts that are defined as follows.

Reference volume: The reference volume (V_{ref}) is the volume of the entire structure of interest. The entire structure of interest must be available at the initial stages of the sampling hierarchy. If an unknown portion of the entire structure is unavailable for sampling, then it is not possible to determine the absolute number of particles in that structure, simply because that missing region remains unknowable (see Commentary).

Optical disector: The optical disector consists of an unbiased counting frame (Fig. 12.6.1). The boundaries of the frame are determined by the exclusion lines (heavy lines in Fig. 12.6.1) and their extensions (indicated by the arrowheads in Fig. 12.6.1). Any particle (e.g., a neuron cell body) that touches the forbidden lines (i.e., out of bounds) is not counted, whereas any particle inside the frame or touching the in-bounds boundary lines is counted. Particles that touch the forbidden lines belong to the adjacent disector(s), which in practice are never used; however, one should imagine that the entire surface of

Contributed by Jay S. Charleston
Current Protocols in Toxicology (2000) 12.6.1-12.6.19

the tissue section had been tiled in disector frames. These rules ensure that each particle has the potential of being counted only once.

The disector frame is optically focused through the central portion of a relatively thick tissue section (e.g., 20 to 70 μm), and particles are counted as they come into focus. Moving the focal plane in effect turns the lines of the disector frame (i.e., in bounds and forbidden lines) into in-bounds and forbidden planes and creates a counting volume (see Fig. 12.6.2). The bottom plane of the disector volume also forms a forbidden plane. Particles touching this plane, by rule, belong to the disector volume associated with a

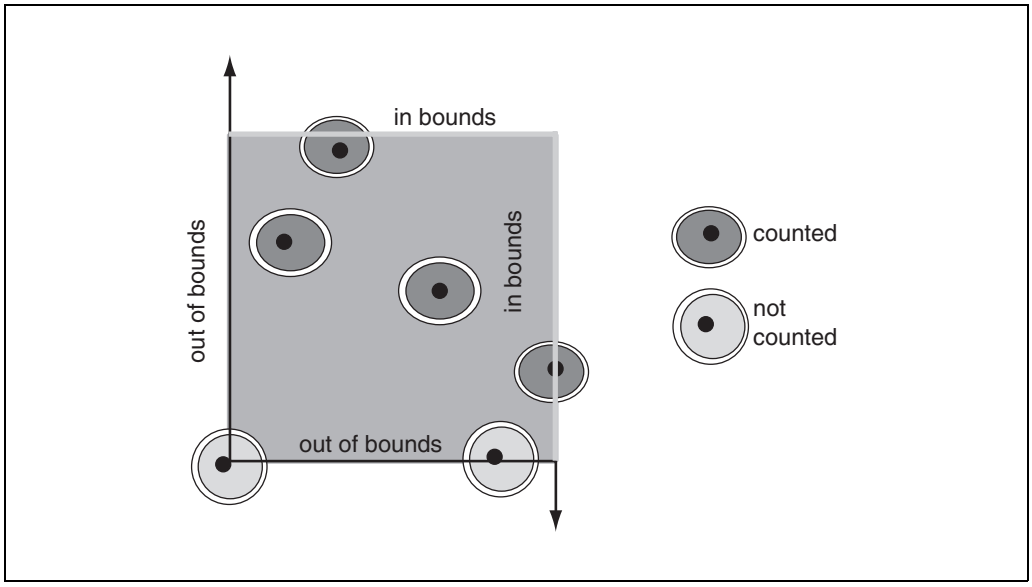

Figure 12.6.1 Disector frame and counting rules. The left and lower sides of the disector frame represent out of bounds lines. Note that the extensions of these two lines, represented by the arrows, are also out of bounds. Particles touching these lines are not counted. Particles touching the shaded area, including the in-bounds lines, are counted.

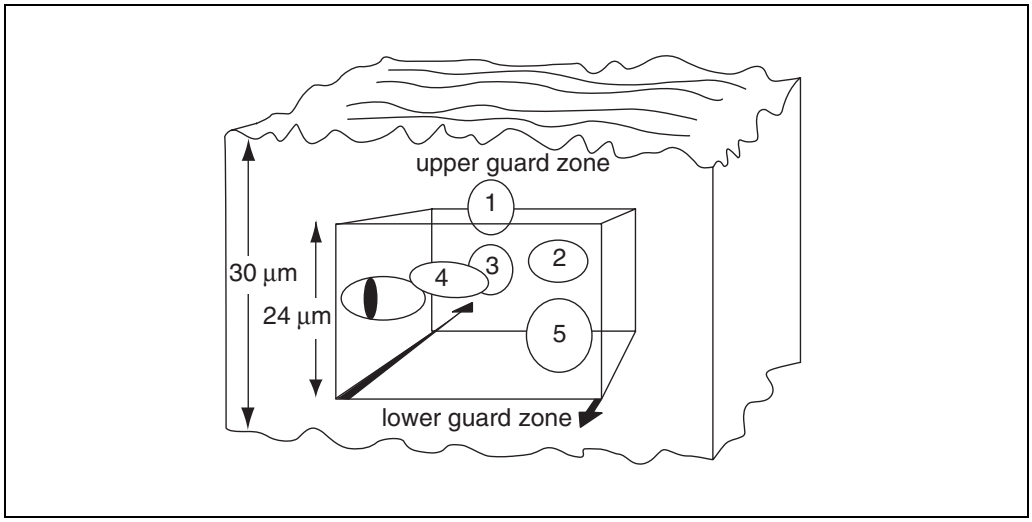

Figure 12.6.2 Optical disector. The disector frame is "moved" through the center of a relatively thick tissue section by focusing the microscope. The movement of the frame creates a counting volume. The out of bounds lines of the frame create out of bounds planes. By rule, the bottom plane is also out of bounds. The example here shows five objects belong to this volume. The sixth object intersects the out of bounds left plane (shaded area) and is not counted. The top and bottom surfaces of the section are not part of the counting volume (they are separated by guard zones), hence defects (e.g., chatter, pits) do not interfere with the counting.

disector that could have been placed immediately below the current disector (in practice this disector is also never used). The disector is a number-weighted counting probe that samples particles independently of their size or orientation.

Fractionator: The fractionator is an integral part of the sampling procedure. It is based on the simple premise that any quantity determined for a known (usually small) fraction of the entire structure can be used to determine the quantity in the entire structure by multiplying this determined quantity by the inverse of the sample fraction from which it was derived. The fractionator is ideally suited for combining with unbiased systematic random sampling (see below), which in turn can be readily combined with commonly practiced histology techniques. The optical disector can be combined with the fractionator principle to directly estimate particle number (i.e., the optical fractionator) or can be used to generate a numerical density (number counted per volume, N_v) estimate of the particles. This N_v estimate can in turn be combined with a volume estimate derived with the fractionator principle (V_{ref}) to produce an estimate of total number (the so-called N_v,V_{ref} method; see Alternate Protocol 1).

Systematic random sampling: Systematic random sampling is employed throughout the sampling hierarchy. It is random because the position of the first sample at each stage of the sampling hierarchy is determined by random chance. It is systematic in that all subsequent samples are systematically determined after the first random position has been established. For example, if an adult rat brain were slabbed in the coronal plane at 1-mm intervals, ~≥20 slabs could be expected. If every third slab were desired, a random number between 1 and 3 would be generated. If 2 were selected, then the 2nd, 5th, 8th, 11th,... slab would be selected at this sampling stage. The systematic random sampling extends across the entire sampling procedure (brain slabbing, sectioning, and disector placement;

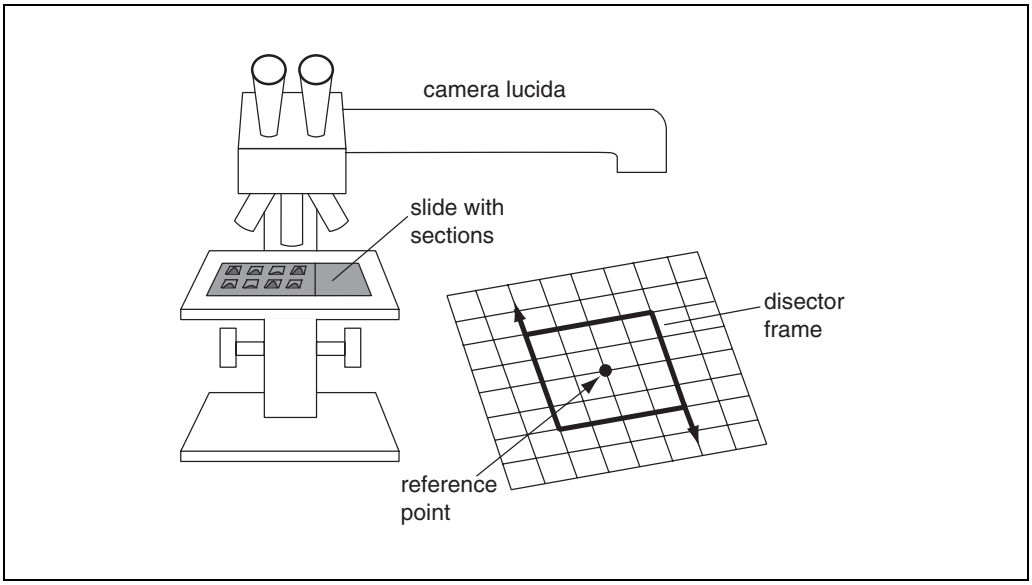

Figure 12.6.3 Optical disector microscope. A relatively inexpensive optical disector microscope can be established by projecting an image of a point grid and disector over the image of the tissue section by use of a camera lucida (drawing tube). At relatively low power, intersections of the grid lines can be counted as points for estimating the surface area of the tissue sections examined. A high-power oil-immersion lens is used when counting with the disector frame. The reference point, placed at the center of the optical path of the microscope, can be used in conjunction with the point grid to facilitate a systematic stepping across the section for placement of each disector (see Fig. 12.6.5). The linear tracking device for measurement of movement of the microscope in the *z*-axis is not shown. Mechanized stages and computer-aided video systems can also be utilized to automate these steps (e.g., see West, 1993b; Pakkenberg and Gundersen, 1997).

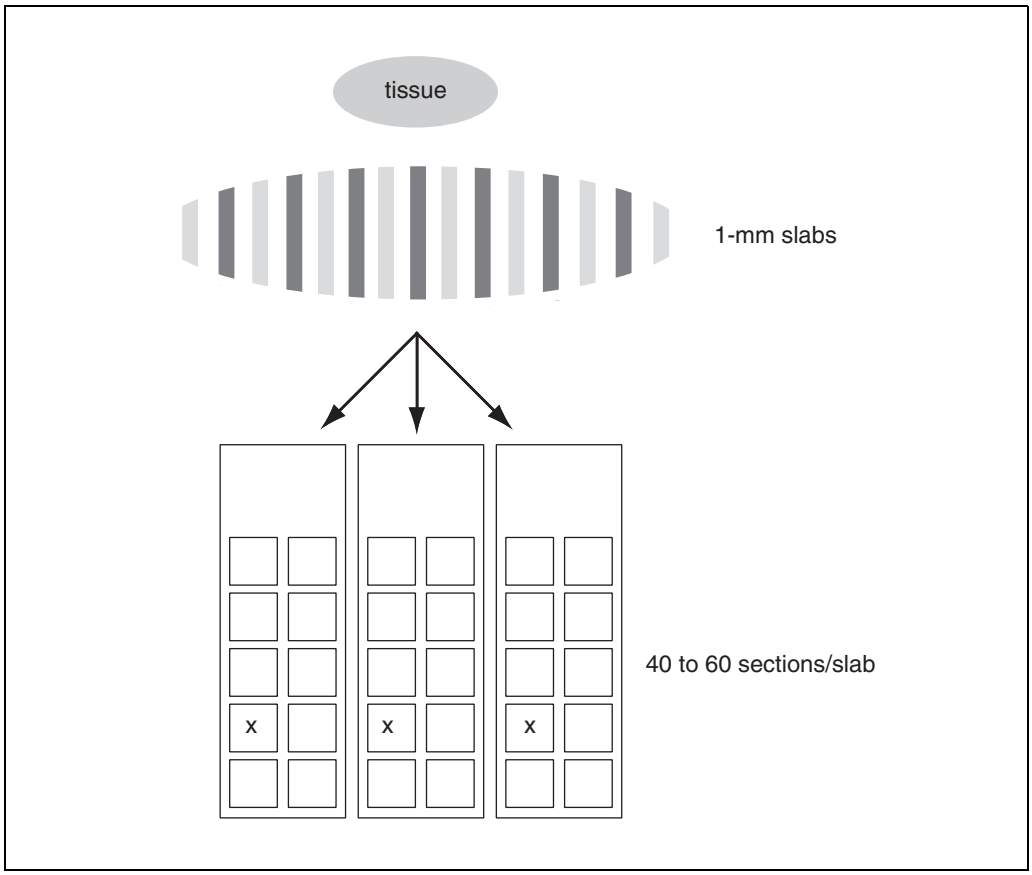

Figure 12.6.4 Systematic random sampling. A structure is systematically cut into equal slabs. In the example of a sampling design presented here, it was determined that every other slab should be sampled, and every 10th section examined. For the slabs, a random number between one and two is drawn (in this case it was 2). Therefore the 2nd, 4th, 6th, ...14th slabs are selected, embedded and sectioned. For the sections, a second random number between 1 and 10 is drawn (in this case it was 4). Therefore, the fourth section on each slide (*x*) is sampled for counting.

Fig. 12.6.3 and Fig. 12.6.4). Systematic random sampling is fair in that all portions of the original structure have equal probability of being sampled.

BASIC PROTOCOL

ESTIMATING TOTAL PARTICLE NUMBER USING OPTICAL FRACTIONATOR

The instructions for counting, provided below, represent the least demanding methods in terms of equipment for implementing the techniques. The disector counting frame and grids for disector placement can be generated by projecting them into the optical path of a microscope with the use of a camera lucida attachment (current prices for retrofitting a microscope range from ~$2,000 to $4,000; contact individual microscope manufacturer). The projected grid image can be used for stepping across the section for placing sequential disector frames. Commercially available software/hardware solutions are also available and can greatly automate the application of the methods (e.g., StereoInvestigator, MicroBrightField and Bioquant, R&M Biometrics). These solutions, featuring real-time digital-image capture, stepper-motor-driven computer-controlled microscope stages, and accessories, can cost between $30,000 and $50,000 without considering the cost of a microscope.

The optical fractionator (West et al., 1991; West, 1993a,b) combines the optical disector directly with the fractionator. The optical fractionator method is the method of choice, provided the structure of interest is represented by a naturally occurring boundary so that

a true nonarbitrary V_{ref} can be recognized (see Alternate Protocol 1 for N_v,V_{ref}, below). A point lattice is projected across the surface of a set of sections. A set of disectors is placed at every point. The ratio (fraction) of the area of the disector frame to the area per point in the point lattice is known. Therefore the sum of the total of the disector areas employed represents a known fraction of the total area of the structure (derived from the point lattice). A guard area (see Fig. 12.6.2) is established at the top and bottom of the optical disector. This fraction (disector height/section height) is also used as one component of the fractionator calculation. The number of particles counted in all the disectors is multiplied by the inverse of the known sampling fractions (including the slabs, sections, disector aerial fraction, and guard area fractions). The volume of the structure is never calculated and does not need to be calculated. This protocol represents a pure fractionator application and volume artifacts are not a confounding factor.

Materials

Test animal
4% (w/v) paraformaldehyde (see recipe), prepare fresh

Razor blades
Humidified chamber: Petri dish containing moistened filter paper *or* compartmented boxes (e.g., Brain Research Laboratories) filled with buffer
Sharp dissecting pins
Hand-operated microtome (e.g., Sorvall JB-4 or Reichert-Jung 820-II) with glass knives or disposable microtome razor blades (e.g., MB35, Shandon)
Frosted glass microscope slides (acid-cleaned in 5 N HCl for 2 min, then rinsed in H_2O)
70°C heated slide tray
Optical disector microscope
Tabletop linear tracking device (e.g., Microcator, Heidenhain)

Additional reagents and equipment for perfusion fixation (*UNIT 9.5*), glycolmethacrylate embedding (see Support Protocol 1) or cryosectioning (see *APPENDIX 3* for reference) and Giemsa staining (see Support Protocol 2)

Fix and isolate tissue

1. Perform whole-body perfusion of animal (*UNIT 9.5*) with freshly prepared 4% paraformaldehyde. Fix brain for 2 hr prior to dissection from skull to allow for dimensional stability prior to handling brain.

   Preservation of all particle types and structure (e.g., cell, synapse) is the goal. The only assumption inherent in these methods is that all target particles are preserved and that the actual boundaries of the structure of interest are preserved. It is not possible to count cells that are not preserved in the tissue and it is not possible to associate these particles with a structure whose boundaries cannot be recognized.

   The choice of fixative may be limited by requirements for other methodologies. For example, glutaraldehyde fixative may be required for optimal preservation of structure for ultrastructural examination of tissue (e.g., later characterization of synapse surface area). However, glutaraldehyde fixation may reduce immunocytochemical reactivity of the tissue.

   Immersion fixation may also be required (e.g., with human brain tissues). Several months of immersion fixation, featuring several changes of fixative, may be required to ensure adequate fixation of tissues prior to further sampling.

2. Cut the entire region of interest into systematic random slabs in the preferred plane with thin razor blades. Collect slabs in order and orientation generated (be careful not to flip left and right sides while collecting slabs) and place in a humidified chamber/box. Make a permanent physical mark (remote from target structure) with

a sharp dissecting pin after each slab is cut, which can be recognized later in the tissue sections.

Slabs should be maintained in a humidified chamber or held in compartmented boxes (e.g., Brain Research Laboratories) filled with buffer during collection to prevent surfaces from drying out as subsequent slabs are collected. Small humidified chambers can be constructed from Petri dishes fitted with filter paper that has been saturated with buffer. It is important to maintain the order of collected slabs.

Commercially available or custom-made cutting guides will greatly facilitate generation of uniform slabs (see Commentary). Embedding the entire brain in an agar matrix (see recipe) will stabilize the tissue during the slabbing step.

The use of long, thin razor blades knives (e.g., disposable microtome blades, MB35, Shandon) will facilitate a smooth cutting stroke and provide optimal surfaces of the slabs. Avoid compression and tissue distortion during this slabbing phase of the sampling. The surface of the cut slabs may yield sections that are selected later in the systematic random sampling hierarchy; therefore these faces must be preserved.

Small structures, such as a gestation-day 14 fetal mouse brains, can be conveniently processed in toto without any need for slabbing prior to processing.

3. Select a systematic random subsample of slabs (see Fig. 12.6.4).

The required frequency of slab sampling (e.g., every slab, every other slab) depends on the structure of interest and how much sequential slabs differ in regard to the particles to be counted. Several published examples featuring detailed analysis of the sampling strategy employed are available for consultation (see Commentary).

Slabs may be inspected with a stereomicroscope to ascertain which slabs contain the structure of interest. The slab before the first and after the last slab believed to contain the structure should also be embedded, as a precaution to ensure that the entire V_{ref} is collected.

Cut and prepare tissue sections

4. Section selected tissue slabs exhaustively (completely) using appropriate histology techniques.

Slabs may be embedded in paraffin or plastic (glycolmethacrylate is preferred; see Support Protocol 1), or cryosectioned. Paraffin-processed tissue is dimensionally unstable and should be avoided if possible. In addition, paraffin-processed tissue is difficult to section at thickness required for the optical disector. The less efficient physical disector (see Alternate Protocol 2) may be required for paraffin sections.

Entire slabs are serially and exhaustively sectioned.

5. Collect an appropriate systematic random subset of the sections on glass microscope slides.

For example every tenth section may be required at this stage of the sampling scheme. The fractionator concept requires that the fraction of the entire structure which is represented by the collected sections be known (hence the requirement that the collected slabs be exhaustively sectioned). Single "nice" histology slides will not suffice. Both the initial and trailing fragments of the individual slabs, as well as the full sections faces must be collected as part of this stage of the sampling hierarchy.

Sections are routinely cut at 30 µm using dry glass knives (i.e., without water-filled boat). 12-mm glass knives can completely span the height of the entire coronal plane of an adult rat brain. Larger glass knives (e.g., Ralph knives) or disposable microtome razor blades (e.g., MB35, Shandon), commonly used for cutting paraffin blocks, can be used for larger specimen blocks.

Hand-operated microtomes are ideal for this type of sectioning (e.g., Sorvall JB-4, Reichert-Jung 820-II). Knife advancement is achieved by manually advancing the knife holder with a fine-advance screw or with automatic advance as appropriate. Do not use the cutting motor on motorized microtomes due to possibility of damage to the block.

a. Grab individual glycolmethacrylate sections with forceps as they are cut. Cut one section at a time (ribbons are not possible). Float and relax sections on a 60°C water bath and pick up onto glass slides. Use normal histology procedures for paraffin and cryosections.

b. Dry completed set of glycolmethacrylate sections immediately on a 70°C heated slide tray for a minimum of 2 hr prior to staining.

Scrupulously clean microscope slides are essential for retaining the majority of sections on the microscope glass slide during the staining process. Acid cleaning (i.e., 5 N HCl, 2 min, followed by rinsing in water) is recommended even for "precleaned" slides; otherwise, an occasional "bad" batch of slides will result in costly loss of entire sets of sections.

Frosted slides are used and labeled with pencil or permanent markers (i.e., xylene- and alcohol-resistant, e.g., Securline MarkerII/Superfrost, Precision Dynamics).

Stain sections

6. Stain a systematic random subset of slides.

For example, in the rat hippocampus, every twelfth section might be examined as part of the fractionator design of the sampling protocol. Since three coronal sections of an adult rat brain can be positioned onto a standard 1 × 3–in. frosted glass slide, every fourth slide (with 3 sections), is stained. Other slides are held in reserve. Use systematic random sampling to determine which slides will be stained.

The selected staining protocol depends upon the target particles and the requirements of a particular study. Water-based stains, immunohistochemical methods, and in situ hybridization have all been used successfully with the optical disector (see Commentary).

Giemsa staining (see Support Protocol 2) works well on glycolmethacrylate-embedded tissue.

Perform systematic random sampling

7. Position the first disector frame over the tissue section without regard to any reference of the tissue section to be counted (see Fig. 12.6.5).

Placement of the disectors is easily achieved by randomly positioning a grid lattice over the image of the region of interest. This stage is also part of the systematic random sampling hierarchy; therefore do not attempt to align the grid with the region of interest. Disectors are placed only at grid points which overlay the region of interest.

8. Determine and record the thickness of the section.

Section thickness is determined by focusing from the top to the bottom of the section and recording the movement of the microscope stage with a linear tracking device. The tracking device should have a linear resolution of 0.5 μm that matches the focal plane of high oil objectives with numerical aperture >1.2. This linear tracking device will also be used to monitor disector heights and guard areas (see below).

Heidenhain produces a tabletop linear tracking device (Microcator, see Gundersen et al., 1988a,b) suitable for this purpose.

With practice, the operator will be able to learn to recognize the top and bottom of section surfaces. Practice can be gained by following capillaries that have been cut in cross-section to the respective surfaces.

9. Establish a guard area by focusing down from the top of the tissue section (Fig. 12.6.2).

This distance is read off from the linear tracking device. The guard area should be at least half the height of the particle of interest. In practice, 4 μm is a reasonable starting point.

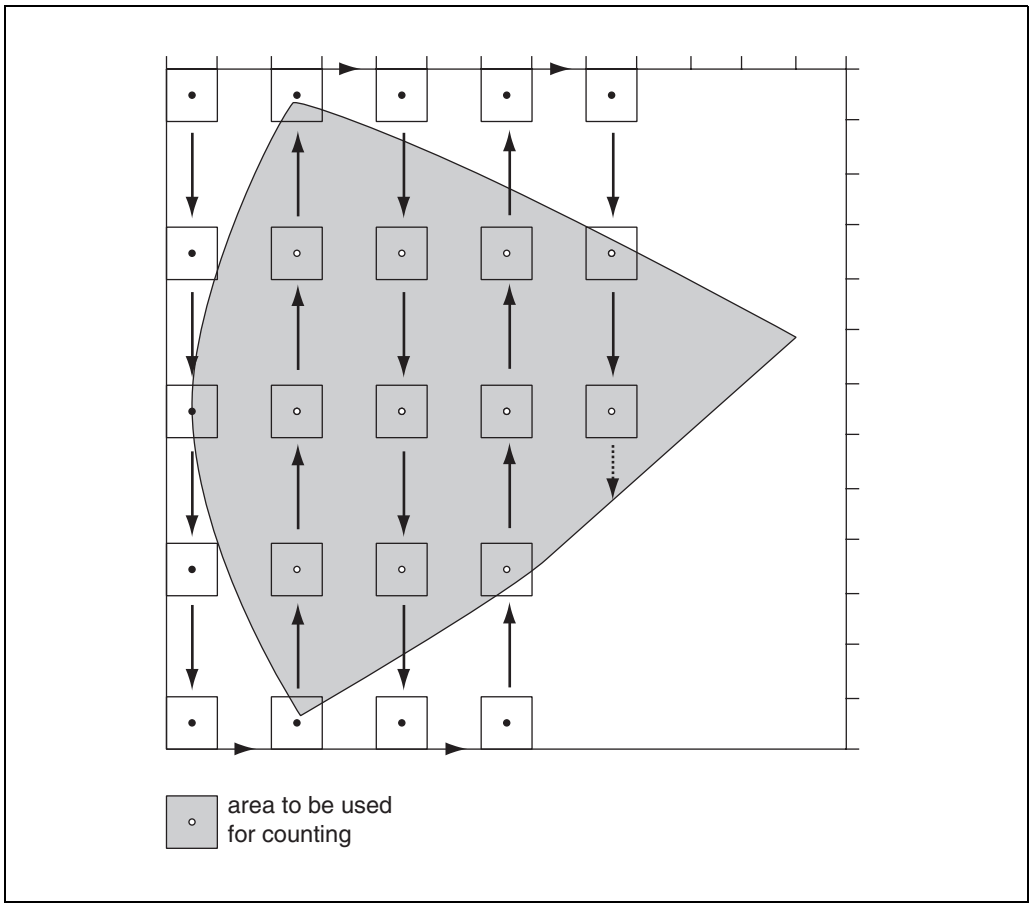

Figure 12.6.5 Systematic stepping across a section. A point is selected outside of the area of the tissue section without any reference to the tissue section (upper left corner). The microscope stage is moved systematically until the region of interest is encountered. At this point the first disector is placed. Additional disectors are placed at each subsequent position that a step encounters in the region of interest.

10. Count particles with the optical disector as they come into focus as the disector frame is "moved" down through the center of the thick section. Stop counting when the guard area at the bottom of the section is encountered (determined by monitoring the linear tracking device).

    Nucleoli make convenient counting particles assuming that there is only one per nucleus. Nuclei can also be used as counting particles.

    In practice, multiple disector frames may be combined so that common and rare objects may be counted simultaneously (e.g., see Bolender and Charleston, 1993).

11. Position all subsequent disectors by continuing the stepping process (Fig. 12.6.5) and repeating step 10.

    Set the spacing and size of disector frames so that between 100 and 200 particles of interest are encountered across the entire set of sections. The size of the disector frame is adjusted so that between one and two particles are encountered in each disector. Pilot projects should be conducted to optimize counting designs.

12. Calculate total particle number by combining total counted with sampling fractions according to the following equation (after West, 1993a,b):

    $N = \Sigma Q^{-} \times t/h \times 1/\text{asf} \times 1/\text{ssf} \times 1/\text{slsf}$

where ΣQ^- is the particle number counted, h = height of optical disector, t = section thickness, asf (area sample fraction) = area disector frame/area of each sampling grid step, ssf (section sampling fraction) = fraction of sections sampled, and slsf (slab sampling fraction) = fraction of slabs sampled.

ESTIMATING TOTAL PARTICLE NUMBER USING N_v,V_{ref}

ALTERNATE PROTOCOL 1

As stated, the optical fractionator represents the preferred method for estimating total particle number, provided that a natural V_{ref} exists. However, in some cases, investigators may be encountering situations wherein artificial structures (i.e., lesions) may vary considerably between animals. Examples would include models for artificial induction of embolic stroke, percussion injury, or lesion produced by direct infusion into the brain (e.g., 6-hydroxydopamine as a model of Parkinson's disease). In these types of models, determining the absolute number of surviving neurons or reactive glia may not be relevant if there is inherent variability in the volume of tissue involved in the lesion. In these cases, estimation of the N_v and V_{ref} may provide more relevant information. The optical fractionator does not provide this information.

It is important to note that reliance on observed N_v, a ratio of the number per volume, may directly lead the investigator to the "reference trap." The reference trap occurs when experimental treatment or outcomes involves changes to the V_{ref}. For example, edema may result in an apparent thinning of neuron (reduction in observed N_v) when no neurons may have actually been lost. This problem can be further confounded by artificial volume changes introduced by fixation, dehydration, embedment, and sectioning artifacts.

Finally, the N_v,V_{ref} method is capable of estimating the total number of particles in an equivalent manner as the optical fractionator. Simply combining N_v and V_{ref} will result in the arithmetical elimination of the volume component of the equation leaving only a number estimate.

For materials, see Basic Protocol.

1. Perform all tissue sampling and preparation (see Basic Protocol).
2. Place optical disectors and count particles with the optical disector as described in the Basic Protocol for the optical fractionator technique. Record number of optical disectors used.

   The total optical disector volume used equals the area of the disector frame multiplied by the height of the disector multiplied by the total number of disectors. N_v equals number of particles (Q^-) divided by the total disector volume.
3. Determine the volume of the sections examined by point counting. Project an image of a point lattice over each tissue section examined and count the number of points over the structure of interest.

   The section volume sampled, V(section), will be determined as:

   $V(sections) = \Sigma P(sections) \times A(point) \times meanT(sections)$

   where $\Sigma P(sections)$ is the total number of points hitting the region of interest, A(point) is the area per point (corrected for magnification), and meanT(sections) is the average section thickness (measured during disector placement).

   In practice, steps 1 to 3 are performed prior to moving to the next tissue section in the systematic random selected sequence. The optical disector is performed under high oil immersion optics. Point counting can be achieved at a much lower relative magnification (e.g., a 4× or 1× low-power objective). The lower-power objectives have a relatively short

working distance and will not contact the immersion oil. However, point counting of the section can be carried out prior to particle counting with the optical disector if desired.

In practice, a separate step of point counting may not be required to estimate the volume of a structure. The distance of the steps utilized for disector placement, and thus area per disector step (note that this is different from the area of the disector frame), is known. Therefore the total number of disectors do, in effect, form a point grid that can also be used for the estimate of the volume sampled.

4. Determine the structure volume by use of the fractionator concept.

   The reference volume, V_{ref}, will be estimated by multiplying the $V_{section}$ estimate by the inverse of the previous sampling fractions:

   $V_{ref} = V_{sections} \times f_{slabs} \times f_{sections}$

   For example, if every other slab was exhaustively sectioned, and if the volume of every 12th section was estimated, the fraction sampled would be 1/2 × 1/12 = 1/24th of the original volume. Therefore the total volume of the structure (V_{ref}) would be 24× the volume of the sampled sections.

   As a general rule of thumb, only ~100 to 200 points, spread across eight or more systematically separated sections of a structure, are all that are required to generate a sufficient estimate of the total volume of a structure.

5. Determine the total number of particles of interest in the structure by combining the N_v estimate (derived from the optical disector) with the volume estimate (derived from point counting and the fractionator).

   Combining N_v with V_{ref} results in the volume component canceling out, producing a pure number estimate.

   $N\ (cells, structure) = N_v \times V_{ref}$

ALTERNATE PROTOCOL 2

ESTIMATING TOTAL PRACTICAL NUMBER USING THE PHYSICAL DISSECTOR

The physical disector represents the first implementation of the disector counting principle. The basic premise is to compare the number of particles of interest that are unique to each of two sequential sections. The sequential section compared may be an adjacent section or represent skipped sections of known interval. Particles that are present in one section (reference section) but not the adjacent section (look-up section) belong to the volume of their respective sections (Fig. 12.6.6). No guard area is required. The optical disector is now the preferred method, due to efficiency and ease of use, for counting cells in the CNS. However, the physical disector still represents a simple method and may be of practical use in counting larger particles that do not require the use of high-powered objectives for unambiguous particle identification (e.g., Popkin and Farel, 1996; Miller et al., 1997), where high-resolution images (achieved by cutting thinner sections) are required for proper identification of particle type, or where special staining methods may not be compatible with the thicker sections that the optical fractionator requires. Finally, the physical disector can be applied to paraffin sections cut at traditional thickness (i.e., 4 to 5 μm).

Additional Materials *(also see Basic Protocol)*

One of the following setups for performing physical disector:

Camera lucida for attachment to microscope, acetate sheets, and water-soluble colored markers

Two projecting microscopes in darkened room

Commercial software/video system for capture and alignment of sequential section tracings (e.g., StereoInvestigator, MicroBrightField; Bioquant, R&M Biometrics)

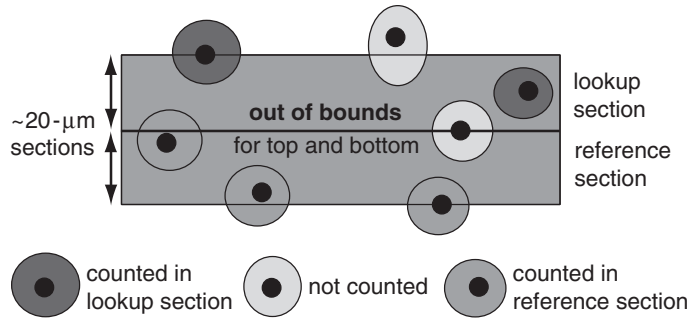

Figure 12.6.6 Physical disector counting rules. Particles unique to the reference section volume are counted (using a disector frame). In the example given here, the two adjacent sections (reference and look-up section) are shown viewed edge wise and stacked upon each other (no disector frame is visible). In practice, these two sections are not stacked on top of each other, but are shown that way here to clarify the counting rules. Nucleoli are the counting particle. The nucleolus that lies on the boundary between the two sections is not counted because its profile would be visible in both the reference and look-up section. Likewise, the nucleolus above the look-up section (which is not counted) would not even be present in the section. Only a cell fragment would be visible and not counted. Reversing the reference and look-up sections results in two disectors, thereby doubling the efficiency.

1. Prepare and section tissue (see Basic Protocol).

   Tissue thickness in the physical disector should be set as a function of at least half the height of the particle of interest.

2. Position disectors in a systematic random manner over the section (see Fig. 12.6.4).

3. Using one of the methods below, perform the physical disector. Count particles of interest in first section. Locate and align corresponding region in adjacent look-up section. Count particles of interest in look-up section. Delete from counts those particles of interest that appear in both sections.

   a. The easiest and least expensive method is to draw outlines of particles on acetate sheets using water-soluble colored markers (e.g., type used for overhead projectors) with the aid of a camera lucida attached to the microscope. First, trace reference marks (e.g., section borders, large vessel) at low power with one color of pen from the reference section. These marks will facilitate lining up the adjacent look-up section. At higher power, outline particles of interest with second color. Shift to look-up tissue section and align reference marks (first color) with new section. Trace particles of interest with third color. Determine particles of interest number by counting outlines of each appropriate color. Do not count outlines of particles that are coincident to both sections (i.e., if outlines overlap).

      Note that two separate disectors have been accomplished by reversing the order of the reference and look-up sections (i.e., the counts of the second and third colors that do not overlap).

   b. Use two projecting microscopes in darkened room (Fig. 4 in Møller et al., 1990) to alternately project images of the two adjacent sections. Mark and count particles of interest in similar manner as described above.

      Sequential sections must be mounted on separate microscope slides. Microscope stages should rotate so as to facilitate alignment of fields.

c. Use commercial software/video systems that allows for capture and alignment of sequential section tracings.

SUPPORT PROTOCOL 1

GLYCOLMETHACRYLATE EMBEDDING

The following support protocol describes steps for embedding brain tissue in glycolmethacrylate. Glycolmethacrylate is the preferred embedment medium in that it is dimensionally stable during tissue processing stages, optically transparent, and facilitates cutting relatively thick sections (20-70 μm) required for using optical disectors.

Materials

Fixed specimen
50%, 70%, 90%, and 95% ethanol
50% (v/v) ethanol/glycolmethacrylate solution
100% glycolmethacrylate (e.g., Jung Historesin; Leica Instruments)
Polymerizer
Embedding molds (e.g., EBH block holder and molds; Polyscience)

1. Dehydrate fixed specimen in graded ethanol series (50%, 70%, 90%, 95%, 95% again) 2 hr in each ethanol concentration, at 4°C.
2. Infiltrate in 50% ethanol/glycolmethacrylate solution for ≥2 hr, 4°C.

   Follow manufacturer's direction for preparing glycolmethacrylate. Glycolmethacrylate and activator are stable for several months if refrigerated.
3. Incubate in 100% glycolmethacrylate twice, each time for ≥8 hr (convenient overnight step), 4°C.
4. Polymerize in molds with labels using fresh 100% glycolmethacrylate following manufacturer's instructions. Allow to polymerize ≥3 hr prior to breaking out of mold.

   Working solution time for glycolmethacrylate is 5 to 10 min after accelerator is added; therefore mix in small batches that can be used in this time interval.

   Commercially available block holders and molds are available for small samples such as rat brain slices (e.g., EBH block holder and molds, Polyscience). Larger molds for larger samples are available (e.g., Super Metal base molds, Surgipath Medical Ind.). Coat these larger metal molds with a thin layer of petroleum jelly (e.g., Vaseline) or equivalent prior to use, to facilitate block release.

   Additional curing time of 8 hr (overnight) is recommended for consistency in sectioning characteristics. Cool large metal molds at −20°C for 1 hr, then invert under hot water to ease removal from mold.

SUPPORT PROTOCOL 2

GIEMSA STAIN PROCEDURE FOR GLYCOLMETHACRYLATE SECTIONS

Giemsa stain will primarily stain the nuclei of all cell types (Iñiguez et al., 1985; Brændgaard et al., 1990; Bjugn and Gundersen, 1993). Neuron nuclei stain moderately dark and characteristically have a single prominent nucleolus. Neurons are further differentiated by substantial staining of their Nissl substance, thereby providing for a distinct cell body shape. Nuclei of astrocytes characteristically stain very pale, have a weakly stained nucleolus, and have little if any cytoplasm stained about the perimeter of their nuclei in their cell bodies. Oligodendrocyte nuclei stain darkly and lack a single distinct nucleolus, but have considerable condensed chromatin. Microglia stain darkly, usually have an irregularly shaped nucleus, and have numerous regions of condensed chromatin. Pericytes and endothelia are also stained, but are distinguishable by their curved shape about capillaries and vessels. The neuropil itself is not stained, but may have a faint pink cast to it. Overall the thick plastic section is optically transparent.

Materials

Giemsa blood staining stock solution (Baker Analyzed, e.g., Fisher)
2% (v/v) acetic acid
50%, 70%, 90%, 95%, and 100% ethanol
100% xylene
High-viscosity mounting medium (e.g., Cytoseal 280, Stephens Scientific)

60°C water bath
Coverslips

1. Mix 10 ml Giemsa stock and 40 ml water and warm to 60°C for a working solution.
2. Add 3 to 4 drops 2% acetic acid.
3. Place slides in working solution, cover, and incubate for 70 min.

   The working solution will gradually cool.
4. Dip slides ten times in 2% acetic acid, then soak 5 min in 2% acetic acid.
5. Dehydrate in graded ethanol (50%, 70%, 90%, 95%, 100%, 100% again), 5 min in each solution.
6. Clear in 100% xylene for 10 min. Repeat.
7. Mount with coverslips.

   Mount coverslips with high-viscosity mounting medium. Edges of some sections may curl during dehydration stage. Use of 2-in. binding paper clips (Boise Express, available from stationary stores) ensures that coverslips will dry flat and tight to sections.

REAGENTS AND SOLUTIONS

Use Milli-Q-purified water or equivalent for all recipes and protocol steps. For common stock solutions, see ***APPENDIX 2A****; for suppliers, see* ***SUPPLIERS APPENDIX.***

Agar matrix

Combine 3 g agar with 100 ml water in a 250-ml Erlenmeyer flask using a stirring rod. Place flask inside a 1000-ml beaker, on stirring hot plate, with sufficient water to form a "double boiler" (dissolved agar will form a clear pale brown solution). Pour agar into mold (medium-sized weighing boats are inexpensive and disposable molds), and let cool on benchtop until cooled but still liquid. Place fixed and buffer-rinsed brain into agar, orient brain, and allow to cool until agar is completely solidified. Trim excess agar so embedded brain fits snugly into cutting guide.

The double boiler prevents scorching of the molten agar to the bottom of Erlenmeyer flask.

Paraformaldehyde in phosphate buffer, 4%

Mix 22.6 g dibasic sodium phosphate in 1 liter of water. Separately mix 12.6 g NaOH in 500 ml water. Heat 170 ml of this sodium hydroxide solution in a fume hood to 60°C (but not over 70°C). Add 40 g paraformaldehyde and stir until dissolved. Add 830 ml dibasic sodium phosphate and mix well. Filter and cool. Adjust pH to between 7.0 and 7.4. Store up to 2 weeks at 2° to 8°C.

COMMENTARY

Background Information

Recent developments in stereology, based on the optical disector and fractionator methods, have revolutionized the ability to perform unbiased cell counts in the central nervous system (Gundersen et al., 1988a,b; Mayhew, 1992; West, 1993a,b). Although only recently gaining in acceptance, these methods are now

increasingly being employed. For example, a search of the term "disector" and "fractionator" on Medline will produce over 300 published manuscripts since 1990. Furthermore, several science journals now have editorial policies that require contributors of stereology manuscripts to employ these new stereological methods or justify why they have not been employed (e.g., *J. Comparative Neurology,* Saper, 1996; *Neurobiology of Aging,* West and Coleman, 1996).

Examples in the literature can readily be found demonstrating counting in plastic sections (Brændgaard et al., 1990; Pakkenberg and Gundersen, 1997), as well as examples of in situ hybridization (West et al., 1996), and immunohistochemical methods (Mouton et al., 1997) for labeling specific cell subsets and synapses using cryosectioned material. Any embedment and compatible staining protocol can be considered for use with these new counting methods. The primary consideration remains that of ensuring that the entire V_{ref}, or a correctly generated known fraction of the V_{ref}, be used to fulfill the requirement of a true fractionator sampling design.

The new methods are design-based

The new stereology methods are design-based as opposed to the more traditional model-based methodologies. No assumptions, based on an unproved model (i.e., it is meaningless to verify a model by use of the same model), are required to generate the cell number estimates. The resulting estimates are free of any biases inherent in the model-based approach. Excellent reviews of the limitation of the model-based methods have been presented (Williams and Rakic, 1988; West, 1993a, 1999; Coggeshall and Lekan, 1996).

The new methods are efficient

The sampling design can readily be evaluated to determine the precision of the number estimate for individuals within the experimental population. The systematic random sampling that is performed at all levels of the tissue sampling hierarchy in effect generates a linear transect through the subject matter (this is why it is important to maintain all samples in the order generated). Matheron's theory of regionalized variables (Matheron, 1971) forms the theoretical basis for a quadratic approximation formula developed by Jensen and Gundersen (Gundersen and Jensen, 1987) for estimating the precision (coefficient of error, CE) of number estimates for individuals. The sampling design therefore readily allows for the assessment of the contribution of the observed coefficient of error (OCE) of the sampling in each individual relative to the observed coefficient of variation (OCV) in the study population. This in turn allows for sampling optimization and a reduced workload at all levels of the design (Gundersen and Jensen, 1987). This analysis of the sampling design should be carried out in the early stages of a new investigation (say after the first five animals have been counted) and the sampling scheme adjusted if indicated. Examples for estimating the OCE and OCV, and suggestions for optimization of sampling designs, are available in the literature (e.g., Brændgaard et al., 1990; West and Gundersen, 1990; West et al., 1991; West, 1999). The goal is to count only enough particles correctly in an individual until the interanimal variation comes to predominate the observed variation (see West, 1993a,b). At this point, additional counting produces little additional information because inherent interanimal variation is not reduced by more sampling.

The systematic random sampling scheme also provides one additional important benefit. The CE associated with systematic random sampling is inversely proportional to the number of samples ($1/N$). The CE associated with independent random sampling, however, is inversely proportional to the square root of the number of samples (i.e., $1/\sqrt{N}$). Far fewer additional samples are required with systematic sampling to improve the precision of the estimate if this is indicated for the study after initial assessment of the sampling design.

The efficiency of the methods is illustrated by the fact that ~400 neurons were required to be counted in the total human neocortex in an 80-year-old man (out of an average of 13.7×10 neurons) to produce an estimate of the total number, which could not be readily improved by additional sampling and counting (Brændgaard et al., 1990; see also Pakkenberg and Gundersen, 1997). Rarely will >100 to 200 cells need to be counted. The example cited above exceeds this number only because the neocortex was divided into four separate regions prior to sampling (parietal, frontal, temporal, and occipital poles).

The reference trap is eliminated

Experimental treatments, disease states, developmental deficits, and trauma in the CNS are all known to produce changes in the apparent volume of tissue and/or the number of cells. Differentiating between a decrease in apparent cell density due to an increase in the reference

volume (e.g., swelling that moves the cells farther apart) from a decrease in apparent cell density due to cell loss (which also results in an increase in space between cells) is problematic and leads directly to the "reference trap" (Brændgaard and Gundersen, 1986). Consideration of numerical density alone is a poor predictor of cell number (Gundersen, 1992; West, 1993a). An excellent example of a reference trap that was avoided using these methods has been presented by Pakkenberg and Gundersen (1988). This problem is further compounded by unknown effects on tissue volume due to tissue processing (fixation, dehydration, embedding, sectioning, staining). For example, fixation of tissue alone was found to produce an average 8% linear loss in monkey brain (van Essen et al., 1984) which translates into a >22% reduction in volume.

The fractionator sampling designs outlined here eliminate problems of volume changes in the V_{ref} during experimental treatment and tissue processing. The N_v,V_{ref} method, which combines the optical disector (which produces N_v estimates) with the fractionator-derived volume estimate (V_{ref}), eliminates the volume component when the final total number is calculated. The optical fractionator never requires a volume estimate. The only requirement for either of these methods is that the entire nonarbitrary structure originally be available for sampling. Small samples of the whole (such as tissue cores, needle biopsy, or randomly collected wedges of tissue), representing an unknown portion of the total structure, can never provide an unbiased estimate of the total number. They can only provide an estimate of the apparent density at that one sample site. Therefore they likely may lead to a reference trap.

The optical fractionator represents the method of choice if it is practical to implement. The volume of the structure is not (and need not be) estimated. The optical fractionator has the potential to be used with embedment media that are prone to tissue volume distortion during tissue processing (e.g., paraffin or frozen sections) thereby opening the door for using this stereological method with procedures not generally compatible with glycolmethacrylate-embedded tissues (West et al., 1996). The optical fractionator, however, is limited in its practical application by the requirement that the entire structure (or a systematic subsample of slabs from the entire structure) be sectioned exhaustively. This may preclude work with larger structures such as the human neocortex or hippocampus. For these larger types of structures, additional subsampling of the slabs can be carried out (Brændgaard et al., 1990; Pakkenberg and Gundersen, 1997), and estimations of the reference volume from sections of the subsampled tissue slabs is possible (Bolender and Charleston, 1993; Charleston et al., 1994).

Alternatively, it has been proposed that single complete sections can be collected from each slab (West and Gundersen, 1990; West, 1993b). In these cases, the volume of the structure is estimated separately by use of the Cavalieri principle (Gundersen et al., 1988a,b). However, this type of volume estimate requires that a careful assessment of tissue shrinkage be carried out because the volume estimate is made on wet tissue slabs prior to dehydration, embedment, and sectioning, whereas the N_v or number estimate is generated from the dehydrated, embedded, and sectioned material. The two estimates are no longer directly linked as they are when the volume estimate is generated from the same set of sections from which the N_v or number estimates are generated (the procedure described in this unit). The assumption that there have been no differential changes in the V_{ref} between the wet and processed tissue represents a divergence from a true design-based method.

Critical Parameters

Slabbing

The plane of slabbing should be selected to match the plane featured in a reference brain atlas. This assists in defining structure boundaries (i.e., V_{ref}) during the counting stage.

Rodent brains can be successfully slabbed in the coronal plane at ~1-mm intervals using commercially available cutting guides, or custom cutting guides can be designed and manufactured (Michel and Cruz-Orive, 1988). In the latter device, embedment of entire brain in 3% agar matrix facilitates uniform slabbing of brain and systematic random determination of the position of the slabs. Position the agar-embedded brain independent of any cutting guide. Systematic random sampling requires that the position of the first slab be random relative to the position of the region of interest. Therefore, the first slab will often be less than the full width of the selected slab width. All subsequent full-width slabs will be systematic.

Complete coronal slabs allow for left and right sides of brain to be available for stereological study. Alternatively, slabs can be accurately separated into left and right hemi-

spheres after slabbing, and one side can be devoted to stereological analysis while the other is available for alternative investigations. It is recommended that right and left hemispheres be separated after this initial slabbing stage so that the entire V_{ref} is accurately separated and preserved in each half of the brain. Freehand gross dissection of a whole brain into left and right hemispheres prior to slabbing often results in slightly unequal separation of hemispheres along the midbrain structures, thereby violating the V_{ref} concept.

Embedding

Tissue slabs shrink considerably during paraffin embedment, and tissue sections expand as a function of water temperature during "relaxing" when collected onto a water bath. These extreme dimensional changes may lead to a violation of the V_{ref} concept, especially when assuming that they are equivalent across different treatment groups. Relatively small linear dimensional changes translate into relatively large apparent density changes for particles when converted into three-dimensional space. These dimensional changes can easily mask small treatment effects. However, it should be noted that a true fractionator design can overcome the dimensional instability problem of paraffin-embedded material.

Glycolmethacrylate is dimensionally stable, optically transparent, permeable to many water-based stains, and can readily be sectioned at 1 to 70 μm. A minimum of 20 μm is recommended for the optical disector. Embedment kits (e.g., Jung Historesin and Jung Historesin Plus, Leica Instruments) and embedment molds and block holders (see Support Protocol 1 for glycomethycrylate directions) are available.

It is crucial to hydrate the glycolmethacrylate block face with water prior to cutting each section; otherwise the tissue will fracture during the cutting stroke. Touch the surface of the block with a wet paint brush and allow water in imbibe into the block face for ~4 to 5 sec before each cutting stroke.

Glycolmethacrylate imbibes water during the sectioning process and swells slightly; therefore sections will usually dry to a slightly thinner height than originally cut. In addition, the outside edges of the block trapezoid will also imbibe water and soften as cutting progresses. For this reason, the edges of the sections may develop a ruffled appearance that may impede setting coverslips after staining. The ruffles can be trimmed away from the edges of the sections with a sharp acetone-cleaned single-edge razor blade prior to drying down the sections onto the slide. Use of a stereomicroscope facilitates this step. The relatively thick sections are very robust and can tolerate considerable handling.

Troubleshooting

Histology

It is not anticipated that there will be any problems encountered in the preparation of tissues for the sample. Virtually all of the procedures described in this unit represent variations on standard histological methods (e.g., paraffin embedding, cryosections, plastic embedding) and therefore are not unique to the stereological counting procedures that are the focus of this unit. If problems are encountered with histology procedures, consult any proficient histology laboratory for fundamental advice.

The one procedure that may be somewhat unique to the stereology protocol is the cutting of relatively thick plastic sections on a standard microtome. If problems are encountered in cutting 20- to 70-μm sections, it is usually the result of not wetting the block face sufficiently with water or not allowing sufficient time for the water to be imbibed into the tissue block. Sections should cut easily. Sections that are too dry when cut will contain shattered tissue, and a noticeable "crunching" sound will be heard during the cutting stroke. Glycolmethacrylate without tissue present will cut easily. It is the infiltrated, embedded tissue that must be softened by the water. In practice, this is accomplished by wetting the entire block face.

Sampling efficiency

The method for deterimining the correct sampling intervals to produce results with sufficiently small sampling error (OCE) is described in the Basic Protocol. The goal is to sample just enough (and thereby reduce the workload) so that the observed variance which predominates is due to true individual variance and not to sampling error related to insufficient sampling. An example of the method for determining sampling efficiency for the optical fractionator method is presented in Table 12.6.1 and is based on the method of West et al. (1991). A spreadsheet template can easily be constructed to perform the calculation for each individual. The goal is to sample enough to produce an OCE for the individual that is less than half of the observed group variation for the group in which that individual belongs. Once this level

Table 12.6.1 Estimating Sampling Efficiency

Section	Q^-_1	$Q^-_1 \times Q^-_1$	$Q^-_1 \times Q^-_{1+1}$	$Q^-_1 \times Q^-_{1+2}$
1	5	25	55	80
2	11	121	176	99
3	16	256	144	320
4	9	81	180	207
5	20	400	460	60
6	23	529	60	276
7	3	9	36	48
8	12	144	192	348
9	16	256	464	464
10	29	841	841	1276
11	29	841	1276	957
12	44	1936	1452	968
13	33	1089	726	297
14	22	484	198	—
15	9	81	—	—
SUM	$\Sigma Q^-_1 = 281$	A = 7093	B = 6269	C = 5400

has been achieved for the individual, improvement of the estimate for the group mean (if desired) is achieved by increasing group number and not by additional work (counting) for the individual group members. Initially, in a new study, it is recommended that a higher rate of sampling be employed (i.e., systematically collect more sections), but particle number be estimated using a smaller fraction of collected sections. For example, collect every third section but perform particle counting on every ninth section. Perform sampling analysis and increase section frequency for counting if indicated.

The coefficient of error (CE) of the sum of the particles counted can be calculated using Equation 12.6.1. The data of estimated sampling efficiency given in Table 12.6.1 produces an estimated CE of 0.041.

$$\begin{aligned} \mathrm{CE}\Sigma Q^- &= \frac{\sqrt{(3\mathrm{A} + \mathrm{C} - 4\mathrm{B})/12}}{\Sigma Q^-} \\ &= \frac{\sqrt{(3\times 7093 + 5400 - 4\times 6269)/12}}{281} \\ &= 0.041 \end{aligned}$$

where CE is the coefficient error. ΣQ^- is the sum of the particle number counted.

Anticipated Results

This method should result in an unbiased estimate of the total particle number in a structure. The particles can be cells (e.g., neurons, astrocytes, oligodendrocytes) or particles (e.g., synapses). The N_v/V_{ref} method can also produce a separate volume estimate, but as described, volume estimates on fixed and processed tissue can lead to a reference trap. Unbiased estimates of the total number of particles in an unbiased structure can be used to compare the effects of treatment across groups.

Time Considerations

The amount of time required to process tissues for stereology counting is variable depending on the tissue. Slabbing an entire rodent or rabbit brain requires about 30 min to embed in agar and about 30 min to slab. A primate brain may require 2 hr. If the tissue will be embedded in paraffin, processing through dehydration and infiltration can be achieved in 24 hr. Automatic tissue processors can substantially increase the efficiency of this stage. Tissue embedding in glycolmethacrylate takes a minimum of 4 days, but the actual hands-on time is a few minutes at each step. Simultaneous processing of the tissue from 5 to 10 brains can increase the efficiency of this stage of the operation.

Tissue blocks must be exhaustively sectioned to satisfy the requirements of the fractionator design. Exhaustively sectioning a 1-mm block at 20 µm would produce 50 sections. The sampling design may require that every tenth section be collected. This can be achieved in <2 hr. Exhaustively sectioning a 1-mm glycolmethacrylate-embedded block at 30 µm will produce ~35 sections. Again, assuming every tenth section is collected for sampling, the process requires ~2 hr. Multiply this estimate by the total number of embedded slabs to estimate the total time required for sectioning and collecting samples. Tissue staining may require 1 to 2 hr per set. Multiple small slabs or structures (e.g., entire fetal rat brains) can be embedded in single large blocks to increase efficiency.

The actual counting procedure requires 4 to 6 hr to count neurons in a single region. Additional time allowance should be budgeted if more than one cell type is to be counted. Time should also be budgeted to allow for reasonable breaks for the person doing the counting.

Isolation of Cerebellar Granule Cells from Neonatal Rats

The present unit describes the isolation of cerebellar granule cells from neonatal rats. Primary cultures of rat cerebellar granule cells consist of post-mitotic, glutamatergic neurons that undergo "maturation" in vitro (see Background Information). As a result of this maturation, the granule cells require depolarizing concentrations of extracellular KCl to survive >5 days after isolation. This unit describes isolation of the cells (see Basic Protocol), preparation of culture surfaces (see Support Protocol 1), determining cell numbers with crystal violet (see Support Protocol 2), and preparation of heat inactivated fetal bovine serum (see Support Protocol 3).

NOTE: All protocols using live animals must first be reviewed and accepted by an Institutional Animal Care and Use Committee (IACUC) and must conform to governmental regulations regarding the care and use of laboratory animals.

CAUTION: The cytosine arabinoside and crystal violet solutions are hazardous. See Material Safety Data Sheet for handling guidelines.

PREPARATION OF CEREBRAL GRANULE CELLS

BASIC PROTOCOL

To isolate the neurons, rat pups are sacrificed on postnatal day 8 and the brains removed. The cerebellum is separated from the brain and the meninges are detached. The cerebellum is then minced and the tissue digested with trypsin and deoxyribonuclease I (DNase). The tissue homogenate is suspended in complete Dulbecco's modified Eagle's medium (DMEM) and filtered through a 100-µm nylon mesh. The cells are then pre-plated in a poly-D-lysine coated T-flask to remove astrocytes. After shaking the flask to detach the neurons, the medium containing the neurons is filtered sequentially through 70- and 40-µm nylon mesh and then cells are plated onto culture dishes coated with poly-D-lysine. On day 1 and day 5 after isolation, the cells are treated with the anti-mitotic agent cytosine arabinoside (AraC) for 24 hr to remove any proliferating cells. The culture medium is changed every 3 days and the cerebellar granule cells can be used for experiments 8 days after isolation.

Materials

8-day-old postnatal Sprague-Dawley rats
70% ethanol
Antibiotic DMEM (see recipe)
2.5% (w/v) trypsin solution (e.g., Life Technologies), 4°C
100× DNase solution (see recipe)
Complete DMEM supplemented with 10% (v/v) heat-inactivated fetal bovine serum (see recipe for DMEM; see Support Protocol 3 for heat-inactivated fetal bovine serum)
Crystal violet solution (see recipe)
500× AraC solution (see recipe)

Surgical gloves
165-mm large curved operating scissors
Laboratory pad (VWR)
Animal disposal plastic bags
Curved forceps (114-mm length and 0.8-mm tip width)
115-mm delicate dissecting scissors

Contributed by Jan Oberdoerster
Current Protocols in Toxicology (2001) 12.7.1-12.7.10

Rounded weighing spatula (e.g., VWR)
100-mm an 60-mm sterile tissue culture plastic dishes with and without treatment with poly-D-lysine (e.g., Falcon; see Support Protocol 1)
Dumont forceps
115-mm angled delicate dissecting scissors
50-ml and 15-ml sterile conical tubes (e.g., Falcon)
10-ml and 25-ml sterile serological pipets
37°C water bath
10-ml syringe and 20-G needle
40-, 70-, and 100-µm sterile nylon mesh cell strainers (e.g., Falcon), sterile
75-cm^2 tissue culture flasks treated with poly-D-lysine (e.g., Falcon; see Support Protocol 1)
Inverted compound microscope
Hemacytometer (see Support Protocol 2)
Glass coverslips

NOTE: All solutions and equipment coming into contact with living cells must be sterile and aseptic techniques should be used accordingly.

NOTE: All cultured incubations should be performed in a humidified 37°C, 5% CO_2 incubator unless otherwise specified.

Dissect neonatal rat

1. Wear surgical gloves and gently hold the 8-day-old pup with thumb and forefinger between shoulder blades.

   Postnatal 8-day-old pups should be used. It is convenient to order pregnant time-mated dams from a common commercial supplier. The gestation period of a rat is 20 to 22 days.

   Steps 1 through 9 can be performed at the lab bench. All instruments should be autoclaved using autoclave bags and opened only when needed.

2. Rapidly decapitate pup onto a laboratory pad using large sterile curved scissors. Place body into plastic bag for disposal.
3. Decapitate remaining pups in the litter.

   This should be done rapidly to reduce the time that the brain remains in the cranium.

4. Place all heads onto a fresh laboratory pad and douse with 70% ethanol to reduce potential bacterial/fungal contamination.

   A standard laboratory squirt bottle is useful for gently dousing the heads with ethanol.

5. Discard surgical gloves and replace with a fresh pair.

   Surgical gloves with textured fingertips will enhance dexterity and facilitate steps 6 through 9.

Isolate neonatal rat brain

6. Grasp head with thumb and forefinger at the base of the head and place sterile forceps into the eye-sockets to firmly secure the head.
7. While holding the head in place with the forceps, cut the skin from the base of the skull to the eyes along the midline and then at right angles toward the ears with sterile dissecting scissors.
8. Insert the 115-mm sterile dissecting scissors into the base of the skull and cut along the midline. Cut away the skull flaps to expose the brain.

   Maintain a shallow cutting angle to prevent damage to the brain.

9. Use a sterile weighing spatula to remove the brain and place into a 100-mm tissue culture dish containing 10 ml ice-cold antibiotic DMEM.

   The culture dish should be maintained on ice for the duration of the isolation.

10. Repeat from step 6 until all remaining brains are isolated.

    Pool up to five brains into one 100-mm tissue culture dish.

Dissect neonatal rat cerebella

11. Move the dishes containing the brains into a laminar flow hood.

    Only sterile dissecting instruments should be used in the laminar flow hood.

12. Using a new set of sterile forceps, transfer the brains to new 100-mm tissue culture dishes containing 10 ml ice-cold antibiotic DMEM.

13. Remove one brain and place ventrally into a 100-mm tissue culture dish containing 5 ml ice-cold antibiotic DMEM.

14. Grasp brain with the forcep placed into the forebrain and gently remove the cerebellum by inserting a sterile curved forcep behind the cerebellum and pulling it away from the brain.

15. Transfer the cerebellum into a 60-mm tissue culture dish containing 3 ml ice-cold antibiotic DMEM.

    Pool up to five cerebella in one 60-mm tissue culture dish and maintain on ice.

Prepare cerebellar cells

16. Gently remove the meningial cover from the cerebellum using Dumont forceps and place cerebellum into a 60-mm tissue culture dish containing 3 ml ice-cold antibiotic DMEM.

17. Repeat procedure until all cerebella have been processed.

18. Finely mince the cerebella in the 60-mm tissue culture dish with 115-mm angled dissection scissors.

    Cerebellar pieces should be ~1 mm^2 in size.

Dissociate cells

19. Transfer all the tissues into a 50-ml conical tube with a 10-ml serological pipet and centrifuge 5 min at $1000 \times g$, 4°C.

    Handling of tissue in open tissue culture dishes/tubes should occur only in a laminar flow hood.

20. Carefully aspirate the DMEM and resuspend the pellet in 10 ml antibiotic DMEM containing 0.125% trypsin, 0.2% DNase solution. Incubate the conical tube for 15 min in a 37°C water bath.

    The remaining manipulations of the cells with culture medium (e.g., plating and subsequent "feeding" of the cells) should occur using prewarmed (i.e., ~37°C) culture medium.

21. Triturate the tissue five times using a 20-G needle attached to a sterile 10-ml syringe.

22. Centrifuge 5 min at $1000 \times g$, room temperature, and aspirate the medium. Replace with 10 ml complete DMEM with 10% heat-inactivated fetal bovine serum (DMEM/10%FBS).

23. Using a 10-ml serological pipet, strain tissue thought a 100-µm nylon mesh cell strainer into a new 50-ml conical tube.

Allow astrocytes to attach

24. Transfer the tissue homogenate into a 75-cm^2 tissue culture flask treated with poly-D-lysine (see Support Protocol 1) and incubate 15 min at 37°C.

No more than four cerebella should be plated onto one 75-cm^2 tissue culture flask.

25. Shake the flask back and forth by sliding the flask along a level surface for 1 min to detach the neurons. Remove the medium using a 10-ml serological pipet.

The back and forth motion should be rapid but slow enough so that the serum in the medium does not turn foamy.

Separate neurons

26. Strain the tissue contained in the medium through a 70-µm nylon mesh cell strainer into a new 50-ml conical tube.

27. Using a 10-ml serological pipet, strain tissue through a 40-µm nylon mesh tissue strainer into a new 50-ml conical tube.

Plate cells

28. Count the cells under an inverted compound microscope using a hemacytometer (see Support Protocol 2) by combining 20 µl cells with 20 µl crystal violet solution.

29. Plate cells at a density of 1.7×10^6 cells/cm^2 (i.e., 3×10^6 cells/well of 24-well plate; 48×10^6 cells/60-mm culture dish) onto culture dishes coated with 500 µg/ml poly-D-lysine.

30. On day 1 and day 5 after isolation, treat the cells with complete DMEM/10% FBS containing 10 µM AraC for 24 hr to remove any proliferating cells.

The characteristic "grape clusters" of cerebellar granule cells should be evident under 100× magnification after 6 days in vitro.

31. Maintain cells in complete DMEM/10% FBS in a 37°C, 5% CO_2 humidified atmosphere, and change culture medium every 3 to 4 days.

SUPPORT PROTOCOL 1

PREPARATION OF THE CULTURE SUBSTRATE OF CELL CULTURE PLATES

Cerebellar granule cells require a poly-D-lysine substrate in order to attach to the tissue culture plate. A lower concentration of poly-D-lysine is used to coat 75-cm^2 tissue culture flasks to allow the granule cells to detach after shaking (see step 25).

Materials

100× poly-D-lysine stock solution (see recipe)
Phosphate-buffered saline, pH 7.4, store at room temperature (PBS; *APPENDIX 2A*)

75-cm^2 tissue culture flasks, sterile
10-ml pipets, sterile
36-, 60-, and 100-mm tissue culture dishes, sterile

1. Work in a laminar flow hood and use sterile plates, pipets, and solutions.

2a. *Tissue culture flasks*: Coat 75-cm^2 tissue culture flasks by adding 10 ml of 50 µg/ml poly-D-lysine solution to each flask before start of tissue preparation. Coat one 75-cm^2 tissue culture flask for every 4 pups in the litter.

2b. *Tissue culture plates*: Coat tissue culture plates by adding 500 µg/ml poly-D-lysine solution to each plate before start of tissue preparation. Add 1.5 ml/35-mm culture dish, 3 ml/60-mm culture dish, and 8 ml/100-mm culture dish.

Alternatively, Poly-D-lysine can be added and left on the plates, dishes, or flasks overnight.

3. Wait ≥40 min and then rinse the flasks, plates, and dishes three times with phosphate-buffered saline. Leave the third phosphate-buffered saline rinse in flasks or plates until ready to seed cells.

Do not let the flasks or plates dry between PBS rinses.

DETERMINING CELL NUMBER WITH A HEMACYTOMETER

SUPPORT PROTOCOL 2

Cells must be counted prior to plating in order to ensure proper cell density in culture. Seeding cells at a density that is too high or too low will adversely affect cell viability. Cerebellar granule cells are tightly clustered cells that contain a small amount of cytoplasm. These qualities make cell number evaluation with the traditional trypan blue exclusion technique difficult and thus the use of crystal violet is recommended. The crystal violet solution will disrupt the cell membrane (releasing the clustered cells) and brightly stain the cell nuclei, allowing for facilitated counting of the cells with a hemocytometer.

For materials see Basic Protocol.

1. Place a clean coverslip on the counting area of the hemacytometer (see Fig. A.3B.1).
2. Combine 20 µl cells with 20 µl crystal violet solution in a 0.5-ml microcentrifuge tube.

   Work in the laminar flow hood and use sterile micropipet tips when removing the aliquot of cells.

3. Transfer ~10 µl of the crystal violet/cell solution into the groove on the edge of the hemacytometer chamber and let the solution be drawn under the coverslip by capillary action.

   Do not overfill or underfill chamber.

4. Observe under an inverted compound microscope and focus on the grid lines in the chamber at 100×.

   At this magnification, one of the nine 1-mm^2 squares should be fully visible.

5. Count the cells lying within this 1-mm^2 area. Count cells that are touching the top and left-hand lines of each square but not those on the bottom or right-hand lines.
6. Count at least four squares of the hemacytometer.
7. Each of the 1-mm^2 squares of the hemacytometer contains 0.1 µl solution. Determine cell concentration.

   To determine cell number/ml, count the number of cells present in four 1-mm^2 squares of the hemacytometer and multiply by 5000 [i.e., cell number/ml = cell number in 4 squares × 10,000 × dilution factor (2)/number squares counted (4)].

   CAUTION: *The crystal violet solution is hazardous. Refer to the Material Safety Data Sheet for handling guidelines.*

SUPPORT PROTOCOL 3

HEAT-INACTIVATION OF FETAL BOVINE SERUM

Heat-inactivation of fetal bovine serum is important to destroy heat-labile complement. Degradation of these proteins by raising the temperature of the serum to 56°C for 30 min will ensure that antibody binding will not lyse the cells. Heat inactivation may change the appearance of the fetal bovine serum and result in precipitation. This is normal and does not indicate that the serum has been compromised.

Materials

Fetal bovine serum, qualified (Life Technologies)
56°C water bath

1. Thaw the bottle of fetal bovine serum overnight at room temperature.

   Open serum bottles only in a sterile laminar flow hood.

2. Immerse the fetal calf serum bottle in the 56°C waterbath for 30 min. Swirl the bottle every 5 min to ensure proper mixing.

   The water level should be even with serum level inside the bottle.

3. Allow serum to cool for 1 hr at room temperature and store at 4°C until needed.

   If storing heat-inactivated fetal bovine serum for >3 weeks, dispense into 50-ml aliquots and store at −20°C.

REAGENTS AND SOLUTIONS

Use ultrapure water for all solutions. Filter sterilize solutions that will be used in cell culture. For common stock solutions, see ***APPENDIX 2A****; for suppliers, see* ***SUPPLIERS APPENDIX****.*

Antibiotic DMEM

DMEM (Life Technologies) containing 100 U/ml penicillin and 100 µg/ml streptomycin. Store up to 1 month at 4°C in the dark.

AraC solution, 500×

Make a 5 mM cytosine arabinoside (e.g., Sigma) solution in DMEM (Life Technologies). Dispense in 5-ml aliquots to avoid repeated freeze/thaw. Store up to 6 months at −20°C.

Complete DMEM

DMEM (Life Technologies) supplemented with:
10% (v/v) heat-inactivated fetal bovine serum (see Support Protocol 3)
24.5 mM KCl
50 mM glucose
100 U/ml penicillin
100 µg/ml streptomycin
Store up to 3 weeks at 4°C in the dark

Crystal violet solution

Make a 0.1 mg/ml crystal violet (e.g., Sigma) solution in 0.1 M acetic acid. Store up to 6 months at room temperature and protect from light.

DNase solution, 100×

Make a 2% (w/v) deoxyribonuclease I (e.g., Sigma) solution in antibiotic DMEM (see recipe). Dispense in 5-ml aliquots to avoid repeated freeze/thaw. Store up to 6 months at −20°C.

Poly-D-lysine stock solution, 100×

Make a 50 mg/ml poly-D-lysine (M.W. 150,000-300,000; e.g., Sigma) solution in ultrapure water. Store up to 6 months at 4°C in the dark.

Dilute 100× stock solution 10-fold for coating tissue culture plates or dishes or 100-fold for coating 75-cm^2 tissue culture flasks for preplating.

COMMENTARY

Background Information

Cerebellar granule cells are interneurons in the granular layer of the cerebellar cortex that represent the most numerous neuronal population in the cerebellum. The short dendrites of the cerebellar granule cells are located within the granular layer and form synapses with one of the afferent systems of the cerebellum, the glutamatergic mossy fibers. This mossy fiber input exerts a neurotrophic effect on the granule cells during development. Granule cells are the only excitatory neurons whose cell bodies are located within the cerebellar cortex and their axons project into the molecular layer of the cerebellar cortex where they bifurcate into two branches, forming parallel fibers. These parallel fibers travel to the long axis of the folium to form excitatory synapses with Purkinje cells, which act as modulators and are the only outlet for processed information from the cerebellar cortex.

As mentioned above, rat cerebellar granule cells are glutamatergic neurons. Five days after isolation, the granule cells require either K^+-induced membrane depolarization or a glutamate-receptor agonist [e.g., *N*-methyl-D-aspartate (NMDA)] to remain viable in culture (Balazs et al., 1988; Copani et al., 1995; Marini et al., 1999). This time-dependent requirement for membrane depolarization has been suggested to represent a maturation of the granule cells (Burgoyne et al., 1993; D'Mello et al., 1994; Copani et al., 1995). In the absence of depolarizing conditions that apparently mimic the in vivo stimulation by glutamatergic mossy fibers (Balazs et al., 1988), mature cerebellar granule cells undergo apoptotic cell death (D'Mello et al., 1994; Copani et al., 1995; Oberdoerster and Rabin, 1999). When maintained in complete medium (i.e., supplemented with KCl and fetal bovine serum), however, granule cells differentiate and acquire the morphology, biochemistry, and electrophysiology of mature neurons in vivo (Levi et al., 1984; Gallo et al., 1987; Cull-Candy et al., 1988; Wyllie and Cull-Candy, 1994). Mature granule cells are sensitive to excitotoxicity and changing of the culture medium has been reported to cause granule cells to undergo NMDA receptor-mediated excitotoxic cell death (Schramm et al., 1990), possibly due to glutamate present in the serum-supplemented culture medium. The authors, however, have not experienced this excitotoxicity with cultures (Oberdoerster and Rabin, 1999; Oberdoerster et al., 2000). In fact, although the first week in culture is typically characterized by a continual dying of cells, the granule cell population subsequently stabilizes and provides a uniform population of cells for up to 3 weeks in culture (Oberdoerster and Rabin, 1999).

The use of primary neuronal cultures instead of clonal cell lines has both advantages and disadvantages. The advantage of primary neuronal cultures is that the cells are derived from normal tissue as opposed to neuronal tumors (e.g., SY5Y neuroblastoma; LA-N-5 neuroblastoma). Thus, cerebellar granule cells have a normal neuronal physiology in vitro and, as pointed out previously, take on the morphological, biochemical, and electrophysiological characteristics of mature neurons. A disadvantage of primary neuronal cultures is that they are more expensive and more time consuming to produce compared to clonal cell lines. Another potential advantage of clonal cell lines is that these cultures consist of a more uniform population of cells than primary cultures. The purity of cerebellar granule cell cultures, however, is excellent. When isolated from rat pups on postnatal day 8, these cultures consist of an almost pure population of granule cells. The reason for this high purity is, at least in part, that granule cells are by far the most abundant neuronal population in the cerebellum. Furthermore, in the rat, proliferation and differentiation of cerebellar granule cells occurs postnatally and, as undifferentiated neurons survive better than differentiated neurons when seeded in culture, the viability of the neurons is enhanced. As primary cultures of rat cerebellar granule cells are post-mitotic, it is important to treat the cultures with the antimitotic agent AraC to eliminate proliferating cells such as astrocytes or fibroblasts. If the cultures are not treated with an antimitotic, the neurons can

Table 12.7.1 Potential Problems Associated with Production of Cerebellar Granule Cell Cultures

Problem	Possible cause	Solution
Medium contains viscous clumps after centrifugation	No DNase I added	Add fresh DNase I and incubate for ≥15 min at 37°C
Low cell yield prior to plating	Cerebellum not minced thoroughly prior to sieving through cell strainers	Thoroughly mince cerebellum. Increase trituration though 20-G syringe needle.
Low cell yield/viability after plating	No poly-L-lysine coating	No solution
	Prolonged dissection time	Decrease dissection time and keep tissue on ice whenever possible
Cell viability decreases after 5 days in vitro	Lack of depolarizing conditions	Add 24.5 mM KCl to cell culture medium
Floating/nonadherent cells	Contamination	Discard cells
	Old cultures	Use cultures within 2-3 weeks
Presence of proliferating cells	Cultures not treated with AraC	Treat cells with AraC on days 3 and 5 after isolation
	No preplating during isolation	Preplate cells on tissue culture flask to remove proliferating cells
	Meninges not removed during isolation	Thoroughly remove meninges during dissection

rapidly be overgrown by proliferating cells. It should be noted, however, that AraC has been shown to be cytotoxic to granule cells (Dessi et al., 1995; Saunders et al., 1997) and thus, exposure to AraC should be limited to a total of 48 hr.

Critical Parameters and Troubleshooting

A number of potential problems associated with the production of primary cultures of rat cerebellar granule cells are presented in Table 12.7.1.

Dissection of tissue

Neonatal rats (i.e., 8 days old) should be used. Rapid removal of the brains into ice-cold sterile medium is critical for good neuronal viability in vitro. The pups should be sacrificed and brains removed one at a time until the researcher is confident that the brains will not remain in the cranium for >5 to 10 min after decapitation. The tissue should be maintained on ice until enzymatic digestion with trypsin and DNase. Even though the two AraC treatments will reduce the presence of proliferating cells, thorough removal of the meningial layer is important to minimize fibroblast contamination.

Cell dissociation and maintenance in vitro

The tissue must be thoroughly minced prior to enzymatic digestion with trypsin and DNase to ensure a maximum surface area. The culture medium should not be supplemented with serum until after the enzymatic dissociation as serum contains trypsin inhibitors. Preplating of the cultures onto 75-cm^2 tissue culture flasks coated with low concentrations of poly-D-lysine (i.e., 50 µg/ml) is critical in removing contaminating astrocytes and ensuring that the neurons can easily be dislodged by shaking. A poly-D-lysine substrate (i.e., 500 µg/ml) is important for efficient granule cell plating. In addition to 10% heat-inactivated fetal bovine serum, cerebellar granule cells maintained in vitro require depolarizing concentrations of extracellular KCl (25 mM) and high glucose (50 mM; i.e. complete DMEM) to survive >5 days in vitro.

Contamination

Contamination usually involves fungi or bacteria. Long fibrous processes that may appear as mats in the culture dish typically characterize fungal contamination. Bacterial contamination, on the other hand, usually alters the color of the culture medium overnight resulting in a yellow appearance (i.e., a change in pH).

The culture medium may also appear yellow if the medium is not changed every 3 days or if the cells are plated at a very high density. To identify bacterial contamination, examine the culture with a microscope (with a 200× objective). Contaminating bacteria will appear as floating round or rod-shaped objects that are smaller than the granule cells. The presence of penicillin/streptomycin in the culture medium should reduce bacterial contamination; however, careful handling of the cells and the use of a laminar flow hood will minimize the likelihood of fungal/bacterial contamination. Further, any bottles containing solutions, pipet tips, or other disposables that are used for tissue culture should be labeled as such and should only be opened in the laminar flow tissue culture hood. If contamination of the cultures is detected, the contaminated dishes should immediately be discarded and the laminar flow hood and tissue culture incubator thoroughly cleaned and wiped down with 70% ethanol. In addition, all solutions (e.g., culture medium) that were used in maintaining the contaminated cultures should be discarded or filter sterilized.

Contamination of the granule cell cultures can also be due to the presence of impurities such as non-neuronal cells (i.e., glial cells or fibroblasts). These cells can be identified as rapidly proliferating cells that, unlike granule cells, appear flat in culture. In addition, the contaminating cells are usually significantly larger that the granule cells and often form foci of dividing cells. As mentioned previously, even though the two AraC treatments will reduce the presence of proliferating cells, thorough removal of the meningial layer and preplating the cells in poly-D-lysine coated flasks is important to minimize fibroblast and astrocyte contamination. Further, even though the majority of neurons in these cultures are granule cells, GABAergic interneurons (i.e., stellate, basket cells) account for a small number of contaminating cells. These GABAergic neurons, however, are selectively lost during the first 8 days in vitro (Aloisi et al., 1985). Identification of cerebellar granule cells in vitro is described in Anticipated Results.

Anticipated Results

Primary cultures of rat cerebellar granule cells isolated as described above should have a rounded, "cluster of grapes" appearance with long processes extending in all directions after ~5 to 6 days in vitro. Cell yields should be ~2.1 $\times 10^7$ cells per cerebellum. The number of cells will decrease for the first week in vitro, after that, the population of cells will stabilize. After ~7 days the number of cells remaining will be ~30% to 35% of the initial plated amount (Oberdoerster and Rabin, 1999). This initial loss of cells has been reported by others (Fields et al., 1982; Pantazis et al., 1993) and probably reflects the trauma of isolation as well as the exposure of the cultures to AraC.

Time Considerations

The time required for the preparation of primary cultures of rat cerebellar granule cells is ~5 to 6 hr. The time required for changing of the medium every 3 days will vary depending on the number of tissue culture plates but may range from 30 min to 2 hr.

Measurement of Glial Fibrillary Acidic Protein

A characteristic feature of toxicant-induced injury of the developing or adult central nervous system is astrocytic hypertrophy at the site of damage (Norton et al., 1992; O'Callaghan, 1993; Norenberg, 1994; O'Callaghan et al., 1995). Astrocytic hypertrophy, also known as reactive gliosis or simply gliosis, is characterized by an accumulation of glial filaments, of which glial fibrillary acidic protein (GFAP) is the principal protein constituent (Eng, 1988). Thus, an increase in the brain concentration of GFAP serves as a biochemical indicator of neurotoxicity. In aggregate, the results of a number of studies show that a large variety of toxic insults of the CNS result in an increase in GFAP; moreover, these effects are dose-related, they correspond to regions of neural damage and they can be observed in the absence of overt cytopathology (O'Callaghan, 1993; O'Callaghan et al., 1995).

This unit describes a single method for assaying the concentration of GFAP contained in detergent homogenates of brain tissue. The method presented includes a protocol for tissue homogenate preparation (see Support Protocol 1), a protocol for assaying total brain protein in detergent homogenates (see Support Protocol 2), and a protocol for a GFAP sandwich ELISA (see Basic Protocol). Although other protocols exist for assaying GFAP (see Commentary), the sandwich ELISA is the method of choice due to its simplicity, cost, speed, and high-throughput.

GFAP SANDWICH ELISA

BASIC PROTOCOL

The GFAP sandwich ELISA is suitable for assaying the concentration of GFAP present in homogenates of brain tissue. This method has successfully been applied to analysis of at least the following species: mouse, rat, guinea pig, dog, monkey, man, chicken, pigeon, trout, and cod. Because GFAP is evolutionarily conserved, it is likely that this assay can be very broadly applied across many species. The assay does not require preparation of any special materials or reagents; all components are available from commercial sources at modest cost. However, it is dependent on the use of specific, commercially available antibody reagents. The 96-well microtiter plate format lends itself to processing large numbers of samples, and it makes the assay suitable for automation with a variety of liquid handling systems. It takes a minimum of 5 hr to process a single 96-well plate after preparation of the tissue homogenates (Support Protocol 1).

Materials

Bovine GFAP (American Research Products)
PBS/Triton: PBS containing 0.5% (v/v) Triton X-100 (Bio-Rad)
Sample: brain homogenate from treated animal (Support Protocol 1)
Rabbit anti-glial fibrillary acidic protein antibody (see recipe; Dako, cat. #Z0334)
Phosphate-buffered saline (PBS; e.g., Pierce; *APPENDIX 2A*; see recipe)
Blocking solution (see recipe)
Detection antibody solution (see recipe) consisting of mouse anti-glial fibrillary acidic protein monoclonal antibody (clone GA5; Oncogene Research Products) and alkaline phosphatase–conjugated anti-mouse IgG (Jackson Immuno Research, cat. #315-055-003)
Blocking solution containing Triton
Alkaline phosphatase substrate kit (e.g., Bio-Rad) containing:
  Alkaline phosphatase substrate: *p*-nitrophenylphosphate tablets (see recipe)
  5× diethanolamine buffer
0.4 N NaOH (e.g., Labchem)

Contributed by James P. O'Callaghan
Current Protocols in Toxicology (2002) 12.8.1-12.8.12

Vortex mixer or ultrasonic cell disruptor (e.g., PGC with 2-mm probe)
96-well flat-bottom, microtiter plates (e.g., Immulon 2, Dynatech)
Microtiter plate reader, 405 nm

NOTE: Detergents act as wetting agents, therefore, more than a single use of a pipet tip with SDS- or Triton X-100-containing samples can lead to carry-over errors. Thus, it is recommended to use a single pipet tip per sample and to withdraw the sample only a single time per tip.

Prepare standards

1. Prepare a standard, a brain homogenate (Support Protocol 1) from control, untreated animals.

   This standard should be prepared from the same species that was used to prepare the samples to be assayed for GFAP because GFAP immunoreactivity with a given set of immunodetection reagents will differ among different species. A large number of standards can be prepared in advance from a single "pool" of a 1% SDS homogenate prepared as described in Support Protocol 1. This homogenate can be aliquoted (50 µl) and stored frozen at −70°C prior to use. Thus, the GFAP standard essentially consists of a control sample. This is preferable over using a pure GFAP standard because using control tissue as a standard obviates any influence of the tissue "matrix" on the assay performance. Moreover, where absolute values of GFAP per total tissue protein are not required, data simply can be presented as arbitrary units of GFAP immunoreactivity.

   If it is deemed necessary to express the data in units of GFAP per unit of total protein, aliquots of a 1% SDS homogenate should still be used as a GFAP standard. This can be accomplished by "standardizing the standard" with addition of a known amount of pure GFAP to the 1% SDS homogenate (i.e., an internal standard; O'Callaghan, 1991). Immunoreactivity values generated from standard curves of the GFAP "spiked" homogenate and the homogenate alone then can be used to determine the concentration of GFAP in the homogenate.

   For analysis of GFAP in regions of rat brain, the authors routinely use aliquots of a hippocampal homogenate as a standard. It contains ~2.5 µg GFAP/mg total protein. Other species (e.g., mouse) contain different levels of GFAP in hippocampus.

2. To prepare dilutions of the GFAP standard, remove a tube of the GFAP standard from the freezer, thaw it at room temperature, and vortex or sonify it prior to dilution. With a rat hippocampal homogenate as a typical standard (~2.5 µg GFAP/mg total protein), use the total protein value for this homogenate (~10 mg/ml) to prepare a standard curve in PBS/Triton.

   For rat hippocampal homogenate, the protein values for the standard curve should be between ~0.25 to 10 µg/100 µl/microtiter plate well (i.e., 0.25, 0.5, 1.0, 2.5, 5.0, 7.5, 10 µg total protein/100 µl). Table 12.8.1 shows an example of dilutions needed to prepare a standard curve from a homogenate of rat hippocampus (hippocampus std.). Typically, standards are run in duplicate.

Prepare sample

3. Remove sample from the freezer, thaw at room temperature, and vortex or sonify prior to dilution.

4. Prepare dilutions of the sample in PBS/Triton to a concentration of ~10 µg total protein/100 µl.

   Samples high in GFAP (e. g., cerebellum) may need to be diluted to a concentration of 5 µg total protein/100 µl of PBS/Triton. Samples low in GFAP (e.g., striatum) may need to be diluted to 20 µg total protein/100 µl of PBS/Triton. These dilution factors are determined empirically. The best practice is to prepare multiple dilutions of each sample to ensure that

Table 12.8.1 GFAP Standard Curve Preparation

Tube no.	Total protein (µg)/100 µl/well (ng GFAP)	Hippocampus std. (10.34 mg/ml) added (µl)	Amount transferred for dilution (µl)	PBS/Triton
1	10 (25.00)	29		2971
2	7.5 (18.75)		2063 from tube no. 1	687
3	5.0 (12.50)		1833 from tube no. 2	917
4	2.5 (6.25)		1000 from tube no. 3	1000
5	1.0 (2.50)		800 from tube no. 4	1200
6	0.5 (1.25)		1000 from tube no. 5	1000
7	0.25 (0.625)		700 from tube no. 6	700

optical density readings for a given sample fall on the linear portion of the standard curve. Typically, samples (like standards) are run in duplicate.

Coat microtiter plates

5. Coat an Immulon-2 96-well flat-bottom microtiter plate with rabbit anti-GFAP antibody. Add 1.0 µg total immunoglobulin protein/100 µl PBS/well.

   Rabbit anti-GFAP antibody is used as the "capture" antibody for the sandwich ELISA.

   For each 96-well plate, ~25 µl of anti-GFAP (Dako) in 10 ml of PBS is needed.

6. Incubate the plate at 37°C for 1 hr.

   This coating step may be done at the beginning of the assay or it may be done the night before with storage in coating antibody overnight at 4°C. Perform all other incubation and reagent addition steps at room temperature.

7. Empty the plate into a sink and tap (upside down) on absorbent paper to remove excess liquid.

   This latter procedure is important to eliminate the possibility of any reagent carry-over between steps.

8. Wash plates four times with 200 µl/well PBS, tapping and blotting between each wash.

Block plates

9. Block 1 hr with 100 µl/well blocking solution.

10. Empty plate, tap on absorbent paper to remove excess liquid.

Perform sandwich ELISA

11. Load diluted standard curve and samples in a volume of 100 µl/well. Incubate for 1 hr.

    The template below (Table 12.8.2) is an example of a typical 96-well microtiter plate layout for GFAP standards and unknowns.

12. Empty plate and tap on absorbent paper.

13. Wash four times with 200 µl/well PBS/Triton, tapping and blotting between each wash.

14. Incubate for 1 hr in 100µl/well of a detection antibody solution consisting of monoclonal anti-GFAP antibody diluted 1:500 and alkaline phosphatase conjugated anti-mouse IgG diluted 1:3000 in blocking solution containing Triton.

Table 12.8.2 Microtiter Plate Template

	Standards		Samples									
Row	1	2	3	4	5	6	7	8	9	10	11	12

The assay is based on the use of the monoclonal antibody as a "detection" reagent and the alkaline phosphatase conjugate to bind to the detection antibody and generate a colored reaction product proportional to the amount of antigen (GFAP) present in the samples. Substitution of antibodies from other vendors may not yield suitable results.

15. Wash four times with 200 µl/well PBS/Triton. Tap and blot between each wash.

Visualize results

16. Add 100 µl/well alkaline phosphatase and substrate and incubate for 20 min.
17. Stop reaction with 100 µl/well of 0.4 N NaOH.
18. "Pop" any bubbles in the plate wells with a needle or pipet tip to ensure uniform and accurate readings of standard and sample optical density (OD). Read plate at 405 nm in a microtiter plate reader.

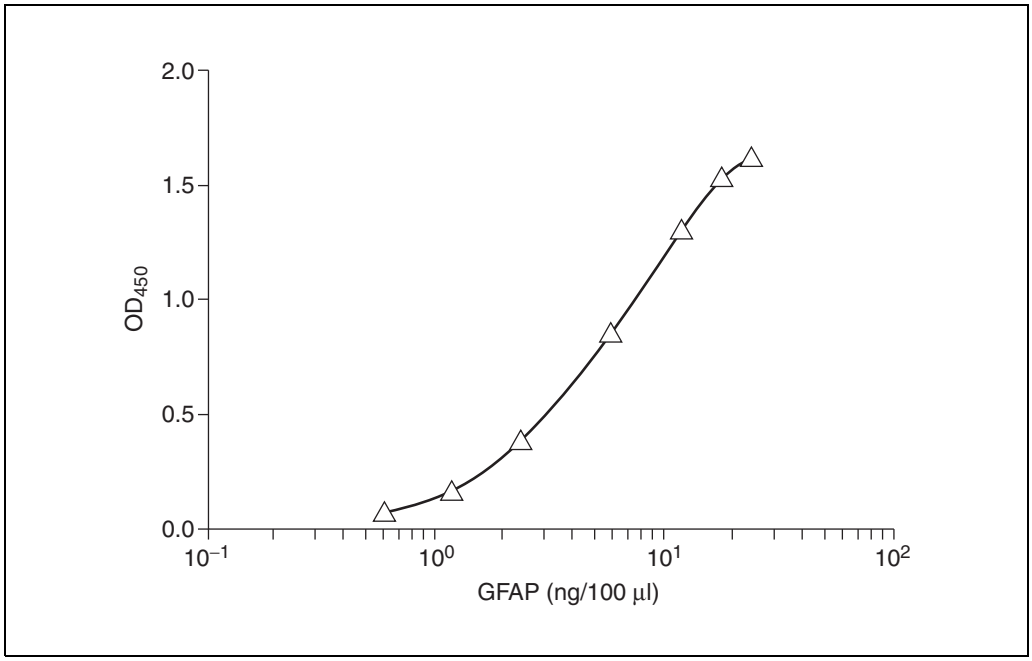

Figure 12.8.1 Sample GFAP standard curve. GFAP values in nanograms correspond to levels found in 0.25 to 10 µg total hippocampal homogenate protein. Dilutions of this homogenate were used to construct the GFAP standard curve shown.

Table 12.8.3 Sample Values for GFAP Standard Curve

Standard	Total protein (μg) (ng GFAP)	Well	OD	Mean	Std. dev.[a]	CV[a]
Blank		A1	0.001	0.0	0.001	0.0
		A2	–0.001			
STD01	10 (25.00)	B1	1.694	1.632	0.087	5.4
		B2	1.570			
STD02	7.5 (18.75)	C1	1.537	1.543	0.008	0.5
		C2	1.549			
STD03	5.0 (12.50)	D1	1.295	1.314	0.027	2.1
		D2	1.334

		E2	0.861			
STD05	1.0 (2.50)	F1	0.386	0.386	0.000	0.1
		F2	0.386			
STD06	0.5 (1.25)	G1	0.175	0.164	0.016	10.0
		G2	0.152			
STD07	0.25 (0.625)	H1	0.072	0.076	0.006	7.6
		H2	0.080			

[a]Abbreviations: CV, coefficient of variation; std. dev., standard deviation.

19. Calculate the GFAP concentration in each of the samples by comparing the sample OD value to those obtained for the linear portion of the GFAP standard curve.

    Software programs linked to specific plate readers should be programmed to plot OD versus GFAP values in linear versus log-linear fashion. Typically, the authors utilize the 4-parameter curve fit equation and generate curves as shown in Fig. 12.8.1 and Table 12.8.3. Most programs allow for automatic subtraction of blanks and incorporation of dilution factors.

    Data are expressed as microgram GFAP per milligram total protein or, if the absolute amount of GFAP in the standard is not available, data are expressed as GFAP-like immunoreactivity per milligram total protein. Total protein concentration in the samples is estimated from the total protein assay described in Support Protocol 2. Data can also be expressed on the basis of tissue wet weight (microgram GFAP per gram wet weight or GFAP immunoreactivity per gram wet weight). Although this approach permits elimination of the total protein assay, the authors find that the GFAP values obtained are slightly more variable.

BRAIN TISSUE PREPARATION

SUPPORT PROTOCOL 1

This protocol describes the procedure for preparing brain tissue as standards or samples for subsequent analysis of GFAP by sandwich ELISA (Basic Protocol). This procedure does not describe or recommend a specific approach for dissecting brain tissue. It is noted, however, that reliable dissections are essential for obtaining reproducible results with the GFAP ELISA (see Commentary).

NOTE: All protocols using live animals must first be reviewed and approved by an Institutional Animal Care and Use Committee (IACUC) and must follow officially approved procedures for the care and use of laboratory animals.

Materials

Control or treated animal
1% (w/v) SDS, 85° to 95°C
Dissecting instruments
Ultrasonic cell disruptor (e.g., PGC with 2-mm probe)

1. Sacrifice animal by an approved method and remove the brain as rapidly as possible.

   Animals should be sacrificed one at a time to prevent tissue degradation.

2. Dissect brain regions.

   If a number of regions are to be dissected, this process can be aided by keeping the brain firm on a cold plate (e.g., Thermoelectrics cold plate, Aldrich Chemical Co., or simply an inverted petri dish placed on ice) maintained at ~4°C. Rat or mouse brains can be dissected free hand into ten to fifteen region within ~10 min. This number of regions can be prepared on a cold plate or at room temperature without degradation of GFAP as assessed by immunoblot analysis. All brain regions can be stored frozen indefinitely in capped microcentrifuge tubes at this step in the protocol, or they can be homogenized immediately.

3. Weigh and homogenize the dissected brain parts. Tare an appropriately labeled microcentrifuge or other suitable storage tube. Place individual brain regions in a tube, obtain the weight, and immerse the tissue in 10 vol hot (85° to 95°C) 1% (w/v) SDS.

   For example, 0.1 g of tissue would be immersed in 1.0 ml of SDS.

4. While the SDS is still hot, homogenize the tissue by sonification with a 2-mm ultrasonificiation microprobe.

   A motor-driven Teflon pestle/glass homogenizer can be substituted for an ultrasonification device to homogenize most brain areas. This method is not as desirable as sonification, however, because it is much slower and often does not result in complete homogenization.

5. Store samples frozen at −70°C prior to assay.

   Samples prepared and stored in this manner retain their GFAP content for ≥5 years.

SUPPORT PROTOCOL 2

ASSAY FOR TOTAL PROTEIN

This protocol describes the procedure for assaying the concentration of total protein in the SDS-homogenates. The procedure described is essentially the bicinchoninic acid (BCA) method described by Smith et al. (1985), which is available in kit form. To assay total protein concentration of the SDS homogenates the assay must be compatible with 1% SDS. Use of the BCA assay is not an absolute requirement as other detergent-compatible methods are available (e.g., Bio-Rad DC protein assay). Bovine serum albumin (BSA) is used as the protein standard in the described procedure. Other protein standards can be substituted.

Materials

Bovine Serum Albumin (BSA), RIA grade, fraction V (Sigma)
1% (w/v) SDS (Bio-Rad)
Brain homogenates (Support Protocol 1)
BCA Protein Kit (Pierce) containing:
  Solution A
  Solution B

96-well microtiter plates
Microtiter plate reader, 562 nm

NOTE: Detergents act as wetting agents, therefore, more than a single use of a pipet tip with SDS-containing samples can lead to carry-over errors. Thus, it is recommended to use a single pipet tip per sample and to withdraw the sample only a single time per tip.

1. Prepare total protein standard stock as a 1 mg/ml solution of BSA in 1% (w/v) SDS.

   Aliquots (600 µl to 1.0 ml) of this standard can be stored frozen at −70°C for future use. Thaw as needed, but do not refreeze.

2. Prepare a total protein standard curve by making dilutions of the BSA standard in 1% SDS as follows: 1.0, 2.5, 5.0, 7.5, and 10 µg/10 µl of 1% SDS (no dilution is required for last standard).

3. Vortex each tube and add 10 µl of each standard to a well of the microtiter plate; add 10 µl of 1% SDS to a well to serve as a blank.

   Typically, standards are run in duplicate.

4. Prepare dilutions of the sample. Thaw the sample, vortex, and dilute a 10-µl aliquot with 190 µl of 1% SDS. Vortex the dilution tube and add a 10-µl aliquot into a well of a microtiter plate.

5. Add 200 µl of the BCA protein assay reagent (composed of 50:1 ratio of solution A/solution B of the Pierce BCA reagent) to each standard and sample.

6. Incubate the plate 30 min at 37°C.

   Other incubation temperatures are permissible; follow directions provided with the kit.

7. "Pop" any bubbles in the microtiter plate wells with a needle or pipet tip to ensure uniform and accurate readings. Read the plate at 562 nm.

8. Calculate the concentration of total protein in the sample from the standard curve.

   Software programs linked to specific plate readers should be programmed to plot OD versus total protein in a linear fashion. Most programs allow for automatic subtraction of blanks and incorporation of dilution factors. Because the samples are prepared in 10 vol of diluent, typically, total protein values are ~10 mg/ml.

REAGENTS AND SOLUTIONS

Use Milli-Q-purified water or equivalent for the preparation of all reagents and in all protocol steps. For common stock solutions, see ***APPENDIX 2A****; for suppliers, see* ***SUPPLIERS APPENDIX****.*

Alkaline phosphatase substrate

Mix 2 ml diethanolamine buffer on a stirrer with two *p*-nitrophenylphosphate tablets and 8 ml of deionized water. Make this solution fresh on the day of use and do not save.

Blocking solutions

Add 5 grams of non-fat powdered milk (Carnation) to 100 ml PBS (see recipe) or 100 ml PBS/Triton (see recipe). Make these solutions fresh the day of assay and do not save.

Prepare at least 100 ml of each to facilitate dissolving the powdered milk; PBS may be warmed slightly to facilitate this process.

Also, do not retain the powdered milk for longer than a month or two at room temperature. The dry milk tends to discolor and will not go into solution at shelf times longer than 2 months.

Detection antibody solution

Make up stock solutions of monoclonal anti-GFAP antibody (clone GA5; Oncogene Research Products) and alkaline phosphatase–conjugated anti-mouse IgG (Jackson Immuno Research) according to the vendors' instructions. Store both stocks at 4°C per the vendors' instructions. Add 20 µl of the monoclonal antibody solution stock and 3.3 µl of the alkaline phosphatase conjugate stock to 10 ml blocking solution containing Triton (see recipe). Make this solution fresh on the day of use and do not save.

Phosphate-buffered saline (PBS)

Mix one packet of PBS (Pierce) thoroughly with 500 ml of water to give a final concentration of: 137 mM NaCl, 1.0 mM KCl, 2 mM KH_2PO_4, 8.0 mM $Na_2HPO_4 \cdot 7H_2O$, pH 7.4. Store up to 1 month at 4°C.

PBS washes require ~20 ml/plate.

PBS/Triton

Add 2.5 ml of Triton X-100 (0.5% v/v) to 500 ml of PBS (see recipe). Store up to 1 month at 4°C.

PBS/Triton washes require ~20 ml/plate.

Rabbit anti-GFAP antibody

Add 25µl of polyclonal rabbit anti-GFAP antibody (Dako, cat. #Z0334) to10 ml PBS. Make this solution fresh on the day of use and do not save.

COMMENTARY

Background Information

It has long been known that damage to the central nervous system results in astrogliosis (gliosis, reactive gliosis, glial activation), a response to brain injury characterized by hypertrophy and, less often, hyperplasia of astrocytes, a sub-type of CNS glia (Eng, 1988; Norenberg, 1994). At the electron microscope level, astrogliosis is characterized by the accumulation of glial filaments. GFAP was found to be the major protein component of these filaments (Eng, 1988). As such, GFAP serves as a biomarker for filament accumulation and, therefore, of gliosis (Eng, 1988; Norton et al., 1992; O'Callaghan, 1993). With the development of antibodies to GFAP, immunohistochemical analysis of this protein soon documented that gliosis occurs in response to diverse insults of the CNS, including trauma, disease, and toxic exposures (Eng, 1988; Norton et al., 1992; O'Callaghan, 1993; Norenberg, 1994; O'Callaghan et al., 1995). Thus, a large body of evidence now has been accumulated demonstrating the ubiquity of the glial response to all types of CNS damage based on immunhistochemistry of GFAP. Only recently, however, have methods been introduced to assay levels of GFAP as a means of quantifying gliosis.

While GFAP immunohistochemistry has proven useful for revealing patterns of gliosis after brain injury, this approach does not lend itself to quantification or the analysis of large numbers of samples. Small (25% to 50%), but toxicologically significant increases, also may be difficult to detect by immunohistochemistry. These drawbacks, combined with the need to develop quantitative biomarkers of neurotoxicity (O'Callaghan et al., 1995) and to define quantitative aspects of toxicant- and disease-induced gliosis, have prompted the development and implementation of a number of GFAP assays. These assays have been applied to examine gliosis in specific brain areas already known to be affected by disease or other insult. In addition, they also can be broadly applied in a risk assessment context (U.S. EPA; see O'Callaghan, 1991) to screen for potential sites of neural damage resulting from toxic exposures of the CNS. Recently, analysis of GFAP has been used to demonstrate that the degree of cortical gliosis in postmortem brain tissue from victims of Alzheimer's disease correlates with the severity of dementia scores in these individuals prior to death (G. Webster Ross, unpub. observ.). Analysis of GFAP in cerebrospinal fluid (CSF) has also been applied to the human condition as an indicator of the severity of

traumatic injury to the brain (Rosengren et al., 1994). Finally, analysis of GFAP can be used as an indicator of the presence of brain or spinal cord contamination of meat (Schmidt et al., 1999).

Of the number of GFAP assays that have appeared in the literature over the last 15 years; all essentially fall into two categories: (1) solid-phase immunoassays where GFAP is immobilized on a solid support matrix and detected by mono- or polyclonal antibodies, or (2) liquid-phase assays where GFAP from brain extracts, solubilized brain tissue, or cerebrospinal fluid is "captured" by one antibody and then detected by another antibody raised in a different host species (Butler et al., 1986). The assay described in this unit is of the second type, and it has a number of advantages over the solid-phase assays. Specifically, solid-phase detection and "quantification" of GFAP most commonly involves the time-consuming resolution of a protein mixture by SDS-PAGE, followed by electrophoretic transfer to a solid support membrane. Anti-GFAP antibodies coupled to a variety of detection reagents can then be used for quantification of GFAP bound to the membranes. Unfortunately, this approach has been found to severely underestimate the concentration of GFAP in the resolved mixture of proteins and the effects of treatments known to increase GFAP (O'Callaghan et al., 1999). Other solid-phase assays for GFAP have been developed that do not rely on prior resolution of protein mixtures by SDS-PAGE (Wang et al., 1990; O'Callaghan, 1991). These assays incorporate manual spotting of brain homogenates on solid supports, with or without the aid of a template. The membranes are then incubated with anti-GFAP polyclonal or monoclonal antibodies, which, in turn, are bound by ^{125}I-labeled protein A. Quantification is achieved by gamma spectrometry or by densitometry of the autoradiogram. These assays give a linear signal over a fairly large range of spotted protein. However, they require large amounts of reagents, including radiolabeled reagents, and they do not have impressive throughput.

The sandwich ELISA for GFAP described in this unit or similar ELISAs described previously (Eng et al., 1986; Kretzschmar et al., 1985; O'Callaghan, 1991; Rosengren et al., 1994), have several advantages in comparison to the other methods for assaying GFAP described above. They are easier to perform because they have fewer steps. They are more sensitive (liquid-phase assays are generally five to ten times more sensitive than solid-phase assays). Although they may require a greater number of reagents, ELISAs adapted to the microtiter plate format permit the use of very small volumes, which results in a significant overall cost reduction. The 96-well microtiter plate format also has the advantage of speed and high throughput. From sample application to data collection, all steps can be performed in the plate. Moreover, the microtiter plate–based format permits the entire assay to be automated through the use of robotic liquid handling processors. Finally, radioactivity is not involved, making the assay safer to perform, and allowing the user to avoid costly and time-consuming radioactivity disposal procedures.

Although most of the GFAP sandwich ELISAs described to date are similar and share the advantages afforded by this technique, the assay described in this unit may have a few additional advantages. Because it is based on detergent-solubilized homogenates of a given brain area, any treatment effects can be directly related to effects in that brain area, rather than an arbitrarily defined extract or subfraction that may contain only a portion of the total GFAP in that area. Using a solubilized homogenate rather than a subfraction of a given brain area also facilitates comparisons of quantitative data on GFAP to immunohistochemical staining of GFAP in that area. Moreover, it also helps rule out inter-laboratory differences associated with assaying GFAP content in one type of extract in one lab and another type of extract/fraction in another lab. Finally, the same SDS-denatured homogenate used to assay GFAP can be subjected to multiple assays for additional glial or neuronal proteins, thereby permitting comparisons to be made among multiple markers of neurotoxicity in a single sample. For example, the dopaminergic neurotoxicant, 1-methyl-4-phenyl-1,2,3,6-tetrahydropyridine, causes a large increase in GFAP that results from damage to dopaminergic nerve terminals. This damage can be quantified by immunoassay of tyrosine hydroxylase (TH), a marker of dopamine-containing nerve terminals in the target region (O'Callaghan et al., 1990). Both markers can be assayed from aliquots of the same tissue sample and, on this basis, the authors find that larger decreases in TH predict greater increases in GFAP.

Critical Parameters and Troubleshooting

The most critical aspect of the GFAP assay is the absolute requirement for preparation of consistently dissected regions of the brain (see

Support Protocol 1). Consistent dissections yield consistent GFAP values with the use of only a few animals per dose or time point (see Anticipated Results). The particular regions to be dissected depend on the questions being addressed. If a target region is known or suspected, dissections can be limited to the region of interest. If the GFAP assay is being applied in a screening context, multiple (ten to fifteen) brain regions must be dissected in order to avoid the possibility of diluting localized increases in GFAP. The possibility exists that extremely localized increases in GFAP may fail to be detected with the assay. While GFAP immunohistochemistry is relatively insensitive in comparison to the GFAP assay, and it may not detect small increases in GFAP, it can reveal small "hot spots" of gliosis (e.g., see effects of MK-801 in Fix et al., 1995). Such discrete astrocytic responses could escape quantification with the GFAP assay due to dilution of signal by surrounding tissue. No one approach can be broadly applied to detect all toxicant-induced damage of the CNS. Therefore it is prudent to use the GFAP sandwich ELISA in conjunction with GFAP immunohistochemistry and other sensitive morphological approaches for detection of neural damage, such as silver degeneration stains (Switzer, 2000), Fluoro-Jade (Schmued and Hopkins, 2000), and stains that detect activated microglia (Streit et al., 1999).

In terms of the GFAP sandwich ELISA itself, the key requirements for optimal performance of the assay include: (1) use of the speci-

Table 12.8.4 Troubleshooting Guide for GFAP Sandwich ELISA

Problem	Possible Cause	Solution
No color reaction	Incorrect preparation of color reagent	If color reaction has not been terminated, remove reagent, add new color reagent and continue assay
	Antibody was not as specified in the protocol	Obtain correct antibody and repeat assay
	One or more antibodies were omitted or used at the wrong dilution	Repeat assay with proper reagents used at the correct dilutions
Color reaction abnormally low	Incubator was set at less that 37°C	Repeat assay with incubator temperature set at 37°C
	Antibody solution too dilute; incorrect preparation of color reagent	Repeat assay with correct reagent dilutions
Color reaction abnormally high	Alkaline phospatase substrate kit is out of date	Repeat assay with fresh kit
	Color reaction was not terminated	Repeat assay and terminate reaction with 0.4 N NaOH
Standard curve not sigmoid	Incorrect plate template set in the plate reader	Use correct plate template and reread plate
	Incorrect standard dilution	Repeat assay with correct standard dilution
Samples not on linear portion of curve	Incorrect standard dilution	Repeat assay with correct dilution of standard
	Incorrect sample dilution	Run multiple dilutions of samples to obtain OD values from the linear portion of the curve
Duplicates are not similar	Carry over from using same tip	Change tips after each use
	Poor pipetting technique	Check pipettor precision by weighing
	Plate washer malfunction	Check plate washer for even dispensing and aspiration
	Bubbles throughout the plate	Pop bubbles and reread plate
Color reaction obtained for standards and samples, but OD values not as expected	Plate read at incorrect wavelength	Read plate at 405 nm

fied antibodies, (2) addition of the reagents at room temperature, (3) fresh (daily) preparation of all reagents containing antibodies and/or non-fat dry milk, and (4) mixing of the standards and samples prior to their dilution or addition to the microtiter plate wells. A troubleshooting guide is provided in Table 12.8.4 that covers most problems encountered with the assay.

Anticipated Results

GFAP assay values obtained for different regions of the rat brain are presented in Fig. 12.8.2. Absolute values for GFAP (microgram per milligram total protein) may vary depending on the GFAP standard used and the species subjected to evaluation. Region-to-region differences in GFAP values from untreated animals of a given species, however, should remain stable, if consistent dissections are performed.

Time Considerations

The GFAP assay requires ~5 hr for one person to process a 96-well microtiter plate. The time required to prepare brain samples depends on the number of brain areas to be dissected and on whether the areas are stored frozen prior to homogenization. With practice, ten brain areas can be prepared (and homogenized) from 50 rats in 1 day. Two people are required: one to dissect the brains and one (or more) to weigh and homogenize the tissue. The total protein assay requires ~1 hr for one person to process a 96-well microtiter plate.

Aggregating Neural Cell Cultures

Aggregating cell cultures are primary cell cultures derived from embryonic tissues and consist of numerous free-floating spheroids exhibiting histotypic cellular maturation and organization. These three-dimensional cell structures form spontaneously when freshly dissociated embryonic cells are kept under gyratory agitation. After the initial reaggregation, the cells are able to migrate and reorganize themselves within the aggregates. The three-dimensional architecture, allowing direct cell-to-cell interactions and the formation of a natural cell matrix, is fundamental in the acquisition of the histotypic properties of these cultures. Aggregating cell cultures are able to reproduce a series of processes involved in organogenesis. In general, the cultures require several weeks to attain maximal cellular differentiation, and they can be maintained at this level for months. To obtain highly reproducible cultures, it is important to take into account a number of variables such as the developmental stage of the embryonal tissue, the mode of cell dissociation, the cell density at incubation, the intensity of agitation, and the composition of the cell culture medium (see Critical Parameters). This unit describes the preparation of aggregating brain cell cultures from embryonal rodent (rat and mouse) forebrains using simple mechanical dissociation of the original tissue, and a chemically defined medium for their culture. The Basic Protocol describes the technique for obtaining cultures derived from the forebrains of rat embryos, giving rise to relatively large amounts of cultures for routine tests and investigations requiring large quantities of material and/or numerous culture replicates. Of the two alternate protocols, Alternate Protocol 1 describes specific points for the preparation of mouse-derived aggregating brain-cell cultures; Alternate Protocol 2 provides the details for the preparation of neuron-enriched aggregates of both rat- and mouse-derived brain cells. All these approaches require the rigorous application of aseptic and refrigerated working conditions from the moment the uterus containing the embryos is removed from the sacrificed dam.

NOTE: All protocols using live animals must first be reviewed and approved by an Institutional Animal Care and Use Committee (IACUC) and must follow officially approved procedures for the care and use of laboratory animals.

PREPARATION OF AGGREGATING CELL CULTURES FROM RAT FOREBRAIN

BASIC PROTOCOL

This protocol is used routinely for 16-day embryonic rat forebrain. For cultures to be derived from other brain parts or other species, slight modifications are necessary (see below). The protocol is broken down into the following major stages: preliminary work, sacrifice of the dams and excision of the embryos, isolation and dissection of the embryos, mechanical dissociation of embryonic brain tissue, and initiation and maintenance of the cultures.

To estimate the number of culture flasks required, one can rely on data from previous preparations. For example, one flask is typically sufficient for 1.6 embryos using 16-day rat forebrains. Thus, with an average of 13.3 fetuses/dam, approximately twelve pregnant rats will be required to prepare 100 initial cultures. When preparing large numbers of cultures, one has to keep in mind that the duration of the culture preparation is a critical factor. Ideally, for the preparation of 100 cultures, two to three persons should participate in the first part of culture preparation: one that sacrifices the timed-pregnant animals and excises the embryos, the other(s) dissecting them under refrigerated and aseptic conditions.

Contributed by Paul Honegger

Current Protocols in Toxicology (2003) 12.9.1-12.9.17

Materials

Rats, 16-day pregnant (e.g., Sprague-Dawley)
Puck's D-GS (see recipe), 4°
96% ethanol denatured with 2% (v/v) 2-butanone, in a squirt bottle
0.4% trypan blue solution
Chemically defined medium (complete DMEM; see Support Protocol 1), 4°C

Sterile laminar flow hood with horizontal air flow
Dissecting block (optional) perfused with cooling liquid and equipped with wells to hold 60-mm petri dishes
Dissecting microscope(s), if required
Cold light source to illuminate embryos and tissues during dissection
250-ml beaker
60-mm plastic petri dishes, sterile
Guillotine for rats
Scissors (large; small and pointed; curved, Vannas)
Forceps (large; small and curved; fine, curved; extrafine, Dumont no. 5)
Disposable absorbent pads
Plastic waste bags
50-ml conical plastic tubes, sterile (e.g., Falcon)
Surgical gloves and mask
Scalpel holder and no. 11 blade
Nylon mesh bag, 200-µm and 100-µm pore size, nylon mesh purchased in large sheets from Sefar (see recipe for construction of nylon mesh bags)
Glass rods (0.6-cm diameter, 20 cm-long) with blunt, fire-polished ends
1-ml and 5-ml sterile serological plastic pipets (e.g., Falcon)
Hemacytometer and hand-held counter
100-ml or 500-ml plastic culture flask, graduated and sterile (e.g., Falcon)
25-ml and 50-ml modified Erlenmeyer flasks (see step 34)
Gas-permeable, autoclavable plastic caps for Erlenmeyer flasks (e.g., Bellco)
37°C, 10% to 11% CO_2 humidified incubator (with inside dimensions sufficient to place a gyratory shaker with large platform)
Gyratory shaker with shaking speeds up to 80 rpm, 25-mm shaking diameter with a large platform to hold up to 100 culture flasks that fits inside a CO_2 incubator, functions at 100% humidity, driven by magnetic induction rather than by a driving belt, and does not destabilize the internal temperature of the incubator
37°C water bath
Supports with a removable slanted base for media replenishment and transport of flasks—manufactured in alumina to hold 5 flasks, requiring inside dimensions of 27-cm width, 6-cm depth, 3-cm height, with removable insert (27 × 6–cm)

NOTE: All solutions and equipment coming into contact with living cells must be sterile, and aseptic technique should be used accordingly. For additional washing and sterilizing procedures, see Support Protocol 2.

Mate rats and prepare for surgery

1. Mate Sprague-Dawley rats during the daytime for 5 hr, then return them to their home cages.

   They should be mated for no longer than 24 hr. The day of separation is designated gestation day 0.

2. On the day of sacrifice (gestation day 16), place the following dissection instruments in a horizontal flow hood: the dissecting block (optional), the dissecting microscope(s) (if needed), a cold light source, a bottle of ice-cold Puck's D-GS, a bucket of ice, a 250-ml beaker for liquid waste, and a stock of 60-mm plastic petri dishes.

3. Add 5 ml of Puck's D-GS to each of two 60-mm plastic petri dishes and place them on the refrigerated dissecting block (or on ice, if no dissecting block is available).
4. Set up the operating room for the decapitation of the animals (guillotine for rats), and for the excision of the embryos (large scissors, small pointed scissors, large foreceps, small curved foreceps, adsorbent pads, squirt bottle containing denatured ethanol, and plastic bags for disposal of the carcass).
5. Under a sterile hood, add 40 ml ice-cold Puck's D-GS to 50-ml sterile plastic tube(s) destined for storage of the dissected tissue and keep on ice in the laminar horizontal flow hood; and add 25 ml ice-cold Puck's D-GS to 50-ml sterile plastic tubes (one per pregnant rat) to be used for the reception and transfer of the fetuses and place into another bucket of ice for operating.

Sacrifice dams and excise the embryos on gestation day 16

6. Wear gloves and a surgical mask. Decapitate the 16-day pregnant rat using an appropriate guillotine.

   Make sure to avoid all unnecessary stress to the animal and to follow the ethical guidelines.

7. Lay the decapitated animal on its back on an adsorbent pad. Douse the abdomen with denatured alcohol.
8. Using the large forceps, grasp a fold of skin at the base of the abdomen and gently lift. With the large scissors, cut below through skin and fascia at the midline, and extend the cut on both sides of the abdomen until the entire peritoneal cavity lays open. Displace intestines to the side to reveal the uterus.
9. With the small, curved forceps gently grasp and lift the uterine horns containing the fetuses. With the small, pointed scissors excise the uterine horns. Try to remove as much associated fat as possible during this operation. Transfer the excised uterine horns to the 50-ml plastic tube containing ice-cold Puck's D-GS.
10. Transfer the tube containing the uterine horns to the hood for dissection, place the dam's body and head into a plastic bag for disposal.
11. Repeat steps 6 to 10 until all dams have been sacrificed and the embryos recovered.

Isolate and dissect the embryos

Perform all subsequent procedures in a sterile laminar flow hood under aseptic conditions.

12. Put a petri dish containing ice-cold Puck's D-GS in the hood at the side of the dissecting block and place the uterine horns of one animal into the dish.
13. Rapidly open the uterine horns with the Vannas scissors. With the small forceps and the Vannas scissors, extract the embryos from the uterine horns and then from the amniotic sacs. Transfer them to a petri dish containing Puck's D-GS on the dissecting block.
14. Isolate the brains of all embryos in the dish one after the other as follows:
    a. Hold the head of the embryo fixed in a lateral position with the aid of the Dumont forceps.
    b. Make an extended lateral incision at the base of the brain using the Vannas scissors by cutting skin and cartilage from the region of the brain stem to the most frontal point.
    c. Extract the entire brain by lifting it through this opening using the blunt side of the closed Vannas scissors. Remove the meningeal cover as much as possible. Keep the brain and discard the rest of the embryo.

15. Using the scalpel, dissect the forebrains.
16. Transfer the dissected forebrains to the 50-ml plastic tube filled with 40 ml of Puck's D-GS.

    Up to 70 forebrains can be pooled in the same tube (batch), but replace the supernatant at regular intervals during dissection, e.g., every 20 to 30 min, adding fresh cold Puck's D-GS. Discard supernatant into waste beaker.

17. Repeat steps 12 to 16 for each pair of uterine horns.

    The duration of the dissection should not exceed 2 hr. An experienced person can dissect ~40 to 60 embryos per hour.

Rinse the collected brain tissue

18. Remove from the horizontal laminar flow hood all equipment used previously (or use another hood). Put the sterile material for the mechanical dissociation, i.e., glass rods, Nitex mesh bags with 200-µm and 100-µm pores, into the hood.
19. Place a bottle with cold Puck's D-GS in one ice bucket together with the tube(s) containing the excised brain tissue. Place two sterile 50-ml plastic tubes per batch into another ice bucket.
20. Rinse each pool of dissected tissue three times with ~40 ml of cold Puck's D-GS.
21. Add 25 ml of cold Puck's D-GS to one of the 50-ml plastic tubes.

Mechanically dissociate the tissue

22. Place a 200-µm mesh bag (with a glass funnel fitted inside) on the 50-ml conical plastic tube containing 25 ml of Puck's D-GS. Keep on ice.
23. Pour the pooled brain tissue of one batch into the bag. Rinse the funnel, if necessary, with 2 to 3 ml of Puck's D-GS. Disinfect hands (gloves) with 98% ethanol and let dry within the hood.
24. Remove the funnel, close the bag, and hold its upper end against the outer side of the tube wall. Make sure that the brain tissue remains immersed.
25. Using the sterile glass rod, gently stroke downward at the outside of the bag, to squeeze the tissue through the mesh into the surrounding solution. Repeat this movement until the bag looks empty.
26. After this first dissociation step, take the second nylon bag (100-µm mesh) attached with tape to a short glass funnel, and place it on top of an empty 50-ml conical plastic tube.
27. Using a 5-ml serological plastic pipet, transfer the cell suspension to the nylon bag, and let the suspension pass through the filter by gravity flow into the 50-ml conical tube. Toward the end of the filtration, add Puck's D-GS up to a final volume of 50 ml.

    This filtration process can be accelerated by gently moving the filtering device up and down in the tube. If there is a second batch, repeat steps 21 to 27.

28. Centrifuge the resulting filtrate(s) 15 min at $290 \times g$, 4°C, with slow acceleration and slow deceleration.
29. After centrifugation, bring the tube(s) back to the hood, wipe (disinfect) around the closure with an ethanol-soaked cloth, and put on ice. Discard the supernatant and resuspend the cells as follows.

a. Remove the supernatant using a pipet.
b. Add 2.5 ml of fresh cold Puck's D-GS and resuspend the pellet by triturating five to six strokes up and down using a 5-ml plastic pipet. Avoid foaming.
c. Bring the volume of this suspension to 50 ml with cold Puck's D-GS and take a 0.1-ml aliquot for cell counting. Transfer the 0.1-ml aliquot to 0.9 ml of Puck's D-GS.

30. Centrifuge the cell suspension(s) 15 min at $300 \times g$, 4°C, as in step 28.

Determine cell number

31. Count the cells (from step 29c, see *APPENDIX 3B*).

    a. Determine the total cell number per batch using the ten-fold diluted aliquot of step 29c. Determine cell density using a hemacytometer. For testing cell viability, add the test dye (e.g., trypan blue or nigrosin) to the Puck's D-GS used for dilution (see step b below).
    b. It may be useful (particularly in the first preparations) to also examine cell viability (determination of the percentage of cells that exclude a test dye such as trypan blue, *APPENDIX 3B*).

       Typically, 30% to 40% of the cells are stained by trypan blue. Protocols for the determination of cell viability with trypan blue are published widely (e.g., Sigma catalogue). The total cell number provided here include both stained and unstained cells.

32. At the end of the second centrifugation, remove the supernatant with a sterile plastic pipet and discard. Resuspend the pellet in Puck's D-GS by trituration to yield a total volume of 5 to 6 ml (triturate as described for step 29b).

Initiate cultures

33. Fill a 100-ml or 500-ml graduated plastic culture flask with the calculated amount of cold culture medium required to obtain a minimal final cell density of 2.7×10^6 total cells/ml. Add the cell suspension of step 32 to the medium and mix well by turning the closed flask several times upside-down. Avoid foaming.

    The size of the graduated plastic culture flask depends on the final volume of the cell suspension.

    The initial phase of reaggregation is most critical. Culture initiation must proceed rapidly to avoid prolonged periods of non-physiological conditions for the cells, and it requires optimal control of the gyratory agitation to balance between attracting and shearing forces acting on the cells. Cell aggregation starts immediately after the cell suspension has been placed in the incubator. However, during the warming period, the pH of the culture medium will rise above physiological values. In order to keep this critical period as short as possible, two persons should work together during culture initiation, one to pipet the aliquots of the cell suspension, and one to transfer the flasks to the incubator. During the initial phase, the gyratory agitation must be kept relatively low (68 rpm) to favor cell-to-cell adhesion. Thereafter, the speed of agitation is progressively increased to the final speed of agitation (80 rpm) to avoid the agglomeration (clumping) of the formed aggregates.

34. Place the required number of 25-ml Erlenmeyer flasks into the laminar (vertical, if possible) flow hood. Loosen the gas-permeable plastic caps so that they can be removed and held with the left hand while pipetting with the right hand.

    Ideally, use Schott Duran–modified flasks. Uniform Erlenmeyer-type culture flasks are required for aggregating cell cultures. It is difficult to find a large batch of uniform so-called DeLong flasks commercially (there are considerable geometric variations between batches of flasks). Therefore, it is best to purchase a large batch of standard Erlenmeyer flasks

directly from the factory (e.g., Schott Duran 25- and 50-ml Erlenmeyer flasks), if possible, with unfinished necks, and to have the necks modified by a glass blower to short straight necks (outside diameter 18 mm), fit for commercially available, autoclavable plastic caps (e.g., Bellco).

35. Transfer 4-ml aliquots of the final cell suspension to the culture flasks.

    The volume to be placed into the flasks depends on the geometry of the flask. Thus, using other types of culture vessels may require adjustment of the initial volume to obtain a similar vortex. It is recommended to adjust the volume rather than changing the protocol for the speed of agitation (see Critical Parameters).

36. Place the flasks onto the platform of a rotating gyratory shaker (68 rpm) in a 37°C, 10% CO_2 humidified incubator.

37. In the evening of the day of culture preparation (day 0), increase the agitation speed to 70 rpm.

38. On the next day (day 1), increase agitation to 74 rpm.

Transfer cultures

39. On day 2, transfer the cultures to 50-ml modified Erlenmeyer flasks equipped with gas-permeable plastic caps. Pour the content of each flask along the glass wall quickly into the new flask and repeat exactly the same movement by adding an additional 4 ml of fresh prewarmed medium, with which the original flask was rinsed.

    Ideally, no aggregates should remain attached on the wall of the new culture flask. Again, this procedure will cause an increase in the pH of the medium (as at culture initiation, see above). Therefore, care should be taken to keep this procedure as short as possible (not exceeding 30 min/series). Allow to equilibrate for 1 to 2 hr before a further series is transferred. For volume adjustments with other types of culture vessels, see step 35 and Critical Parameters.

40. After completion of the transfer, increase the frequency of agitation to 80 rpm (the maximal rotation speed).

Maintain cultures

41. On day 5, replenish the culture medium for the first time as follows:

    a. Warm the required amount of fresh culture medium in a 37°C water bath (maximum 15 min).

    b. Take the culture flasks in groups of five, put them on a support with a slanted base, and allow the aggregates to settle.

    c. With a 5-ml pipet, remove 5 ml of medium, and add an equal volume of fresh prewarmed medium.

       To avoid contamination, always use a fresh pipet when pipetting fresh medium.

42. Replenish the medium every third day (step 41) until day 14, and every other day thereafter.

43. On day 20, because of the greatly increased metabolic rate of the cultures, divide the content of each flask into two separate cultures ("split") by using the following steps.

    a. Preincubate 50-ml culture flasks with 4 ml of fresh complete medium (1 to 2 hr).

    b. Prewarm in 37°C waterbath the required amount of complete medium for replacement (see step *e* below).

    c. Use a 2-ml plastic pipet to split the cultures. Tilt the flask containing the aggregates, quickly resuspend the aggregates by short aspiration and brisk expulsion of the supernatant medium, and then quickly transfer a 2-ml aliquot to a fresh flask containing 4 ml of medium.

d. Transfer a second 2-ml aliquot in exactly the same way.

e. Replace the missing volume in the original flask with 4 ml of fresh medium.

A second split may be necessary at day 30 if the metabolic rate is too high (medium turning yellow).

MOUSE-DERIVED BRAIN CELL CULTURES

ALTERNATE PROTOCOL 1

Aggregating brain cell cultures are prepared from mouse embryos essentially as described in the Basic Protocol with only a few modifications. The brains of mice, compared to rats, mature at an accelerated rate. Therefore, mouse embryos are taken for culture preparation at an earlier stage, e.g., at gestation day 14, when preparing cultures from the telencephalon. To obtain uniform mouse-derived aggregate cultures, a two- to three-fold higher initial cell density is required as compared with rats, e.g., with 14-day mouse telencephalon, the final cell density is 7.3×10^6 total cells/ml. Furthermore, cell aggregation occurs less vigorously and the cultures show a more pronounced requirement for growth factors as compared to the rat-derived cultures. In particular, platelet-derived growth factor (PDGF) is required for oligodendrocyte proliferation and maturation, while epidermal growth factor (EGF) is mitogenic predominantly for astrocytes. Nevertheless, a considerable number of the initially proliferating glia cells is lost into the supernatant due to their migrating properties.

Taking into consideration the specificities encountered with mouse-derived cultures, Basic Protocol, steps 1, 2, 33, 37, and 38 have been modified for this protocol.

Additional Materials *(also see Basic Protocol)*

Mice, 14-day pregnant (e.g., C57/BL)

1. Mate mice overnight then return them to their home cages.

   The day of separation is designated gestation day 0.

2. Perform Basic Protocol, step 2 on gestation day 14 for mice.
3. Perform Basic Protocol, steps 3 to 32.
4. Fill a graduated plastic culture flask with the appropriate amount of cold culture medium to obtain a minimal final cell density of 7.3×10^6 total cells/ml.
5. Perform Basic Protocol, steps 34 to 37.
6. On the next day, increase agitation to 73 rpm and start treatment with growth factors and neurotrophins (minimal treatment: 20 ng/ml PDGF-BB for the development of oligodendrocytes, if desired).
7. Perform Basic Protocol, steps 39 to 43.

PREPARATION AND MAINTENANCE OF NEURON-ENRICHED AGGREGATE CULTURES

ALTERNATE PROTOCOL 2

Neuron-enriched cultures are prepared from the regular (mixed neuron-glia) cultures using cytosine arabinoside (Ara-C) to eliminate the proliferating glial cells (Honegger and Werffeli, 1988; Corthésy-Theulaz et al., 1990; Braissant et al., 2002; Honegger et al., 2002). Ara-C is added to the culture at an early stage (on days 1 and 2) and at a relatively low concentration (0.4 μM). The resulting aggregates contain >90% neurons (Honegger et al., 2002). However, the virtual absence of glial cells greatly affects neuronal survival and maturation. Therefore, supportive measures are required. This is best achieved by regularly replenishing the culture medium with conditioned medium obtained from parallel cultures of mixed-cell aggregates. This conditioned medium is diluted 1:1 with fresh medium (Honegger and Pardo, 1999). This protocol is identical to that of the Basic Protocol with modifications to steps 38, 40, 41, and 42.

Additional Materials *(also see Basic Protocol)*

2000× Ara-C (see recipe)

1. Follow Basic Protocol, steps 1 to 37.
2. On the next day, increase agitation to 74 rpm and add 2 µl of 2000× Ara-C per flask.
3. Perform Basic Protocol, step 39.
4. After completion of the transfer, increase the frequency of agitation to 80 rpm (the maximal rotation speed). Allow to equilibrate (minimum 2 hr), then add 2 µl of 2000× Ara-C solution per flask.
5. On day 5, replenish the culture medium for the first time as follows:
   a. Warm the required amount of fresh culture medium in a 37°C water bath.
   b. Replenish first cultures of the ordinary (mixed-cell) aggregates and collect their supernatant (i.e., the conditioned medium) in sterile 50-ml conical tube(s). Take the flasks in groups of five, put them on a support with slanted base, and allow the aggregates to settle.
   c. With a 5-ml pipet, remove 5 ml of medium, and add an equal volume of fresh prewarmed medium.

      To avoid contamination, always use a fresh pipet when pipetting fresh medium.

   d. Centrifuge the collected medium for 15 min at 3000 × *g*, 4°C. Mix the resulting supernatant 1:1 with fresh medium. Prewarm this medium, then go through steps *a* to *c* for media replenishment of the Ara-C-treated cultures.
6. Replenish the medium every third day until day 14, and every other day thereafter according to step 5.

SUPPORT PROTOCOL 1

PREPARATION AND USE OF CHEMICALLY DEFINED MEDIA

The basal medium used for aggregating brain cell cultures is derived from Dulbecco's modified Eagle's medium (DMEM, high glucose). The standard medium also contains high concentrations of glutamine, but low-glutamine DMEM is needed for acute experiments involving the redistribution of highly differentiated aggregates (see Critical Parameters). Because the commercially available DMEM in liquid form differs considerably in composition and osmolarity from the DMEM used for aggregate cultures, it is easier to prepare the media from the commercially available powdered medium. Thus, the following protocol describes the preparation of the two basal (incomplete) DMEM from powder mixtures, (a) the standard medium containing high glucose and high glutamine, and (b) the low-glutamine medium. Furthermore, medium completion is described (c) for both types of basal medium. Thus, the final (complete) chemically defined media are completed with the addition of metabolites, vitamins, trace elements, and hormones.

Materials

Dulbecco's modified Eagle's medium (DMEM containing high glucose (4.5 g/liter) and high L-glutamine (580 mg/liter), but no bicarbonate and no pyruvate; powder from GIBCO-Invitrogen)
Ultrapure water
Choline chloride (Sigma)
L-Carnitine (Fluka)
Lipoic acid (Sigma)
Vitamin B12 (Fluka)

50 µM $CdSO_4 \cdot 8H_2O$ (Merck)
100 µM $CuSO_4 \cdot 5H_2O$ (Merck)
50 µM $MnCl_2 \cdot 4H_2O$ (Merck)
150 µM Na_2SeO_3 (Serva)
2.5 mM $NaSiO_3 \cdot 5H_2O$ (Fluka)
5 µM $(NH_4)_6Mo_7O_{24} \cdot 4H_2O$ (Sigma)
2.5 µM $NiSO_4 \cdot 6H_2O$ (Merck)
2.5 µM $SnCl_2 \cdot 2H_2O$ (Merck)
50 µM $ZnSO_4 \cdot 7H_2O$ (Merck)
Sodium bicarbonate
CO_2 gas
Dulbecco's modified Eagle's medium (DMEM devoid of glucose, glutamine, phenol red, bicarbonate, and pyruvate powder mix, e.g., Sigma)
D-Glucose
Phenol red
100× BME vitamins (GIBCO-Invitrogen)
1 mg/ml transferrin (Sigma)
30 µM triiodothyronine (Na^+ salt; Sigma)
5 mg/ml insulin (Sigma)
20 µM hydrocortisone-21-hemisuccinate (Na^+ salt; Sigma)
3 mg/ml linoleic acid (Na^+ salt; Sigma)
Vitamin A and E solution (see recipe)
500× gentamicin sulfate stock solution (see recipe)
170 mM L-glutamine (see recipe)

10-liter glass jar (Pyrex)
Magnetic plate and stir bar
5-ml serological pipet
Hollow fiber filters (0.2-µm MediaKap-10, Spectrum Laboratories)
Peristaltic pump
500-ml bottles with gas-tight closures (Pyrex)
0.2-µm syringe filters (e.g., Acrodisc, Gelman), sterile

Prepare 10 liters of basal culture medium from powder

1a. Obtain Dulbecco's modified Eagle's medium (DMEM) powder mixture for 10 liters, containing high glucose (4.5 g/liter) and high L-glutamine (580 mg/liter), but no bicarbonate and no pyruvate.

2a. Fill a 10-liter glass jar with 9 liters of ultrapure water.

The entire preparation is at room temperature.

It is important to use water of the highest purity and devoid of pyrogens.

3a. Add the powdered medium to the water and let it dissolve under gentle continued stirring (use large magnetic stir bar).

4a. Add the following supplements:

1.35 g choline chloride
20 mg L-carnitine
2 mg lipoic acid
13.6 mg vitamin B12.

5a. Add 1 ml of each of the following 10^4-fold concentrated stock solutions of trace elements (stored frozen at −20°C):

50 µM $CdSO_4 \cdot 8H_2O$
100 µM $CuSO_4 \cdot 5H_2O$
50 µM $MnCl_2 \cdot 4H_2O$
150 µM Na_2SeO_3
2.5 mM $NaSiO_3 \cdot 5H_2O$
5 µM $(NH_4)_6Mo_7O_{24} \cdot 4\ H_2O$
2.5 µM $NiSO_4 \cdot 6H_2O$
2.5 µM $SnCl_2 \cdot 2H_2O$
50 µM $ZnSO_4 \cdot 7H_2O$

6a. Add 37 g sodium bicarbonate and immediately apply CO_2 gas (bubble through a 5-ml serological pipet into the liquid until the pH is adjusted to 7.0, color of smoked salmon).

The pH of the basal medium is kept somewhat lower than the final pH in the incubator, taking into account that the pH of the medium tends to increase during aliquot dispensing and prewarming.

7a. Measure the osmolarity of the medium and adjust to 340±2 mOsm by adding the required volume of water.

8a. Sterilize the medium by filtering through 0.2-µm hollow fiber filters and a peristaltic pump. Test the first and the last 100-ml portions of the filtrate for sterility (by incubation at 37°C or at room temperature). Dispense the remaining medium in 500-ml bottles with gas-tight closures and store at 4°C in the dark.

Maximum storage time is 1 month.

Prepare 10 liters of basal DMEM devoid of glutamine

The powder mixture of DMEM closest to the required composition can be obtained from Sigma. Besides its glutamine deficiency, it also lacks glucose, bicarbonate, and phenol red, which can be added during medium preparation.

1b. Obtain Dulbecco's modified Eagle's medium (DMEM) powder mix for 10 liters devoid of glucose, glutamine, phenol red, bicarbonate, and pyruvate.

2b. Perform steps 2a and 3a.

3b. Add the following supplements:

1.35 g choline chloride
45.0 g D-glucose
75 mg phenol red
20 mg L-carnitine
2 mg lipoic acid
13.6 mg vitamin B12.

Note that glutamine (final concentration 0.25 mM) is added only after completion of the medium (see below).

4b. Follow steps 5a to 8a.

Complete the basal DMEM

Just before use, the basal media are completed by the addition of the following sterile components (volumes are given per 500 ml of medium).

1c. Add 5 ml of 100× BME vitamins to 500 ml of basal culture medium (with or without glutamine).

With this supplementation, the concentration of the DMEM vitamins is increased. Also, biotin is added, which is not present in the regular DMEM.

2c. Add 500 µl of each of the following four 1000× concentrated stock solutions (stored frozen at −20°C):

1 mg/ml transferrin
30 µM triiodothyronine (Na^+ salt)
5 mg/ml insulin
20 µM hydrocortisone-21-hemisuccinate (Na^+ salt).

3c. Add 250 µl of 3 mg/ml linoleic acid.

Cultures >20 days may be given albumin-bound lipids (Albumax II, Gibco-BRL; final concentration 0.1% w/v) instead of linoleic acid. The Albumax II stock solution (stored at 4°C) is prepared 100-fold concentrated (10% w/v), its pH adjusted to 7.4 with 0.2 N NaOH, using phenol red (15 mg/liter final concentration, from a 50-fold concentrated sterile stock solution) as indicator.

4c. Add vitamin A alcohol and vitamin E (both are present in the medium only at trace concentrations). Of a concentrated mixture of vitamins A and E (see recipe), transfer 50-µl aliquots to 10-ml aliquots of medium, partially solubilize by sonication, and add directly to 500 ml medium after sterile filtering through 0.2-µm Gelman Acrodisc.

5c. Add 1 ml of 500× gentamicin sulfate.

6c. If medium devoid of glutamine is used (see steps 1b to 4b), add components 1c to 5c, and L-glutamine to a final concentration of 0.25 mM in the medium by adding 170 mM L-glutamine (150 µl per 100 ml of medium).

WASHING AND STERILIZING PROCEDURES

SUPPORT PROTOCOL 2

As long as there are no suitable commercially available disposable Erlenmeyer culture flasks, glass flasks have to be used and recycled. Also, it may be more economical to use recyclable glass pipets for media replenishment when working on a larger scale. However, the glassware must be free of any impurities, including traces of detergent. The detergents used should be devoid of organic additives. It is recommended to use a product line such as Neodisher (*http://www.sic.uk.com/neo_disher.htm* or *http://www.labwashers.com/models/lab_300.html*). The used culture glassware should never be allowed to dry before it is cleaned. Therefore, it must be stored immersed in a basic detergent solution (e.g., Neodisher LM-10; 5% v/v) capable of dissolving protein deposits. After washing with a special detergent (e.g., Neodisher FT), the glassware is rinsed with cold tap water and neutralized with a citric acid solution (e.g., Neodisher Z) to remove traces of detergent. Thereafter, the glassware is rinsed several times with deionized water, and finally with ultrapure water. After drying in an oven, the glassware is sterilized. The culture flasks with gas-permeable plastic caps in place are sterilized in an autoclave (120°C) with pulsed vapor. After a first sterilization, a layer of aluminum foil is wrapped around neck and cap, and the flask sterilized once more. The nylon filter bags, each with an appropriate glass funnel inside, are loosely wrapped in aluminum foil and autoclaved in a vapor-permeable box at 120°C. Cotton-plugged glass pipets are sterilized in an oven

(4 hr at 180°C). Dissecting instruments are sterilized either in the autoclave (135°C) or in a hot bead sterilizer (250°C). Instruments may also be sterilized by immersing in 70% ethanol for 5 to 10 min and letting dry inside the laminar flow hood.

REAGENTS AND SOLUTIONS

Use Milli-Q-purified water or equivalent in all recipes and protocol steps. For common stock solutions, see ***APPENDIX 2A****; for suppliers, see* ***SUPPLIERS APPENDIX****.*

Ara-C stock solution, 2000×

Add 1.92 mg cytosine arabinofuranoside (Sigma) per 10 ml water. Sterilize by filtration (0.2-µm filter). Always prepare fresh.

Gentamicin sulfate stock solution, 500×

Add 1.0 g gentamicin sulfate (Sigma) per 80 ml water. Sterilize by filtration (0.2-µm filter) and store up to 24 months at −20°C.

L-Glutamine stock solution, 170 mM

Add 24.8 mg L-glutamine (Fluka) per milliliter of water. Sterilize by filtration (0.2-µm filter). Prepare fresh or store 5 ml aliquots at −20°C.

Nylon mesh filter bags and appropriate funnels

The nylon meshes (Sefar; *http://www.sefar.com*) are sold in large sheets. Manufacture the filter bags by taking two layers of sheets, one on the other, and then dividing the bags with a hot soldering iron (40 W for 200-µm mesh and 30 W for 100-µm mesh), adjust the force applied and the rapidity of the passage such that the bags are sealed and cut at the same time.

Prepare the filter bags and appropriate funnels in the following sizes:

a. Construct 200-µm mesh bags with a 3.5-cm diameter and 14-cm length; use funnels that have a 12-cm long stem and outside diameters of 2.5 cm (top) and 1.6 cm (bottom).

b. Construct 100-µm mesh bags with a 5.0-cm diameter and 5.5-cm length; the appropriate funnels have a 4-cm long stem, and outside diameters of 4.5 cm (top) and 2.5 cm (bottom).

PBS for washing aggregate cultures prior to their harvest

6.43 g/liter NaCl
395 mg/liter KCl
540 mg/liter $Na_2HPO_4 \cdot 7H_2O$
4.5 g/liter D-glucose
24 g/liter sucrose
160 mg/liter $MgCl_2 \cdot 6H_2O$
200 mg/liter $CaCl_2$

Neutralize the solution before adding the Mg^{2+}- and Ca^{2+}-salts. Adjust to pH 7.3 and 340 mOsm then sterilize by filtration (0.2 µm filters). Store at 4°C.

This PBS is used to wash aggregate cultures before they are harvested.

Puck's D (Puck's solution D without Ca^{2+} and Mg^{2+}; Wilson et al., 1972)

8 g/liter NaCl
400 mg/liter KCl
45 mg/liter $Na_2HPO_4 \cdot 7H_2O$
30 mg/liter KH_2PO_4
1 g/liter D-glucose

continued

20 g/liter sucrose
5 mg/liter phenol red

Adjust osmolarity to 340 mOsm then sterilize by filtration (0.2 μm filter). Store up to 24 months at 4°C. Just before use, adjust the pH to 7.4 with sterile 0.2 N NaOH (~0.5 ml/500 ml).

Puck's D-GS (Puck's solution D without Ca^{2+} and Mg^{2+}, containing gentamicin sulfate)

Just before use, add to sterile Puck's D (see recipe) 1 ml of 500× of the antibiotic gentamicin sulfate per 500-ml bottle. Adjust the pH to 7.4 with sterile 0.2 N NaOH (~0.5 ml/500 ml). Store up to 24 months at 4°C.

Vitamin A and E solution

Preparation of the concentrated stock solution of vitamins A and E: dissolve 114 mg vitamin A alcohol (Fluka) in 200 μl of absolute alcohol and mix with 2.0 ml of α-tocopherol (Sigma). Store under nitrogen up to 9 months at −20°C.

COMMENTARY

Background Information

Cell culture systems, in general, provide means for the study and manipulation of living structures in vitro, which is of wide interest for practical, economical, and ethical reasons. Since the beginning of the 20th century, the number and sophistication of techniques devised for culturing isolated tissues and cells has increased at a steady pace. Today, there are a large number of culture systems of diverse complexity, ranging from single transformed cells to explanted tissue fragments. Since every culture system offers specific advantages as well as inconveniences, it is important to select the system that is most appropriate for a given task. Characteristic features of aggregating brain cell cultures include their three-dimensional architecture permitting the formation of a natural extracellular matrix and extensive cellular maturation. During the early culture period, the reaggregated cells are able to migrate and create a tissue-specific environment favoring cellular maturation and the development of specialized structures such as neurites, synapses, and myelinated axons. Therefore, aggregating cell cultures have been classified as organotypic cultures (Doyle et al., 1994). With respect to their applications in neurotoxicology, aggregating brain cell cultures were found useful to study aspects of developmental neurotoxicology (Monnet-Tschudi et al., 1995b, 2000; Zurich et al., 2000, 2002; Braissant et al., 2002). This culture system also offers the possibility to investigate cascades of neurotoxic effects occurring in response to a primary insult, as well as secondary aggravating or attenuating effects through gliosis and/or microglial activation (Monnet-Tschudi et al., 1995a, 1996, 1997; Zurich et al., 2000; Eskes et al., 2002). Besides the study of toxic processes following a chemical insult, aggregating brain cell cultures were also used as a model to investigate the consequences of hypoglycemia (Pardo and Honegger, 1999; Honegger et al., 2002). The ease of handling the free-floating aggregates, together with the high yield and high reproducibility of these cultures also makes them a suitable system for neurotoxicological routine testing (Honegger and Werffeli, 1988; Honegger and Schilter, 1992; Kucera et al., 1993).

The technique of rotation-mediated aggregating cell culture was introduced by Moscona (1961), who observed that embryonic cells taken from diverse organs and from various species were able to reaggregate spontaneously after dissociation, and to form histotypic structures when cultured under agitation for several weeks. Subsequently, the method was applied specifically to cells of the central nervous system (CNS), and predominantly morphological techniques were used for their characterization (Moscona, 1961; DeLong and Sidman, 1970). Biochemical criteria for the analysis of these cultures were used first by Seeds (1971). This approach was extended in the following decades and combined with the techniques of molecular biology. The original culture procedure was considerably modified, in particular, with respect to the method of tissue dissociation. Although enzymes (e.g., trypsin) are still used (e.g., Choi et al., 1993), Honegger and Richelson (1976) found that dissociating cells by mechanical means rendered more reproducible

cultures. The sieving technique described in this unit is a modification of the method described first by Rose (1965) and subsequently used also by Varon and Raiborn (1969). It facilitated culture preparation and greatly increased the number of replicate cultures that could be obtained. Interestingly, despite this nonselective dissociation method, only neural cells are found in the aggregates (no fibroblasts and no endothelial cells are detectable). This may be explained by the selectivity of the reaggregation process. The development of a chemically defined culture medium suitable for these cultures (Honegger et al., 1979) further simplified the culture technique and, in addition, opened new opportunities to study the role of endocrine and paracrine signaling in brain physiolgy and pathology. Over the years, an increasing number of morphological, immunocytochemical, biochemical, and molecular biological criteria were applied for the characterization of aggregating brain cell cultures. For more technical details concerning culture analyses, see Honegger and Monnet-Tschudi (2001) and Braissant et al. (2002).

Critical Parameters

Developmental stage of the embryos

The preparation of reproducible cultures requires the use of well-staged fetuses. The animals should be mated for no more than 24 hr, and the day of separation and vaginal plug control is designated as day 0. Spontaneous reaggregation occurs only with immature dissociated cells. Also, more highly differentiated cells are likely to be damaged during the mechanical dissociation process. Therefore, one must select a developmental stage that yields a maximum of relatively immature cells. This depends on the species and on the particular brain region to be used. By taking CNS tissue from different regions, it has to be kept in mind that there is a developmental caudal-to-rostral gradient in the CNS, such that the maturation of spinal cord and brainstem precedes that of the cortex.

Sterility

From the moment the uterine horns are isolated, all procedures require aseptic working conditions, and the sterility of all instruments and solutions that come in contact with the tissue and dissociated cells. In addition, the Basic Protocol prescribes the use of an antibiotic (gentamicin) in all media. While antibiotics are essential during the initial phase of culture preparation, it may be possible to omit them in more advanced cultures. During aseptic procedures, hands (gloves) must be disinfected regularly with ethanol. Also, the caps of all bottles transferred to the hood must be disinfected with ethanol. However, care must be taken to ensure that no ethanol is introduced into the liquids.

Duration of culture preparation

The dissociation, washing, and final incubation of the cells is an extremely stressful procedure for the cells, and only the immature cells can tolerate the process. To facilitate the mechanical dissociation, the tissue and cells are kept in ice-cold Ca^{2+}- and Mg^{2+}-free media during the entire preparation until the final resuspension of the cells in complete culture medium. Therefore, the duration of the procedure is critical and should not exceed a total of 4 hr.

Speed of gyratory agitation

Determining the optimal conditions for aggregation is crucial. It is important to obtain homogenous cultures, i.e., aggregates that have similar size. Also, the size of the aggregates needs to be limited to a diameter of 200 to 300 μm, to avoid the development of necrosis in the center of the aggregates due to limited diffusion of energy substrates and oxygen. Therefore, an optimum balance between adhesive and centrifugal forces must be determined, and depends on the geometry of the incubation vessel, the volume of cell suspension therein, and the speed of agitation. If using culture vessels with different shapes than those proposed in the protocol, it is recommended to vary the culture volume rather than the speed of agitation until an optimal vortex is obtained. In most cases, inhomogenous cultures indicate that the initial agitation was not sufficiently vigorous. In this respect, rat-derived brain cells reaggregate more readily, whereas mouse-derived brain cells require more careful control to avoid excessive agitation during the initial phase of aggregation. In any case, during this initial phase it is crucial to use a batch of culture vessels with identical geometry in order to obtain satisfactory replicate cultures.

Chemically defined medium

The chemically defined medium proposed here is sufficient for the growth and maturation of aggregating brain cell cultures. It should, however, be considered as a minimal culture

Table 12.9.1 Troubleshooting Guide for Neural Cell Aggregate Cultures

Problems	Possible causes	Suggested solutions
Low viable cell yield after dissociation	Mechanical dissociation too harsh	Check pore sizes of nylon sieves
		Dissociate tissue more delicately and be sure to maintain tissue in cold solution
		Resuspend and triturate cells more carefully
	Improper saline solution	Check composition and osmolarity of saline solutions
Irregular aggregates, mostly too big	Agitation too slow, particularly in the beginning	Decrease volume of cell suspension in culture vessel
	Concentration of EGF or other mitogen(s) too high	Decrease (or omit) mitogens (particularly those stimulating astrocyte proliferation)
	Initial cell density too low	Increase cell density
Most aggregates too small (e.g., at day 5)	Agitation too vigorous in the beginning	Increase volume of cell suspension in culture vessel
	Initial cell density too high	Reduce cell density
	Lack of mitotic activity	Use a mitogen or try serum (decomplemented 5% FCS)
	Toxic factor	Check media components and purity of water; make fresh medium
	Infection	Check sterility of equipment and media
Low values for total protein and cell type-specific biochemical properties	Too low level of media component(s) or toxic component in the medium	Check media components and purity of water; make fresh medium
	Damage due to prolonged periods at high pH	Reduce the duration of aggregate manipulation (including media changes), increase the pCO_2 in the incubator during the first 2 weeks of culture
	Infection that is not visible by the naked eye (e.g., mycoplasma)	Check sterility of equipment and media

medium, since the addition of certain growth factors can enhance maturational processes. The presence of serum (1% to 5%) also has beneficial effects, e.g., on the formation of myelin (Honegger and Matthieu, 1980) and on the spontaneous electrical activity of neuronal networks within highly differentiated aggregates (P. Honegger, unpub. observ.). Media preparation from powdered mixtures requires the use of pyrogen-free high-quality water, and the osmolarity of all media must be controlled.

Variability of the pH in the medium

Because of the bicarbonate/CO_2 buffering system used in DMEM, pH shifts in the medium occur frequently. Each time the cultures are manipulated outside the incubator, the pH increases because of the rapid loss of CO_2. On the other hand, pH values decrease in cultures at more advanced maturational stages because of lactate accumulation in cultures of high density. Elevated pH levels are particularly detrimental to neurons. Therefore, the time allowed

for aggregate manipulation should be kept to the strict minimum, and during recovery, the incubator has to be kept shut until a physiological pH is attained. For acute experiments with highly differentiated aggregates, it is recommended to use media with low concentrations of glutamine (0.25 mM) to prevent the spontaneous formation of ammonia. While at physiological pH the ammonium ion prevails, the diffusible neurotoxic form (NH_3) forms with increasing pH. The use of an additional or replacement buffer system (20 mM HEPES) is another option for stabilizing the pH during acute experiments lasting only a few hours.

Troubleshooting

Deficits in certain cell types or in the extent of maturation may not be apparent by the criteria discussed in Table 12.9.1. To this end, more extensive analyses are necessary using cell type-specific biochemical and immunocytochemical criteria.

Anticipated Results

Each flask of aggregating cell cultures contains ~1000 individual aggregates. They should have similar sizes with diameters not exceeding 300 to 400 μm. Although at the outset the dissociated cells appear to reaggregate in a random fashion, they are able to reorganize themselves within the resulting spherical structure. Except for the most peripheral layer where astrocytes are predominant, all four cell types (i.e., neurons, astrocytes, oligodendrocytes, and microglial cells) are found distributed throughout the sphere. Nevertheless, as observed in rat cell–derived cultures, neuronal cell bodies tend to be more concentrated in the inner half of the aggregate, while prominent neurite bundles are observed in the outer half of the aggregate where the population of oligodendrocytes is most dense. A small population of microglial cells is found scattered throughout the aggregates. Neither fibroblasts nor endothelial cells can be found in these cultures. During the first 2 weeks in vitro, most of the macroglial cells (astrocytes and oligodendroglial cells) proliferate. Thereafter, little mitotic activity is observed. The differentiation of neurons and glial cells progresses for several weeks. Synaptogenesis accelerates between the third and fourth week. During the same period, the myelination of axons progresses, and spontaneous electrical activity can be detected by extracellular and intracellular recordings. With the advancement of maturation, the metabolic rate increases drastically. More details of the criteria and techniques used for culture characterization by a multidisciplinary approach are provided elsewhere (Honegger and Monnet-Tschudi, 2001; Braissant et al., 2002).

Time Considerations

The time allowed for culture preparation is limited to 4 hr. Therefore, the number of cultures that can be prepared per batch depends primarily on the investigator's skill and on the number of participating persons. Two persons are able to prepare up to 120 individual cultures per batch. For most experimental approaches, these initial cultures can be subdivided up to six fold for experimentation. Thus, from 100 starting cultures, one can obtain up to 600 replicates. Therefore, it is important to remember that culture maintenance is relatively time-consuming. Media can be replenished for only a limited number of flasks at a time (e.g., 20 to 30) because care has to be taken to avoid extremes in pH. It is therefore convenient to use several incubators. After replenishment, the cultures require time for equilibration (1 hr for immature cultures; 30 min for mature cultures counting from the moment the CO_2 atmosphere in the incubator has recovered).

Coculturing Neurons and Glial Cells

In the development and maintenance of the nervous system there is a complex interdependency between neurons and glial cells. This relationship is vital for their individual differentiation, development, and functionality but also seems to play an important role in progressive neurodegeneration and in the modulation of neurotoxic effects.

Glial cells maintain normal functioning of the nervous system both by controlling the extracellular environment and by supplying metabolites and growth factors. Neurons may interfere with the proliferation and maturation of glial elements (Steward et al., 1991; Gegelashvili et al., 1997) and dynamically regulate the glial signaling pathway through the release of substances such as glutamate (Bezzi et al., 1998). Nevertheless, there is evidence that glia can be neurotoxic both in vivo and in vitro and can exacerbate neuronal damage caused by a variety of agents (Brown et al., 1996; Meucci and Miller, 1996; Rogrove and Tsirka, 1998; Viviani et al., 1998). This effect may be attributable to an altered supply of trophic factors to neurons, establishment of contacts, and an altered buffering of the extracellular microenvironment by glia, but also to direct release of substances toxic to neurons such as reactive oxygen species (ROS), glutamate, and some cytokines—e.g., interleukin-1β (IL-1β), tumor necrosis factor-α (TNF-α).

The general impression is that glial activation is in some way triggered by damaged neurons (Viviani et al., 2000). The hypothesis is that when a neuron is damaged it sends out signals. Usually, these are signals for help and the glia adopt a neuroprotective strategy, but sometimes, depending on the signal released or the severity of the damage, the signals elicit a lethal response. If this is the case, neural cell death could activate a self-propagating cycle sustained by neurotoxic factors released by glia, which promotes further neurodegeneration and hence more glial activation. This scheme, important in studying neurotoxicity, is part of a bicellular death pathway that has been recognized and experimentally investigated only recently.

Cocultures of different cells of the nervous system (i.e., neurons, astrocytes, and microglia) represent the easiest approach to: (1) study intercommunication between the different cell populations of the nervous system following a toxic insult, (2) evaluate its relevance in the propagation of the damage, and (3) study the molecular mechanisms involved. Other possible approaches are to use aggregate cultures of neural and glial cells and the more complex organotypic slices of hippocampus (Harry et al., 1998).

This unit, which is complementary to *UNITS 12.3 & 12.4*, describes procedures to set up a sandwich coculture system with a combination of neurons and glial cells (see Basic Protocol 1), or astrocytes and microglia cells (see Basic Protocol 2), as well as methods for the preparation of hippocampal neurons (see Support Protocol 1), glial cells (see Support Protocol 2), coated glass coverslips (see Support Protocol 4), and the separation of astrocytes and microglia from glial cells (see Support Protocol 3). A sandwich coculture is an in vitro cell system formed by two different cell populations growing on different surfaces, usually a coverslip and a petri dish. These surfaces are separated by small paraffin dots at the edges of the coverslip, on which one of the cell populations is seeded. In this way the two cell populations face each other without touching (Fig. 12.10.1) and soluble substances can diffuse between them. This cell system is therefore suitable for the study of biological responses that are due to the release of soluble mediators but not of those dependent on the contact of the two cell types.

Current Protocols in Toxicology (2003) 12.10.1-12.10.17

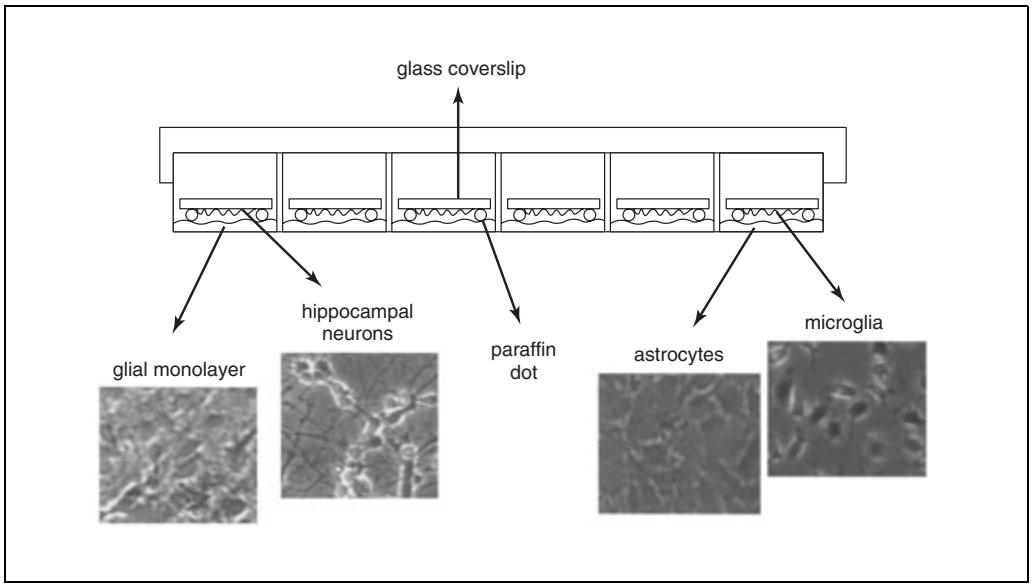

Figure 12.10.1 Scheme of a typical coculture (i.e., hippocampal neurons–glia and microglia-astrocytes) in a 24-well plate. Bright-field photographs are at 10× magnification. Note that cells populations are separated by parrafin dots on the edges of 12-mm round glass coverslips.

NOTE: All protocols using live animals must first be reviewed and approved by an Institutional Animal Care and Use Committee (IACUC) and must follow officially approved procedures for the care and use of laboratory animals.

NOTE: Working conditions must ensure the highest degree of sterility. Thus, brain tissues should be dissected and cells plated and grown under a laminar flow hood. Equipment must be sterilized before use and stored in 95% ethanol when not in use. All solutions and reagents that come into contact with tissues or cells must be sterile.

NOTE: All culture incubations should be performed in a 37°C, 5% CO_2 incubator with 95% relative humidity unless otherwise specified. As soon as prepared, cultures must be maintained in this type of incubator.

BASIC PROTOCOL 1

PREPARATION OF HIPPOCAMPAL NEURON-GLIA-SANDWICH COCULTURES

In the author's laboratory, the neuron-glia sandwich coculture is used not only to study the interaction between glia and neural cells during a toxic insult, but also to obtain a highly differentiated neural culture. Since glial cells are a valuable source of neurotrophic substances, cultures of cortical glial cells (see Support Protocol 2), consisting mainly of astrocytes and a small number of microglial cells, are prepared and allowed to reach confluence (~10 days). These monolayers can be used for up to 1 month from their preparation. Next, cultures of hippocampal neurons are prepared by plating onto glass coverslips. These coverslips are then placed above the glial monolayer as shown in Figure 12.10.1. In the author's laboratory, the coculture is set up in 24-well plates, with one coverslip for each well. This avoids overlapping of different coverslips, which can occur if petri dishes are used. The main steps in preparing a neuron-sandwich coculture are summarized in Table 12.10.1. The dissection and culture techniques described here are largely based on the method of Goslin and Banker (1991) but have undergone minor changes in the author's laboratory.

Table 12.10.1 Preparation of Neurons-Glia Coculture

Day	Action
1[a] (Thursday)	Prepare primary glial cultures
8 (Friday)	Add paraffin dots and coat glass coverslips (see Support Protocol 4)
10 (Monday morning)	Wash and condition glass coverslips
	Substitute DMEM with SFM in glial cells
10 (Monday afternoon)	Prepare and seed hippocampal neurons (see Support Protocol 1)
11 (Tuesday)	Transfer coverslips with neurons over glial cells and add cytosine arabinoside to the coculture
18 (Tuesday)	Perform experiments

[a]Note this is 10 days before hippocampal dissection.

Materials

Confluent cortical glial monolayer in 24-well plates (see Support Protocol 2)
SFM (see recipe)
Coated glass coverslips seeded with hippocampal neurons (see Support Protocol 1)
2 mM cytosine arabinoside (see recipe)
Sharpened forceps

1. On the day hippocampal neurons are to be prepared (Table 12.10.1), replace the medium in confluent cortical glial monolayers with 1 ml serum-free medium (SFM) and return them to the incubator overnight.

   The addition of SFM to glia prior to adding glass coverslips with hippocampal neurons allows conditioning to favor early phases of neural maturation. SFM is chosen since the ingredients are totally defined and the absence of serum limits the growth of glial cells together with neurons on the glass coverslip.

   Since the author's laboratory usually prepares a number of 24-well glial plates, an amount sufficient for cocultivation with neurons produced over 1 month (i.e., more than will probably be used in one experiment), the medium is replaced only in wells that will receive a coverslip plated with neural cells the following day.

2. The next morning, use one tip of a pair of sharpened forceps to lift the edge of a coated glass coverslip plated with hippocampal neurons. Seize the coverslip with the forceps, and transfer and turn it over the glial monolayer. Repeat for each well to be used.

3. To each well containing neurons and glia, add 2 mM cytosine arabinoside to a final concentration of 5 μM to reduce the proliferation of glial cells.

   Addition of cytosine arabinoside, toxic to dividing cells, is important to block astrocyte proliferation in the neuronal culture.

   In other workers' hands, cytosine arabinoside is usually added on the second to fourth day of culture. Under the experimental conditions used in the author's laboratory, such delayed addition of arabinoside did not satisfactorily reduce astrocyte contamination. This is probably because of the large number of neural cells seeded by the author (160,000/coverslip), which enriches the cell suspension with rapidly dividing astrocytes. Addition of cytosine arabinoside immediately after neuronal cells are attached allows this laboratory to obtain a 98% pure neuronal culture on the glass coverslip, as assessed by immunocytochemistry of microtubule-associated protein 2 (a marker for neurons) and glial fibrillary acidic protein (a marker for astrocytes).

   Under these experimental conditions cytosine arabinoside is not toxic to neurons.

4. Maintain the cocultures, routinely feeding once every 7 to 10 days with SFM.

Neurons are very sensitive to temperature and environmental conditions. Thus if the incubator is opened often during the day it is better to keep the plates towards the bottom where the temperature, percentage CO_2, and humidity are better preserved.

During feeding, it is important not to change the culture medium completely, since neurons depend upon glial cells to condition the medium for long-term survival. Thus, replace ~1/3 the medium each time. Under such conditions, neurons survive for several weeks and become richly innervated.

These cells reach a high degree of maturation (i.e., developed neuronal network, functional glutamatergic system, and almost complete development of the post-synaptic density) after ~7 to 9 days of culture.

SUPPORT PROTOCOL 1

ISOLATION AND SEEDING OF HIPPOCAMPAL NEURONS

The author prepares hippocampal cultures from 18-day-old fetal rats. At this stage, the generation of pyramidal neurons is complete while the generation of dentate granule cells has only just begun. Thus, the culture obtained will consist mainly of pyramidal neurons, which constitute the principal cell type in the hippocampus (85% to 90% of total neurons). From one litter of 18-day-old embryos (i.e., nine to twelve embryos), ~7×10^6 cells for 30 to 40 coverslips 12 mm in diameter (160,000 cells/coverslip) are obtained. The number of coverslips is of course related to the plating density, which has to be chosen according to the experiment to be performed and the techniques available in the laboratory.

Low-density cultures suitable for the study of the development of individual cells and their synaptic interactions or the distribution of antigens within single cells require the application of microscopic techniques because of their sparse distribution. The author's group found that a plating density of 160,000 cells/coverslip yielded a highly differentiated hippocampal culture with a sufficient number of cells for the independent measurement of several parameters of neurotoxicity by nonmicroscopic and quantifiable techniques (Table 12.10.2).

Table 12.10.2 Parameters of Neurotoxicity in Hippocampal Cultures at Low and High Density

Parameter	Low-density cultures	High-density cultures
Neural cell death	Vital dye exclusion and count of living cells	MTT test[a]
Apoptosis	Conformation of nuclei using Hoechst 33258 or propidium iodide dyes (*UNIT 2.2*)	Quantification of oligonucleosomal fragments
Intracellular Ca^{2+} homeostasis	Confocal microscopy (*UNIT 2.8*), video imaging (*APPENDIX 3A*)	Spectrofluorimetric measurement in cell population stained with Fura 2AM (*UNIT 2.5*)
Reactive oxygen species production		Spectrofluorimetric measurement in cell population stained with 6-carboxy-2',7'-dichlorohydrofluorescein diacetate
Production of cytokines	Immunohistochemistry (*APPENDIX 3A*)	Quantification by ELISA and/or RT-PCR (*APPENDIX 3A*)

[a]Source: Denizot and Lang (1986).

Since the procedures performed for isolating hippocampal neurons from rat embryos in the author's laboratory are identical to those described by Audersirk et al., the reader is referred to *UNIT 12.3* for that technique. This section provides an alternative for the dissociation of the hippocampi obtained and for growth in order to set up a sandwich coculture.

Materials

Hippocampi isolated from rat embryos (*UNIT 12.3*)
1× trypsin/EDTA solution (Sigma)
10 mg/ml DNase I stock solution (see recipe)
High-glucose MEM/10% FBS (see recipe)
0.04% (w/v) trypan blue
24-well plate containing coated coverslips (see Support Protocol 4)

Additional regents and equipment for determination of cell number and viability with a hemacytometer (*APPENDIX 3B*)

Prepare hippocampi

1. Collect hippocampi isolated from rat embryos in a sterile 1.5-ml microcentrifuge tube.
2. Centrifuge 4 min at 100 to 150 × *g*, room temperature. Carefully remove the supernatant.

   Aspiration with a pipet is recommended over a vacuum system to avoid aspirating the hippocampi along with the medium.

Trypsinize hippocampi

3. Add 400 µl of 1× trypsin/EDTA solution and 80 µl of 10 mg/ml DNase I solution. Shake gently (do not vortex) and incubate 5 min at 37°C.

   DNase is added to prevent the DNA released by damaged cells from making the dissociation medium too viscous during digestion.

4. While hippocampi are incubating, prepare four 1.5-ml microcentrifuge tubes with 400 µl high-glucose MEM/10% FBS each.
5. Gently aspirate trypsin/DNase solution with a sterile 1-ml pipet (do not use vacuum). Add 400 µl MEM/10% FBS and shake for until hippocampi are floating in the medium.

   The serum in the MEM inhibits residual trypsin and prevents overdigestion of the cells.

Wash out trypsin and DNase

6. Allow the hippocampi to pellet at the bottom of the tube.
7. Gently collect the pelleted hippocampi with a 1-ml pipet in the smallest possible volume of medium and transfer to the first of the four tubes containing MEM/10% FBS (step 4).

   Take care not to destroy the hippocampi during this and the immediately following steps.

8. Gently shake and allow the hippocampi to pellet at the bottom of the tube.
9. Repeat steps 7 and 8 another three times using the remaining tubes in succession.

   Repetitive passage through microcentrifuge tubes with fresh medium washes the hippocampi free from trypsin and DNase I. Avoiding extensive centrifugation results in a better neural culture.

Disaggregate and assess cell number and viability

10. In the last microcentrifuge tube, disaggregate the hippocampi by gently drawing up and down in a 1-ml pipet first and then a 200-µl pipet tip. Adjust the volume of the cell suspension to 1 ml using MEM/10% FBS.

    It is important to be very gentle in pipetting: too vigorous or extensive pipetting causes significant cell death. Pipetting in sequence through a 1-ml pipet and then a 200-µl pipet tip gradually yields a single-cell suspension. Note that pipet tips must be sterile.

11. Gently mix 10 µl cell suspension with 10 µl of 0.04% (w/v) trypan blue. Determine the total cell number and viability with a hemacytometer and an inverted phase-contrast microscope (see *APPENDIX 3B*).

    Trypan blue is used to distinguish viable from dead cells. Viable cells exclude trypan blue while dead or damaged cells are stained (dark blue).

Plate and prepare hippocampal neurons for the sandwich coculture

12. Pipet 160,000 cells into each well of a 24-well plate containing a coated coverslips.

13. Incubate plates overnight and place the coverslip over the confluent glial monolayer the next morning.

    Remember to keep the plates towards the bottom of the incubator where temperature, percentage CO_2, and humidity are better preserved. Neural cells will attach to the coverslip surface during this incubation.

    Since seeding medium is not suitable for hippocampal neuron survival and differentiation, remember to transfer the coverslips the day after plating.

BASIC PROTOCOL 2

PREPARATION OF ASTROCYTE-MICROGLIA-SANDWICH COCULTURES

Glia include three cell types: astrocytes, microglia, and oligodendrocytes. All glial subtypes, but particularly microglia, can express potentially neurotoxic factors when activated.

Under physiological conditions microglia have a "resting" phenotype adapted to the microenvironment of the central nervous system. However, microglia are able to respond quickly to a variety of signaling molecules. Activation at a very early stage in response to damage or alterations to the microenvironment that precede pathological changes is characteristic of microglia, and its activation often precedes reaction of any other cell type in the brain.

The author has recently observed that microglial cells can influence the response of astrocytes in producing neurotoxic substances. For instance, the production of tumor necrosis factor-α (TNF-α) after a neurotoxic insult is much higher in a culture of astrocytes and microglia than with astrocytes or microglia alone (Viviani et al., 1998; Bezzi et al., 2001). Thus, the progression of neurodegenerative events is also modulated by glia-glia interactions.

On the basis of the experience gained by the author's group in coculturing neurons and glial cells, a similar coculture system of astrocytes and microglial cells has been set up in order to study the molecular mechanisms involved in communication between these two cell populations following neurotoxic insult. First, the MEM/FBS medium present in a 24-well plate seeded with astrocytes (see Support Protocol 3) is replaced with SFM (see recipe) 1 to 2 days after the preparation of the culture. Next, the tip of a pair of sharpened forceps is used to lift the corner of a coated glass coverslip seeded with microglia (see Support Protocol 3), seize it, and transfer it over the astrocyte monolayer. In this fashion, microglial cells are juxtaposed, without direct contact, with a monolayer of astrocytes. Note that in the author's laboratory, the astrocyte-microglia coculture is usually used within 48 hr of its preparation.

ISOLATING AND CULTURING CORTICAL GLIAL CELLS

Glial cells (astrocytes, microglia, and oligodendrocytes) are obtained by mechanical and enzymatic dissociation (e.g., trypsin) of cerebral tissue from 1- to 2-day-old old rat pups (Sprague Dawley). The use of such young rats ensures the absence of viable neurons in the cell suspension. For the dissection of fetal brain and the isolation and dissection of cortices, the reader is referred to *UNIT 12.4*. From one 2-day-old pup, the author usually obtains ~5×10^6 cells.

The author uses glial cells both to obtain astrocytes and microglia, and to cocultivate hippocampal neurons. Shaking a confluent glial culture makes it possible to separate astrocytes from microglial cells and obtain two purified cultures (see Support Protocols 3). For this purpose the author's laboratory seeds 4×10^6 glial cells in 75-cm^2 culture flasks. To obtain a glial monolayer for neuron-glia coculture, cells are seeded in 24-well plates at a density of 50,000 cells/ml per well. Both the cells seeded in the wells and those seeded in the flasks reach confluence in ~10 days.

Materials

Cortices from 1- to 2-day-old Sprague Dawley rat pups (*UNIT 12.4*)
HBSS (see recipe)
10× trypsin/EDTA (Sigma)
10 mg/ml DNase I (see recipe)
High-glucose MEM/10% and 20% FBS (see recipe)
0.04% (w/v) trypan blue

35-mm petri dish
Bistoury (Aesculap)
100-µm nylon cell strainer (Falcon)
24-well plates
75-cm^2 canted-neck flasks with screw caps

Additional reagents and equipment for determining total cell number and viability with a hemacytometer (*APPENDIX 3B*)

Disassociate cells

1. Place cortices from 1- to 2-day-old rat pups in a 35-mm petri dish on ice (no medium). To obtain a homogenate of finely minced cortices, accumulate them together in the center of the dish and cut several times in different directions with a bistoury.
2. Add 2 ml HBSS and resuspend the minced cortices by drawing the mixture in and out of a disposable, sterile, 2-ml plastic pipet.
3. Remove the suspension and transfer to a 50-ml centrifuge tube.
4. Repeat steps 2 and 3 twice more to collect all of the minced cortices from the dish.

At the end of these steps minced cortices are resuspended in 6 ml HBSS.

Trypsinize cells

5. Add 750 µl of 10× trypsin/EDTA and 750 µl of 10 mg/ml DNase I to the suspension.

DNase is added to prevent the DNA released by damaged cells from making the dissociation medium too viscous during digestion.

6. Seal the capped tube with Parafilm. Vigorously agitate 15 min in a 37°C water bath to favor enzymatic digestion of the tissue. While the tube is being agitated, prepare a 50-ml centrifuge tube containing 12 ml high-glucose MEM/10% FBS.

7. After agitation, remove the tube from the shaking water bath and allow the undissociated tissue to collect at the bottom.

   Avoid centrifugation; dissociated cells must remain suspended so they can be collected.

8. Collect 5 ml dissociated cells with a disposable, sterile, plastic 12-ml pipet and transfer to the 50-ml centrifuge tube containing MEM/10% FBS (step 6).

   Take care not to include undissociated tissue pieces.

Repeat trypsinization and consolidate products

9. Add 6 ml HBSS, 750 µl of 10× trypsin, and 750 µl DNase I to the 50-ml tube containing the remaining undissociated tissue.

   The FBS in MEM (step 6) inhibits trypsin and thus prevents overdigestion of the dissociated cells.

10. Repeat steps 6 and 7, and add these dissociated cells to the 50-ml tube containing the cells from the first digestion as described in step 8.

Remove trypsin and DNase

11. Filter dissociated cells through a 100-µm nylon cell strainer and collect in a fresh 50-ml centrifuge tube.

    Filtration eliminates any pieces of tissue accidentally collected with dissociated cells.

12. Pellet pooled cells by centrifuging in a swinging-bucket rotor 5 min at 200 to 300 × *g*, room temperature.

13. Carefully remove the medium from the pelleted cells.

Dissaggregate and asses cell number and viability

14. Disaggregate the pellet by first adding 2 ml MEM/10% FBS and then gently drawing in and out of a 2-ml disposable plastic pipet until the solution becomes homogeneous. Add an additional 3 ml MEM/10% FBS for a total resuspension volume of ~5 ml.

15. Gently add 100 µl cell suspension to 200 µl of 0.04% (w/v) trypan blue. Determine total cell number and viability with a hemacytometer and an inverted phase-contrast microscope (*APPENDIX 3B*).

    Trypan blue is used to distinguish viable from dead cells. Viable cells exclude trypan blue while dead or damaged cells are stained (dark blue).

Plate and prepare glia for the sandwich coculture

16. From the 5-ml cell suspension (step 14) aspirate a volume containing a sufficient number of viable cells to prepare the desired number of 24-well plates at a ratio of 50,000 cells/well. Dilute the cell suspension to 50,000 cells/ml with high-glucose MEM/20% FBS.

    The author usually plates a sufficient number of wells for the cocultivation of neurons prepared over 1 month.

    Glial cells are plated and kept in MEM/20% FBS for 5 days, then the medium is changed to MEM/10% FBS. The cells are maintained in this medium up to 1 month.

17. Pipet 1 ml cell suspension into each well of a 24-well plate.

Plate and prepare glia to obtain astrocytes and microglia

18. From the 5-ml cell suspension (step 14), aspirate a volume containing a number of cells sufficient to prepare the desired number of 75-cm^2 canted-neck flasks with screw-caps at a ratio of ~4×10^6 cells/flask. Dilute 4×10^5 cells/ml in MEM/20% FBS.

Astrocyte and microglial cells are obtained by shaking the glial culture to divide the two cell populations (see Basic Protocol 2). Thus, it is important to use culture flasks having screw caps that can be completely tightened to prevent medium spillage during the shaking period.

19. Pipet 10 ml cell suspension into each flask.

Grow cultures to confluence

20. Incubate plates and flasks 24 hr.

21. To eliminate undetached cells, remove the medium and add 1 or 10 ml fresh MEM/20% FBS for each well or flask, respectively. Repeat 5 days later.

22. Five days later, remove MEM/20% FBS, replace with MEM/10% FBS, and continue to grow to confluence, changing the medium twice a week (e.g., Monday and Thursday or Tuesday and Friday).

    Confluence will be reached in ~10 days.

ISOLATION AND SEEDING OF CORTICAL ASTROCYTES AND MICROGLIA CELLS

SUPPORT PROTOCOL 3

The techniques described here to prepare and separate astrocytes and microglial cells are based on the methods of McCarthy and DeVellis (1980), and Giulian and Baker (1986), which have undergone some changes in this laboratory. The method is based on the selective detachment of microglial cells from astrocytes by shaking mixed glial cultures on an orbital shaker; a result of the difference in degree of attachment to tissue-culture plastic versus each other. Astrocytes are then further depleted of microglial cells by treatment with L-leucine methyl ester (L-LME), which selectively kills microglia.

Both astrocytes and microglial cultures appear >97% pure, as assessed by immunocytochemistry of glial fibrillary acidic protein (GFAP), a cytoskeletal protein found only in astrocytes, and with *Griffonia simplicifolia* isolectin B4, a selective marker of both resting and activated microglia (Cheepsunthorn et al., 2001). From each flask of confluent glial cells the author's group usually obtains ~5×10^6 astrocytes. The number of microglial cells separated by each flask is extremely variable and changes with different preparations (i.e., from ~5×10^5 to ~3×10^6 cells).

Materials

High-glucose MEM/10% and 15% FBS (see recipe)
0.04% (w/v) trypan blue solution
1× PBS (Sigma; *APPENDIX 2A*)
High-glucose MEM/10% FBS containing 5 mM L-LME (Sigma)
1× trypsin/EDTA solution (Sigma)
24-well plate containing coated glass coverslips (see Support Protocol 4)

Additional reagents and solutions for preparing confluent glial cultures in 75-cm^2 cantered-neck flasks (see Support Protocol 2) and determining cell number and viability with a hemacytometer (*APPENDIX 3B*)

Detach microglia

1. Prepare confluent glial cultures in 75-cm2 cantered-neck flasks (see Support Protocol 2).

   Use culture flasks since the caps can be completely tightened to prevent medium spill during the shaking period.

   In the author's laboratory, usually ~4×10^6 cells are seeded per flask. In these conditions glial cells reach confluence after 10 days (i.e., to obtain a confluent monolayer on Monday prepare glial cells on the Thursday two weeks before).

2. Use Parafilm to seal the flask caps and vigorously agitate on an orbital shaker 1.5 hr at 260 rpm, 37°C.

   Within 2 hr of shaking, most of the microglia can be detached from the glial monolayer and subcultured. Astrocytes remain adherent to the flask.

3. Collect the medium from the flasks in one or more 50-ml centrifuge tubes.

   Collect up to 50 ml for each tube; one 50-ml tube is enough for 6 flasks.

Equilibrate astrocytes and pellet microglia

4. Add 10 ml fresh high-glucose MEM/10% FBS to each flask with a sterile pipet.
5. To pellet the suspended cells, centrifuge the 50-ml tubes 5 min in a swinging-bucket rotor at 200 to 300 × *g*, room temperature. Meanwhile, transfer the flasks to an incubator for at least 1 hr.

   To obtain purified astrocytes, the flasks have to be shaken further overnight. Since it is usually impossible to shake the flasks in an incubator, it is better to allow the fresh medium to equilibrate before shaking again. This period usually suffices for the preparation of microglial cultures.

Dissaggregate and assess cell number and viability

6. At the end of the centrifugation discard the supernatant, add 2 ml MEM/10% FBS to microglial-cell pellet using a sterile pipet and disaggregate by drawing up and down. Add an additional 3 ml MEM/10% FBS for a total of 5 ml and resuspend to obtain a homogeneous suspension.
7. Add 100 µl cell suspension to 200 µl of 0.04% trypan blue solution and mix gently. Determine total cell number and viability with a hemacytometer and inverted phase-contrast microscope (*APPENDIX 3B*).

   Trypan blue is used to distinguish viable from dead cells. Viable cells exclude trypan blue while dead or damaged cells are stained.

Prepare and plate microglia for the sandwich coculture

8. Gently resuspend sedimented cells, then dilute to 200,000 cells/ml with MEM/10% FBS.
9. Add 1 ml suspension to each well of a 24-well plate containing coated glass coverslips.
10. Incubate 30 min.

    This short incubation period allows the adhesion of chiefly microglial cells to the substrate.

11. Gently shake the plate, remove the medium, and wash once with 1× PBS.

    By shaking and washing, loosely adhering cells like oligodendroglia are removed.

12. Add 1 ml high-glucose MEM/15% FBS to each well and transfer plates to an incubator.

Purify astrocytes

13. Transfer the flasks containing partially purified astrocytes (step 5) to an orbital shaker and agitate overnight at 260 rpm, 37°C.
14. The next morning, remove the medium and wash the monolayer three times with 1× PBS.
15. Add 10 ml high-glucose MEM/10%FBS/5 mM L-LME to each flask.

    L-LME selectively kills microglial cells and is used to reduce any microglial contamination of astrocytes.

16. Incubate 2 hr.

17. Wash twice with PBS.

Trypsinize astrocytes

18. Add 2 ml of 1× trypsin/EDTA to each flask to detach astrocytes and gently rotate so that the trypsin can spread over the surface where astrocytes are attached. Incubate 5 min.

    Do not exceed this time, otherwise there is danger of overdigestion. If it is necessary to detach astrocytes from several flasks, do not add trypsin to all of them at the same time.

    To detach cells without using trypsin, incubate the monolayer 5 min in 5 ml PBS without calcium and magnesium, supplemented with 5 mM EDTA; however, this procedure gives lower cell recovery than by trypsinization.

19. Detach astrocytes by gently shaking and washing the surface of the flask.

20. Transfer the trypsin solution containing astrocytes to a tube containing 2 ml MEM/10% FBS in each flask.

    The serum contained in the medium inactivates trypsin. Thus, to avoid overdigestion the cells resuspended in trypsin are immediately added to an equal volume of cell culture medium. If more than one flask is to be trypsinized, the cells can be pooled in a single tube containing cell culture medium. Add 1 ml of cell culture medium for each milliliter trypsin.

Prepare and plate astrocytes for the sandwich coculture

21. To pellet cells, centrifuge 10 min in a swinging bucket rotor at 100 to 200 × *g*, room temperature. Aspirate the medium and resuspend in 2 ml of MEM/10% FBS.

22. Repeat steps 7 and 8 with the astrocyte suspension.

23. Add 1 ml cell suspension to each well of a 24-well plate.

24. Transfer to an incubator.

    Astrocytes can be maintained up to 1 month.

PREPARATION OF GLASS COVERSLIPS FOR SANDWICH COCULTURES

SUPPORT PROTOCOL 4

Hippocampal neurons and microglial cells do not readily adhere to glass. Thus, to promote their attachment, maturation, and survival, coverslips are coated using poly-L-ornithine, or poly-L-lysine. In addition, three dots of paraffin are placed on each coverslip to create a narrow gap between the two cultivated cell populations.

The use of 24-well plates and 12-mm coverslips to obtain a coculture does not allow an open-face-sandwich coculture, as described for hippocampal neurons and astrocytes in *UNIT 12.3*. This is basically because the cell monolayer below the coverslip degenerates. In 24-well plates, where the well is slightly bigger than the coverslip, this means the destruction of the glial or astrocyte monolayer.

The coverslips are prepared at least one day before the hippocampal neurons (see Support Protocol 1) or microglial cells (see Support Protocol 2) are dissociated. In the author's laboratory, if hippocampi are dissected on Monday, coverslips are prepared the Friday before and kept in polyornithine at room temperature until Monday morning. Next they are washed and incubated in growth medium before being seeded with cells.

Materials

Paraffin wax
1× poly-L-ornithine solution (see recipe)
1× PBS (Sigma)
High-glucose MEM/10% FBS (see recipe)

12-mm glass coverslips
24-well tissue-culture plates
Microwave oven
5- to 10-ml sterile syringe with 0.95 × 40–mm needle
Germicide lamp (e.g., as equipped on a flow hood)

1. Place one 12-mm glass coverslip in each well of a 24-well tissue-culture plate.

   Each time, prepare the exact number of coverslips to be used. This will reduce the possibility of contamination.

2. Sterilize the coverslips by microwaving 10 min at the highest power setting.

3. Place the plates next to a beaker half full of water in order to avoid melting the plastic plates.

4. Heat paraffin wax to ~100°C. Take an ~2-ml aliquot in a 5- or 10-ml syringe and apply three small drops near the outer edge of each coverslip at roughly equal distances from each other.

   To melt paraffin, place 4 pieces in a beaker and place the beaker on a hot plate.

   By working rapidly, it is possible to place several dots over 2 to 3 coverslips. The temperature of the paraffin is very important. If it is too hot, it spreads too thin and wide, while if it is too cool, the dots do not adhere to the coverslip and will subsequently detach.

5. Resterilize the coverslips by UV irradiation for 30 min with a germicide lamp.

   The germicide lamp of a flow hood is sufficient. Avoid exposing coverslips to UV after they have been coated with polyornithine.

6. In a laminar flow hood, add 1 ml of 1× poly-L-ornithine solution in each well containing the coverslips.

   Check that the coverslips do not float in the well but are completely covered by polyornithine. To prevent floating, be sure to eliminate any air bubble under the coverslip by gently pressing over it.

7. Incubate the plates up to 2 days at room temperature or for 2 hr at 37°C.

   When plates are out of the laminar flow hood, store them sealed with Parafilm in the dark.

8. Immediately before isolating cells (see Support Protocol 2), remove polyornithine and rinse twice with 1× PBS.

   To obtain the best result in the attachment of cells and their development do not let the coverslips dry at any stage.

9. After the final rinsing add 1 ml high-glucose MEM/10% FBS and incubate until the end of cell preparation.

   When isolated and dissociated, cells will be seeded in this same medium.

   The coverslips are now ready to be seeded. Add the desired number of cells over the coverslips without changing the incubation medium.

   In the author's laboratory unused coverslips are discarded.

REAGENTS AND SOLUTIONS

Use sterile Milli-Q-purified water or equivalent for all recipes and protocol steps. For common stock solutions, see ***APPENDIX 2A****; for suppliers, see* ***SUPPLIERS APPENDIX****.*

Cytosine arabinoside, 2 mM

Dissolve 2 mg cytosine-1-β-*D*-arabino-furanoside (cytosine arabinoside) in 5 ml water. Store up to 6 months at −20°C.

DNase I, 10 mg/ml

Dissolve 100 mg of 536 Kunitz units/mg DNase I (Sigma) in 10 ml HBSS (see recipe). Store up to 6 months in 1.5-ml aliquots at −20°C.

HBSS

To 850 ml H_2O add:
Hanks Balanced Salts powder (Sigma), enough for 1 liter
10 ml 10 mM HEPES (Sigma)
10 ml penicillin/streptomycin stock solution (Sigma)
Adjust volume to 1 liter with H_2O
Sterilize using a 0.22-µm cellulose-acetate disposable vacuum-filtration system (Millipore)
Store up to 1 month at 4°C

The stock solution of penicillin/streptomycin contains 10,000 U/ml penicillin and 10 mg/ml streptomycin. Store this stock solution up to reported expiration date in 5-ml aliquots at −20°C.

High-glucose MEM/10%, 15%, or 20% FBS

500 ml minimal essential medium with Earle's salts (MEM; Sigma)
0.6% (w/v) D(+)-glucose (Sigma)
5 ml penicillin/streptomycin stock solution (Sigma)
5 ml of 200 mM L-glutamine
Shake vigorously to dissolve glucose
10%, 15%, or 20% (v/v) FBS (Sigma)
Sterilize using a 0.22-µm cellulose-acetate disposable vacuum-filtration system (Millipore)
Store up to 1 month at 4°C

Do not add FBS before shaking, otherwise there is excessive foam formation.

The stock solution of penicillin/streptomycin contains 10,000 U/ml penicillin and 10 mg/ml streptomycin (100 U and 100 µg/ml final, respectively). Store this stock solution up to indicated expiration date in 5-ml aliquots at −20°C.

See APPENDIX 3B for more information regarding preparation of medium.

Insulin, 5 mg/ml

100 mg insulin from bovine pancreas (Sigma)
20 ml sterile H_2O
100 µl glacial acetic acid
Store up to 6 months at 4°C

Poly-L-ornithine solution, 1×

Prepare a 100× stock solution by dissolving 10 mg poly-L-ornithine (Sigma) in 6.67 ml water. Store up to 6 months in 1-ml aliquots at −20°C. Dilute to 1× with water.

Progesterone, 0.1 mM

Dissolve 0.314 mg progesterone in 10 ml of ethanol. Store up to 6 months at −20°C.

Putrescine, 1 M

Dissolve 1.6 g putrescine (Sigma) in 10 ml water. Store up to 6 months at −20°C.

SFM

To 850 ml H_2O add:

Dulbecco's modified Eagle's medium nutrient mixture F-12 Ham powder (Sigma), enough for 1 liter

3.7 g $NaHCO_3$

0.11 g sodium pyruvate (1 mM final; Sigma)

1 ml 5 mg/ml insulin (see recipe)

100 mg >97% human apotransferrin (Sigma)

100 µl 1 M putrescine (1 µM final; see recipe)

120 µl 0.25 M sodium selenite (30 nM final; see recipe)

200 µl 0.1 mM progesterone (20 nM final; see recipe)

10 ml penicillin/streptomycin (100 U/ml and 100 µg/ml final, respectively; Sigma)

Adjust pH to 7.2

Adjust volume to 1 liter with H_2O

Sterilize using a 0.22-µm cellulose-acetate disposable vacuum-filtration system (Millipore)

Store for up to 1 month at 4°C.

See APPENDIX 3B for more information regarding preparation of culture medium.

Sodium selenite, 0.25 mM

Dissolve 1 mg sodium selenite (Sigma) in 10 ml water. Store up to 1 month at room temperature.

COMMENTARY

Background Information

Coculture systems provide an easy controlled way to study how a cell population can influence the function, viability, and response of another cell population. Other in vitro systems suitable for the study of the interactions between different cell populations are brain reaggregate cultures or organotypic explants. Brain reaggregate cultures are rotation-mediated aggregating cultures constructed from single-cell suspensions of fetal brain characterized by an organotypic cell association.

A more complex situation is represented by the organotypic cultures. These are derived from explants of undifferentiated embryonic brain and retain some of the structural and functional characteristics of the area of origin.

Both organotypic and reaggregate cultures differ from cocultures since they retain a three-dimensional organization. While a flat coculture system is particularly well suited to detect changes in cell function or differentiation and the interference of a neurotoxicant on these parameters, organotypic and reaggregate cultures are designed to detect changes in cellular organization by morphological and electrophysiological features. Thus, the choice of the cell system largely depends on the question to be answered.

The great advantage of a sandwich coculture system in toxicological studies over the other in vitro systems is the possibility of separating the two cell populations at any time (e.g., prior to or after a treatment) while retaining their integrity. This allows the investigator to (1) treat the cell types differently before they are exposed together to a toxicant, thus providing information on the involvement of specific mediators or biochemical pathways, (2) perform different biochemical measurements on the two cell populations separately at the end of the treatment, and (3) evaluate the effect of a toxicant on highly differentiated neurons in the presence or absence of the glial feeder layer. For example, the author used this system to study the molecular mechanisms involved in the glia-mediated neurotoxicity of the human immunodeficiency virus glycoprotein 120 (gp-120). The question of whether the production of reactive oxygen species (ROS) induced by gp-120 in glial cells could be responsible for an increased production of IL-1β from glia and

subsequent neural death was assessed (Viviani et al., 2001). For this purpose, glial cells were loaded with an antioxidant, washed, and exposed together with hippocampal neurons to gp-120. In this way, the ability of glial cells to produce ROS as a consequence of gp-120 exposure without altering the neural cells was blocked. As a control, hippocampal neurons and unloaded glia were exposed to gp-120. At the end of the treatment, glia and neurons were separated, neural cell death was assessed by the MTT test, and the results compared with the death rate of neurons exposed to gp-120 in the presence of an unloaded glial monolayer. The synthesis of IL-1β in glial cells was also measured by RT-PCR. It was observed that antioxidant pretreatment of glial cells reduced gp-120 production of IL-1β and neural cell death.

This model has also been used to monitor the influence of neural degeneration on glial response in modulating neural cell death (Viviani et al., 2000).

Because there is no contact between the cell populations, sandwich coculture allows one to study how different cell populations can reciprocally influence their functions/viability through the release of soluble mediators. The lack of contact between neurons and glia, or astrocytes and microglia may, however, represent a disadvantage since it does not mirror physiological conditions. Hippocampal neurons can be plated directly onto glial cells, as can microglia onto astrocytes, but the advantage of manipulating one of the two cell populations forming the coculture would be lost.

Critical Parameters and Troubleshooting

Three very important parameters to obtain successful primary cultures are sterility, rapidity in dissecting brain tissues and plating the obtained cells, and satisfactory reagents. Problems encountered during cell isolation and growth, their possible causes and possible remedies are reported in Table 12.10.3. Also see the equivalent section in *UNITS 12.3 & 12.4*.

Sterility

Working conditions must ensure the highest degree of sterility. This means that, wherever possible, cell isolation, culturing, and preparation of all solutions should be performed in a laminar flow hood. If nonsterile ingredients are added to a solution, the product has to be filtered through a 0.22-μm filter. To maintain sterility, solutions must never be opened outside the laminar flow hood and must be stored in small aliquots. The addition of antibiotics such as penicillin and streptomycin to the culture medium helps to avoid bacterial contamination.

The use of disposable materials for culturing cells reduces the possibility of contamination and is strongly recommended. All disposable materials (even plastic pipets) should be used only once.

Autoclave surgical instruments (i.e., 21 min at 121°C) to sterilize and store in 95% ethanol when not in use. If, during dissection, tools touch nonsterile surfaces or materials, spray them with 70% ethanol and let the ethanol evaporate before using again.

If any contamination occurs, it is wise to eliminate the contaminated cultures, prepare fresh reagents, and clean the laminar flow hood prior to new culture preparation. To clean the laminar flow hood, wash with a detergent first and then with 70% ethanol. Contaminated solutions can be filtered, but sterility has to be checked prior to use by incubating in culture dishes for a few days at 37°C.

Tissue dissection

Rapid dissection of both hippocampi and cortices is essential to obtain a successful neural or glial culture. In the author's experience the shorter the time of dissection the better the culture obtained. The author's group never exceeds 2 hr to obtain brains and dissect hippocampi and cortices. Preparation time for cultures can be considerably shortened by using a team of two people, one removing brains from the skull and the other cleaning, removing, and dissociating hippocampi or cortices.

Reagent lots

Lot-to-lot variability of reagents such as trypsin, poly-L-ornithine, and all the ingredients of SFM as well as FBS, influences the viability, development, and functionality of glia and particularly of hippocampal neurons. Wherever possible, it is better to test different lots of the same reagent before the routine cultivation of glia and neurons. Measurements to identify the best lot are: the number of cells obtained after tissue dissociation (which can depend on the lot of trypsin used), the growth rate of glial cells (dependent on serum), the cell viability, the differentiation of neural cells (dependent on the poly-L-ornithine or the ingredients of SFM). If poor neural differentiation is observed, check also that all the requisite ingredients have been added to the culture medium.

Table 12.10.3 Troubleshooting Guide to Coculturing Neurons and Glial Cells

Problem	Possible cause	Solution
Low cell viability	Prolonged dissection time	Never exceed 2 hr to obtain brain and dissect hippocampi or cortices
Poor neuronal differentiation	SFM is incomplete (e.g., without apotransferrin)	Prepare fresh SFM and check that all ingredients are added
	L-Polyornithine lot is unsatisfactory	Test different lots and choose the best
	Glial feeder layer is too old	To cocultivate hippocampal neurons use a glial feeder layer within 3 to 4 weeks
	Damaged glial feeder layer	Check the morphology of glial cultures every time before adding neurons
Floating cells in cultures	Contamination	See Critical Parameters and Troubleshooting, Sterility

Anticipated Results

Healthy hippocampal neurons readily attach to coated glass coverslips and are initially characterized as small round shapes. Within a day of coculture they extend short processes (Fig. 12.10.1). A well-developed network is clearly evident at the third or fourth day of coculture. In the following weeks, even if great morphological changes are not evident any more, hippocampal neurons develop a functional glutamatergic system and a complete post-synaptic density. Hippocampal neurons become sensitive to glutamate, showing an increase in cell death and intracellular calcium, starting from the eighth day of culture.

Glial cultures at confluence are characterized by the presence of an overwhelming percentage of astrocytes and ~5% of microglia. Astrocytes have a flat polygonal appearance and form a uniform layer over which small, dark microglial cells can be observed. Microglial cell numbers can increase considerably with aging of the culture. Once detached from astrocytes and plated on a glass coverslip, microglial cells acquire a round shape that tends to ramify as the number of days in culture increases. A "ramified" morphology is typical of resting microglia. The author's group observed no morphological difference in microglia or astrocytes cultivated alone or in coculture <48 hr from their preparation.

Time Considerations

Preparation of hippocampal neuron-glia sandwich cocultures (Basic Protocol 1) or of astrocyte-microglia-sandwich cocultures (Basic Protocol 2) requires 35 to 45 min. Hippocampal neuron-glia cocultures can be maintained up to 3 to 4 weeks. In the author's laboratory, the astrocyte-microglia coculture is used within 48 hr from its preparation.

Isolation and seeding of hippocampal neurons (Support Protocol 1) require 1.5 hr to 2 hr. Hippocampal neurons seeded by following the described protocol can be maintained without glial cells up to a couple of days.

Isolating and culturing cortical glial cells (Support Protocol 2) requires 2 hr. Cortical glial cells can be maintained up to 1 month.

Isolation and seeding of cortical astrocytes (Support Protocol 3) require 19 hr. Astrocytes can be maintained up to 1 month. Isolation and seeding of microglial cells (Support Protocol 3) require 2 hr. In the author's laboratory, microglia are maintained up to 48 hr from preparation.

Preparation of glass coverslips for sandwich cocultures (Support Protocol 4) requires 2 days when glass coverslips are incubated with poly-L-ornithine at room temperature or 3 hr when glass coverslips are incubated with poly-L-ornithine at 37 °C.

Determining the Ability of Xenobiotic Metals to Bind a Specific Protein Domain by Electrophoresis

BASIC PROTOCOL

Environmental metals are potentially toxic and can interfere with the metal-binding motifs of various critical proteins. This unit describes an electrophoretic method that can be used to measure the ability of a xenobiotic metal to bind a zinc-finger motif. Information gained using this protocol can lead to the identification of protein targets of metals and shed better light on their mechanisms of action.

The zinc-finger motif belonging to the Cys_2-His_2 family provides a structural framework for a number of critical proteins which are essential for cellular function. Proteins that contain this motif perform a variety of functions and are present in transcription factors, enzymes, cell-surface receptors, and a number of other cellular intermediates. This protein domain is naturally tailored to serve as a specific binding region for endogenous zinc; however, this domain may be a potential target for the binding of other xenobiotic metals. The interactions of heavy metals with this protein region may lead to functional and structural perturbations of the protein.

To perform this assay, first a synthetic zinc-finger apopeptide (26 amino acids) resembling a single-finger domain of specificity protein 1 (Sp1; Fig. 12.11.1) is reconstituted with a metal of interest. Then, the ability of this metal-peptide complex to specifically bind a cognate DNA consensus sequence is examined electrophoretically. A metal that is able to bind such a peptide and maintain a specific structural configuration will interfere with the mobility of the DNA consensus sequence on an SDS-PAGE gel. As confirmed by one- and two-dimensional NMR studies (Razmiafshari and Zawia, 2001) this specific configuration requires that the metal be able to bind both the cysteine and histidine residues that are involved in the zinc-coordination sphere of this domain. The concentration, affinity, and specificity at which such a metal can bind can also be determined. This unit describes the electrophoretic method that may be used to measure the ability of a xenobiotic metal to bind the zinc-finger motif that may be present in any protein of interest.

CAUTION: Institutionally approved safety protocols must be followed when working with radioactivity. Experiments must be conducted in designated areas and the use and disposal of radioactive materials must be done according to established guidelines.

CAUTION: Radiolabeled probes are hazardous; see *APPENDIX 1A* for guidelines on handling, storage, and disposal.

NOTE: All glassware should be acid washed with 4 N nitric acid. Peptide handling must be performed with metal-free tips using metal-free tubes. To prevent peptide oxidation, all manipulations must be performed in an anaerobic environment. All buffers containing peptides and/or metal solutions should be degassed with nitrogen prior to use.

Materials

1.75 pmol/µl Sp1 consensus oligonucleotide (annealed before use):
5′-ATTCGATC*GGGGCGGGGC*GAGC-3′
3′-TAAGCTAG*CCCCGCCCCG*CTCG-5′
3000 Ci/mmol [γ-^{32}P]ATP
10× kinase buffer (see recipe)
10 U/µl T4 polynucleotide kinase
TE buffer (*APPENDIX 3C*)

Contributed by N.H. Zawia, Md. Riyaz Basha, and M. Razmiafshari
Current Protocols in Toxicology (2003) 12.11.1-12.11.8

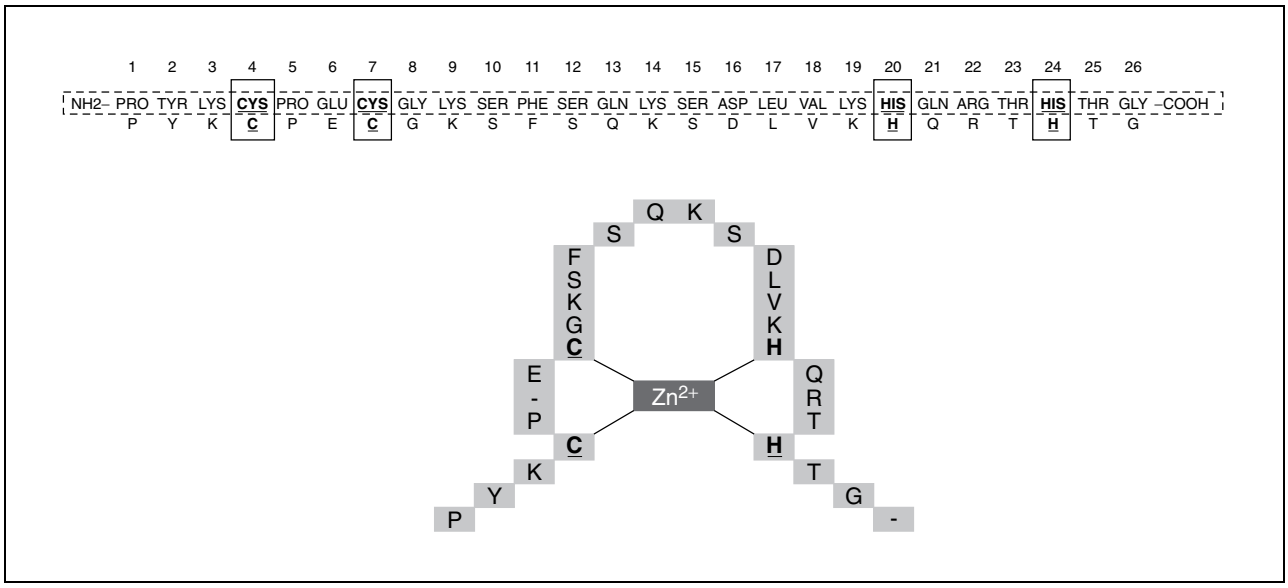

Figure 12.11.1 Schematic diagram of the amino acids sequence of a zinc-finger motif and its deduced form. This sequence was used in the studies summarized in this unit.

Synthetic zinc-finger apopeptide stock solution (see recipe)
Divalent metal solutions (see recipe)
Gel-shift binding buffer (see recipe)
Gel loading buffer (Sigma)
Sephadex G-25 spin column (Sigma)

Additional reagents and equipment for preparing and running polyacrylamide gels (*APPENDIX 3F*) and autoradiography (*APPENDIX 3D*)

Label DNA

1. Prepare the following labelling reaction mixture:

   2 µl of 1.75 pmol/µl Sp1 oligonucleotide
   1 µl of 3000 Ci/mmol [γ-^{32}P]ATP
   1 µl 10× kinase buffer
   1 µl of 10 U/µl T4 polynucleotide kinase.

   Adjust the final volume to 10 µl with water.

   The nucleotides in italics in the oligonucleotide sequence comprise the CG-rich sequence to which a transcription factor binds.

2. Incubate the reaction mixture 10 min at 37°C.

3. Dilute the resultant labeled probe to a final volume of 100 µl (optional) with TE buffer.

   Each reaction requires 55,000 to 65,000 cpm for better binding and to obtain a good signal in the autoradiogram. TE buffer helps maintain optimal reaction conditions.

4. Pass the labeled DNA probe through a Sephadex G-25 spin column for purification of labelled probe from reaction components.

Make metal-peptide complexes

5. Prepare sufficient 10 µM working solution from a synthetic zinc-finger apopeptide stock—82.5 nmole peptide (~0.25 mg) in 500 µl in buffer—for metal-binding and displacement studies.

6. Form metal-peptide complexes by preparing a series of tubes containing 0.5 µl of 10 µM synthetic peptide, and 0.5 µl of a range of low (1 to 200 µM) to high (0.4 to 3.5 mM) concentration divalent metal solutions (Zn, Ca, and metals of interest in Milli-Q-purified water).

   Zinc will serve as a positive control, while calcium, which is unable to coordinate with the Cys residues in the Cys_2-His_2 motif to form a tetrahedral structure, can be used as a negative control in these experiments.

Perform metal-peptide-DNA-binding reactions

7. Prepare the final binding reaction containing 1 µl (500 ng) purified peptide–metal complex and add 17 µl gel-shift binding buffer.
8. Incubate the reaction mixture 30 min at room temperature.
9. Add 1 µl of 0.025 ng/µl labeled DNA probe (step 4) to the above reaction mixture.

   The final reaction volume is 20 µl.

10. Incubate the resultant reaction mixture 20 min at room temperature.

Analyze the DNA-binding reaction by gel electrophoresis

11. Prepare a 15% 1.0 to 1.2-mm thick (29:1) polyacrylamide gel (*APPENDIX 3F*), and prerun 1 hr at 155 V using 90 mM Tris-borate, pH 8.3, as the running buffer.
12. Add 1 µl gel loading buffer to the sample. Load the samples (reaction mixtures) and allow for electrophoresis to proceed 3 to 3.5 hr at 155 V (15 mA; *APPENDIX 3F*).

    The color of the gel loading buffer will help when loading the gel.

13. Dry the gel and expose it to X-ray film overnight (*APPENDIX 3D*).
14. Analyze the resulting autoradiograms for shifted bands.

REAGENTS AND SOLUTIONS

*Use metal-free water (e.g., Milli-Q-purified) for all recipes and protocol steps. For common stock solutions see **APPENDIX 2A**; for suppliers, see **SUPPLIERS APPENDIX**.*

Divalent-metal solutions

Prepare 1 mM stock solutions from each metal (i.e., Zn, Ca, metal of interest) salt or nitrate in metal-free water and store up to 1 week at 4°C.

Gel-shift binding buffer

35 mM Tris·Cl, pH 8.0 (*APPENDIX 2A*)
60 mM NaCl
3 mM DTT
375 µg/ml BSA
0.2% (v/v) protease inhibitor cocktail (Sigma)
300 ng poly(dI·dC) in 10% (v/v) glycerol
Store up to 3 months at less than −20°C

Kinase buffer, 10×

700 mM Tris·Cl, pH 7.6 (*APPENDIX 2A*)
100 mM MgCl
50 mM DTT
Store up to 3 months at less than −20°C

Follow the instructions given by the company for the buffer obtained from the commercial sources (e.g., Promega).

Synthetic zinc-finger apopeptide stock solution

Synthesize a zinc-finger peptide resembling a single-finger motif of Sp1 (P-Y-K-C-P-E-C-G-K-S-F-S-Q-K-S-D-L-V-K-H-Q-R-T-H-T-G) using standard procedures. Store it as a powder at −80°C until use. Make a stock solution by dissolving 82.5 nmol (~0.25 mg) peptide in 500 µl of 100 mM HEPES (pH 7.0)/50 mM NaCl. Store up to 4 to 6 months at −20°C.

COMMENTARY

Background Information

Environmental metals are potentially toxic and can interfere with the metal-binding motifs of various critical proteins of the cell. The zinc finger is a major structural motif involved in protein–nucleic acid interactions and is present in the largest known superfamily of eukaryotic transcription factors, such as Sp1 (Dynan and Tijian, 1983). In order to maintain structural integrity, zinc ions coordinate this finger-like structure through bonds created with cysteine and histidine residues. Metal-induced perturbations of the structural integrity of this motif may alter protein function and can result in a variety of adverse effects including neurological diseases and aggressive malignancies.

A zinc-finger peptide may be utilized as a model to study the interactions of various environmental metals with this motif. This approach provides the advantage of designing apopeptides that resemble the binding sites of endogenous metals and complexing them in vitro with heavy metals suspected to bind to them. The properties of the peptide-metal complexes may then be compared to the action of these metals on an entire protein that normally contains the motif. Furthermore, details on the exact binding site of these metals to these small synthetic peptides may be examined by nuclear magnetic resonance spectroscopy. These models can help to reveal the mechanisms of action of certain metals, especially metal-induced alterations in gene expression.

Critical Parameters and Troubleshooting

The rationale for choosing the peptide used in this unit is that the residues involved in stabilizing the three-dimensional structure of the metal-bound forms of the zinc-finger domains are present in such an amino acid sequence, leading to increased affinity for metal ions (Krizek et al., 1991). Since the peptide synthesized is part of the DNA-binding domain of Sp1, one can investigate whether these metal complexes show specific DNA-binding properties. The binding and activity of zinc-finger peptides have been shown to be modulated by heavy metals (Zawia et al., 1998). Various proteins, which contain zinc-finger domains of the Cys_2-His_2 type, have been shown to bind specifically to DNA, RNA, and DNA-RNA hybrids (Shi and Berg, 1996). Also, previous DNA binding studies employing gel shift assays have suggested that single zinc-finger peptides bind to DNA only in the presence of zinc (Lee et al., 1991). Hence, for a proper metal-peptide DNA complexation and specific binding, metal ions and the peptide must cooperatively adopt the proper structure necessary for DNA sequence recognition.

The DNA-metal-peptide complex may exhibit an increased mobility on the gel. This may be due to the ability of zinc-finger proteins to cause winding and unwinding of DNA. Structural and biochemical analyses have shown that DNA was slightly unwound when bound to zinc-finger peptides (Pavletich and Pabo, 1991; Nekludova and Pabo, 1994; Shi and Berg, 1996). Although the zinc-finger motif may play a role in changing DNA shape and form, the addition of specific metals to the peptide may also change the packing structure of the peptide altering its mobility on the gel. This appears to be linked to the concentration of DNA present, because an excess of cold DNA competes and restores the accelerated band to its original position.

In the procedure describe in this unit, the following guidelines should be observed.

1. Use a concentration range for each metal because the threshold for perturbation of the motif may be different for each.

2. Follow a specific order in the reaction sequence. Prepare the peptide and metal complex first and then add the labeled DNA oligonucleotide.

3. Check the purity of the DNA consensus element, as commercially available oligonucleotides may contain mixtures of ssDNA and dsDNA, and the peptide may have different affinities for binding each of these strands.

4. Avoid or minimize the use of chelating agents such as EDTA. Although such agents

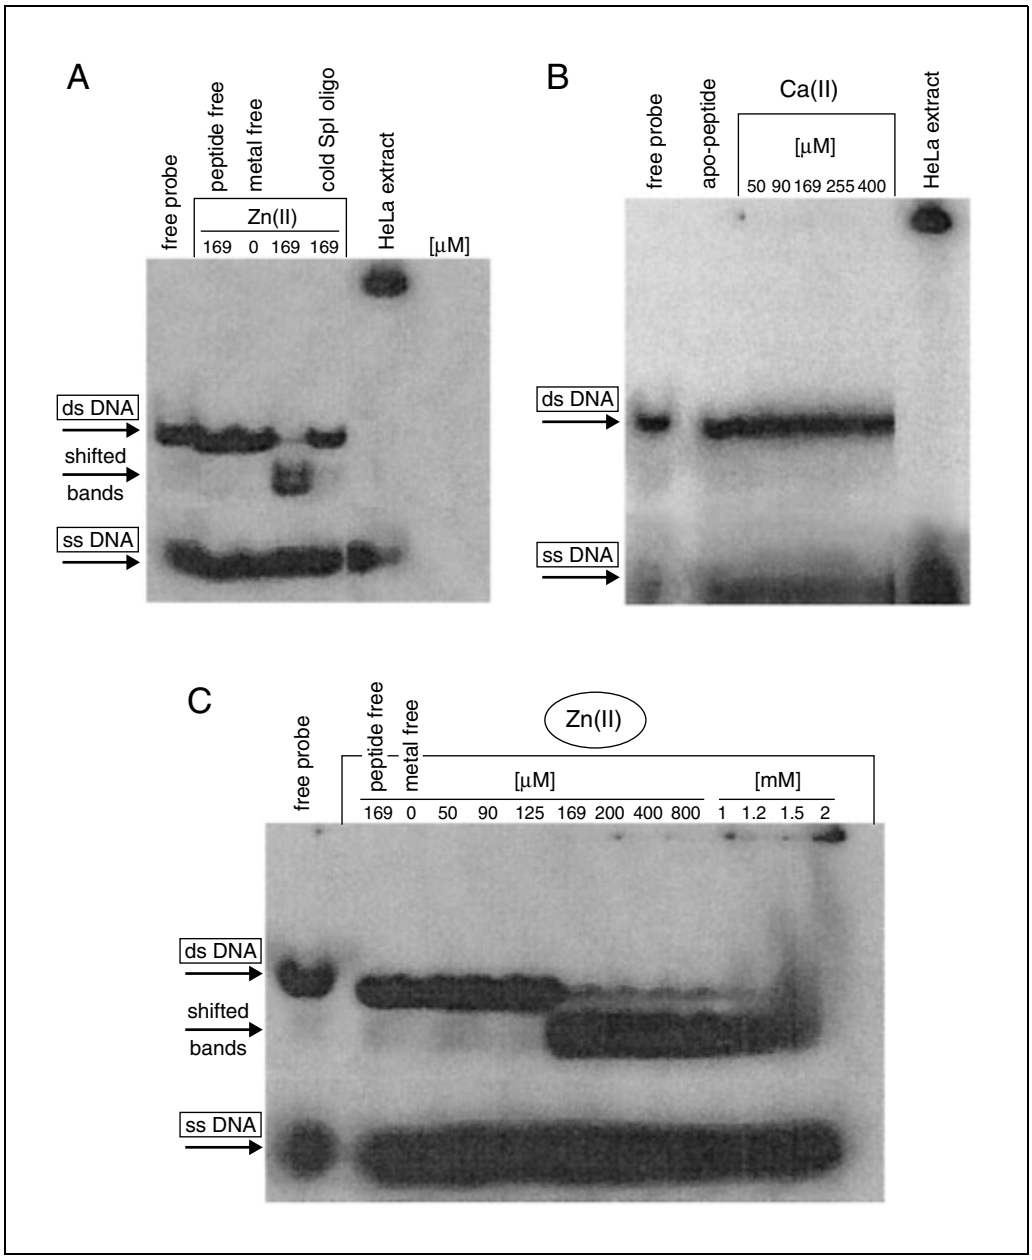

Figure 12.11.2 Concentration-dependent DNA-binding of Zn(II)- and Ca(II)-peptide complexes when reacted with a GC-box consensus DNA element. Shown are autoradiograms of (**A**) competition studies of a Zn(II)-peptide complex with hot and cold Sp1 oligonucleotide, (**B**) Ca(II)-peptide complex, and (**C**) Zn(II)-peptide complex. These reactions contained a ^{32}P-labeled oligonucleotide sequence recognized by Sp1 in each lane. The concentrations of zinc and calcium used and the shifted bands are clearly marked. Zawia, Utilization of a synthetic peptide as a tool to study the interaction of heavy metals with the zinc finger domain of proteins critical for gene expression in the developing brain, pp. 1-12, 2000, with permission from Elsevier.

may stabilize DNA-protein complexes, they can also chelate the free metals in the reaction.

Anticipated Results

The zinc-finger motif belonging to the Cys_2-His_2 family provides a structural framework for a number of critical proteins that are essential for cellular function. To determine whether these domains are potential targets for heavy-metal perturbation, the authors examined the interaction between various metals and a synthetic Cys_2-His_2 finger peptide of the type present in the transcription factor Sp1 (Razmiafshari and Zawia, 2000). Sp1 has a DNA-binding domain composed of three contiguous zinc-finger motifs (26 residues), which binds

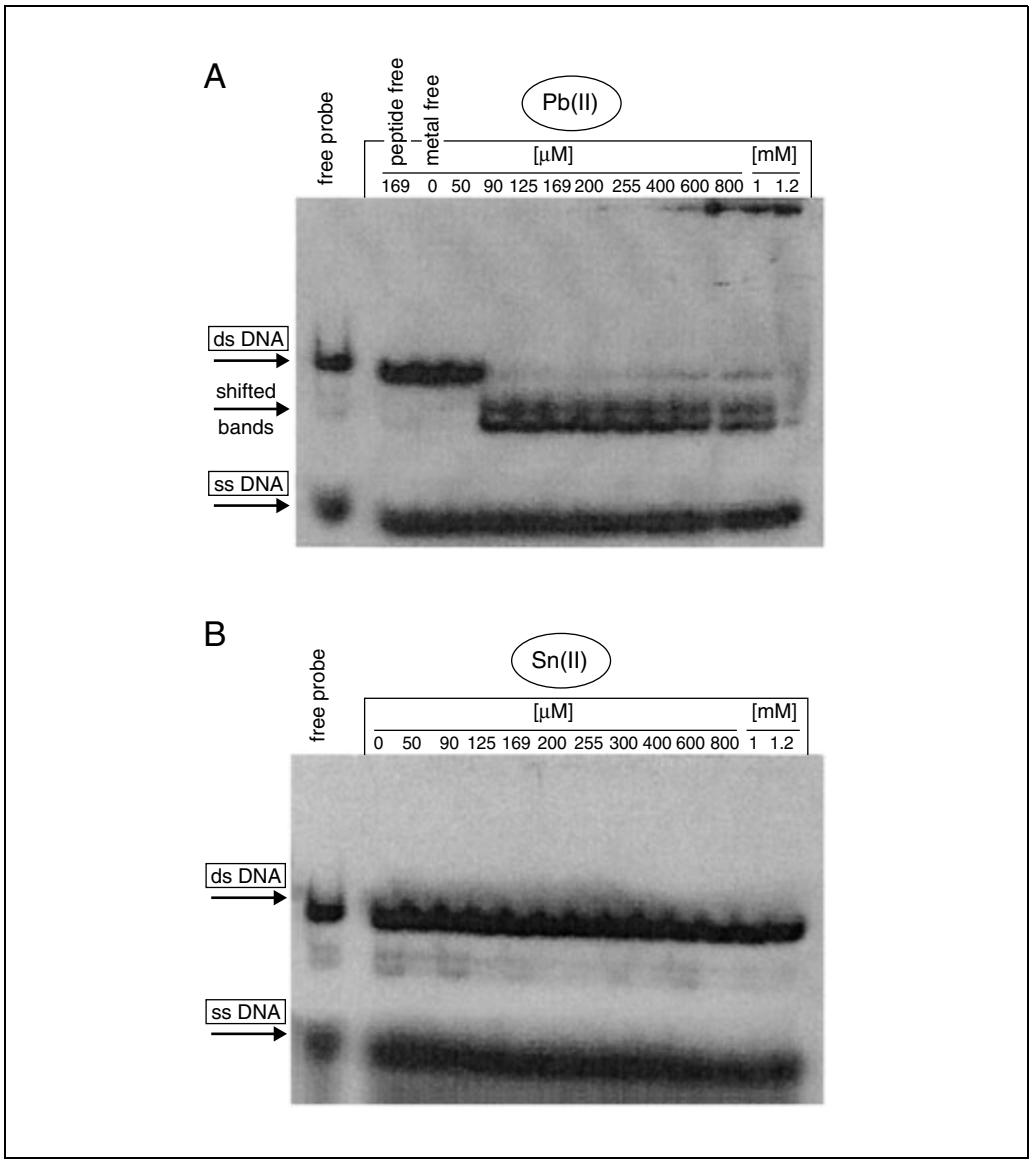

Figure 12.11.3 DNA-binding activity of metal(II)-peptide complexes when reacted with a GC-box consensus DNA sequence. Shown are autoradiograms of (**A**) Pb(II)- and (**B**) Sn(II)-peptide complexes. These reactions contained a ^{32}P-labeled oligonucleotide sequence recognized by Sp1 in each lane. The concentrations of metals used and the shifted bands are clearly marked. Reprinted from *Toxicology and Applied Pharmacology*, 166, M. Razmiafshari and N.H. Zawia, Utilization of a synthetic peptide as a tool to study the interaction of heavy metals with the zinc finger domain of proteins critical for gene expression in the developing brain, pp. 1-12, 2000, with permission from Elsevier.

to the GC box. The DNA-binding activity of these various metal-peptide complexes to their cognate DNA consensus sequence was examined electrophoretically.

Several divalent metals were complexed with the apopeptide and the resultant structural forms were analyzed using the methods outlined above. Titration experiments with the metal-peptide complexes and the DNA consensus sequence were utilized to determine optimum binding conditions. Using the optimum binding concentration of the Zn(II)-peptide complex, the binding specificity to the cognate DNA sequence was explored (Fig. 12.11.2). Under these conditions, a downward gel shift of the DNA-metal-peptide complex was observed. Gel-shift competition experiments revealed that the apopeptide in the absence of zinc ions failed to bind the double-stranded DNA. Additionally, in the absence of the peptide, zinc ions at the optimum concentration did not alter the gel mobility of the oligonucleotide (Fig. 12.11.2). Introducing a 4-fold excess of cold Sp1 oligonucleotide to the same reaction mix-

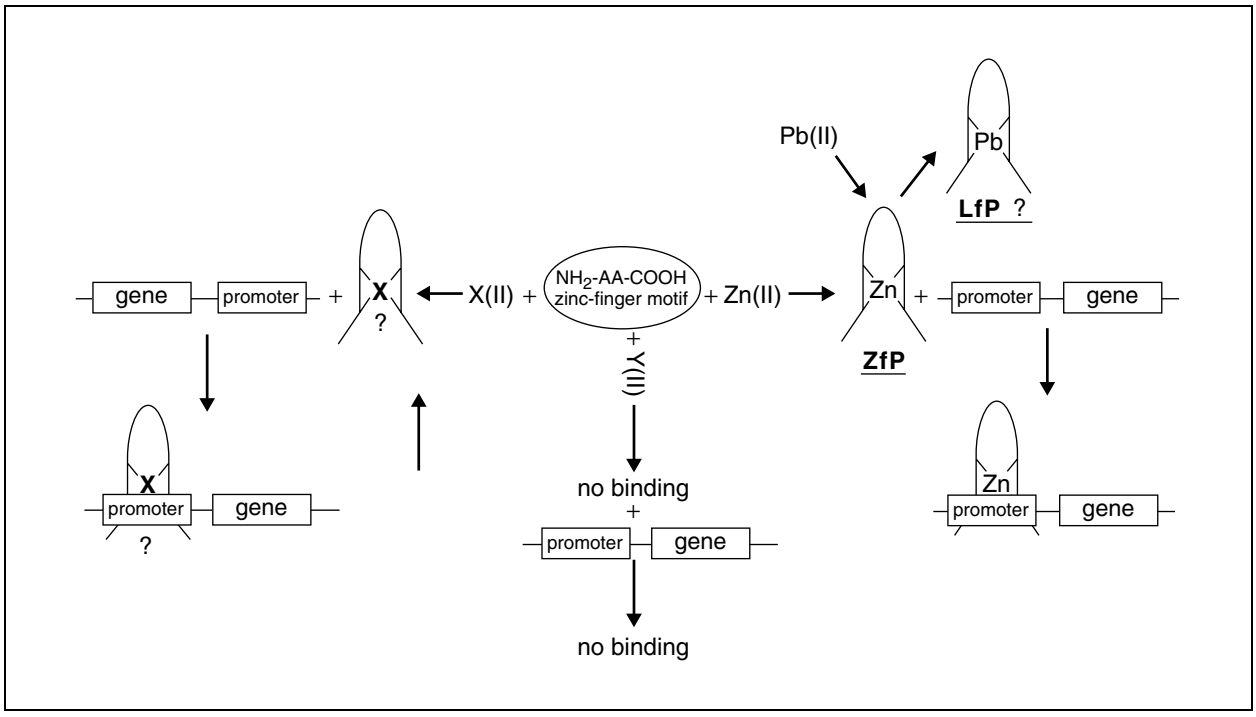

Figure 12.11.4 Predicted mechanism for the interaction of various divalent metals with the zinc-finger motif and their metal-peptide complex reactions with their DNA consensus element. Reprinted from *Toxicology and Applied Pharmacology*, 166, M. Razmiafshari and N.H. Zawia, Utilization of a synthetic peptide as a tool to study the interaction of heavy metals with the zinc finger domain of proteins critical for gene expression in the developing brain, pp. 1-12, 2000, with permission from Elsevier. Abbreviations: X(II) is Pb, Cd, or Hg; Y(II) is Ca, Ba, Mg, or Sn; ZfP, zinc-finger peptide; LfP, lead-finger peptide, AA is a sequence of 26 variable amino acids.

ture competed out the Zn(II) peptide DNA-binding ability and eliminated the shifted bands. Furthermore, Ca(II)-peptide mixtures (Fig. 12.11.2) failed to exhibit any DNA-binding activity, as demonstrated by the unchanged mobility of the DNA sequence in the presence or absence of the complexes (Fig. 12.11.2). The optimum binding concentration of the Zn(II)-peptide complex was determined to be 169 μM, using titration experiments with the metal-peptide complexes and the DNA consensus sequence. Zinc binds to this peptide in 1:1 ratio. Therefore this can happen at very low concentrations in the physiological range. However, in order to be able to detect this interaction in a gel, it is necessary to increase the amount of peptide used and proportionately the amount of metal used.

Pb(II)-peptide complexes (Fig. 12.11.3A) exhibited enhanced DNA-binding ability compared to Zn(II) (Fig. 12.11.2C). Optimal DNA-binding of the Pb(II)-peptide complex occurred at 90 μM. Pb(II) and Sn(II) are in the same group in the periodic table (IVB); however, Sn(II) failed to show any significant DNA-binding (Fig. 12.11.3). This showed that the ability to interact with the zinc-finger motif is limited to specific metals. See illustration for the properties of metals expected to interact with this motif (Fig. 12.11.4).

Time Consideration

Peptide and oligonucleotide synthesis or acquisition is the only process that may be time consuming. Once the peptide and DNA are on hand, the entire process can be accomplished in a few hours. Allow 1 hr for DNA-labeling and 1 hr for peptide complexation and DNA-binding. Running, and drying the gel may take 5 hr. Autoradiographic exposure can range from minutes to hours depending on the specific activity of the labeled DNA (*APPENDIX 3D*).

Morphological Measurement of Neurotoxic Injury in the Peripheral Nervous System: Preparation of Material for Light and Transmission Electron Microscopic Evaluation

An important method of assessing experimental neurotoxic injury is the pathologic examination of the nervous system. The basis of such evaluation is an organized light microscopic study of relevant tissues. While most attention has been given to histopathologic examination of the central nervous system (brain and spinal cord) and to methods relevant to such study, neurotoxicologists have placed less emphasis on the study of its projections outside the neuroaxis. Yet the latter provides an accessible portal for determination of important pathogenetic information in those neurotoxic conditions affecting the peripheral nervous system alone or in concert with central effects. Thus, pathologic study of the peripheral nervous system is an important part of neurotoxicology.

This unit reviews contemporary methods of preparing peripheral nervous system tissue for critical pathological (light and electron microscopy) study. It begins with approaches to proper fixation of tissue, using either perfusion fixation of laboratory animals or immersion fixation of dissected nerve segments (see Basic Protocol 1 and Alternate Protocol 1, respectively). These are followed by dissection of the peripheral nervous system (from perfusion-fixed animals) to allow for multilevel sampling (see Basic Protocol 2). As noted in the Commentary, the use of sections cut from epoxy resin–embedded tissue gives specimens providing excellent light microscopic resolution. Thus, methods for processing tissue for such embedding (see Basic Protocol 3), sectioning (see Basic Protocol 4), and staining (see Basic Protocol 5) are provided. Materials fixed as noted above and embedded in epoxy resin medium are suitable for transmission electron microscopy, and methods for sectioning and staining tissues for this purpose are also included (see Alternate Protocol 2). Lastly, fixed peripheral nerve is suitable for teasing and microscopic study of individual myelinated fibers, a valuable technique (see Basic Protocol 6).

CAUTION: Perform all procedures using solutions containing glutaraldehyde, paraformaldehyde, formalin, or osmium tetroxide in a chemical fume hood or on a downdraft necropsy table capable of removing noxious fumes (this latter method is not suitable for osmium tetroxide). This includes perfusion, immersion fixation, tissue dissection, and tissue trimming. Wear coveralls or laboratory coats, eye protection, and nitrile (or double latex) gloves to protect against exposure to fixatives. Collect chemical waste generated during all procedures in waste containers for proper hazardous waste disposal according to institutional policies.

NOTE: All protocols using live animals must first be reviewed and approved by an Institutional Animal Care and Use Committee (IACUC) and must follow officially approved procedures for the care and use of laboratory animals.

PERFUSION FIXATION IN RATS

Excellent fixation is the basis for sophisticated pathological assessments of peripheral nerves (and for other regions of the nervous system). For experimental animals, such as the rat, perfusion fixation is optimal. The basic idea is to allow fixation to occur with minimal autolytic or handling artifacts: the fixative perfuses through the blood circulatory system with the animal under deep anesthesia. There are several approaches to this (Fix and Garman, 2000), but the basic steps include anesthesia, cannulation of the cardiac left ventricle/aorta, washout of blood, and administration of fixative. Fixatives for perfusion may vary depending upon desired use of tissue. As examples, glutaraldehyde enhances the quality of samples for transmission electron microscopy, but high concentrations can interfere with immunohistochemistry. For transmission electron microscopy, perfusion fixatives such as 5% glutaraldehyde or glutaraldehyde/paraformaldehyde (PF) combinations are preferred. If immunohistochemistry and electron microscopy are the objects of the study, then paraformaldehyde with a small amount of glutaraldehyde (such as 4% PF/0.2% glutaraldehyde) is suitable. All of the above are suitable for light microscopy. Specific detail is provided in this protocol for vascular perfusion of rodents. Modifications may be necessary if another species is used.

Materials

Fixative for perfusion (see recipe)
Heparinized saline washout solution (see recipe)
65 mg/ml pentobarbital sodium anesthesia solution
Rat, control or treated

Peristaltic pump with variable speed control (e.g., Masterflex pump; Cole-Parmer)
Pump tubing (e.g., Masterflex C-flex tubing, 3.1-mm i.d.) and connectors
Graduated carboys with spigots
3-way plastic Luer stopcock (Cole-Parmer)
3-in. 16-G straight stainless-steel feeding needles (Popper)
Dissecting board
Heavy push pins or plastic-coated wire
Shears
Forceps
Hemostats
Microdissecting scissors
Carcass storage bags

Set up perfusion station

1. Prepare fixative and heparinized saline. Store fixative at 4°C and saline at room temperature until use.

   Paraformaldehyde-containing fixatives must be fresh. Prepare within 1 day of the perfusion and use within 24 hr.

2. Set up the peristaltic pump. Run separate pieces of pump tubing to the spigot of each of two graduated carboys (one carboy will deliver saline, one will deliver fixative). Using a 3-way stopcock with Luer-lok fittings, join the tubing running from each carboy to a single line that is loaded into the pump. Connect the 3-in. 16-G feeding needle to the end of the tubing. Adjust the flow rate of the pump to 85 to 90 ml/min.

   It is important that saline and fixative are pumped through the animal in the correct order, so clearly label carboys and tubing running from carboy spigots with contents.

   To prevent needle from slipping off during perfusion, use a plastic, male Luer-lok fitting to connect the needle to the tubing.

3. Warm fixative to room temperature before use. Fill fixative and saline carboys.

Table 12.12.1 Guidelines to Determine Dosage of 65 mg/ml Sodium Pentobarbital for Rats

Weight (g)	Pentobarbital (ml)
150–200	0.5
201–300	0.6
301–350	0.7
351–400	0.8
>400	0.9

4. Turn on pump and open 3-way stopcock to tubing delivering fixative until the fixative fills the tubing system. Complete setup by flushing saline through the system for 1 to 2 min.

   It is important to remove all air bubbles in the tubing lines. Bend tubing at connector to carboy spigot until all air is flushed from the line.

Anesthetize animal

5. Administer pentobarbital i.p. to the rat to induce a deep plane of anesthesia.

   Rat dosage is weight-dependent. Use Table 12.12.1 to determine dosage of 65 mg/ml sodium pentobarbital for rats.

6. Place animal in a safe location and wait until adequately anesthetized. For rodents, use the tail- or foot-pinch response to determine level of anesthesia.

   If the animal is still responsive to pinch after 4 min, administer additional anesthetic in 0.2- to 0.3-ml increments.

   Do not overdose with anesthesia. If heart stops beating during anesthesia, continue with perfusion as quickly as possible. These animals can be used for light microscopy if the perfusion is successful.

7. Once deeply anesthetized, move the animal to perfusion station in chemical fume hood. Immobilize animal with dorsum down. Pin dorsum to dissecting board by stretching limbs and pushing heavy pins through the loose skin covering the four legs.

   Perfusions can also be performed on a down draft necropsy table. This has the advantage of collecting fixative/blood waste in a contained reservoir for later disposal. To immobilize, stretch limbs and fasten feet to mesh of table surface with plastic-coated wire. Twist ties are useful for this.

Prepare animal for perfusion

8. Open chest cavity. Use shears to cut through the skin immediately caudal to the end of the sternum. Cut the skin along the caudal aspect of the rib cage and along the ventral midline along the sternum. Use blunt dissection to separate the subcutaneous fascial plane on the ventral and lateral chest wall on each side. Reflect the skin.

9. Cut the ribcage and the diaphragmatic attachment to the ribs on each side. Be careful not to cut into the liver or heart while reflecting the sternum. Clamp the sternum at the xiphoid process with hemostats and fold back toward the head to expose the heart.

10. Reflect the thin, transparent pericardium surrounding the heart. Make a small cut in the apex of the heart into the left ventricle with microdissecting scissors. Insert a 16-G feeding needle through the opening upward to the base of the aorta and clamp across the ventricles with hemostats or a tissue clamp.

    It is helpful to hold the heart with the clamping instrument during placement of the needle.

Perfuse animal

11. Turn on pump to flush with saline. Incise the right atrium of the heart when it distends to allow for exit of blood and fluids.

    If the animal immediately begins to show severe muscle spasms, the tubing has not been adequately flushed with saline and/or the system is open to the fixative. Check stopcock valve and adjust as needed.

12. Flush with saline for 45 to 60 sec.

    Fluid exiting right atrium will become clear and liver will blanch.

    If lungs inflate, the gavage needle is likely not properly sited and should be repositioned. The aorta starts branching almost immediately after it leaves the heart, therefore, position the tip of the feeding needle so that it is barely visible at the base of the aorta.

13. Close stopcock valve from saline and open valve to fixative.

    Muscle spasms indicate fixative is reaching tissues. If using glutaraldehyde, light-colored tissues turn yellow as fixation takes place. If muscles do not twitch, back the needle out 2 to 4 mm. A discharge from nose, mouth, or eyes indicates too much pressure or a misplaced needle, such as in the pulmonary artery. Reduce the perfusion pump setting and/or reposition the needle.

14. Perfuse rat with 800 to 1000 ml of fixative (~10 min).

    As the perfusion continues, the muscles of the neck and legs will stiffen.

15. When the perfusion is complete, turn off the pump and remove the needle. Assess the quality and extent of the perfusion by manipulating the muscles and organs of the animal.

    In a successful perfusion, all tissues will be equally firm. If a poor perfusion has occurred, some tissue will remain flexible (such as the legs). If the perfusion is poor or has failed completely, dissect the tissue of interest immediately (see Basic Protocol 2) and use immersion fixation.

    If the perfusion is poor or has failed, carefully check the location of the needle at the completion of perfusion to determine the cause of inadequate perfusion. Adjust the placement of the needle for the next perfusion as necessary.

16. Place the animal in a sealed plastic bag and store at 4°C until tissue dissection.

    The fixative that has collected in the body cavity should be poured into a hazardous waste container prior to placing animal in storage bag. One-gallon sealable food storage bags work well for storing individual perfused carcasses.

17. Flush tubing sufficiently with saline (1 to 2 min) before perfusing the next animal.

ALTERNATE PROTOCOL 1

IMMERSION FIXATION OF PERIPHERAL NERVE

While optimal fixation of the nervous system is obtained with properly performed perfusion (see Basic Protocol 1), immersion fixation of peripheral nerve may be adequate. The latter is used to fix human nerve biopsies (Dyck et al., 1993; King, 1999). This procedure should be part of routine necropsies where perfusion is not being conducted.

Additional Materials *(also see Basic Protocol 1)*

Fixative: 10% neutral buffered formalin, 3% glutaraldehyde, or mixture of paraformaldehyde and glutaraldehyde (see recipes)
Fine, non-toothed forceps
Scalpel handles and blades
Index card
Specimen vials and labels
Dental wax pads

Dissect nerve

1. Following euthanasia of the rat, expose the nerve of interest.

   Preferred methods of euthanasia are carbon dioxide asphyxiation and pentobarbital sodium overdose (150 to 200 mg/kg i.p.).

2. With fine, non-toothed forceps, grasp the proximal level of the nerve segment to be sectioned.
3. Gently dissect the nerve free from surrounding connective tissue. Cut and lift the proximal end of the nerve with the forceps.
4. Cut the nerve with a scalpel at the distal site.
5. Gently adhere the nerve segment to an index card in an elongated state and release the forceps.

   If proximal/distal orientation is important, mark orientation on the ends of the card using a pencil or, alternatively, cut one end of the card or nerve diagonally.

Fix nerve

6. Cut out the segment of the card with the adherent nerve and immerse both in a vial of fixative.

   Use enough fixative to completely cover the card.

7. For all fixatives, except 10% formalin, fix 12 to 24 hr at 4°C. Fix tissues in 10% formalin at room temperature.

   Fix larger diameter nerves, e.g., sciatic nerve, at least 24 hr.

Trim nerve

8. Remove the index card from the vial of fixative. Using forceps, grasp an attached end of the nerve, gently peel the segment from the card, and place it on a dental wax pad.
9. Using a scalpel, trim away the ends of the nerve segment that have been cut in the unfixed state or grasped by the forceps.

   Do not let the tissue dry out during this step. Keep it moist with fixative.

   If the proximal/distal orientation has been marked on the card, cut the ends of the nerve straight and diagonally to differentiate orientation.

10. Trim nerve to suitable size for subsequent tissue processing (see Basic Protocol 2).

DISSECTION OF PERIPHERAL NERVOUS TISSUE SAMPLES FROM PERFUSION–FIXED RATS

BASIC PROTOCOL 2

Following appropriate fixation, samples of nervous tissue of interest must be obtained. Dissection of tissues may be done on the day following perfusion, or sooner if time allows. If tissues are dissected on the perfusion day, wait several hours after the perfusion before starting the dissection. Multi-level sampling of the peripheral nervous system is useful to determine a proximo-distal pattern of lesions. As an example, for the somatic nervous system of the rear leg, study of the following would represent a reasonable proximo-distal sampling of the peripheral nerves: lumbosacral dorsal root (spinal) ganglia with dorsal and ventral spinal nerve roots (see below), sciatic, tibial, and sural nerves, and selected intramuscular branches (obtained in muscle samples).

Materials

Fixative (see recipe)
Perfused animal (see Basic Protocol 1)

Specimen vials
Indelible marker
Chemical fume hood or downdraft table
Forceps
Scalpel handles and blades (no. 11 or 15)
Bone-cutting forceps
Rongeurs
Dental wax pad

Dissect peripheral nerve and dorsal root (spinal) ganglia

1. Place fresh fixative in each specimen vial. Label vials with an indelible marker and cover label with clear plastic tape.

   For perfusion-fixed animals, the fixative used will usually be that which was used for perfusion.

2. Place perfused carcass in a chemical fume hood or on a downdraft table and expose the tissues of interest using methods that subject them to the minimal amount of trauma possible.

   For example, use bone cutters or rongeurs to unroof the cranial cavity or spinal canal, without pressure on underlying nervous tissue.

3. Once the nerve is exposed, gently grasp a section of the nerve with forceps in a region distal from the area to be examined. Cut the nerve segment using a scalpel blade (no. 11 or 15) and place in a specimen vial.

   The tissue should be completely immersed in fixative.

4. To dissect dorsal root ganglia, unroof the spinal canal and remove the spinal cord.

   A useful method for the latter is the use of a periosteal elevator to lift the cord and separate it from the nerve roots. Portions of the latter will remain in the spinal canal and are most obvious in the cauda equina, noted in the lumbosacral region.

5. With a fine forceps, trace the spinal roots to the intervertebral foramena, in which the ganglion usually lies.

   This is easiest for the lumbosacral ganglia.

6. Carefully chip away the overlying bone with bone-cutting forceps or rongeurs. Grasp the nerve roots and gently pull them to provide tension. Dissect free and remove the ganglion (with attached nerve roots) using a scalpel and no. 11 blade. Place the ganglion in the specimen vial.

   If necessary, use a magnifying loupe to assist in visualizing the ganglion.

7. Store dissected tissues in fresh fixative for up to 7 days at 4°C prior to trimming for tissue processing.

Trim tissue

8. Place the tissue on a dental wax pad and, using a sharp blade, trim dissected tissues from designated sample regions to a size not exceeding 1 mm in thickness. Trim the tissue block so that it contains a full face of the region of interest.

   Use a razor blade held in a blade or needle holder or a scalpel blade for trimming. Change blades often.

9. Collect appropriate segments of peripheral nerve. Trim away tissue regions grasped by forceps during handling, as they will be artifactually damaged. Cut nerve segments for cross or longitudinal sections.

   If the proximal-distal orientation of the peripheral nerve is important, cut the ends differently, e.g., a straight cut for distal and a diagonal cut for proximal, so that the samples may be appropriately embedded.

10. Trim spinal ganglion and attached nerve roots for longitudinal embedding, which allows examination of the ganglion and both nerve roots in one section (see Basic Protocol 3).

    If cross-sections of the spinal nerve roots are needed, trim 1- to 2-mm segments for this purpose.

11. Place trimmed tissues in a labeled vial containing fresh fixative.

    Place trimmed tissues from animals perfused in formalin, which are to be processed for epoxy embedding in 3% glutaraldehyde in 0.1 M sodium phosphate buffer, pH 7.4 (see recipe).

12. Store trimmed tissues at 4°C prior to tissue processing (see Basic Protocol 3).

    It is recommended to retain reserve dissected tissue until examination of all tissues is complete. Store reserve tissue up to 6 months at 4°C, and periodically replace the fixative.

EMBEDDING TISSUES IN EPOXY RESIN

BASIC PROTOCOL 3

This protocol delineates steps in epoxy resin embedding of nerve (and other) tissue samples. Embedding in such relatively rigid medium allows sections to be cut so that they provide optimal light microscopic resolution. In addition, these tissues are suitable for transmission electron microscopic study.

Materials

Vials containing trimmed tissues in fixative (see Basic Protocol 2)
0.1 M sodium phosphate buffer, pH 7.4 (see recipe for 0.2 M sodium phosphate stock)
2% (w/v) osmium tetroxide solution in 0.1 M sodium phosphate buffer, pH 7.4 (see recipe)
15%, 30%, 50%, 70%, 95%, and 100% (v/v) ethanol
Propylene oxide
Epoxy resin embedding medium (e.g., Poly/Bed 812; Polysciences)
Chemical fume hood
Glass or plastic disposable transfer pipets
Disposable plastic beakers
Wooden applicator sticks with beveled ends
Plastic dishes (e.g., mincing dishes or weigh boats)
Flat embedding molds
60°C oven
Cardboard boxes (e.g., pill boxes)

NOTE: For all processing steps, use a transfer pipet to remove the liquid in the vial from the previous processing step and replace it with liquid from the next processing step. Recap vials at each step. Perform all steps at room temperature unless otherwise noted.

Post-fix and dehydrate tissue

1. Place specimen vials with fixed tissue in the chemical fume hood.
2. Rinse tissue at least two times, 30 min each rinse, in 0.1 M sodium phosphate buffer, pH 7.4.

   When processing a large number of samples, dispense buffer from a squirt bottle. Use 20 to 30 times the volume of tissue for buffer rinses.
3. Post-fix the tissue in 2% osmium tetroxide in 0.1 M sodium phosphate buffer for 2 hr at room temperature. Add enough osmium tetroxide to completely immerse the tissue.
4. Rinse tissue at least two times, 30 min each rinse, in 0.1 M sodium phosphate buffer, pH 7.4.

   If there is a time constraint, the second buffer rinse step may continue at 4°C overnight.
5. Dehydrate tissue 30 min in 15% ethanol, 30 min in 30% ethanol, 30 min in 50% ethanol, 15 min in 70% ethanol, 15 min in 95% ethanol, two times, 15 min each, in 100% ethanol, and two times, 15 min each, in propylene oxide.

   When processing a large number of samples, dispense ethanol solutions from a squirt bottle. The 100% ethanol must be free of water. Use a plastic disposable pipet to transfer propylene oxide into and out of vials.

   If there is a time constraint, the 70% ethanol–step may continue overnight at room temperature.

Infiltrate and embed tissue

6. Prepare a 1:1 (v/v) transition mixture of epoxy resin and propylene oxide in a disposable plastic beaker. Cover tissue with the mixture using at least 20 to 30 times the volume of the tissue. Leave for at least 12 hr at room temperature.

   CAUTION: *Use nitrile gloves when handling propylene oxide. Latex gloves are not adequate.*

   Place tissue vials on a rotator or rotating plate to improve infiltration of larger tissue pieces.
7. Prepare fresh epoxy resin. Remove the epoxy-propylene oxide mixture from the vial and dispose appropriately. Cover tissue with the fresh resin and allow to infiltrate for at least 24 hr at room temperature.

   When preparing the epoxy resin from its components, avoid rapid stirring that may beat air bubbles into the mixture. The bubbles may interfere with proper infiltration of tissue.

   It is good practice to prepare a test resin block at this point in the procedure. Place fresh resin in a flat embedding mold and polymerize for 24 hr at 60°C prior to embedding and polymerization of the tissue pieces.
8. Gently remove the tissue sample from the vial using a wooden applicator stick with a beveled end and place the sample in a plastic dish with a small amount of fresh epoxy resin. Use the wooden applicator stick to transfer the sample from the dish to a labeled embedding mold. Fill the mold with fresh epoxy resin.

   Use a pencil to write labels or use printed labels. Check that label ink does not bleed when it comes into contact with epoxy resin. Place label in a visible position in the mold that does not obscure the tissue sample.

   Embed tissues with large block faces, such as longitudinal peripheral nerve, dorsal root ganglion, and associated nerve roots, in an inverted BEEM capsule with the tip cut off. Place tissue in the cap of the capsule and gently press flat with the flat end of a wooden applicator stick. Close capsule and fill it with embedding medium. Embed peripheral nerve for cross-section in a flat embedding mold.

9. Polymerize embedded tissues for 24 to 48 hr at 60°C.
10. Remove epoxy resin blocks from molds and store in cardboard boxes (e.g., pill boxes) until sectioning (see Basic Protocol 4).

The epoxy resin blocks may be stored indefinitely in cardboard boxes at room temperature.

SECTIONING EPOXY-EMBEDDED TISSUE

BASIC PROTOCOL 4

This section defines the procedures for sectioning resin-embedded samples for light microscopy. Producing high quality sections requires training in the use of an ultramicrotome, an instrument primarily used in sectioning of transmission electron microscopy (TEM) specimens.

Materials

Epoxy resin tissue blocks (see Basic Protocol 3)
3:1 (v/v) Permount/xylene mounting medium

Ultramicrotome or Butler Block Trimmer (Electron Microscopy Sciences)
Dissecting microscope
Single-edge razor blades
Glass knives
Frosted precleaned glass microscope slides
Fine forceps
70° to 90°C hot plate
Coverslips
Chemical fume hood
Dissection needle
Bibulous paper
Microscope slide boxes
Diamond knife
Copper grids
Petri dishes, glass
Filter paper
Grid storage boxes

Additional reagents and equipment for staining sections with toluidine blue and safranin (see Basic Protocol 5) and staining thin sections (see Alternate Protocol 2)

Section tissue block for light microscopy

1. Immobilize the epoxy resin tissue block using the specimen holder of an ultramicrotome or a device such as the Butler Block Trimmer.
2. Under a dissecting microscope, roughly trim the epoxy resin block using a fresh single-edge razor blade. Using cuts oblique to the surface of the block, remove the excess epoxy resin on the sides of the tissue. Using cuts parallel to the surface, trim the resin until 0.2 to 0.4 mm of tissue has been trimmed away.

   This is the same procedure used in preparing semi-thin sections prior to transmission electron microscopy (Hayat, 1970).

   Trimming the tissue at the surface of the tissue block removes any tissue that may have been artifactually damaged during tissue trimming.

3. Using an ultramicrotome, section the tissue block with a glass knife using a 5- to 7-μm advance. Continue sectioning until sections contain a complete profile of the tissue sample. Discard the sections and replace the glass knife with a new knife.

The initial sections are discarded because they are incomplete, too thick (7 μm), and contain knife-mark artifacts due to glass knife dulling during rough trimming. Sections are collected from a new glass knife and those sections are 1-μm thick.

4. Label a frosted glass microscope slide to properly identify the tissue.
5. Cut sections at a thickness of ~1.0 μm (referred to as thick or semi-thin sections), collect each section with fine forceps, and place in a drop of water on a clean glass microscope slide.

   Sections are easiest to pick up from a knife edge if they are floating in a droplet of water. Place a drop of fingernail polish ~10 mm from the cutting edge of the glass knife. Add a drop of water to the knife edge to create a trough for the section to float in as it is cut. Scoop up each section with forceps.

   For large block faces, e.g., dorsal root ganglia and nerve roots, collect enough sections to ensure that at least one section adheres completely flat to the slide (usually six sections are sufficient).

6. Place the slide on the 70° to 90°C hot plate and heat-fix the sections to the slide for a minimum of 1 hr.

   It may be necessary to heat large tissue sections on the hot plate overnight.

   To avoid trapping air bubbles in large sections, it is helpful to let sections float in a water droplet for 1 to 2 min prior to placing the slide on the hot plate.

7. Stain sections with toluidine blue and safranin (see Basic Protocol 5).
8. Coverslip the slide in a chemical fume hood by placing a drop of the 3:1 Permount/xylene mounting medium on the slide over the tissue sections. Hold the coverslip on the edge of the solution and slowly lower the coverslip over the sections, dispersing the solution without forming air bubbles. Using a dissection needle, push extra mounting medium and any air bubbles out the side of the coverslip onto bibulous paper.
9. Dry slide overnight in the chemical fume hood.
10. Permanently label each slide and store in slide box.

Section tissue for transmission electron microscopy (TEM)

11. Identify the areas of interest from the thick sections (steps 1 to 10).

    It is helpful to use a marked hand drawing or photomicrograph of the section to identify the area to be examined by TEM.

12. Retrim the epoxy resin specimen block so that the area designated for ultrathin sectioning is in the center of the block face. Trim the block face into a trapezoid shape with the longest side no longer than 0.75 mm.

    For longitudinal peripheral nerve and spinal nerve root, trim the block face so that the nerve fibers are perpendicular to the parallel sides of the trapezoid. This will help control chatter in the section during thin sectioning.

13. Using an ultramicrotome, cut silver/silver-gold sections with a diamond knife.

    User must be experienced in the use of the ultramicrotome and diamond knife.

14. Collect sections on copper grid. Note whether sections are collected on the dull or shiny side of the grid. Collect at least two grids per specimen block. Place grids with tissue sections on filter paper in a glass petri dish.
15. Stain thin sections as outlined in Alternate Protocol 2
16. Store stained grids in a grid storage box.

    Stained grids may be stored indefinitely at room temperature.

STAINING EPOXY SECTIONS FOR LIGHT MICROSCOPY

BASIC PROTOCOL 5

This section describes the routine procedure for staining epoxy sections for light microscopy (Jortner, 2000). The stain described, a combination of toluidine blue and safranin, stains myelin intensely blue, nuclei lighter blue, collagen pink, and adipose tissue gray. Axoplasm is relatively pale, although intra-axonal inclusions are faintly stained. Other stains such as thionin and acridine orange and methylene blue and acridine orange have been recommended by other investigators (King, 1999). The toluidine blue and safranin stain procedure is as follows.

Materials

Slides with heat-fixed epoxy tissue sections (see Basic Protocol 4)
1% (w/v) toluidine blue in 1% (w/v) sodium borate (see recipe)
0.5% (w.v) safranin in 0.5% (w/v) sodium borate (see recipe)

12-ml syringes and syringe filters (0.2-μm)
70° to 90°C hot plate
Slide holder for drying slides vertically
Coverslips
Cardboard slide trays
Microscope slide boxes

1. After epoxy sections are heat-fixed to the slide (see Basic Protocol 4), cover the sections with 1% toluidine blue stain in 1% sodium borate. Use 12-ml syringes with attached 0.22-μm filters to deliver stains.
2. Reheat the slide on a 70° to 90°C hot plate until the edges of the stain begin to dry (∼1 to 2 min).
3. Gently rinse the slide in deionized, distilled water from a wash bottle and wipe the excess water from the bottom edge of the slide.
4. Cover the sections with 0.5% safranin stain in 0.5% sodium borate and heat the slide 15 to 20 sec on the hot plate.
5. Rinse the slide with water and air dry in a vertical slide holder.

   If either stain is too dark or too light, adjust the stain intensity by decreasing or increasing, respectively, the length of time the sections are heated in the stain on the hot plate.
6. Coverslip the slide (see Basic Protocol 4, step 8).
7. Store the slide in a cardboard slide tray until labeled and then store in a slide box.

STAINING SECTIONS FOR ELECTRON MICROSCOPY

ALTERNATE PROTOCOL 2

This section describes the routine procedure for staining epoxy thin sections for transmission electron microscopy.

Materials

Uranyl acetate (see recipe)
Reynold's lead citrate (see recipe)
NaOH
Thin sections collected on grids (see Basic Protocol 4, steps 11 to 16)

Parafilm
Petri dishes, glass
Glass, disposable transfer pipets
Anti-capillary forceps

Small beakers
Filter paper
Grid storage box

CAUTION: Uranyl acetate is radioactive. Wear latex gloves when handling uranyl acetate and lead citrate. Dispose of labware contaminated with uranyl acetate according to institutional radioactive waste policies.

1. Set up both uranyl acetate and Reynold's lead citrate stain chambers before starting stain procedure.
2. Place a square of Parafilm in a glass petri dish chamber and, using a glass transfer pipet, add one drop of uranyl acetate stain on Parafilm for each grid to be stained.

   Uranyl acetate is light sensitive. Protect the stain from light by covering the petri dish with a box or aluminum foil.
3. Place a square of Parafilm in a second petri dish chamber and arrange several pellets of NaOH around the Parafilm. Place one drop of Reynold's lead citrate on the Parafilm for each grid to be stained.

   Lead citrate will react with CO_2 and form a precipitate on the sections; the NaOH will scavenge any CO_2 in the chamber.

   To avoid CO_2 contamination, blow the air out of the transfer pipet before withdrawing the lead citrate from the volumetric flask. Discard the first few drops of the lead citrate. Limit the time the lid of the lead citrate chamber is opened.
4. Place each grid on a uranyl acetate stain drop with the section side down. Use fresh stain for each grid. Float the grid for 10 to 30 min.

   Stagger the times that the grids are placed on the stain by 60 sec to allow time for rinsing prior to lead citrate staining.

   The optimum staining time for uranyl acetate depends on the tissue type and may require stain trials.
5. Remove the grid from the uranyl-acetate stain droplet using anti-capillary forceps.
6. Rinse the grid in a stream of distilled, deionized water for 30 to 45 sec or rinse the grid by dipping it in two beakers of water, 20 to 30 dips in each beaker.

   Bacterial contamination can appear on the surface of a grid when the water used for rinsing is contaminated. To prevent this artifact, use wash bottles and beakers that have been cleaned with sodium hypochlorite solution (bleach) and rinsed well with distilled deionized water. For beaker-dipping rinses, filter water before use.
7. Place the grid on a fresh droplet of Reynold's lead citrate and stain from 30 sec up to 10 min.

   The optimum staining time depends on the tissue type and stain trials may be required.
8. Remove the grid from the stain and rinse thoroughly with water as in step 6. Place grid on filter paper to dry. Store stained grid in grid box.

BASIC PROTOCOL 6

PERIPHERAL NERVE FIBER TEASING

This section describes procedures for preparing teased preparations of peripheral nerve myelinated fibers for light microscopic study. Such preparations allow the nerve fibers to be examined over proximo-distal distances, assessing myelin internodes, nodal regions and axons, and are an integral part of peripheral nerve pathology studies (Krinke et al., 2000).

Materials

Fixed peripheral nerve (see Alternate Protocol 1 or Basic Protocol 2)
Fixative (see recipe)
0.05 M sodium phosphate buffer (see recipe for 0.2 M sodium phosphate buffer stock)
2% (w/v) osmium tetroxide in 0.1 M sodium phosphate buffer (see recipe)
30%, 50%, 70%, 95%, and 100% ethanol
Cedarwood oil
3:1 (v/v) permount/xylene mounting medium

Razor blades and blade holders
Scalpel handles and blades
Dental wax pads
Labeled specimen vials
Glass or plastic disposable transfer pipets
Fine forceps
Glass microscope slides
Watchmaker's forceps
Butterfly needles inserted into wooden applicator sticks
50°C oven
Glass coverslips
Cardboard slide tray
Slide boxes

NOTE: For all processing steps, use a transfer pipet to remove the liquid in the vial from the previous processing step and replace it with liquid from the next processing step. Recap vials at each step. Perform all steps at room temperature unless otherwise noted.

Trim nerve

1. Obtain a nerve that has been immersion fixed (see Alternate Protocol 1) or dissected from a perfused carcass (see Basic Protocol 2).

   Samples from most proximal levels of peripheral nerve, such as the spinal nerve roots, are difficult to tease.

2. Remove nerve from the fixative. If sample is trimmed for proximal and distal orientation (i.e., transverse cut for distal and diagonal cut for proximal levels), maintain orientation while trimming.

3. Trim nerve to a sample length of at least 1.5 cm by cutting with a sharp razor or scalpel blade on a dental wax pad. Gently trim away adipose and other extraneural tissues.

4. Place trimmed tissue samples in labeled vials containing fresh fixative.

   The tissue should be completely immersed in fixative.

Post-fix and dehydrate the nerve

5. Rinse tissue at least two times, 15 min each, in 0.05 M sodium phosphate buffer.

6. Post-fix the tissue in 2% osmium tetroxide in 0.1 M sodium phosphate buffer for 2 hr at room temperature. Add enough 2% osmium tetroxide to completely immerse the tissue.

7. Rinse tissue at least two times, 15 min each, in 0.05 M sodium phosphate buffer.

   The second buffer rinse step may continue at 4°C overnight if there is a time constraint.

8. Dehydrate the tissue 15 min in 30% ethanol, 15 min in 50% ethanol, 15 min in 70% ethanol, 15 min in 95% ethanol, and three times, 15 min each, in 100% ethanol.

   Continue the 70% ethanol step at 4°C overnight if there is a time constraint.

9. Rinse the tissue sample in cedarwood oil and drain it off.

   Use cedarwood oil in a chemical fume hood during tissue processing and in a well-ventilated area during nerve fiber teasing. Prolonged exposure to cedarwood oil may cause irritation to skin or nasal passages.

10. Replace with fresh cedarwood oil. Leave at room temperature overnight.

    If the cedarwood oil gels during the last step, place vial 15 min in 50°C oven to melt the gel, pour off the oil, and replenish with fresh cedarwood oil.

Expose nerve bundle

11. Remove the nerve from the vial and place on a clean glass microscope slide. Mark the slide to identify the sample.

    Do not compress, pinch, or crush the tissue when removing it from the vial.

    If the proximal/distal orientation of the nerve is important, mark the orientation on the label area of the slide.

12. Place a drop of cedarwood oil on top of the tissue to prevent drying.

13. Using a fine teasing instrument (e.g., watchmaker's forceps) and butterfly needles inserted into wooden applicator sticks, begin to remove excess epineural connective and adipose tissue from the nerve bundle.

    This step and steps 14 through 18 are done using a dissecting microscope.

14. Under a dissecting microscope, continue to remove excess tissue until all is stripped from the nerve bundle. Remove the stripped tissue from the slide.

15. Cut the perineurium (a cylindrical sheath of specialized fibroblastic cells surrounding fascicles of nerve fibers) with a scalpel blade. Using two forceps, pull the perineurium away from the nerve fibers by pulling half of the perineurium in one direction and the other half in the opposite direction.

    Grasp the perineurium at the ends of the sample so there is no damage to the fibers.

16. Remove stripped perineurial tissue from the slide. Continue to divide the exposed nerve bundle by gently pulling it apart from one end, using two forceps in the same manner as the perineurium.

Dissect individual nerve fibers

17. To remove an individual myelinated nerve fiber from the parent portion of the nerve bundle, use the butterfly needles to orient the bundle and fiber in a V-shape. Place the tips of the needles on the slide within the V-shape. Slowly slide the needles away from each other and gradually toward the narrowing of the V so as to separate the fiber from the bundle of individual fibers. Repeat this process until a number of individual fibers are obtained.

    Best results are achieved with the tissue wet with cedarwood oil and with fibers separated from subdivided nerve bundles having fewer than 100 fibers. Larger fibers are easier to tease out. However, take all fibers as they are separated from the bundle to provide a sampling of all fiber sizes.

18. As each fiber is separated, carefully orient it with the dissecting needles, lining it parallel to other fibers and to the shorter edge of the slide.

19. When enough fibers are obtained for the slide (usually 20 to 25), remove all remaining tissue to the vial for storage.

20. Prepare other slides using the same procedure. Collect at least 50 fibers per nerve for examination.

21. Place the slide for at least 3 days in a 50°C oven to dry. Once dried, place a drop of 3:1 Permount/xylene mounting medium on top of the fibers. Place the edge of the cover slip in the mounting medium parallel to the fibers. Slowly and carefully, lower the coverslip onto the slide.

    Once the coverslip is on the slide, do not move it. Do not press on the coverslip to remove excess mounting medium or air bubbles. Movement of the cover slip can cause disorientation of the vertically placed fibers.

22. Dry the slide overnight in a chemical fume hood. Store the slide in a cardboard slide tray until labeled and then store in slide box.

    Light microscope interpretation has been described by Krinke et al. (2000).

    The use of cedarwood oil as a medium for peripheral nerve fiber teasing was suggested to the authors by Dr. Thomas Bouldin, Department of Pathology, School of Medicine, University of North Carolina at Chapel Hill. Other media, such as glycerin, are also used (Krinke et al., 2000)

REAGENTS AND SOLUTIONS

Use Milli-Q-purified water or equivalent for the preparation of all buffers. For common stock solutions, see ***APPENDIX 2A****; for suppliers, see* ***SUPPLIERS APPENDIX****.*

Fixative solutions

3% Glutaraldehyde in 0.1 M sodium phosphate buffer, pH 7.4, solution for immersion fixation:

Add 6.0 ml of 50% glutaraldehyde to 50 ml of 0.2 M phosphate buffer, pH 7.4 (see recipe) and mix well. Add 44 ml water to the solution and continue stirring until mixing is complete. Cover container with Parafilm and store up to 1 week at 4°C.

Stock solutions of 50% and 70% glutaraldehyde are available from various suppliers. Adjust the recipe proportionately for larger volumes.

5% Glutaraldehyde in 0.1 M sodium phosphate buffer, pH 7.4, for perfusion for electron microscopy:

Add 100 ml of 50% glutaraldehyde to 500 ml of 0.2 M phosphate buffer, pH 7.4 (see recipe) and mix well. Add 400 ml water to the solution and continue stirring until mixing is complete. Cover container with Parafilm and store up to 1 week at 4°C.

Adjust the recipe proportionately for larger volumes.

4% paraformaldehyde stock solution:

For ~1000 ml, add 40 g paraformaldehyde to 1000 ml water. Heat, while stirring, for 5 min at 60°C. Slowly add drops of fresh 1 N NaOH to solution until the solution clears. Immerse paraformaldehyde solution into ice until cooled. Filter through Whatman no. 1 filter paper if necessary. Use within 24 hr and store at 4°C.

Adjust the recipe proportionally.

2% paraformaldehyde/2% glutaraldehyde in 0.1 M sodium phosphate buffer:

Cool the 4% paraformaldehyde solution (see recipe). Add 500 ml of 0.2 M sodium phosphate buffer stock solution (see recipe), 500 ml of 4% paraformaldehyde, and 40 ml of 50% glutaraldehyde to flask. Mix well. Recheck pH of solution and adjust

continued

if necessary. Cover container with Parafilm, label, and store at 4°C until needed. Use paraformaldehyde-containing solutions as soon as possible after preparation, within 48 hr.

If smaller amounts of paraformaldehyde-containing fixatives are needed, the following formula is used to calculate volumes:

$$V_1C_1 = V_2C_2$$

where V_1 = desired volume, C_1 = desired concentration, V_2 = volume of stock solution, and C_2 = concentration of stock solution.

10% neutral-buffered formalin (final 3.7% to 4%):
100 ml 37% to 40% commercial formaldehyde
900 ml H_2O
4 g NaH_2PO_4
6.5 g Na_2HPO_4 (anhydrous)
Add reagents to flask and stir until dissolved. Store up to 1 year at room temperature.

Alternatively, this solution can be purchased from a chemical supplier

CAUTION: *Prepare all solutions containing glutaraldehyde, paraformaldehyde, formalin, or osmium tetroxide in a chemical fume hood. Wear coveralls or laboratory coats, eye protection, and nitrile (or double latex) gloves to protect against exposure to fixatives.*

Heparinized saline

Add 9.0 g NaCl to a flask and bring up to 1000 ml with water. Stir until dissolved. Add 10 ml of 1000 U/ml heparin to the flask and stir. Store up to 1 month at room temperature.

Osmium tetroxide stock solution, 4%

Add 25 ml water to a brown bottle. In a fume hood, open the 1-g ampule containing the crystalline osmium tetroxide over the brown bottle. Break the ampule at the scored neck and place the entire ampule containing osmium tetroxide crystals into the brown storage bottle. Cap tightly, Parafilm, and periodically agitate or sonicate, as needed (~30 min for sonication). For storage, cap tightly, seal the bottle with Parafilm, place in a plastic storage bag, and place in a tightly covered metal can sealed with Parafilm. Store up to 4 months at 4°C.
To make up a 2% osmium tetroxide solution in 0.1 M sodium phosphate buffer, pH 7.4:
Add equal amounts of the 4% osmium tetroxide stock solution and 0.2 M sodium phosphate buffer, pH 7.4, stock solution to a clean brown bottle. Gently mix. The solution is stable stored in a brown bottle, capped tightly, and wrapped in Parafilm for up to 2 months at 4°C.

Clean the outside of the osmium ampule with scouring powder followed by soap. Rinse well with tap water followed by distilled water. Clean the brown bottle in which the osmium tetroxide stock solution will be stored in the same manner.

Osmium tetroxide crystals go into solution slowly. If possible, make up the solution at least 1 day before it is needed, and agitate periodically. It is best to make only small quantities of osmium solutions, i.e., only as much as needed for the batch of tissue being processed. If stored osmium solutions are used, check the color of the solution before use. The aqueous solution is light yellow in color. If the solution has turned black or brown during storage, do not use. Dispose of it according to procedures described below.

continued

CAUTION: *Osmium tetroxide is a heavy metal. It readily sublimes (forms a vapor) in air. These vapors are hazardous and can cause choking, eye irritation, corneal clouding, and skin discoloration. The compound is poisonous. Wear disposable nitrile gloves, laboratory coat, and eye protection at all times during preparation and handling of osmium tetroxide. Prepare and use in a chemical fume hood. Dispose of osmium-containing solutions in a hazardous waste container, as indicated by MSDS (Material Safety Data Sheet) and local environmental regulations.*

Reynold's lead citrate

In a 50-ml volumetric flask, add 1.33 g lead nitrate, 1.76 g sodium citrate, and 30 ml distilled water. Shake vigorously for 1 min. Gently shake intermittently for 30 min Add 8.0 ml of fresh 1.0 N NaOH and mix gently. Bring the volume to 50 ml with boiled, cooled distilled water. Mix by inverting the container gently until well-mixed. Store *tightly covered* (stain reacts with CO_2 in air) for up to 1 year at 4°C. Do not use stain if it contains visible precipitate.

This recipe is based on Reynolds (1963).

Safranin, 0.5% (w/v)

Add 0.5 g safranin O and 0.5 g sodium borate to a flask and bring up to 100 ml with water. Mix at least 30 min using stir plate. Filter through Whatman no. 1 filter paper using a Buchner funnel. Store up to 1 year at room temperature.

Sodium phosphate buffer stock solution, 0.2 M (pH 7.4)

Make up the following 0.2 M stock solutions:
A: 27.6 g/liter NaH_2PO_4 stock
B: 28.4 g/liter Na_2HPO_4 stock
Add ~1 part solution A to 4 parts solution B. Adjust to pH 7.4 with solution A or B, as needed. Store up to 4 months at room temperature.

Storage at 4°C will result in crystallization of the buffer solution.

Toluidine blue, 1% (w/v)

Add 1 g toluidine blue and 1 g sodium borate to a flask and bring up to 100 ml with water. Mix at least 30 min using stir plate. Filter through Whatman no. 1 filter paper using a Buchner funnel. Store the stain up to 1 year at room temperature.

Uranyl acetate stain, 2% to 5% (w/v)

Add 2 to 5 g uranyl acetate to 100 ml of 50% ethanol. Stir well. Store in brown bottle up to 1 month at 4°C.

Optimum stain concentration may be tissue dependent. Adjust uranyl acetate concentration as needed to reach desired staining quality. Stain may precipitate. If this happens, use stain from the top of the bottle for staining grids.

CAUTION: *Uranium is radioactive. Use gloves and wear a laboratory coat when preparing this solution.*

COMMENTARY

Background Information

Pathological examination of the peripheral nervous system (nerve roots, peripheral ganglia, peripheral nerves, nerve endings) is an important component in assessing neurotoxic states.

Some pathogenetic questions can be more easily addressed by study of the peripheral nervous system (Jortner, 2000). In axonopathic and neuronotoxic conditions, an important issue is the proximo-distal extent of axonal involvement. In those conditions involving the peripheral nervous system, various levels of the axon can be readily evaluated. Thus, examination of the spinal nerve roots provides proximal levels, with study of regions such as

the sciatic and tibial and/or sural nerves giving progressively more distal sites. Preterminal and terminal levels can be seen by examining intramuscular nerve branches and muscle spindles or presynaptic motor terminals.

Contemporary methods for histopathological examination of peripheral nerve have been developed for clinical application, but have relevance for experimental neurotoxicology. Three main preparative approaches are utilized (Schaumburg et al., 1992; King, 1999). (1) Conventional paraffin-embedded tissue is useful for evaluation of cellular inflammatory infiltrates and vascular changes. In addition, such specimens when appropriately fixed are the standard for immunohistochemical studies. However, subtle changes in axons, myelin, Schwann cells, and endoneurial constituents are not appreciated in sections from this type of preparation. This is due to the poorer resolution (compared to resin sections) and greater thickness of the paraffin sections (King, 1999). (2) Single-teased myelinated nerve fibers provide preparations that are useful for identification of axonal degeneration and segmental demyelination. It allows evaluation of changes along a length of the fiber. As an example, the degree of demyelination along an individual nerve fiber can only be determined in teased peripheral nerve preparations. Quantitative evaluation of the lengths of myelin internodes and fiber diameter can be done. (3) Light microscopic examination of epoxy resin-embedded tissue sections is the standard approach to assessment of peripheral nerve and ganglia. This approach allows sections of 0.5- to 1.0-μm thickness, which provide optimum light microscopic resolution (Spencer et al., 1980; King, 1999). Axons, neuronal cell bodies, Schwann cells, myelin, and the endoneurium are clearly demonstrated in appropriately stained sections obtained with this embedding procedure. As examples, degeneration, loss, and demyelination of myelinated fibers can be readily determined. The unmyelinated fibers are too small to be effectively evaluated by light microscopy. Changes in size of axons and nerve fibers can readily be assessed in cross-sections of a nerve, and thus epoxy resin embedding is a standard for such morphometric studies. Properly fixed nerve embedded in these media can also be utilized for transmission electron microscopic evaluation, allowing ultrastructural examination (King, 1999).

These diagnostic/interpretive advantages can only be obtained with properly fixed, processed, and sectioned (or teased) peripheral nerve. Such methods have long been employed by those interested in the pathology of peripheral nerve as it relates to human or animal disease. Applying these to neurotoxicology will enhance the information obtained from these pathologic studies. This unit describes methods for fixation applicable to experimental studies, tissue embedding (with an emphasis on epoxy resin procedures), sectioning and staining of such tissues for light microscopy (with some comments on relative electron microscopic procedures), and preparation of nerve tissue for fiber teasing.

Critical Parameters and Troubleshooting

Major sources of difficulty in using these protocols are in the areas of handling and fixation of tissue, embedding, and sectioning. Compression of the nerve tissue, especially in the unfixed state, leads to a series of artifacts, which can distort the appearance of myelinated fibers when viewed at the light- and electron-microscopic levels (King, 1999). Thus, it is critical to trim away the ends of nerves which have been held in forceps. When sections are too thick (>1 mm in one dimension) they may not fully infiltrate with epoxy resin embedding media. This results in sections in which the deeper regions are unevenly sectioned and poorly stained. This defect is, unfortunately, usually determined only after the sections are prepared. Lastly, since staining is done on an individual slide basis, it is important to be as consistent as possible, to avoid over- or understained sections.

Anticipated Results

The procedures outlined above should provide the pathologist with sections which would allow high resolution histological study of the peripheral nervous system. These provide clear definition of cytological elements of the nerves and ganglia in the tissue sections, which permits detailed interpretation of morphological change–related toxicant effects. These sections are of such quality that morphometric procedures can be conducted in tissues sectioned in an appropriate plane (such as cross-sections of peripheral nerve). The protocols call for sections at multiple levels of the peripheral nervous system. Examination of this nature is an important issue in neurotoxicology.

Time Considerations

Time requirements will vary, but in general the following are reasonable estimations.

Perfusion fixative and other solutions need to be made up 1 day before perfusion. For large studies, this may take 1 entire day for one person. Perfusion of a single rat takes ~20 to 30 min, with two people involved.

Dissection time devoted to dissection of the nervous system will depend on the number of samples desired. As an example, it takes the authors ~1 hr to collect samples of vagus, sural, tibial, and sciatic nerves, dorsal root ganglia as well as the entire spinal cord and brain from a rat.

Tissue processing is a long procedure, taking ~3 to 5 days. One reason for this prolonged time is that a number of steps need to run overnight. These include infiltration by the 50% propylene oxide/50% resin mixture, and infiltration by the 100% resin. These are not hands-on procedures, in that the tissues do not need to be manipulated during these procedures. Smaller specimens can be processed more rapidly, which could shorten the time committed to this exercise.

Embedding takes 48 to 72 hr and mainly consists of time the tissue remains in the embedding oven to allow the resin to polymerize. This again is not a hands-on procedure after the tissue is placed into the embedding molds in the non-polymerized resin mixture. The latter does require manipulation and takes 2 to 5 min per block.

For sectioning thick sections (for light microscopy), an experienced technician will take up to 30 min for each sample. Thin sections (for transmission electron microscopy) can take up to 45 min to 1 hr each.

Staining and coverslipping takes 6 to 10 min per slide. Staining of thin sections on grids for electron microscopy takes up to 1 hr. This is based upon times determined for optimization of the stain (see Basic Protocol 5). Multiple grids can be stained together by staggering the times.

For nerve fiber teasing, experience will reduce the time, but 2 to 4 hr per nerve is reasonably required.

CHAPTER 13
Teratology

INTRODUCTION

Teratology is the study of structural birth defects, and its name derives from the Greek word for monster, *teras*. As such, it is part of the field of developmental toxicology, a more recent term that includes all manifestations of abnormal development, including functional and behavioral impairments. During the twentieth century, a variety of environmental conditions were found to perturb the development of different species, including mammals. Full appreciation of the potential deleterious impact of exogenous substances on human embryonic and fetal development came from the discovery in 1960 in Europe of a large number of newborns with limb malformations, later linked to the use of the sedative/hypnotic drug thalidomide by pregnant women. As a result of this catastrophe, regulatory agencies began to require toxicity testing specifically addressing the possible adverse impact of any new chemical on the developing embryo and fetus.

This chapter focuses on the traditional and more recent approaches to investigate the teratogenic potential of chemicals. *UNIT 13.1* provides an introduction on the field of teratology and on its unique role within toxicology. *UNIT 13.2* examines the rat embryo culture as an in vitro method to screen for potential teratogens; this system can have useful applications also for mechanistic studies. Another model for in vitro teratology testing, micromass cultures, is described in *UNIT 13.3*. *UNIT 13.4* describes another *in vitro* model for teratology studies: the chicken embryo. Methods of assessment of in vivo prenatal developmental toxicity in rodents are described in *UNIT 13.5*. These include evaluations of skeletal and soft tissue morphology (Segment II study) as well as postnatal growth and viability (Chernoff/Kavlock assay). *UNIT 13.6* discusses an interesting in vitro system to assess the effects of chemicals on development of the palate.

Forthcoming units will address additional methodologies for screening industrial and environmental teratogens, as well as methodologies currently used to investigate specific mechanisms of teratogenesis.

Overview of Teratology

HISTORICAL PERSPECTIVE

Since the middle to late nineteenth century, teratology, the study of how congenital malformations arise, has been the subject of scientific explorations (see Warkany, 1971, for an extensive history of ancient and modern teratology). Gregor Mendel's work in the late 1800s first spawned genetic explanations for altered embryonic development, and, for a while, genetic theories were used to explain most congenital defects that occurred. Experimental mammalian teratology began in the 1920s and 30s. Hale's discovery that vitamin A–deficient diets fed to sows resulted in pigs with defects of the eyes, face, and head began a series of studies that have continued to this day on the effects of nutritional alterations during development. In particular, Warkany and colleagues in the 1940s conducted a number of studies on the effects of nutritional deficiencies on development. The importance of nutritional factors in pregnancy is still being realized, as exemplified by the discovery in the early 1990s of the role of folic acid supplementation in preventing many cases of neural tube defects. Infectious diseases were implicated as teratogens when Gregg, in 1941, discovered that infection with the Rubella virus during early pregnancy could lead to a syndrome of congenital defects. The effects of the drug thalidomide in producing limb reduction defects in children born in the late 1950s and early 1960s made it clear that chemical exposures during pregnancy can affect the developing embryo, and that the so-called "placental barrier" is not really a barrier to many agents. Following that disaster, efforts began worldwide to develop more extensive premarket testing approaches for drugs, and eventually for food additives and environmental chemicals, to prevent such occurrences. In the last 20 years, more concern has been placed on developmental effects, in addition to malformations or the study of teratology, spawning the field of developmental toxicology, as well as developmental neurotoxicology, immunotoxicology, and others.

PRINCIPLES OF TERATOLOGY AND ABNORMAL DEVELOPMENT

In the late 1960s and early 1970s, Wilson (1973) began to formulate several principles of teratology and abnormal development. These principles, further discussed in Wilson (1977), have stood the test of time and continue to serve as an excellent basis for evaluating and interpreting data on teratology and developmental toxicology. A brief summary discussion is presented here, as there are several references that discuss them in detail (e.g., Scialli, 1992; Schardein, 1993; Sadler and Hunter, 1994; Schmidt and Johnson, 1997).

Susceptibility to Abnormal Development Depends on the Genotype of the Conceptus and the Manner in Which this Genetic Composition Interacts with the Environment

A number of studies in the experimental literature show the effect of the genetic background of animals, particularly inbred strains of mice, on the incidence and types of congenital defects produced by various chemical agents. For example, certain strains of mice have a relatively high incidence of exencephaly and cleft palate. In some cases, treatment with teratogenic agents will increase the incidence of these defects in those strains that have a high background incidence to a greater extent than in those strains that show the defect less often. Species differences in susceptibility are also evident for a number of agents. For example, glucocorticoids are especially effective in producing cleft palate in mice and rabbits, but most strains of rats are highly resistant.

In humans, there are certain racial and ethnic differences in background rates of developmental alterations, but it is not always clear whether these differences are due to genetic differences or to other nutritional, social, or lifestyle differences. For example, the rate of infant mortality differs in the African-American and Caucasian populations. Some of this difference may be due to socioeconomic status and related prenatal care and nutrition. However, in comparisons between middle-class white and African-American women, African-Americans continue to show a higher infant mortality rate. Whether such differences in background rates of various developmental outcomes influence the susceptibility of certain groups of individuals to the effects of chemical exposure during development is not known. In addition, only a portion of individuals (both humans and experimental animals) exposed to a given agent will show an adverse developmental outcome. That is, the

Current Protocols in Toxicology (2000) 13.1.1-13.1.8

risk of an effect following exposure is never 100% and is often in the range of ≤10%. Because of this fact, Sokol et al. (1986) attempted to determine factors involved in susceptibility to alcohol teratogenicity. Their analysis indicated that race was a significant determinant of fetal alcohol syndrome regardless of adjustments for other possible contributing or confounding factors, such as extent of exposure and parity. Scialli and Lione (1998) have reviewed extensively the factors involved in variability of response to chemical agents related to reproductive and developmental toxicity.

More recently, efforts have been made to evaluate specific gene-environment interactions in susceptibility to various agents. Data have been published indicating an interaction between maternal cigarette smoking during pregnancy and an uncommon allele of transforming growth factor α (TGFα) which results in a 6- to 10-fold increased risk of cleft lip with or without cleft palate, or cleft palate alone (Hwang et al., 1995; Shaw et al., 1996; Shaw and Lammer, 1997). Because of the advances currently being made in identifying genes associated with certain malformations and syndromes, such interactions using genetic biomarkers of both effect and exposure are actively being pursued.

Agents that Cause Abnormal Development Vary with the Developmental Stage at the Time of Exposure

The developing embryo is constantly changing in size, number and position of cells, and degree of differentiation, and there are a number of critical events that are required for normal development. The delicate balance of these cascades of events, which lead to the formation of a normal organism, can be exquisitely sensitive to perturbations by chemical or physical agents during development. Most of the information available on critical periods comes from data during major organogenesis (i.e., gestation days 6 to 15 in mice and rats, 7 to 58 in humans). Some information is also available on periods of sensitivity for systems that develop into the fetal and postnatal periods, e.g., the nervous system, kidney, skeleton, and reproductive system. A recent workshop report (Selevan et al., 2000) summarizes the information available on pre- and postnatal critical periods of susceptibility for several organ systems and cancer.

In general, the developing embryo is most sensitive to the induction of malformations, growth retardation, and death during the period of major organogenesis, inferred from the fact that it usually requires a smaller dose (i.e., on a milligram/kilogram basis) during this time to produce effects than either earlier or later. Exposure of either parent before conception may also be an important time for induction of developmental defects. There have been several studies showing the induction of developmental effects following exposure of the father prior to conception (Olshan and Mattison, 1994; Hales and Robaire, 1997). For example, exposure to chemotherapeutic or mutagenic agents prior to conception may cause chromosomal or DNA changes in germ cells that result in heritable effects, including death, malformations, growth retardation, functional deficits, or cancer in the offspring. Experimental studies have suggested that epigenetic changes may also be responsible for some male-mediated developmental effects.

During very early embryogenesis, before implantation occurs (i.e., zygote to blastocyst stages), cells are multiplying at a rapid rate and are relatively undifferentiated; exposure to a variety of agents during this time tends to result in death or compensation and continued normal development. For several genotoxic agents, exposure during this period has been shown to result also in malformations and growth retardation. As organogenesis begins, cells become more and more differentiated and the major structure of organs is formed, although not all organs develop at the same time or rate. Exposure to many different agents during this period has been shown to cause major structural defects, as well as death, growth retardation, or postnatal functional changes.

As major organ structure is completed, organization at the histological level as well as physiological and biochemical differentiation proceeds; in most mammals, these processes occur to a varying extent during pre- and postnatal development. Exposure to a number of agents during this period may result in alterations that are detected as histopathology, growth retardation, and/or functional changes. Rodier (1976) has shown that morphological defects in brain development are induced by exposure at several specific times in late gestation to a chemotherapeutic agent, and that there are differences in the pattern of neurobehavioral effects associated with exposure at each time point. Cancer also has been induced during late fetal and neonatal stages by several genotoxic agents. Exposure during pregnancy may also affect the placenta, which can in turn affect the developing embryo/fetus. Effects on the placenta may include alterations in blood flow and

perfusion, alterations in metabolism, or in extreme cases, necrosis and separation from the uterine wall.

Later stages of development include further growth and functional maturation of organs/systems, some of this occurring at several years of age. Exposure during this period may affect the same target organs as in adults, but with different consequences because of the lack of maturity.

Data on ionizing radiation, which produces many different types of developmental effects, have been summarized by Brent (1977) and can be used to demonstrate the times in development during which various types of outcomes may be induced. For example, exposure to 100 rads during the preimplantation period results in significant embryolethality, but not many other types of effects. Exposure during early organogenesis—gestation day (gd) 8 to 10 in the rat—results in lethality, growth retardation that persists into adulthood, gross malformations, cataracts, neuropathology, and behavioral disorders. Exposure during the fetal period (gd 13 to 22 in the rat) causes less lethality, persistent growth retardation, sterility, cataracts, neuropathology, and cytogenetic abnormalities.

For functional disorders, timing of the evaluation is just as important as the timing of exposure. For example, effects on motor activity will not become apparent until a young animal or child is locomoting sufficiently to test activity patterns. Effects on cognitive function are more easily tested when children reach school age and can read and write as well as understand complex reasoning. Degenerative neurological diseases that are induced or influenced by environmental exposures may not become apparent until well into adulthood or old age. Effects on reproductive function, especially reproductive senescence, will not be detectable until adulthood. Such effects with long latency from the time of developmental exposure to the outcome observed years later are not detected easily, unless carefully controlled studies are done.

Teratogenic Agents Act in Specific Ways (Mechanisms) on Developing Cells and Tissues to Initiate Abnormal Embryogenesis (Pathogenesis)

Development is an extremely complex and carefully integrated process involving a variety of genetic controlling functions, cell interactions, and tissue interactions. All of this requires accurate timing of events, e.g., turning on and off of genes at the right time and in the correct sequence to control normal replication, cell death, differentiation, and migration of cells to their correct final positions at the appropriate time for normal tissue and organ development.

There are two types of mechanisms that must be considered in the developmental toxicity of drugs and other agents. First, there are pharmacological and biochemical mechanisms by which agents can interact with a target site and alter development, and second, there are mechanisms by which target molecules, cells, and tissues react to that initial interaction, i.e., the initial steps in pathogenesis. Although not totally distinct, both types of events must be appreciated to understand the complexities of development and how this process can be altered.

Because of the many types of processes involved in development, there are many mechanisms by which agents may potentially act to alter development. However, partial mechanisms for only a few agents have been shown. Wilson (1977) proposed a list of potential mechanisms by which agents might act on developing cells and tissues (shown in Table 13.1.1).

This list of general mechanisms by and large relates to the initial interaction of the agent at the target site or receptor. Much more specific information is now available for some agents on the ways in which they may interact with the target site to alter development. In particular, specific receptor-binding agents that act as agonists or antagonists and alter development have been studied extensively. For example, diethylstilbestrol (DES), a potent synthetic estrogen-receptor agonist, was shown to affect development of the reproductive system in both male and female offspring of women treated for premature labor in the 1950s, and in some cases it caused a rare form of vaginal adenocarcinoma that did not show up until the late teens or early

20s in DES daughters. Androgen receptor binding by agonists or antagonists (e.g., dihydrotestosterone, vinclozolin, hydroxyflutamide, *p,p′*-DDE) has been shown experimentally to alter reproductive development as well. Agents that bind to the retinoid receptor may also interfere with development. For example, Accutane (13-cis-retinoic acid, isotretinoin), an endogenous retinoid that is extremely important in development, was marketed for treatment of recalcitrant cystic acne in the early 1980s and caused craniofacial, cardiovascular, central nervous system, and neurobehavioral deficits in a number of children whose mothers took the drug in early pregnancy.

In addition to the initial interaction of an agent with the target site, the progression of events that follow, i.e., pathogenesis, must also be considered in the ultimate manifestation of abnormal development. Some mechanisms that may be altered are listed in Table 13.1.2. Although these general molecular and cellular mechanisms have been known for some time, much new information about them has come from recent studies in molecular and developmental biology. Some are being studied as potential pathways through which alterations in development may occur. Several of these potential mechanisms were reviewed in a recent series of articles in *Reproductive Toxicology* (vol. 11, nos. 2/3, 1997). Discussion of these and other potential mechanisms can be found in Brown (1994), and Faustman et al. (1997).

Signal transduction pathways involved in some of these processes have been identified, and this may help to elucidate more directly the initial target site of action and subsequent steps in the process that can be interfered with during development (Gerhart, 1998). For example, the signaling pathway for apoptosis may involve the *p53* tumor suppressor gene, a negative regulator of the cell cycle and a positive regulator of apoptosis, *bcl-2*, a suppressor of cell death, the ICE genes, *c-myc*, *bax*, and others. Many of these are involved in controlling the cell cycle as well as in regulating apoptosis. Apoptosis is a normal phenomenon in embryonic development, involved in remodeling of many structures in the facial area, nervous system, and limbs. A few teratogenic agents have been studied for their effects on this pathway. For example, Wubah et al. (1996) have shown that cladribine (2-chloro-2U-deoxyadenosine) induces p53-mediated apoptosis and results in eye malformations in mice treated on gd 8. Moallem and Hales (1998) showed that an analog of cyclophosphamide induced different types of cell cycle alterations, cell death, and limb malformations, depending on the p53 genetic background of the mice. The role of p53 in embryogenesis, DNA repair, and apoptosis is still unclear, as it appears to suppress teratogenesis in some cases and enhance it in others.

Agents that act by any of the mechanisms listed in Table 13.1.1, or that interfere with any of the processes listed in Table 13.1.2, should be considered to have the potential for inducing developmental toxicity, and should be tested thoroughly for all types of developmental effects. The embryo appears to be able to repair a certain amount of damage and continue to develop normally, but at this point, the amount of damage that can be repaired has not been elucidated. A number of in vitro systems are being employed in the study of these mechanisms for both normal and abnormal development (see below).

The Final Manifestations of Abnormal Development Are Death, Malformation, Growth Retardation, and Functional Disorders

The four major manifestations of developmental toxicity (death, structural malformations, altered growth, and functional deficiency) are all considered adverse effects. As indicated above, the manifestations of developmental toxicity vary depending on the timing of exposure, dose, and the underlying processes that are occurring, as well as on the time of observation. These manifestations are likely to be interrelated (e.g., embryo/fetal death is frequently associ-

ated with and may be a consequence of severe malformation). Although death, malformation, and permanent functional impairment all clearly represent equally unacceptable outcomes, the significance of effects on growth or on the incidence of structural variations is sometimes questioned, particularly if these only occur at maternally toxic doses or can be shown to be reversible. However, many agents capable of producing death and malformation can also affect growth, depending on the dose and time of exposure. Growth retardation is often associated with functional impairment. While structural variations do not appear to adversely impinge on the health or longevity of affected fetuses, an increase in their incidence may indicate that the embryotoxic threshold is being approached (Kimmel and Wilson, 1973). The significance of these more subtle developmental effects also depends on the context in which they occur. For example, deficient or irregular patterns of ossification that are generalized throughout the fetal skeleton may simply reflect transient growth retardation, but such effects take on added significance when they occur without corresponding reductions in fetal weight or are more prominent in structures in which malformations also occur.

The Access of Adverse Environmental Influences to Developing Tissues Depends on the Nature of the Influences (Agents)

Access of an agent to developing tissues depends on the physico-chemical nature of the agent itself, as well as the physical, biochemical, and physiological aspects and homeostatic mechanisms of the maternal organism. Physical agents, such as ionizing radiation or hyperthermia, can impact the embryo directly and interfere with development. When the mother is exposed externally, the amount of the agent that reaches the embryo/fetus may be modified to some extent by the density of maternal tissues, but the characteristics of the agent that make it harmful developmentally will not be altered.

Chemical agents, on the other hand, are subject to a number of maternal factors that may alter, reduce, or increase the amount reaching the developing organism. For example, maternal pharmacokinetics, which include absorption, distribution, metabolism, plasma protein binding, and excretion, can all have an impact on the amount of active ingredient that is available to the developing embryo/fetus. Physiological changes in the maternal animal during pregnancy may also influence chemical delivery. Placental metabolism can play an important role in the amount of drug that crosses the placenta, as well as whether placental transport is active or passive (see review by Slikker and Miller, 1994). Although species differences in morphology of the placenta have been pointed out by a number of authors as potentially influencing placental transfer, there are very few instances where placental morphology has been demonstrated to play a role. One exception is the differential passage of nutrients as well as drugs and other agents across the yolk sac placenta, which plays a greater role in the early rodent conceptus than in the human. The primary factors that affect placental transport are uterine and placental blood flow, placental permeability, and placental metabolism. These factors change dramatically as pregnancy advances and can affect transfer significantly.

Placental permeability is affected by both physical and chemical characteristics. For example, the degree of ionization, lipid solubility, protein binding, and molecular weight of an agent may affect the ability of an agent to cross the placenta. Almost any maternally administered compound has the potential to cross the placenta, and the question is not whether a compound crosses the placenta, but at what rate, negating the concept of a "placental barrier" that protects the embryo/fetus from harmful agents to which the mother may be exposed.

Chemical biotransformation by the developing conceptus may also occur, and the same factors that influence placental transfer to the embryo/fetus also influence transfer back from the conceptus into the maternal bloodstream. In many cases, the laboratory rodent develops enzyme metabolizing systems in the early neonatal stages, whereas in humans, these events occur or begin before birth. Thus, mimicking of late human fetal exposure may require postnatal dosing of rodents. If a chemical has been conjugated by the fetus (e.g., via glucuronidation or sulfation), or metabolized to a more polar form, the rate of return to the maternal circulation will be slower than for the parent compound, resulting in an accumulation of the material in the fetal compartment.

In some cases, access of an agent to the developing conceptus may not be the deciding factor as to its potential for developmental toxicity. Instead, the effect of the agent may be primarily on the maternal system which, in turn, affects the developing organism and causes adverse effects. In the typical screening studies used for regulatory purposes, it is usually not possible to determine whether an effect is direct

on the embryo/fetus or indirect through effects on the mother. Although it is clear that embryo/fetal development can be affected by maternal toxicity, it is not well understood under what conditions and to what extent this occurs.

Daston (1994) reviews the information available on the relationship between maternal and developmental toxicity, and provides examples of situations in the mother (agents or disease states) that have been shown to affect development. These include toxicity to the placenta, altered nutritional status of the mother, decreased uterine blood flow, anemia or hypoxia, toxemia of pregnancy, autoimmune states, diabetes, acid-base disturbances, decreased milk quantity or quality, and abnormal maternal behavior. Chemical examples that have been shown to affect development by maternally mediated mechanisms include cadmium, cigarette smoking, cocaine, ethanol, and urethane. In most if not all cases, these examples have been delineated through a series of studies specifically designed to address the question of causality. Hood and Miller (1997) further discuss the role of maternally mediated effects on development and experimental approaches to assessing such effects.

Manifestations of Deviant Development Increase in Degree as Dosage Increases, from No Effect to the Totally Lethal Effect

One of the cardinal principles in determining whether or not exposure to a particular agent is related to an effect is that there is a dose-response relationship between the two. Wilson (1973) originally described the overlapping dose-response relationship between malformations, embryolethality, and maternal toxicity. In the case of an agent that causes malformations, as dose increases, the severity of malformations also tends to increase until death intervenes. If death of the conceptus occurs at higher doses as a result of malformations, a nonlinear dose-response relationship for malformations may result. Whether or not there is a low dose at which no effect will occur (i.e., a threshold) has been a controversial issue, but it is well known that compensatory growth and repair mechanisms are present in the developing organism. Several studies reported in the literature have shown that damage to a small or moderate number of cells can result in no obvious effects on development, while damage to a larger number results in malformations and death of the conceptus. Many studies have been published that focus on induction of apoptosis and alterations in the cell cycle by various agents, but the degree of insult that the embryo can tolerate has not been determined.

In recent years, a good deal of effort has been applied to mathematical modeling of the dose-response data from developmental toxicity studies (see Williams and Ryan, 1997, for a review). Such approaches are beginning to be used for risk assessment purposes by establishing a benchmark dose that can be used for comparison among agents, among types of toxicity for a given agent, or to set exposure limits. Catalano et al. (1993) also described an approach to modeling all of the prenatal outcomes of development (i.e., fetal weight, malformations, and fetal death). In recent years, several publications have resulted from efforts to develop biologically-based dose-response models for developmental toxicity (e.g., Shuey et al., 1994a,b; Kavlock and Setzer, 1996). All of these efforts have increased the understanding of dose-response relationships for developmental toxicity, but more importantly, they have highlighted the need for more understanding of the mechanisms of both normal and abnormal development for use in biologically based dose-response models.

EXTRAPOLATION OF ANIMAL FINDINGS TO HUMANS

Adverse effects seen in animal studies have been assumed to indicate a potential risk to humans. Several authors have reviewed the literature on agents known to cause developmental effects in humans and the data, though limited, strongly support this assumption (summarized by Kimmel and Kimmel, 1997). It is also clear that the occurrence of a specific adverse effect in animals does not predict that the same adverse effect will occur in another animal species, including humans; i.e., concordance of a specific effect at a specific target site in multiple species is not necessarily the case. For example, thalidomide does not cause phocomelia in rats as it does in humans, but it will increase intrauterine deaths. Valproic acid produces exencephaly (a cranial neural tube defect) in mice but not in rats, rabbits, or monkeys. Any manifestation of exposure-related developmental toxicity in animal studies can be indicative of a developmental hazard to humans. If, for example, a drug causes tail defects in mice, or an effect on Zymbal's gland in rodents, although there are no direct corollaries in man, such effects are assumed to be relevant to humans, unless it is possible to demonstrate mechanistic differences. The proximity of exposure levels that are developmentally toxic in animals to human exposure levels

is a primary consideration in evaluating human risk. For example, very large oral doses of caffeine produce ectrodactyly in rats whereas the same high levels of caffeine, administered as divided oral doses, or administered in drinking water at levels more comparable to human intake, do not.

The fact that an agent has been shown to cause developmental effects in laboratory animals and not in man does not invalidate the animal models. A few reasons for failed predictions may include: (1) appropriate studies to evaluate the association of an exposure with relevant developmental effects may not have been conducted in humans; (2) the exposure level that occurs in humans is too low to produce an effect; and (3) the incidence of effects in humans is too low to be detectable. Epidemiology studies that evaluate populations with greater phenotypic heterogeneity than in laboratory animals often do not have sufficient information for dose-response evaluations and do not typically ascertain the full spectrum of effects of an agent. Human studies are usually designed to evaluate a single outcome of pregnancy, e.g., spontaneous abortions or malformations. Thus, other possible endpoints, especially functional disorders, may go undetected. Longitudinal studies that follow exposures prior to, during pregnancy, and to infants and children, and evaluate a variety of developmental outcomes will allow linking of exposures and effects that are not possible in cross-sectional epidemiology studies.

USE OF IN VITRO SYSTEMS IN TERATOLOGY

A number of in vitro systems have been developed for use in teratology. The term "in vitro" is generally applied to any test system other than a pregnant mammal. Examples include isolated whole embryos (mammalian or nonmammalian) in culture, as well as tissue, organ, and cell culture assays. These systems afford several qualities that are useful in studying mechanisms of normal and abnormal development, e.g., isolation of the embryo from the maternal environment, removal or transplantation of specific tissues and cells, and the ability to track specific cells and molecules, to genetically alter cells, and to monitor embryo physiology.

In vitro systems have been used for two major applications in teratology and developmental toxicology: (1) screening for the effects of toxic agents; and (2) studying mechanisms of agent-induced alterations in development. Although the use of in vitro systems for mechanistic studies has many advantages (reviewed by Harris, 1997, and described in subsequent units of *Current Protocols in Toxicology*), their use in screening for teratogenic agents is extremely limited. In large part, this is because of deficiencies in the test system that have been identified above as advantages for mechanistic studies—i.e., isolation from the maternal environment that may modulate effects through pharmacokinetics, or maternal toxicity, and the fact that most systems can be maintained in vitro for only a few days in duration. This latter feature, especially for mammalian whole-embryo culture systems, limits exposure and evaluation of responses to only a small portion of the developmental stages that may be important for understanding developmental toxicity in vivo. Kimmel and Kimmel (1997) have discussed the use of in vitro developmental systems, their role in screening chemicals, and the potential for use in risk assessment. Integration of these two uses of in vitro systems, i.e., mechanistic studies and application of that information to designs for screening studies, may ultimately allow further development of in vitro assays or short-term tests to replace the large number of animals currently required for chemical testing.

Rat Embryo Cultures for In Vitro Teratology

Rat embryo culture methods have been used in industrial teratogen screening and for basic mechanistic studies in developmental toxicology. This unit describes whole-embryo protocols for (1) postimplantation embryos (see Basic Protocol 1) and (2) early fetuses (see Basic Protocol 2). Although there are many common features of culture at these stages, there are several key differences that are presented. The morning after mating is considered the beginning of gestational day 0 (gd 0), based on the observation of a vaginal plug.

NOTE: All protocols using live animals must first be reviewed and approved by an Institutional Animal Care and Use Committee (IACUC) and must follow officially approved procedures for the care and use of laboratory animals.

CULTURE OF EARLY POSTIMPLANTATION EMBRYOS (gd 9 through gd 11)

BASIC PROTOCOL 1

This protocol describes culture of postimplantation embryos. Embryos are isolated from the uterine environment and cultured in vitro for up to two days. This protocol is most frequently used in industrial screening applications and mechanistic studies because it covers the gestational stages of greatest teratogenic sensitivity.

Materials

Time-mated gravidas (≤250-g rats, gestational day 8 to 10)
Anesthetic: ether/O_2, halothane/N_2O/O_2 or isoflurane/O_2
Normal saline or Hanks' balanced salt solution (HBSS), ice-cold (see *APPENDIX 2A* for both recipes)
Embryo culture medium (see recipe), prewarmed to 37°C
20 mM potassium phosphate buffer, pH 7.4 (optional; *APPENDIX 2A*)
Compounds to be tested for effects on embryos, dissolved in DMSO if necessary
S-9 supernatant from rat liver (optional; see Support Protocol 2)
NADPH (for use with S-9 supernatant; optional)
Glucose 6-phosphate (G6P; for use with S-9 supernatant; optional)
Gas mixtures (depending on stage and length of culture):
  5% O_2/5% CO_2/90% N_2 (gd 9)
  20% O_2/5% CO_2/75% N_2 (gd 10)
  40% O_2/5% CO_2/55% N_2 (optional late gd 10)
  95% O_2/5% CO_2 (gd 11 and later)
Petri dishes, sterile
Dissecting microscope
Dissecting equipment, sterile, including:
  Forceps
  Watchmakers forceps
  Fine iris scissors
Tissue culture vessels (e.g., 125-ml medium bottles, 10-ml test tubes) with gas-tight seals, sterile
Rotator apparatus for use within incubator:
  Powered bars for round bottles
  Motorized plate for test tubes

NOTE: All solutions and equipment coming into contact with embryos must be sterile, and aseptic technique should be used accordingly.

Contributed by Alan G. Fantel, Rudolf Bechter, and David Beckman
Current Protocols in Toxicology (2000) 13.2.1-13.2.12

Obtain and prepare embryos

1. Anesthetize the gravidas on gd 9 to 11 with ether/O_2, halothane/N_2O/O_2 or isoflurane/O_2, laparotomize the animal, and excise the uterus.

   The pregnancy is timed based on the presence of sperm in vaginal smears prepared in methanol or vaginal plugs the morning after mating.

   Methods for rat embryo explantation have been thoroughly described in several publications (New, 1966, 1971).

2. Place the uterus in a petri dish containing sufficient cold normal saline or HBSS to cover it, and incise it along its antimesometrial border.

3. Under direct observation or low-power stereomicroscopy, peel off individual implantation sites with associated decidua and place them in petri dishes of cold normal saline or HBSS.

   Subsequent steps are most easily performed under the stereoscopic dissecting microscope.

4. Keeping all tissues under the surface of the salt solution and using a pair of watchmaker's forceps, dissect out and discard the Reichert's membrane and parietal yolk sac remnants, taking care not to puncture the underlying vascular membrane (visceral yolk sac).

   Although Reichert's membrane may be difficult to visualize, it covers the visceral yolk sac and can usually be gently grasped with the watchmaker's forceps and torn. In gd 9 sites, it may be visualized most easily at one pole of the implantation sac.

Culture embryos with test compound

5. Transfer embryos to culture vessel containing at least 1 ml prewarmed embryo culture medium.

   See Critical Parameters for guidelines on amount of medium to use as well as for discussion of culture technique.

6. Add compound(s) to be tested, dissolved in DMSO if necessary.

7. *Optional:* Add 5.3 µl S-9 supernatant from rat liver per ml of medium. Add NADPH to a final concentration of 5×10^{-4} M and glucose-6-phosphate (G6P) to a final concentration of 10^{-3} M.

8. Culture embryos 24 to 48 hr in a 37°C humidified incubator with the appropriate gas mixture (based on gestational day) and rotation at 30 to 60 rpm.

   For gd 9 embryos, use 5% O_2/5% CO_2/90% N_2; for gd 10 embryos use 20% O_2/5% CO_2/75% N_2; and for gd 11 and beyond use 95% O_2/5% CO_2. When embryos are cultured for 48 hr, each day the flasks are opened and reflushed with the gas mixture appropriate for the gestational day.

Evaluate treated embryos

9. At the end of the culture period, remove embryos from culture flasks and place in fresh normal saline, 20 mM potassium phosphate buffer, or HBSS.

10. Remove the embryos from the membranes using fine forceps and examine under the stereoscopic dissecting microscope.

    Common endpoints for whole-embryo culture experiments include embryonic protein content, greatest length, somite count, and morphologic development. Embryos may then be histologically processed for internal examination. They can also be stained with dyes such as Nile blue sulfate to examine cell death.

Studies of developmental toxicity in vitro frequently employ a morphologic scaling system such as that devised by Brown and Fabro (1981). This system scales 19 growth and developmental parameters, including yolk sac development, somite number, limb growth, and neural tube formation and closure, as well as other features that can be scored under the dissecting microscope. By totaling the numbers, a score is derived that can be compared with standards for gestational age between gd 9 and 12.

CULTURE OF EARLY FETAL STAGES (gd 12 to 14)

BASIC PROTOCOL 2

Culture of fetal rats is similar to embryo culture (see Basic Protocol 1) with certain exceptions, e.g., that the higher oxygen demand of later stages requires that implantation sites be placed in flasks of warmed, continuously oxygenated EBSS immediately following removal from the uterus and before the completion of dissection. Additional differences are described below. The protocol presented is based on Barber et al. (1993). This protocol has been used primarily for mechanistic studies, but it is also suitable for examining the effects of chemical exposures at later stages of development. There are significant differences in the timing of developmental events in rats and humans, so this is also an important stage for study.

Materials

Time-mated gravidas (≤250-g rats, gestational day 12 to 14)
Fetal culture medium (see recipe), prewarmed to 37°C and fully flushed with 95% O_2/CO_2
Gas mixture: 95% O_2/5% CO_2
Compounds to be tested for effects on embryos, dissolved in DMSO if necessary
S-9 supernatant from rat liver (optional; see Support Protocol 2)
NADPH (for use with S-9 supernatant; optional)
Glucose 6-phosphate (G6P; for use with S-9 supernatant; optional)

Flat-sided 625-ml tissue culture flasks
Rubber stoppers to fit tissue culture flasks
18-G hypodermic needles
Gas regulators and tubing
Side-arm Ehrlenmeyer flask
1-ml syringes
Sintered-glass diffuser
Dissecting microscope
Dubnoff metabolic incubator (Precision Scientific)

NOTE: All solutions and equipment coming into contact with fetuses must be sterile, and aseptic technique should be used accordingly.

Obtain and prepare fetuses

1. Anesthetize the gravida on gd 12 to 14 and excise the uterus. Place the uterus in a large petri dish containing HBSS and dissect individual implantation sites free. As soon as each site is removed from the uterus, place it in a flask of warmed, continuously-oxygenated EBSS. After all sites have been stripped from the uterus, transfer one fetus from the flask to a petri dish containing sterile HBSS and remove decidua, parietal yolk sac, and remnants of Reichert's membrane.

   Explantation is similar to Basic Protocol 1 except that the higher oxygen demand of later stages requires that implantation sites be placed in flasks of warmed, continuously-oxygenated EBSS immediately following removal from the uterus and before the completion of dissection.

   A major difference from earlier-stage cultures (Basic Protocol 1) is the requirement for exteriorizing the fetus. This is described in the following steps.

2. After the external membranes are removed, make an incision in the area of the visceral yolk sac nearest the fetal head, taking care not to sever the larger blood vessels.

   Although some hemorrhage normally occurs from the smaller vessels, this is usually inconsequential.

3. Reaching into the visceral yolk sac with forceps, tear open the amnion and pull the fetus outside, placing it in direct contact with the medium.

4. Place the exteriorized fetus and membranes in a common 625-ml continuously-oxygenated flask containing 125 ml of fetal culture medium. Place this flask flat side down and gently rock in the Dubnoff metabolic incubator. Use a small piece of lead to weight the bottles down and prevent them from floating in the water bath.

Preculture the exteriorized fetuses

5. Culture the fetuses in the common flask for 2 hr under the conditions described below prior to their distribution to experimental flasks.

   This preliminary incubation enables identification and elimination of fetuses that may have hemorrhaged excessively and are no longer viable. They will be evident from their pallor and reduced or absent heartbeat and yolk sac circulation.

   a. After they have been examined for viability, place fetuses in the individual *experimental* culture flasks containing 125 ml warm, oxygenated fetal culture medium and the study agent(s).

      These vessels are identical to the common flask. Medium volume is 125 ml and up to 10 fetuses may be cultured in a single flask.

   b. Culture flasks are flushed continuously throughout the culture period with O_2/CO_2 at a flow rate of 400 ml/min. This rate is most easily controlled with the use of a manometer for each flask.

   c. The screw caps supplied with the flasks are discarded and replaced with tight-fitting rubber stoppers that have been pierced by two 18-G hypodermic needles. One needle is adapted to fit gas-tight tubing, which can be accomplished by cutting off the flat (flanged) ends of 1-ml hypodermic syringes. One end is attached to the needle and the other to the tubing. The second needle serves as a vent. The rubber stoppers are fitted tightly into the necks of the flasks.

   d. In order to prevent evaporative loss of culture medium, it is necessary to humidify the gas mixture before it enters the experimental culture flasks. This is accomplished with an Ehrlenmeyer flask fitted with a side arm. The flask is filled with clean water and covered with a rubber stopper containing a sintered glass diffuser. The gas mixture (95% O_2/5% CO_2) flows through the diffuser, bubbles through the water, and exits through the side arm which is connected by tubing to the manometers, if used, or directly to the inlets of the culture flasks.

   e. The shaker is set to gently rock the flasks from long end to long end at a rate of ~30 cycles/min. Faster rates may force the fetuses onto the neck of the flask where they will dry out, or may cause hemorrhages of the yolk sac vasculature.

Perform experimental cultures

6. Prepare experimental flasks as in steps 5a to 5e, and distribute the fetuses among them using a sterile stainless steel spatula.

7. Add compound(s) to be tested, dissolved in DMSO if necessary.

8. *Optional:* Add 5.3 µl S-9 supernatant from rat liver per ml of medium. Add NADPH to a final concentration of 5×10^{-4} M and glucose-6-phosphate (G6P) to a final concentration of 10^{-3} M.

9. Place the culture flasks in the Dubnoff metabolic incubator, set to 37°C.

   Flasks are arranged flat-side-down, enabling the medium to remain below the incubating water level with the flask neck above the water line. In order to prevent the flasks from floating free, they should be weighted down.

10. Culture fetuses for up to 24 hr.

    Culture has never been successfully extended beyond the morning of gd 15.

Evaluate cultured fetuses

11. After 24 hr, remove fetuses from culture flasks and examine under the stereoscopic dissecting microscope.

    Standard measures include greatest length and protein content. The fetuses are carefully scanned for morphological staging and malformations. They may be fixed and sectioned for finer study. Limb development is especially sensitive at these later stages.

COLLECTING SERUM FOR EMBRYO CULTURE

SUPPORT PROTOCOL 1

Various medium combinations have been successfully employed for rat whole-embryo culture (New, 1979). Most have consisted entirely or in part of immediately centrifuged, heat-inactivated rat serum. The following procedure is commonly used to collect serum for whole-embryo culture.

NOTE: All solutions and equipment coming into contact with live cells must be sterile, and aseptic technique should be used accordingly.

Materials

Nonpregnant rats (often retired breeders or older males)
Anesthetic: ether/O_2, halothane/N_2O/O_2 or isoflurane/O_2

18-G needle
Sterile, nonheparinized syringe
Refrigerated centrifuge
50-ml conical centrifuge tubes
56°C water bath

1. Anesthetize nonpregnant rats with ether/O_2, halothane/N_2O/O_2 or isoflurane/O_2.
2. While under deep anesthesia, laparotomize rats and insert a large needle (18-G), attached either directly or via butterfly tubing to a sterile nonheparinized syringe, obliquely into the descending vena cava below the level of the diaphragm.
3. By gently pulling on the plunger to avoid excessive hemolysis, collect 9 to 15 ml of whole blood from each animal.
4. Sacrifice the rat by cutting the aorta above the diaphragm, after the needle is removed from the vein.
5. After removing the needle from the syringe, gently expel the blood into 50-ml conical centrifuge tubes. Immediately centrifuge 20 min at ~1500 × *g*, 4°C.
6. Remove the supernatant (serum) from the pellet (red cell layer). Incubate the serum 30 min at 56°C to inactivate complement.

   If not used immediately, the serum may then be frozen at −20° or −80°C.

   Many investigators use rat serum alone for the culture of rat and mouse embryos. See Critical Parameters for additional discussion of media.

SUPPORT PROTOCOL 2

PREPARATION OF LIVER HOMOGENATES FOR STUDIES OF BIOTRANSFORMATION

A number of systems have been employed that incorporate features of extraembryonic drug metabolism. Conspecific or allospecific liver homogenates may be prepared and added to culture medium along with appropriate cofactors. Some of the earliest successful systems employed liver from adult rats that had been preinduced with polychlorinated biphenyls, i.e., Araclor 1254 (Fantel et al., 1979; Kitchin et al., 1981), but human liver preparations have also been used (Zhao et al., 1993). Other approaches to metabolism include pretreatment of gravidas with test agents followed by culture of exposed embryos after a suitable time period (Kochar, 1975; Beaudoin and Fisher, 1981) or preparation of culture medium from the serum of nonpregnant animals previously exposed to test compounds (Schmid et al., 1982).

Materials

Adult rats
Polychlorinated biphenyls (PCB, Araclor 1254)
Corn oil
0.05 mM potassium phosphate buffer, pH 7.4

3-ml syringe and 18-G needle
Dounce homogenizer with Teflon pestle
Refrigerated centrifuge

NOTE: All solutions and equipment coming into contact with live cells must be sterile, and aseptic technique should be used accordingly.

1. Dilute Araclor 1254 in corn oil to a concentration of 500 mg/ml. Using a 18-G needle attached to a syringe, give each animal an i.p. injection of 500 mg/kg (1 ml/kg) 5 days before sacrifice.

   The Araclor acts as an oxidase inducer in the liver and will increase the metabolic activity of the S-9 preparation.

2. On day 5 after induction, sacrifice rat by cutting the thorucic aorta under deep anesthesia and remove liver.
3. Using a Dounce homogenizer with a tight-fitting Teflon pestle, homogenize rat livers in 2 vol of ice-cold potassium phosphate buffer, pH 7.4, on ice.
4. Centrifuge 20 min at 9000 × g, 4°C. Decant the supernatant into a sterile vessel on ice.

   The supernatant (S-9) used as the enzyme source is added to culture flasks at a concentration of 5.3 µl/ml. Cofactors are added including NADPH (5×10^{-4} M) as the electron donor and G6P (10^{-3} M) to assure maintenance of saturating NADPH concentrations. This system has been shown to significantly enhance the embryotoxicity of cyclophosphamide (Fantel et al., 1979) while reducing that of cytochalasin D (Fantel et al., 1981).

REAGENTS AND SOLUTIONS

Use Milli-Q-purified water or equivalent for all recipes and in all protocol steps. For common stock solutions, see ***APPENDIX 2A****; for suppliers, see* ***SUPPLIERS APPENDIX****.*

Embryo culture medium

A variety of medium compositions have been used to culture rat embryos. Rat serum (see Support Protocol 1) diluted up to 50% with Hanks' balanced salt solution (HBSS), or culture media such as Weymouth's work well (Bechter et al., 1991; Terlouw et al., 1993), but other sera, including cow (Klug et al., 1985), monkey

continued

(Klein et al., 1982), and human (Fantel et al., 1979; Chatot et al., 1980; Abir et al., 1993) have been used effectively. Fantel et al. (1979) and Chatot et al. (1980) reported considerable variability in the ability of sera from different individuals to support the growth of rat embryos. Most workers add penicillin (100 U/ml) and streptomycin (50 μg/ml) to media.

Fetal culture medium

Medium employed for fetuses may be determined by the gestational stage of the culture, with the percentage of autologous serum decreasing with age. For gd 12 and 13 cultures, medium composition may be identical to that described for embryos (see recipe for embryo culture medium), although serum concentrations as low as 25% are effective on gd 13. For gd 14, no serum is required and embryos are grown successfully in Earle's balanced salt solution (EBSS) supplemented with 0.7% bovine serum albumin (BSA). Medium volume is in the range of 12.5 ml/fetus and penicillin (100 U/ml) and streptomycin (50 μg/ml) are usually added.

COMMENTARY

Background Information

Explantation and culture of whole rodent embryos, developed largely in the laboratory of Dennis New at Cambridge in the 1960s, and 1970s, has proven to be a valuable tool for mechanistic studies in developmental toxicology as well as for teratogen screening by industry. These methods support normal growth and development during postimplantation stages, including most of organogenesis, eliminating the gravida from consideration. This permits exposure of embryos to precisely defined amounts of precisely defined agents at precisely defined developmental stages. Animal maintenance costs tend to be less, as study periods are typically reduced from the complete 21- to 22-day gestation period in rats to 1 to 2 days from exposure to autopsy.

Additional savings derive from the ability to carefully examine and precisely age-match subjects and controls prior to treatment, eliminating a potential confounding variable. Another confounder may be reduced by eliminating nonviable or moribund embryos at the outset of study. Careful age-matching and culling can reduce the total number of animals required for assay. The volume of medium used in cultures ranges from 1 ml/embryo for early postimplantation stages to ~12 ml/fetus on gd 14. Because these volumes, especially those used at earlier stages, are significantly lower than that of the typical gravida, amounts of expensive test compounds may be greatly reduced.

The inherent precision and cost savings of whole-embryo culture methods must be balanced against their limitations. These include relative increases in the time and technical skill required to explant embryos, restricted gestational stage compatible with growth in vitro, the relatively brief culture periods that are practically attainable, required exposure to nonphysiologic oxygen concentrations and, in many cases, inability to expose conceptuses to the full spectrum and proper concentrations of maternally formed metabolites. Despite the inclusion of metabolic systems (S-9 supernatant; see Support Protocol 2), exposure profiles may poorly approximate those that occur in vivo. Additionally, the nonpolar nature of many pharmaceuticals may limit concentrations to which embryos can be exposed and may require the use of additional vehicles such as ethanol or dimethylsulfoxide for solublization. Perhaps the greatest drawback is the inability of culture systems to support growth beyond early fetal stages. As a consequence of these limitations, outcomes of in vitro exposures may fail to accurately represent the results of in vivo exposures, and term effects must be extrapolated from pathological and biochemical findings at earlier gestational stages. As discussed below, the palate of abnormal outcomes of whole-embryo culture exposures is relatively limited, with disparate agents often inducing similar defects, in contrast to their in vivo activity.

Whole-embryo culture in industrial teratogen screening

The cost and time savings associated with short-term tests are useful to industry. These screens enable investigators to determine the embryotoxic and/or teratogenic potential of new drug candidates during early phases of

drug development. They can help limit costly in vivo testing to compounds that demonstrate the lowest probability of adverse effects. Candidate agents can then undergo standard animal testing prior to clinical trials and drug registration. In order to employ a screening system for compound selection, it should be validated for all compound classes in a given pipeline. It is especially important that methodologies and animal strains be held constant in screening studies. In these ways, it is possible to employ accumulated historical control and experimental data (Bechter and Terlouw, 1990) and compare test results from different experiments for compound development.

Critical Parameters

Temporal considerations

Embryo culture is temporally circumscribed, as growth beyond gd 15 has not, to the authors' knowledge, been performed successfully. Furthermore, culture for more than 48 hr is impractical and rarely performed since both medium and gas changes are required. In order to cover teratogenically sensitive stages of organogenesis, exposure studies are generally performed on gd 8, 9, or 10. The consequences of these limitations are that (1) defects induced by an agent at stages before or after the culture period may be missed; (2) defects that might have been induced by exposure during the culture period may not be evident at the end of the culture period; and (3) defects that might have been repaired prior to parturition may be observed at the end of the culture period. On the other hand, absent or incomplete repair may serve as an index of potential developmental toxicity and provide mechanistic insight.

If cultures are started in the morning to midday, culture medium must be replaced in the middle of the night. This is most easily accomplished by preparing two sets of flasks at the outset of the experiment. Fetuses can then be transferred later to the second set of flasks using a small stainless steel chemical spoon. Medium must be fully flushed with 95% O_2, a process taking 20 to 30 min.

Biotransformation, pharmacokinetics, pharmacodynamics

It may not be possible to expose embryos in culture to the full range of drug metabolites in proper concentrations during appropriate stages of gestation. As noted, several schemes have been developed that enable the incorporation of some aspects of drug metabolism, and these protocols have been useful, to an extent, in determining the role of extraembryonic biotransformation. Potential, practical problems are considered below.

A more recent experimental approach to the inclusion of biotransformation in culture was the addition of "conditioned" medium used previously for culture of hepatocytes prepared from the livers of adult animals. By harvesting medium from hepatocyte cultures at different culture times (sequential cultures) these methods enable study of the kinetics of toxification and detoxification of test compounds (Bechter et al., 1989). Other investigators have directly incorporated hepatocytes into embryo culture (coculture). Because of the experimental nature of these systems, details have been omitted. Interested readers are referred to papers by Oglesby et al. (1992) and Ozolins et al. (1995).

Medium prepared from the serum of treated animals may be unable to support embryonic growth even in the absence of the parent compound. Additionally, short-lived and reactive metabolites may be lost during the time required for medium preparation, and heat inactivation of serum may alter parent compounds and/or metabolites. Hepatic preparations tend to be relatively unstable when combined with cofactors (S-9) in culture and short-lived metabolites may be produced at the beginning of culture but not later when homogenates are no longer active.

Because teratogenic metabolites may be absent at sensitive times, other approaches have been developed. For example, by adding conditioned medium from hepatocyte cultures containing drug and metabolites to culture medium (sequential hepatocyte/whole-embryo culture, Bechter et al., 1989), metabolites may be present during the extended culture period. Metabolic capacities of the embryo, per se, and especially those of the yolk sac, are active in vitro during the culture period (Bechter and Terlouw, 1990; Terlouw and Bechter, 1992, 1993; Jones et al., 1993) and such metabolism *may* result in the formation of teratogenically relevant metabolites. Finally, because there is little information on the transfer of drugs and their metabolites from mother to fetus, those metabolites generated by these various systems may poorly represent actual exposures in vivo.

An important consideration when comparing in vitro to in vivo pharmacokinetics is the stability of metabolites under culture conditions. Furthermore, there is evidence that em-

bryos undergo some degree of adaptation to culture conditions (Brown et al., 1991), but little is known about changes in the visceral yolk sac, the primary transfer tissue. Changes in this tissue, for example, could influence the pharmacokinetics of xenobiotics. Direct experimentation is necessary to evaluate whether in vitro pharmacokinetics adequately model in vivo processes.

Culture conditions

A number of protocols have been developed to enable the warming, oxygenation, and circulation of embryo culture medium. A scheme initially adapted by New (1967) attached the embryos by remnants of Reichert's membrane to gauze mats set in glass tubes. The circulation of medium past the stationary embryos was powered by rising gas bubbles. The "Plasmom" of Robkin and Shepard (1972) employed a peristaltic pump that circulated medium through a bundle of silicon rubber tubes. These tubes were suspended in a warm bath of sterile distilled water through which the desired gas mixture bubbled. Although no longer in widespread use, these methods enabled investigators to observe and photograph embryos and to monitor physiological changes resulting from study exposures.

Today, most investigators use one of several types of motorized equipment to roll or rotate culture flasks. These include powered roller bars for round bottles and disks to which smaller test tubes or scintillation vials may be clipped and rotated. Flasks must be placed inside an incubator set to maintain temperatures between 37° and 38.5°C. Various types of glass or plastic flasks may be used, but glass is used most commonly because its wetting properties support exchange of gas with the medium. Culture vessels must have gas-tight seals. They can range from the size of small test tubes or scintillation counter vials containing 1 or 2 embryos and several milliliters of medium to 125-ml (serum) bottles containing up to a dozen embryos in 10 to 12 ml of medium. Most investigators use a ratio of ~1 ml of medium per embryo during organogenesis stages.

The gas phases required for successful embryo and fetal culture are stage-specific, and there is compelling evidence that abnormal growth and/or development result under either hypoxic or hyperoxic conditions (Morriss and New, 1979; Miki et al., 1988; Chen et al., 1999). There are several different protocols for gassing culture vessels but all include 5% CO_2 and ≤95% O_2; the balance of the mixture consists of N_2. Culture on gd 9 requires 5% O_2 while gd 10 cultures utilize 20% O_2 and gd 11 and later generally utilize 95% O_2. Some investigators employ an intermediate O_2 concentration of 40% on late gd 10. Gas is usually allowed to flow on top of the medium in large flasks via a Pasteur pipet for 10 to 20 min and in smaller flasks for 20 to 30 sec. In all instances, care must be taken to avoid bubbling the medium, which can oxidize and denature proteins. After they are flushed, bottles are tightly sealed and set to rotate in the incubator. If cultures are continued for more than 24 hr, they must be reflushed with the gas mixture appropriate for the new stage of development. Cultures generally run from 24 to 48 hr.

Scoring systems

Studies of developmental toxicity in rat embryos in vitro frequently employ a morphologic scaling system such as that devised by Brown and Fabro (1981). Although this system is useful because of common associations between developmental delay and congenital defects, and because it enables inter-laboratory comparison, it has a number of potential drawbacks. First, subtle or internal defects not associated with delays may be missed. Second, as discussed below, agents that disturb structure or function of the yolk sac in vitro may yield results that are not representative of effects in vivo. Third, reduction in growth may be transient, with recovery occurring in vivo after the culture period. Finally, growth retardation may not be observed in the in vivo syndrome of effects.

Yolk sac dysfunction

During organogenesis stages, rat embryos are highly dependent on the visceral yolk sac for maternal-embryonic transfers. Beginning on or after gd 11, the role of the chorioallantoic (labyrinthine) placenta assumes increasing importance in these functions, but since the growth, development, and function of this latter structure cannot be supported by culture methods, the vitelline placenta must perform most or all of the transfer requirements of growth and development. Under control conditions, transfer is adequate to maintain normal rates of growth and differentiation. Under the various stresses imposed by xenobiotic exposures, and without the benefit of the (potential) redundancy associated with the simultaneous function of the yolk sac and chorioallantoic placen-

tas, transfer may become insufficient. Furthermore, as the first cell layer to be exposed to test agents, the yolk sac in vitro may be especially vulnerable to their activities. Transfer differences between placental structures may be responsible for an abnormal exposure profile of cultured embryos.

Studies published during the past 20 years have employed whole-embryo culture techniques to investigate the teratogenic activities of a wide variety of chemical and physical exposures. Despite the diverse nature of these exposures, a strikingly short list of dysmorphic outcomes is commonly reported. These include reduced outgrowth of the prosencephalon/telencephalic vesicle(s), edema in the area of the rhombencephalon, abnormal flexion often manifest as failure of conversion from dorsal to ventral curvature and failure of neural tube closure. These common features may primarily represent deficits in those structures developing during the relatively restricted period amenable to whole-embryo culture. Alternatively, but not exclusively, they may represent deficits and defects resulting from inadequate transfer to and from the embryo. Although these changes are used as indices of teratogenic potential, the outcomes of in vivo exposures may well be different (see Beaudoin and Fisher, 1981).

Various inhibitors of yolk-sac function have been shown to result in abnormal development, reduced growth, or embryonic death in whole-embryo culture, including anti–visceral yolk sac serum (Freeman et al., 1982; Beckman et al., 1990, 1991; Freeman and Brown, 1994), suramin (Freeman and Lloyd, 1986), and leupeptin (Freeman and Lloyd, 1983). When examined in vivo, the effects of these agents on development mirrored those seen in vitro (Freeman and Lloyd, 1983, 1986; Brent et al., 1990; Beckman et al., 1991). Each of these agents inhibits the critical role of the visceral yolk sac in providing nutrition to the developing embryo. Anti–visceral yolk sac serum (Freeman et al., 1982; Beckman et al., 1991; Freeman and Brown, 1994) and suramin (Freeman and Lloyd, 1986) inhibit pinocytosis in the visceral yolk sac. Leupeptin (Freeman and Lloyd, 1983) and aurothiomalate (Freeman and Lloyd, 1986) inhibit lysosomal proteolysis. The resulting abnormal morphology very often includes reduced development of the CNS, edema, failure of conversion from dorsal to ventral curvature, failure of neural tube closure, prosencephalic hypoplasia, rhombencephalic edema, and misplaced and/or small somites. These findings are common in whole-embryo culture studies and may not be representative of in vivo exposures.

Hyperoxia

As noted, the oxygen requirements for whole-embryo cultures are pragmatically based. Consequently, with the possible exception of culture on gd 8 and 9, oxygen concentrations used are well above physiologic ranges for most tissues. Boveris et al. (1972) have demonstrated significantly increased formation of reactive oxygen species (ROS) in tissues under hyperoxic conditions, a process that might be favored by the high reducing potentials and low antioxidant activities of developing tissues (Allen and Venkatraj, 1992). It is therefore reasonable to expect that culture conditions may impose considerable oxidative stress on developing embryos and their membranes—stress that might increase their sensitivity to xenobiotic agents or that might exert outright toxicity. Hyperoxia may therefore represent another explanation of the common "defects" reported in whole-embryo culture experiments. Fantel (1996) has reviewed this subject, and unpublished studies by Fantel and coworkers have shown dramatic formation of superoxide anion radical by the yolk sacs of control fetuses cultured on gd 14. This subject requires further study.

Anticipated Results

A minimum of 90% of control embryos and fetuses should be viable at the end of the culture period, and no gross defects should be evident. Information on expected embryonic growth parameters can be found in Brown and Fabro (1981). Experimental conceptuses should be expected to demonstrate concentration-dependent decreases in viability, as defined by active heart beat and yolk sac circulation, and increases in growth retardation and treatment-related malformations. Percentages of embryos failing to convert from dorsal to ventral flexion, and reductions in somite count and greatest length should also be responsive to concentrations of test agents.

Time Considerations

The time taken to explant rat embryos is strongly dependent on the technical skill and experience of the investigator or technician. Rat serum is generally collected and stored frozen prior to the day of the experiment, but many laboratories collect and process blood from gravidas to use in future experiments. If this step is added, an experienced technician should

be able to explant and treat 4 litters in 4 hr. As noted, culture intervals generally range from 24 to 48 hr. The time required for analysis of the results of exposure are entirely dependent on the parameters studied and the methods used. Thus, procedures such as photography, histology, autoradiography, and enzyme assay will lengthen this phase of study.

Micromass Cultures in Teratology

Interest in the development and application of in vitro models of fetal development has arisen for several reasons. First, well validated in vitro models can serve as an alternative to in vivo testing, thus reducing the number of animals required for a given experiment. Second, in vitro models allow mechanistic research that is otherwise technologically difficult or impossible. Third, compared with in vivo alternatives, in vitro models offer the promise of faster and cheaper screening capabilities for potential teratogenic compounds. Recognition of these strengths led to the development and initial characterization of primary cell cultures derived from embryonic neuroepithelial cells and limb bud cells in the early 1980s (Wilk et al., 1980; Sawyer and Goetinck, 1981; Flint and Ede, 1982; Solursh et al., 1982; Flint, 1983; Flint and Orton, 1984).

Because they are derived from primary cell suspensions of undifferentiated midbrain (mesencephalic) neuroepithelium and forelimb chondrocytes, micromass cultures have been used in the study of developmental cell cycle kinetics and regulation, which are poorly modeled by transformed cell lines. Micromass cultures have also been used to examine the cellular and molecular response to known teratogenic compounds, including analysis of protein and gene expression, intracellular cation signaling, redox status, necrosis and apoptosis, and differentiation (Flint et al., 1984; Brown et al., 1986a,b; Ribeiro and Faustman, 1990; Walum and Flint, 1990; Whittaker and Faustman, 1991, 1992; Sweeney et al., 1992; Whittaker et al., 1993; Ponce et al., 1994; Seeley and Faustman, 1995; Ou et al., 1999a,b). As these studies demonstrate, micromass cultures can be successfully examined using a range of experimental tools, including flow cytometry and attached cell laser cytometry, gel electrophoresis, and light, electron, and immunofluorescence microscopy.

In this unit, methods for isolating embryos, performing microdissection, and plating cultures of midbrain neuroepithelial cells (also termed central nervous system, or CNS, cells) and limb bud (LB) chondrocytes are described (see Basic Protocol). In the Basic Protocol, it is assumed that the researcher would like to conduct experiments on the cells as they grow in culture. In the Alternate Protocol, the researcher may choose to treat the pregnant rat, isolate the embryos, and derive cultures. The objective of the Alternate Protocol is to observe the effects of maternal treatment on the growth characteristics of the cultured cells. Both protocols can provide valuable mechanistic or screening information to the investigator interested in examining the effects of environmental factors on growth and development of the nervous system and the limb. Although variations on the techniques described here are encouraged, the investigator should first obtain an understanding of the fundamental growth characteristics of these cells in culture under the conditions described below.

NOTE: All protocols using live animals must first be reviewed and approved by an Institutional Animal Care and Use Committee (IACUC) and must follow officially approved procedures for the care and use of laboratory animals.

PREPARING NEUROEPITHELIAL AND LIMB BUD CELL MICROMASS CULTURE

BASIC PROTOCOL

This protocol is used to derive micromass cultures of primary neuroepithelial cells and limb bud chondrocytes from normal (untreated) female rats. The purpose of experiments conducted using this protocol is somewhat different than that of experiments conducted using the Alternate Protocol, which is designed to examine the maternally mediated effects on embryonic cell growth characteristics.

Contributed by Rafael A. Ponce

Current Protocols in Toxicology (2001) 13.3.1-13.3.14

The basic method for culturing both primary midbrain (CNS) and limb bud (LB) cells is the same. The only major point of difference is the final plating concentration. The protocol is broken down into the following major stages: setup of dissecting room and microdissection hood, dam sacrifice and dissection, embryo isolation, embryo microdissection, tissue dissociation, cell counting and cell plating, and medium addition and in vitro treatment.

NOTE: All solutions and equipment coming into contact with living cells must be sterile, and aseptic technique should be used accordingly.

NOTE: All culture incubations should be performed in a humidified 37°C, 5% CO_2 incubator unless otherwise specified.

Materials

70% ethanol
Earle's balanced salt solution (EBSS; Life Technologies) with and without calcium and magnesium (CMF-EBSS), sterile, 37°C
4 to 8 time-mated, gestation day 12 to 12.5 rats (where gestation day 12 represents the 12th day after confirming a positive pregnancy)
50% (v/v) heat-inactivated horse serum (see recipe), 37°C
Trypsin solution (see recipe), 37°C
Sterile culture medium (see recipe), 37°C
Collagen solution (see recipe, optional)

Sterile dissecting instruments: 2 dissecting forceps and 1 pair tissue dissecting scissors (straight operating scissors)
Sterile 100-mm petri dishes
Plastic waste bags
Disposable absorbent pads
Laminar flow hood
Dissecting microscope(s) with light source
Sterile microdissecting instruments (1 to 2 sets):
  2 Dumont (watchmaker's) forceps, pattern no. 5 (Fine Science Tools)
  Pair microdissecting Wecker scissors (Fine Science Tools)
  Slotted Moria spoon (Fine Science Tools)
Data recording sheet
15-ml sterile tubes, labeled (labeled as follows: CNS1, CNS2, CNS3, LB1, LB2, LB3, CM, trypsin)
Sterile incubator trays
Pulled-glass pipets (i.d. ~0.7 mm), sterile
10-ml disposable syringes, sterile
13-mm Swinney filters (Millipore) with a 10-μm nylon mesh membrane filter (Spectrum), sterile
Hemacytometer and hand-held counter
Repeater pipettor (Eppendorf)
Sterile 0.5-ml tips for repeater pipettor
35 × 10–mm sterile primaria-coated tissue culture dishes (Falcon)

Set up dissecting room and microdissecting hood

1. Prepare sacrifice area with sterile dissecting instruments, 70% ethanol, two 100-mm petri dishes, and plastic waste bags. Prepare area by thoroughly cleaning surfaces and wipe area with 70% ethanol.

   The room where the dams will be sacrificed and dissected must be separate from the room where the dams are housed.

Preparation of the dissecting room and microdissecting hood prior to initiating animal sacrifice will greatly increase the efficiency of the protocol and will help ensure a high-quality cell culture. Separate rooms for sacrifice and the microdissection will help reduce the possibility of contamination in the cell culture.

2. Lay out a disposable absorbent pad or other surface on which the dam will be dissected. Make sure dissecting area is well lit.
3. Set up microdissecting area by wiping down interior surfaces of the laminar flow hood. Wipe down dissecting microscopes and pipettors with 70% ethanol. Lift sash of hood so that work can be done inside hood with dissecting microscopes.

   Procedures requiring use of dissecting microscopes will be conducted with the hood open. Although this disrupts the air flow in the hood, the hood should be relatively free of contamination during microdissection procedures.

4. Place 1 to 2 dissecting microscope(s) in hood along with the light source and 1 to 2 sets of sterile microdissecting instruments. Place a sterile 250-ml beaker in the hood for liquid waste.
5. Fill five 100-mm petri dishes half way with sterile EBSS. Place one dish on the stage of each dissecting microscope.

   The lid of the petri dish will be used to collect waste tissue, while the dish will be used to isolate the embryo from the uteri.

Sacrifice dam and dissect

6. Humanely sacrifice dams one at a time. Record pregnancy status, litter size, resorptions, and other observations.

   The author typically uses CO_2 asphyxiation to euthanize the dams. See Critical Parameters and Troubleshooting for discussion of alternative methods.

7. Lay dam on its back on a disposable pad with the hind feet closest to the researcher. Cleanse abdomen with 70% ethanol, which helps reduce the amount of loose fur that can fly around and get into the peritoneal cavity. Using dissecting forceps, grip a fold of skin at the midline along the lower abdomen (the base) and gently lift to create a larger skin fold that can be cut using dissecting scissors. Make a V-shaped cut through the skin and underlying muscles. Using this cut as a starting place, expose the peritoneal cavity by cutting along midline from the pubic symphysis to the lungs. Displace intestines to the side to reveal the uterus.

   Some lateral cuts at the base of the abdomen may be useful to help expose the organs. For a right-handed person, it is easier to cut with the right hand while gripping the forceps in the left hand.

8. Using dissecting forceps, locate each horn of the uterus.

   The uterus joins the vagina at the base of the pelvis.

   Locating the uterine horns can be accomplished by gently probing around the intestines with the sides of the forceps on both the left and right side of the peritoneal cavity.

9. Gently pull uterus away from surrounding organs to allow easier inspection. Be careful not to rupture intestines or other organs during this process.
10. By gently lifting the base of the uterus with dissecting forceps, identify the attachment point, and cut it with dissecting scissors. Without releasing the uterus, continue to lift the uterus by the cervical stump upward to clear the uterus from the peritoneal cavity and identify the last embryo on either side of the uterus.

    Take care to create enough tension such that the uterus can be pulled by the cervical stump so as to identify the attachment points along either side, but not so much that the uterus is torn or damaged.

11. Remove associated fat using a second set of dissecting forceps. After identifying the last embryo on either side of the uterus, remove the uterus from the dam.
12. Place uterus in a sterile petri dish and, if working in a team of two, take into the microdissection area in the laminar flow hood.

    After isolating the uterus from the dam, it should be taken to the microdissection hood for immediate microdissection. If working in a team of two, one individual can perform the sacrifice and uterine isolation while the other can prepare the microdissection hood and begin the microdissection. If one individual is performing the experiment, he/she should sacrifice all dams and isolate the uteri prior to beginning microdissection. Typically, one individual can manage 8 dams at a time, though this requires substantial experience and efficiency in order to ensure a high-quality cell culture.

13. Place dam in plastic bag for disposal.
14. Repeat steps 6 to 12 until all dams have been sacrificed and all uteri collected.

Isolate embryo

15. Rinse uterus three times in sterile EBSS and place in a petri dish containing EBSS on the dissecting microscope stage.
16. Using 2 Dumont (watchmaker's) forceps, pattern no. 5, gently tear open the uterus at each site to release the deciduum containing the embryo (see Fig. 13.3.1). First, hold the uterus between two implantation sites with Dumont forceps (the holding forceps) in one hand. Align the uterus so that the muscle edge of the uterus is at the top (antimesometrial side). Next, poke a hole through the muscle layer with the other Dumont forceps (tearing forceps) in the other hand.

    The hole should be next to the holding forceps.

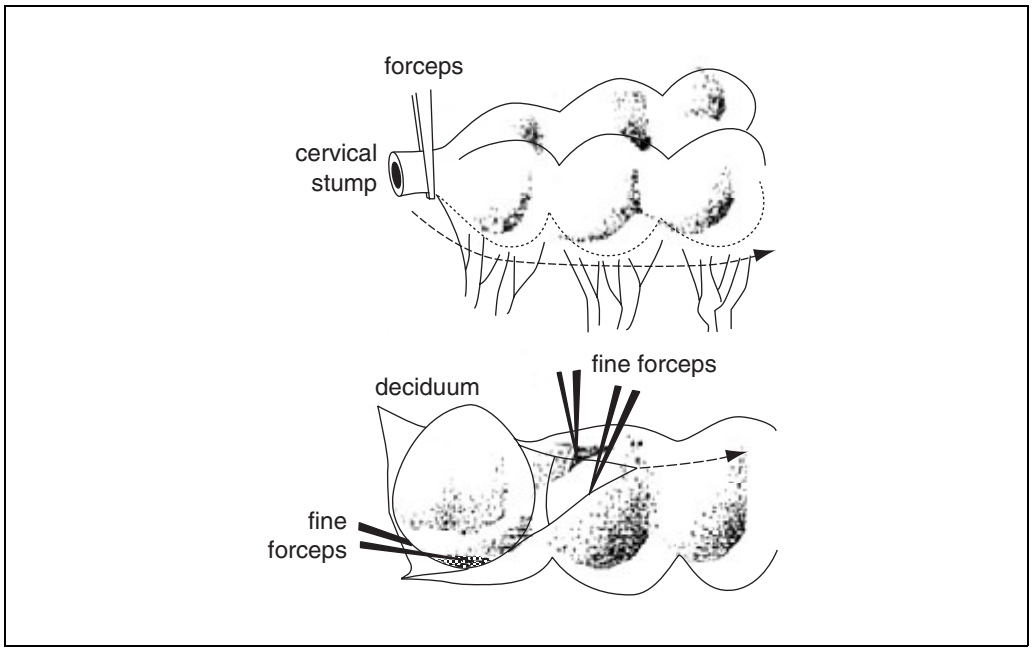

Figure 13.3.1 Removal of uterine horn from dam (top) can be accomplished by cutting the cervix and lifting the uterine horn by the cervical stump. Using a second set of forceps, gently tear away the uterine network to release the uterus (dashed line with arrow). Remove each deciduum from the uterine horn (bottom) using fine forceps. Use the set of fine forceps in the left hand to hold the uterus along the antimesometrial side at one side of the deciduum (in the case as shown, on the left side), and open the uterus along the top of the site by tearing from left to right with the forceps in the right hand. (Figure adapted from Strum and Tam, 1993).

17. Using the tearing forceps, tear away the muscle by pulling the muscle from the hole near the holding forceps across the top of the deciduum to the other side of the implantation site. Dislodge the deciduum from the uterine wall by gently teasing the deciduum away from the uterine tissue using the middle part of the forceps rather than the tips.

    Removal of the decidua may be made easier by starting at the cervical stump and working outward along either horn.

18. Place waste tissue in the petri dish lid throughout this procedure to minimize clutter in the dissecting dish.

19. Repeat steps 15 to 18 until all decidua are removed.

    Embryos from multiple uteri can be combined to generate a homogeneous cell culture unless there is an experimental reason to keep embryos from individual dams separated.

20. Fill 1 to 2 petri dishes (one/person) half way with 50% heat-activated horse serum/EBSS, 37°C, and place on the dissecting microscope stage next to the petri dish containing embryos.

21. Transfer decidua containing the embryos to 50% heat-activated horse serum/EBSS using the slotted Moria spoon. Include both embryos that were still in the embryonic sac and any that were inadvertently released by embryonic sac rupture.

22. Using two forceps, release embryos from the surrounding tissue. Gently hold the decidua along the edge of the broadest end with both sets of Dumont forceps in opposition. Open the deciduum by gently tearing laterally to reveal the embryo contained in the yolk sac.

    In most cases, use of this technique will allow the embryo to fall into the 50% heat-inactivated horse serum/EBSS. Be careful not to grasp too deeply with the forceps, as this will rupture the underlying yolk sac and possibly damage the embryo.

23. After removing the decidua from all embryos, release each embryo by teasing them out the yolk sac with the forceps. Discard decidua and yolk sac membranes in waste lid for disposal.

24. Repeat steps 22 to 23 until all embryos are freed.

Microdissect embryo

While the described steps detail the methods for collecting and plating both CNS neuroepithelial cells and limb bud cells, this procedure can be modified to plate only one or the other cell type.

25. Use a glass pipet and bulb to remove some of the 50% heat-inactivated horse serum solution and gently vacuum away tissue debris.

    If necessary transfer the embryos to fresh serum/EBSS. This will make the cell preparation and tissue isolation cleaner.

    The researcher will have to use trial and error to determine how much solution to remove. If there is too much liquid, the embryos will float and make microdissection difficult. If there is too little liquid, manipulation of the embryos will be difficult.

26. Use microdissecting scissors and forceps for tissue isolation. For a right-handed person, hold scissors in the right hand and forceps in the left.

    Scissors should be held like a pencil, between the thumb and index finger, with the tips pointing upward.

27. Move embryos to one side of the petri dish.

    As the dissection proceeds, it will be easier to move each embryo from one side to the center, where it will be dissected.

28. Slide one embryo to the center of the dish. If necessary, flip the embryo so that it is laying on its right side, with the spine on the right. Rotate the embryo so that its head is at approximately the 2 o'clock position.

    This will place the midbrain in an orientation that can easily be dissected without strain to the right hand.

29. Anchor the body of the embryo to the bottom of the dish with the side of the scissors. Use gentle pressure on the neck area or forebrain lobe of the embryo with the side of the forceps to cause the head to rotate upward during microdissection of the midbrain.

    This will allow easier access to the midbrain for dissection.

30. Dissect the midbrain (mesencephalon) away from the embryo. Start the cut by placing the open scissors at the cephalic flexure (the base of the prominent curve separating the midbrain from the hindbrain) and, making a single straight cut, dissect away the crown of tissue without including tissue from the prominent forebrain lobes surrounding the lateral ventricles at the front of the head (see Fig. 13.3.2). Collect midbrain tissue sections in a pile.

    Check the quality of the cut by examining the midbrain tissue and the remaining embryo to see whether excessive hindbrain or forebrain has been removed.

31. Rotate the embryo to obtain access to the left limb bud. Dissect the forelimb bud by placing the base of the scissors against the body and making a straight cut along the body (see Fig. 13.3.2). Flip the embryo and dissect the right forelimb bud. Collect limb bud tissues in a pile.

32. Repeat steps 27 to 31 until all embryos are dissected.

Rinse tissue

33. Count and record the number of limb buds and midbrains on the recording form.

34. Gently collect midbrain tissue sections into the tube marked "CNS1" using a glass pipet. Take care not to shear the tissue during tissue collection. Collect eight dam's worth of embryos or less in each tube to ensure proper tissue dissociation.

35. Gently collect limb bud tissue sections into tube marked "LB1" using a glass pipet.

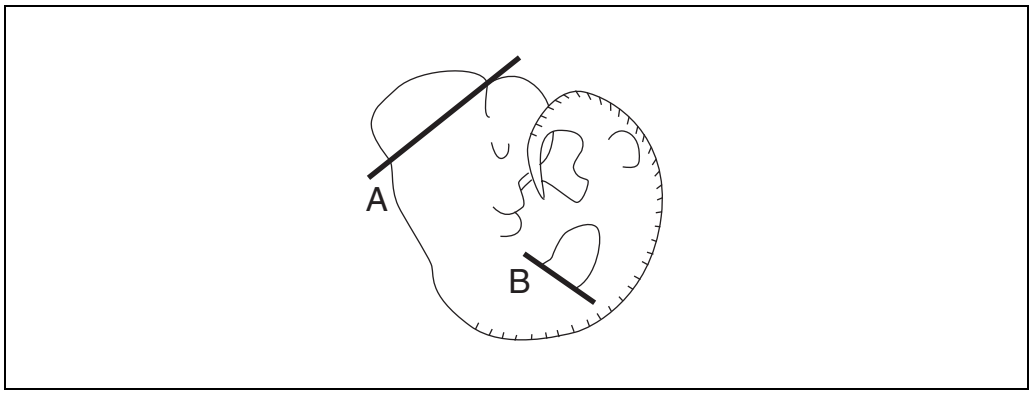

Figure 13.3.2 Dissection landmarks for midbrain (**A**) and limb bud (**B**). The midbrain is dissected away from the cephalic flexure (the indentation near the letter **A**) across the top, excluding the lateral ventricles (the prominent bulbs at the front of the head). Forelimb buds are removed by dissecting at the base of each limb bud as shown (**B**).

36. Allow tissue parts to settle and collect overlying solution. Discard solution into waste beaker. Rinse tissue parts three times or more with sterile CMF-EBSS and discard rinsate into waste beaker. Continue to rinse tissue parts until blood cells and debris are removed.

    The number of rinsing steps can be greatly reduced by maintaining a clean working environment during the tissue microdissection steps.

Dissociate tissue

37. Add 1 to 2 ml CMF-EBSS to each tube (i.e., LB1 and CNS1), and place in 37°C water bath for 20 min.
38. Use the incubation period to wipe down the work surfaces in the dissection room, laminar flow hood, and dissecting microscopes with 70% ethanol. Rinse dissecting instruments to remove debris and blood, store the light source, and discard waste tissue. After laminar flow hood has been wiped down, close sash of hood. Filter trypsin solution and prepare culture medium as necessary.
39. Pipet 10 to 15 ml culture medium in the tube marked "CM" and place tube in 37°C water bath. Pipet 10 to 15 ml trypsin solution in the tube marked "trypsin" and place tube in 37°C water bath.
40. After the first 20-min incubation, remove CMF-EBSS and add 1 to 2 ml trypsin solution to each tube.

    Make sure that addition of trypsin gently resuspends all the tissue sections to ensure good enzymatic dissociation.

41. Place each tube back into the 37°C water bath for 20 min.
42. Use the second incubation period to lay out cell culture dishes on sterile incubator trays and to complete remaining tasks from step 38, above. Pipet 180 µl culture medium into tubes labeled "CNS3" and "LB3."

    These will be used for cell counting.

43. After the trypsin incubation, remove both tubes (CNS1 and LB1) from the water bath. Wipe down exteriors of both tubes with 70% ethanol and place in a tube rack in the laminar flow hood without stirring up tissue sections.
44. Quickly remove overlying trypsin from each tube (CNS1 and LB1) and discard.
45. Add 1.3 ml of culture medium to each tube for each 6 dam's worth of embryos that were used in the experiment. Adjust the volume of medium added to each tube according to the 1.3 ml per 6-dam ratio, as needed, depending on the number of dams used in the experiment.

    The addition of culture medium will stop trypsinization.

    Steps 44 and 45 should be done quickly to avoid over-trypsinization.

46. Dissociate the cells by carefully pulling solution and tissue fragments into a pulled-glass pipet (i.d. ~0.7 mm). Use separate pulled pipets for each tissue type. Continue to pull solution up and down ~15 times, until no aggregates are visible. Avoid bubbles in the solution by keeping solution in both the pipet and tube.

    Rinsing the sterile pulled-glass pipet with culture medium immediately prior to use with the cells can reduce the tendency of cells to stick to the pipet walls.

47. Assemble the 13-mm Swinney filter and 10-ml syringe.

    Make sure to remove plunger from the syringe prior to attaching the Swinney otherwise the filter could be damaged.

48. Using one hand to hold the 10-ml syringe (with the 13-mm Swinney filter attached) over the top of the tube marked "CNS2," transfer contents of CNS1 into the syringe with a pipet. Add plunger to syringe, and gently filter the contents into CNS2. Using a new pipet, Swinney and syringe, filter the contents of LB1 into the tube marked "LB2." Discard tubes marked CNS1 and LB1.

Do not use the same filters or syringes for both culture types as this will lead to contamination of the cultures.

Count and plate cells

49. Immediately add 20 µl of the cell suspension in CNS2 to CNS3 (which contains 180 µl culture medium). Add 20 µl of the cell suspension in LB2 to LB3 (which contains 180 µl culture medium).

With a delay in this step, the cells may settle and require gentle resuspension prior to sampling. This step creates a ten-fold dilution of the cell suspension suitable for cell counting.

50. Ensure that the contents of CNS3 and LB3 are thoroughly mixed prior to sampling for cell counting by flicking each tube with a finger. Take 10 to 20 µl of cells from a tube for counting on a hemacytometer, and allow a small amount of the suspension to flow under the coverslip of the hemacytometer. Add a sufficient quantity of solution so that the entire chamber is just filled.

If too much solution is added, the volume will be off, and cell counts will be inaccurate because cells will be "floating" in the chamber.

Each hemacytometer is different, so estimation of cell number will depend on each manufacturer's specifications. Described here are the steps describing the use of the Improved Neubauer hemacytometer (also see APPENDIX 3B).

51. Count cells in 5 squares along one diagonal with a hand-held counter and record cell count on the data recording form. Repeat the cell count along the other diagonal and record. Count cells that cross the left and bottom edge of any square, and exclude those that cross the right or top edge.

If counts are widely divergent, repeat cell counting with a new aliquot.

52. Calculate the average of the cell counts and record on the data recording form. Estimate the concentration of cells in each tube according to manufacturers' instructions as in the following example for the Improved Neubauer hemacytometer:

70 cells per 5 squares
= 350 cells in entire hemacytometer chamber (which contains 25 counting squares)
$\times 10^4$ (counting chamber conversion)
$= 350 \times 10^4$ cells/ml (estimated cell concentration)
$\times$ 10 (dilution factor)
$= 3.5 \times 10^7$ cells/ml (concentration in undiluted stock).

53. Use a calibrated pipet to determine the volume of suspension in LB2 and CNS2. Record each on data recording form. Rinse the pipet with culture medium before measuring to minimize cell adherence to the walls of the pipet.

Estimate the number of dishes that can be fully plated for each cell type by dividing the volume of limb bud cells by 40 µl/dish and by dividing the volume of CNS cells by 50 µl/dish.

54. Adjust the volume in CNS2 and LB2 to achieve the desired plating concentrations. The desired plating concentrations are:

Plating concentration for limb bud cells = 2×10^7 cells/ml.

Plating concentration for CNS cells = 5×10^6 cells/ml.

55. To adjust cell concentration, multiply the concentration of cells in the undiluted stock (step 52) by the estimated volume (step 53) to determine total number of cells in each tube (LB2 and CNS2). Divide this total cell number estimate by the appropriate plating concentration for each cell type (above) to determine the total volume desired of each cell type. Record this volume on the data recording form.

    The difference between this volume estimate and the volume estimated in step 52 represents the amount of culture medium that needs to be added to that tube (CNS2 or LB2) to achieve the appropriate concentration of cells in each tube.

    Note that addition of too much volume at step 45 may result in a negative volume at this step. If this occurs, centrifuge the sample 10 to 15 min at 1500 × g, room temperature, resuspend the cells in a smaller volume of medium, and repeat cell counting procedure.

56. Add the appropriate volume of culture medium to LB2 and CNS2 as determined in step 55 to achieve the desired plating concentration of CNS cells and LB cells (see step 54). Gently mix to generate a homogenous suspension whenever filling the repeater pipettor to ensure a consistent cell concentration in the plated cell droplets.

57. Working in a laminar flow hood, use a repeater pipettor to plate five 10-µl foci per 35 × 10–mm cell culture for CNS cells and four 10-µl foci per plate for LB cells. Plate until the desired number of dishes is achieved or until cell suspension is exhausted. When plating is completed, place tray gently in incubator. Note initial incubation time on the data recording sheet.

    Use of alternatives to 35 × 10–mm dishes, such as 96-well plates or 2-well chambers, can be accomplished by coating the alternative dish with collagen. For 96-well plates, add 50 µl of 3 mg/ml collagen to each well, whereas for 2-well chambers add 200 to 300 µl per chamber. Let the chambers air dry under UV-light prior to use. These can be stored, wrapped in plastic wrap, in the refrigerator for several weeks before use.

58. Estimate the cell yield for each cell type by calculating the number of 10-µl aliquots of each solution and dividing by the number of tissue parts.

    For example, if there is 1.3 ml of limb bud cells in suspension at the correct plating concentration (as estimated at step 55), this would supply 130 10-µl aliquots (foci). If 100 limb bud sections were used to generate this volume of cells, the yield would be 1.3 foci per limb bud section. CNS yield is estimated in the same manner.

    Optimal yield for limb buds is 1.2 to 1.4 per limb bud section.

    Optimal yield for CNS cells is 10 to 14 per CNS section.

Add medium and treat

59. Add culture medium (with or without test agents) 2 hr after initial plating or later. Because the final medium volume (including the 50 µl of cell suspension) is 2 ml including the test agents, use 1.95 ml of medium with the test agents. Incubate and analyze cells accordingly to experimental protocol.

    Chemical treatments with hazardous volatile compounds, radiolabeled compounds, or photosensitizers should be conducted by constructing an air-tight chamber that can be placed in the incubator. The author's chamber is made of Plexiglas, has a removable faceplate, and two sliding shelves with 1-cm holes to allow uniform gas exchange throughout the chamber. The faceplate has two stop valves that allow initial gas charging, periodic chamber recharging, and chamber purging prior to opening with 5% CO_2/95% air from a gas cylinder. These operations can be conducted inside a fume hood if a sufficient length of tubing is used from the gas cylinder to the chamber. The temperature of the chamber can be maintained by placing the chamber inside an incubator, and humidity can be regulated

by placing petri dishes containing sterile water inside the chamber. The chamber can be made light-tight by wrapping the chamber in foil. In experiments to compare cell growth between the chamber and an incubator, no differences in cell growth have been noted by the author.

Analyses of cell cycle kinetics can be conducted with 5-bromo-2-deoxyuridine (BrdU). However, BrdU causes photo- and radio-sensitization. When using BrdU, conduct cell manipulations under low light, or sodium lamp illumination to avoid DNA damage. Use of a light-proof, air-tight cell isolation chamber as described above is ideal for such experiments.

ALTERNATE PROTOCOL

PREPARING CELLS FROM EMBRYOS OF PRETREATED DAMS

As described previously, the purpose of the experiments conducted using the Alternate Protocol differs from that of the Basic Protocol. Whereas the Basic Protocol yields cultures containing normal, healthy primary cells for study, the Alternate Protocol yields cultures with unknown viability characteristics. The uncertainty of the quality of cultured cells using this method arises due to the potential environmentally or maternally mediated influences on embryonic viability at the time of maternal sacrifice. Nevertheless, the method differs in only a few steps from the Basic Protocol, which are detailed below.

To conduct the Alternate Protocol, treat the dam in a manner consistent with the experimental inquiry (e.g., via the exposure route of interest, using the experimental doses of interest, and on the gestational days of interest). Conduct the Basic Protocol as described above, sacrificing the dam on gestation day 12. However unlike the Basic Protocol, do not aggregate embryonic tissue across treatment groups. Depending on the experimental design, it may be appropriate to aggregate embryonic tissue from multiple dams within a treatment group. Aggregation will increase the availability of cells for subsequent examination, but will reduce the statistical power because of a reduced sample size. Maintaining separation across treatment groups will require careful planning and focus on the part of the microdissector, since tissue parts must be maintained separately, and multiple cell suspension tubes (e.g., CNS1 A, CNS1 B, etc.) will be required. Depending on the experimental goals, treatment with test articles following the 2-hr attachment period may be ignored, though treatment with normal culture medium at 2 hr post-plating should still be conducted.

REAGENTS AND SOLUTIONS

Use deionized, distilled water in all recipes and protocol steps. For common stock solutions, see ***APPENDIX 2A****; for suppliers, see* ***SUPPLIERS APPENDIX****.*

Collagen solution, 3 mg/ml

Prepare collagen type I from rat tail (Sigma) as a stock solution of 3 mg/ml in 0.1% (v/v) acetic acid. For example, add 25 mg collagen to 8.3 ml reagent grade 0.1% acetic acid. Using a stir bar, slowly dissolve the collagen over 2 to 3 hr. Store the stock solution at 4°C. When ready for use, dilute 1:20 of stock solution (1 part collagen stock to 19 parts distilled water). Store up to 1 week at 2° to 8°C.

Culture medium

10% (w/v) heat-inactivated fetal bovine serum (FBS; Qualified, store frozen in a non-frost-free freezer)
2% (w/v) L-glutamine (200 mM stock, store frozen in a non-frost-free freezer)
2% (v/v) penicillin-streptomycin (store frozen in a non-frost-free freezer)
86% (v/v) Ham's F-12 nutrient mixture (store at 4°C and keep away from light)
Prepare fresh on the day of cell culture preparation.

All of the above ingredients are available from Life Technologies.

Freeze aliquots of fetal bovine serum, L-glutamine, and penicillin-streptomycin until ready for use. Because repeated freezing and thawing degrades serum stock quality, store stock in small aliquots that can be used for individual experiments. Warm in water bath or incubator (with a loose lid to allow gas exchange) until ready for use. Equilibrate in incubator during cell attachment period.

The pH should be 7.2 to 7.4. Use sterile techniques throughout to avoid contamination of the cell culture.

Horse serum

Mix 1 part horse serum (Life Technologies; store in 15-ml aliquots in non-frost-free freezer) with 1 part EBSS (Life Technologies; store at room temperature) immediately before use. Thaw in water bath immediately before use.

The pH should be 7.2 to 7.4. Prewarm to 37°C prior to use with the primary cells in culture. Use sterile technique throughout to avoid contamination of the cell culture.

Trypsin solution, pH 7.2 to 7.4

Prepare trypsin (Life Technologies; lyophilized powder) as a 0.1% (w/v) solution (or 100 mg in 10 ml) in CMF-EBSS (Life Technologies; store at room temperature). Adjust pH of trypsin to pH 7.2 to 7.4. Filter trypsin through sterile 0.22-µm mesh nylon filter. Prepare trypsin on the day of the cell culture experiment. Warm in water bath prior to use.

The pH should be 7.2 to 7.4. Prewarm to 37°C prior to use with the primary cells in culture. Use sterile technique throughout to avoid contamination of the cell culture.

COMMENTARY

Background Information

The potential application of primary CNS and limb bud cell cultures as a screening system for teratogenic compounds was demonstrated in experiments conducted by Flint and colleagues in the early 1980s (Sawyer and Goetinck, 1981; Flint and Ede, 1982; Flint, 1983; Flint and Orton, 1984; Flint et al., 1984). These validation studies, which also described the typical growth and differentiation characteristics of cells in these cultures, provided scientific evidence to support the use of these culture systems as a model of the in vivo response to teratogenic compounds. Indeed, when plated in the manner described, these primary cultures develop many characteristics in parallel to those observed in vivo, without the required addition of exogenous growth factors (Flint and Ede, 1982; Flint, 1983; Flint and Orton, 1984; Flint et al., 1984). Although originally proposed as a screening tool for teratogens, the culture of midbrain neuroepithelial cells and limb bud chondrocytes has become important in vitro test models for examining the cellular and molecular processes governing normal development and the cellular response to environmental stresses that may influence development. For example, these culture systems have been used extensively by Faustman and colleagues to examine the mechanisms underlying the developmental toxicity of *n*-nitroso compounds, metals, and pharmaceutical and agricultural compounds (Ribeiro and Faustman, 1990; Whittaker and Faustman, 1991, 1992; Sweeney et al., 1992; Whittaker et al., 1993; Faustman and Sweeney, 1994; Kidney and Faustman, 1995; Seeley and Faustman, 1995).

The protocols described here propose use of gestation day 12 to 12.5 rat embryos for the derivation of the cultures. This developmental period represents a window of vigorous cell growth in both the CNS and limb bud. In particular, the midbrain is experiencing a period of peak neuronal progenitor cell (i.e., neuroepithelial cell) replication. Because these neuroepithelial cells will stop dividing and differentiate into neurons during several days in culture, use of the gestation day 12 neuroepithelium as a source for the neuronal progenitor cells yields a culture enriched in neurons. Thus, although it is possible to derive cultures from earlier or slightly later times, the growth and differentiation conditions will vary. If the investigator chooses to use tissue from earlier gestational periods, they will be faced with limited availability of tissue. If later gestational periods are chosen, the investigator may have

fewer germinal cells and more differentiated cells, and the cultures may grow poorly.

Because both the CNS and limb bud cell cultures are derived directly from the embryo, the cell cultures are of a mixed cell type. Thus, these cultures are most suitable as a model of the developing system rather than as a model of a single specific cell type. The author has found this model to be especially suitable for examining the regulatory interactions that control development, particularly when cell lines cannot be used, such as for examining the regulatory controls governing cell proliferation (Ponce et al., 1994; Ou et al., 1997, 1999a,b).

Critical Parameters and Troubleshooting

Animal acclimation

Acclimate animals, including timed-pregnant animals, in the facility for ≥1 week prior to experimental use, dosing, or sacrifice. Such acclimation will minimize the potential for stress-induced artifacts in cell growth or viability.

Cell growth

Elapsed time between sacrifice of the dam and cell plating should be minimized as much as possible. Thus, the areas used to sacrifice the dam and to conduct embryonic microdissection should be organized, and materials and reagents should be prepared before sacrificing begins. If the cell preparation can be conducted with two people, one individual should be in charge of humanely euthanizing the dams and removing the uteri, while the other begins removing the individual embryos from the uteri. Once all the dams have been sacrificed, both individuals can work together to isolate the embryos and perform embryonic microdissection.

Cell yields are sensitive to both the somite stage and individual microdissection technique. Thus, all researchers involved in micromass culture preparation should be trained to correctly establish embryonic growth stage and to use the appropriate flexures and topological characteristics for proper tissue isolation. Identification of the extent to which members of a research group vary in technique can be gauged by monitoring cell yield.

Be careful that the light source used with the dissecting microscope is not too close to the dish in which dissection is taking place, because it can heat-stress the cells. A heat shield may also be used to protect the embryos from excessive lamp heat.

Cell growth is very sensitive to disturbances that occur during the 2-hr attachment period. The researcher should minimize disturbances that occur during this period, such as repeated incubator opening or physical shock to the dishes.

Cell growth is also sensitive to initial plating concentration. Errors in plating concentration most likely arise from errors in cell counting. Check to ensure that the proper counting procedure is being conducted with the hemacytometer. More accurate cell counts can be accomplished by counting all 25 squares, rather than just 5 squares. Make sure that the tubes marked “CNS2" and ”LB2" are well mixed by flicking the tube with the finger or by pipetting the solution up and down immediately prior to collecting the aliquots to be used in the tubes marked “CNS3" and ”LB3." Because the cells tend to settle in the tubes, failure to ensure sample homogeneity can result in inaccurate cell counts. Likewise, ensure that CNS2 and LB2 are well mixed when refilling the repeator pipettor during cell plating to maintain a consistent cell concentration in each micromass aliquot.

Harsh treatment or use of a pulled pipet that is too small during physical dissociation can create debris that can make proper cell counting difficult.

If cell growth is inconsistent or if cell yields are poor, check the CO_2 and temperature regulation. Excursions in pH and temperature can impair cell growth and viability. Also, ensure that there is sufficient water in the incubator to maintain 100% humidity.

Contamination

Problems with fungal contamination of the cell culture can arise from many sources, but are most commonly attributed to poor sterile technique. Be sure to replace pipet tips and replace gloves often. Ensure that surgical tools and reagents are sterile, and that incubators and water baths are clean.

Animal sacrifice

To avoid potential indirect effects of euthanasia solutions on cell growth characteristics, the author typically uses CO_2 asphyxiation to euthanize the dam. The author has also used ether in the past, though storage and handling concerns make ether a less preferred alternative. If other methods of sacrificing the dam are used, the investigator should consider potential effects on cell growth. Once a method is chosen,

that technique should be maintained throughout an experimental series.

Dissection

Developing an efficient dissection technique that minimizes rupture of the embryonic sac during removal of the embryo from the uterus, and that results in a consistent isolation of limb buds and midbrain sections, takes time. Like any skill, the researcher should pay attention to those techniques that work best for him or herself. Tips to consider include the following.

(1) Use two fine forceps during removal of embryo from uterus. For a right-handed person, it may be easier to hold the uterus between embryo sites with the left hand and tear with the right hand, starting from the left edge of the site. The uterus should be oriented with the muscle edge at the top. Use the tip of the forceps, held in the right hand, to poke a hole in the muscle between the two sites as a starting place to begin opening the site. (2) Note that pressure on the embryo during removal from the uterus will increase the likelihood that the embryonic sac will rupture. Thus, one should be looking for where points of pressure occur as the embryo is released from the uterus, and should gently reduce pressure, when the site is only partially opened, by opening the site along these points of pressure. (3) Use both the forceps and microdissecting scissors to flip and rotate the body as needed for access to the forelimbs and midbrain.

Recording experimental conditions

The data recording form can be an invaluable record of each experiment. Elements that should be recorded include the number of dams, pregnancy status, number of fetuses per dam, gestational stage, researchers involved in the experiment, time of initial sacrifice and time of plating, incubators and reagent lot numbers used in the experiment, calculations used to estimate yield, and cell concentration.

Anticipated Results

Limb bud cells derived from the gestation day 12 rat embryo are predominantly undifferentiated and contain little collagen or glycosaminoglycans. During 5 days in culture, these cells should undergo differentiation. Limb bud cell growth and differentiation can be monitored by numerous methods, including the use of cartilage-specific differentiation stains such as alcian blue or uptake of $^{35}SO_4^{2-}$ or ^{3}H-thymidine into proteoglycans (Faustman, 1988). Alternatively, differentiation-specific processes including aggregation, cell condensation, and cellular differentiation can be used (Flint et al., 1984; Ribeiro and Faustman, 1990).

Proper differentiation of midbrain neuroepithelial cells can be monitored by examination of cell surface markers associated with differentiation, by use of radiolabeling methods (specifically ^{3}H-GABA uptake), or by morphogenetic examination (Whittaker et al., 1993; Flint et al., 1984). When grown in culture, the undifferentiated neuroepithelial cells develop into neuronal cells that project striking neuritic extensions as early as 1 to 2 days, with more extensive development over 5 days in culture. Staining with propidium iodide or other DNA fluorochrome shows that proliferation occurs in the undifferentiated fibroblastic-like cells underlying the differentiated cells. The differentiating CNS cells tend to aggregate into clusters on top of the underlying neuroepithelial cells.

Although the author typically conducts analyses within 5 days of the initial cell culture, he has successfully grown these cells for 14 days; there was no apparent reason why these cultures could not survive longer with periodic changes to the culture medium.

Time Considerations

The author typically begins sacrifice of the dams by 8 a.m.. By having a consistent sacrifice time, the researcher will minimize this potential source of variability in embryonic growth stage. This is a point of critical concern in studies used to characterize growth stage–specific developmental mechanisms or processes.

Elapsed time between initial sacrifice and cell plating is ~4 hr for two researchers who are familiar with the protocol and for an experiment involving eight pregnant dams. The greatest degree of variation in this time estimate stems from researcher microdissection efficiency and, to a lesser extent, plating efficiency. The availability of two researchers during microdissection and plating is helpful, though one highly efficient researcher can conduct this protocol in the same, or slightly less, time. Chemical treatment after the 2-hr attachment period can take between 0.5 and 1.5 hr depending on treatment complexity, the number of plates, and the efficiency of the technician. Allowing 0.5 hr each for set-up and clean-up, total elapsed time is 7 to 8 hr.

Using Chicken Embryos for Teratology Studies

The chicken embryo has been used as a standard animal model for embryonic development, especially embryonic neural development, for close to a century. In the 1930s, Viktor Hamburger began studying chicken embryonic development, focusing on neural development, when he went to work in F.R. Lillie's laboratory at the University of Chicago (Purves and Lichtman, 1985). By 1951, Hamburger and Hamilton published a photographic series documenting the development of the chicken embryo throughout the 21-day incubation period (Hamburger and Hamilton, 1951, 1992; Hamburger, 1992; Sanes, 1992). Romanoff then described the development of the chicken embryonic organ systems throughout the incubation period (Romanoff, 1960) as well as a description of the factors (environmental and some chemical) that can grossly affect embryonic development (Romanoff and Romanoff, 1972). For the past half century, the chicken embryo has been consistently used as a major model for understanding mechanisms underlying control of nervous system development.

About the same time that Romanoff was publishing his seminal work on chicken embryo development, McLaughlin et al. (1963) published a toxicological survey of chemical compounds that can affect chicken embryonic development. It was McLaughlin that developed the yolk-injection method that is most effective at preventing artifactual damage to the embryonic tissues. Verrett (1976), working for the U.S. Food and Drug Administration (FDA), then used the chicken embryo as the animal model for studying the relationship between 2,3,7,8-tetrachlorodibenzo-*p*-dioxin (TCDD) and chick edema disease, a syndrome first noted in the late 1950s, and linked to dioxin in the 1960s (Firestone, 1973). In the past few decades, several groups of investigators began using the chicken embryo as a model for toxicant-induced teratological studies. Hoffman and colleagues (Hoffman and Ramm, 1972a,b; Hoffman, 1975; Hoffman and Campbell, 1978) used the chicken embryo to study chemical-induced teratogenity in a large number of studies that evaluated the teratogenic potency of a broad range of pollutants. Jelinek and colleagues (Jelinek and Marhan, 1994) developed the CHick Embryotoxicity Screening Test (CHEST) to evaluate pharmacological agents with respect to regulatory rat-rabbit procedures. Henshel et al. (1993) developed the Early Embryo Assay, a method of evaluating chick embryo potential for chemically-induced teratogenicity measured within the first week of embryonic development. This broad range of studies has shown that the chicken embryo is an excellent model for assessing potential teratogenicity, so long as the investigator understands the limitations of the design of the protocol, and so long as the investigator uses proper controls and learns how to consistently and gently work with the embryos and hatchlings.

In summary, chicken embryos are good models for teratogenicity studies because they are (a) easily obtainable; (b) relatively inexpensive when compared to other vertebrate and mammalian models; (c) easy to expose, incubate, and handle; (d) counted individually as a test unit rather than in a group such as a litter; (e) dosed individually, making it easier to control the delivered dose; (f) isolated from the mother, eliminating maternal factors such as biotransformation, which may alter the injected parent compound before it reaches the embryo; and (g) fairly non-threatening to the animal rights community because of the widespread use of chickens in agriculture.

This unit describes the steps involved in injecting and incubating fertile, domestic chicken eggs with a suspected teratogenic substance, including handling, storage, and analysis considerations. Age factors for both injection, co-dosing or repeated dosing, and sacrifice/analysis are considered, and the results of one of the authors' preliminary experiments are presented.

EGG INJECTIONS AND INCUBATION

One important step in an avian teratogenicity study is administering the toxicant to the embryo in a way that is consistent, causes little stress to the embryo, and delivers the toxicant to the embryo throughout critical periods of embryonic development. The airspace egg injection method detailed in this protocol can be used for most avian systems and can be performed with few specialized pieces of equipment. Injection into the airspace, when carried out carefully, avoids artifactual damage to the embryo due to contact between the needle and the blastoderm or developing embryo. Injection into the airspace can also be carried out at any time during the incubation period. Yolk-injection methods, described in McLaughlin et al. (1963) and Henshel (1993), are best done at the start of incubation. Both airspace and yolk injections enable embryo exposure from virtually the time of injection. Albumin injections can also be carried out at any time during the incubation process, but the toxicant primarily appears to be delivered during the last third of the incubation period when the embryo is consuming the albumin during the later rapid growth phase of development. Shell application of the toxicant is really only efficient for lipid soluble compounds. However, shell application seems to be the method that least consistently delivers the applied dose to the embryo.

Perhaps the most difficult step in this protocol is obtaining a supplier of readily available, fresh, fertilized eggs. Most agricultural universities have poultry science units that can provide low-cost eggs with relative ease. Several commercial farms will provide fertilized eggs of chickens or other birds as well.

NOTE: All protocols using live animals must first be reviewed and approved by an Institutional Animal Care and Use Committee (IACUC) or must conform to governmental regulations regarding the care and use of laboratory animals.

Materials

Eggs (any commercial or university farm; fertile and free from chemical contamination)
Egg cleaning agents (e.g., 20% povidone iodine, see recipe)
70%, 95% and 100% ethanol
Injection vehicle (see annotation to step 10; also see Critical Paramaters)
Agent to be injected mixed with the vehicle
Uncontaminated vehicle kept separate from injection agent or injection agent vehicle dilution quantity
4% paraformaldehyde or 10% formalin

Kimwipes (or other lintless wipes)
Melted paraffin and a small paintbrush for sealing injection holes
Probe: a small sharp metal object such as an awl or a compass point, sterilized by soaking in 70% alcohol for 15 min, then air dried, for piercing a small hole in the injection site
Syringes for injecting (e.g., Hamilton brand 700 series microliter syringes with cemented needles)
Circulated air incubator with a 99.5°F dry bulb and 87° to 88°F wet bulb

Prepare eggs for injection

1. After unpacking the eggs from their shipping containers and discarding the broken ones, note the overall condition of the eggs in a lab notebook or on a data sheet.

   Eggs that are shaken up too much during shipping, indicated by the number of broken eggs, will have decreased viability and increased risk of gross teratogenic defects.

2. Dip eggs gently into a container of 20% povidone iodine, and dab the shell dry with a clean, lintless wipe such as Kimwipes. Do not wipe the shells; wiping easily removes their protective layer.

   Egg shells are contaminated with bacteria from the hen and the laying site. Estimates published in the popular press suggest that ≥30% of commercial eggs are contaminated with salmonella bacteria. Fertile eggs are not put through the same heavy washing procedure as commercial eggs and are more likely to be contaminated externally with a variety of bacteria. Therefore, all eggs should be cleaned when they are first received into the laboratory. The cleaning agent, 20% povidone iodine, is gentle and effective. Povidone iodine is available in most drug stores.

3. At the time of injection, remove the eggs from storage or from the incubator and let them come to room temperature before starting injections.

   Hot eggs will absorb outside air rapidly through the hole and are more likely to get contaminated; cold eggs accumulate condensation.

4. Randomly assign eggs to dose groups.

   The authors inject their eggs in staggered batches totaling ~10 to 12 eggs (for eggs that will incubate until hatched) or 20 to 30 eggs (for early embryos) so that there is not an overwhelmingly high number of embryos or chicks coming out of the incubator at the same time. See Batches in Critical Parameters.

5. Weigh each egg in a small plastic cup cushioned with clean, lintless paper wipes to prevent the egg from rolling off the scale. Mark the weight in pencil on the side of the egg, but not on the egg equator. Also mark the egg ID number in two places, generally on the top and on the bottom.

   The authors also recommend writing the dose to be injected on the shell to prevent mistakes at the time of injection, as well as the time and day in and time and day out of the incubator for early embryos.

6. Candle each egg and mark the limits of the airspace in pencil. To candle an egg, use a home-made or commercial source of light to illuminate the inside of the egg.

   It is best to use a "cool light" candler, which uses non-tungsten light bulbs. Heat can impair egg viability.

   When candling each egg, check for cracks in the shell. For the early embryo assay, seal cracks with a thin layer of paraffin, painted on just over the crack. If the eggs will go until hatch, using cracked eggs is not recommended as the potential for excess dehydration increases the risk of later embryonic death.

Inject eggs

NOTE: All previous and further steps may be carried out in a relatively clean laboratory. However, to decrease the possibility of contamination, carry out steps 7 to 12 in a 70% alcohol-wiped laminar flow hood.

7. Prepare the injection space (hood, benchtop, etc.) with the appropriate protective material, such as an absorbent, plastic-backed bench protector.

8. Dab the shell above the airspace with 70% ethanol, let dry.

   Prior to injection, the injection site must again be cleaned with a cleaning agent. A lintless wipe squirted with 70% ethanol is effective.

9. Use the sterilized probe to gently make a hole in the shell in the middle of the air space. To protect the egg, cradle the egg in one hand while gently applying pressure to the surface of the egg.

A small dental drill has also been successfully used by some investigators. Do not fully insert the probe into the egg; just poke a hole through the shell. The probe should only go in 1 to 2 mm.

10. Draw up the appropriate amount of vehicle or agent into the corresponding syringe and inject into the injection hole using the following parameters:

    a. Eliminate air bubbles from the agent in the syringe. Air bubbles will result in less consistent dosing volumes.

    b. Wipe off excess agent from the syringe before placing the syringe into the egg. If the agent is in an oil vehicle, wipe off the syringe with a lintless wipe wet with 100% ethanol.

    c. Insert the syringe into the injection hole at a broad angle, with the hole of the needle pointing up toward the egg shell.

    d. Slowly inject the agent into the egg at the edge of the air sac so that the solution drips down the inside shell membrane of the air sac. Give the syringe a gentle twirl to dislodge any agent clinging to the tip of the needle. Be careful not to bring the needle near the blastoderm or embryonic tissue. If the injection volume is high, i.e., 1.0 µl/g of egg, or if the hole of the needle is too close to the edge of the injection hole, some agent may leak back out of the injection hole, potentially disrupting the dose administered to the egg. If there is any leakage, wipe the excess off with a clean, lintless wipe wet in 95% ethanol to prevent contamination of the paraffin.

    Use a separate syringe for each concentration and clearly mark each syringe on the body and the plunger tip so that cross-contamination among doses does not occur.

    See the Study Design section in Critical Parameters for a discussion of injection volume and vehicle/diluent choice.

    The injection vehicle chosen will depend on the relative water or lipid solubility of the chemical. For water soluble chemicals, dissolve the chemical in saline (0.7% to 0.8% NaCl), pH 7.2 to 7.4.

    For lipid soluble compounds, dissolve the material in the chosen lipid vehicle. Most chemical companies will dissolve products into the selected lipid vehicle for an additional fee. Request documentation showing an analysis of the final concentration of the material. Appropriate vehicles may include a vegetable oil (corn, soybean, sunflower, canola, safflower, peanut) or triolein. Some vegetable oils contain biologically significant concentrations of estrogenic compounds, such as genistein. If this will affect the measurement endpoint, choose another lipid vehicle. Some oils are thinner than others (e.g., safflower and sunflower) and will be less likely to occlude thin syringe needles used for injections.

    The agent to be injected is mixed with the vehicle so that the volume injected into the eggs results in the desired concentration per gram of egg. For example, if one wishes to inject in the parts per trillion concentration at 0.1 µl/g of egg, mix the agent into the vehicle based on a ~55- to 60-g egg. See the Injection Volume discussion in Critical Parameters.

11. Using a small paintbrush, seal the injection hole with a small drop of paraffin. Gently rotate the egg side to side to coat the airspace membrane with the agent.

12. If continuing injections with the same dose group, wipe the outside of the syringe with a wipe soaked with 70% or 95% ethanol. If moving on to another dose group, rinse out the syringe 10 to 15 times with clean 70% or 95% ethanol and wipe the outside of the syringe with a wipe soaked in 70% or 95% ethanol. Prior to letting the syringe dry, do a final rinse with clean 100% ethanol.

Incubate eggs

13. Once all eggs are injected, place them, with the airspace pointing up, into a circulated air incubator with a 99.5°F dry bulb and 87° to 88°F wet bulb. Make sure that the incubator has an automatic egg turner or manually turn the eggs every 3 to 4 hr.

14. Depending on the incubator, preferably space eggs so that they are not touching one another and randomize the placement of the dose groups within the incubator (see Randomization in Critical Parameters).

15. If taking the eggs to hatch, candle the eggs every day or every other day between injection and hatch. Remove eggs that have stopped developing. Such eggs will lack visible vasculature, be translucent rather than opaque, and/or excessively "sloshy." After the first week or so, it should be possible to see some movement in viable eggs. Once removed, open the dead eggs, remove the embryo, and assess the embryo for approximate age of death and abnormalities. Archive the embryo in 4% paraformaldehyde or 10% formalin for future reference and comparison to viable embryos.

EMBRYO REMOVAL AND HANDLING

BASIC PROTOCOL 2

Removing the early embryo from the egg requires patience and a gentle hand so that neither the embryo nor the vasculature is damaged. While the steps for removing 48-, 72-, and 96-hr embryos vary somewhat, the basic procedure is the same. The steps below outline the procedures for removing 48-hr embryos, with comments specific to 72- or 96-hr embryos inserted where necessary.

Materials

Hexamethyldisilazane or silane
PBS-azide (see recipe)
10% neutral buffered formalin or 4% paraformaldehyde prepared in pH-neutral buffer

Sharp-edged file or a diamond-tipped glass cutter
Pasteur pipets
Plastic beaker filled with lintless wipes, to hold eggs in fashioned "nest"
Curved and pointed forceps (no. 5 with a 45° angle)
Small dissecting scissors (e.g., Moria curved, blunt-tipped scissors, available from most fine instrument suppliers)
Pipets, disposable
Oval "donuts" made out of filter paper, ~2-cm × 1-2–cm external diameter and 1.5-cm × 0.5-cm internal diameter (for 48- and 72-hr embryos only)
Metal scooper (normally used for measuring out dry chemicals)
Petri dishes or other small containers to hold PBS-azide
Pre-labeled vials for storing embryos, filled with 10% neutral buffered formalin

Prepare silanized, fire-polished, wide-bore pipets

1. Using a sharp-edged file or a diamond-tipped glass cutter, etch a small notch around the end of a glass Pasteur pipet, just around where or before the pipet starts to narrow toward the tip.

2. Cover with a paper towel (or other cloth or fabric to hold the glass fragments). Break at the etched line using finger pressure.

3. Fire-polish the broken end in an open flame such as a Bunsen burner.

   If the opening is over-polished, it will melt together. If the opening is under-polished, sharp edges will still exist.

4. Never touch the glass until it has cooled to room temperature, ~30 min. Put the cooling pipets on a heat-safe surface or in a beaker (labeled "hot") with the heated end sticking up.
5. Coat the inside of the cooled, fire-polished pipet with hexamethyldisilazane, silane, or an equivalent anionic coating, dip the pipet in the coating solution and air dry the pipet in a laminar flow or fume hood.

Prepare egg for embryo removal

6. Remove eggs from incubator exactly 48, 72, or 96 hr from when eggs were placed into the incubator.
7. Place an egg into a plastic beaker filled with lintless wipes that forms a "nest" for the egg.
8. Remove the paraffin covering the injection hole with a pair of forceps.
9. Using the curved forceps, gently remove pieces of shell within the pencil-drawn borders of the airspace, beginning from the injection hole. Be sure to remove only small pieces at a time.
10. Once the shell is removed down to the level of the membrane covering the liquid portion of the egg, use a pair of pointed forceps to carefully peel off this membrane.

    Use extreme caution; occasionally the embryo will stick to this membrane and become damaged if the membrane is pulled off too rapidly or harshly.

Remove the embryo

11. Locate the embryo.
    a. Embryos that are 48 hr will often only have a tiny blood ring (the beginning of vasculature) or no blood ring at all. Look for a slight disturbance or clear area in the yolk membrane. The embryo will appear as a very fine, 2- to 3-mm line in the middle of the disturbance or clear area.
    b. Embryos that are 72 and 96 hr will be visible and have noticeable vasculatures.
12. Using a disposable pipet, remove a small amount of albumen, being careful not to disturb the embryo. Remove more shell so that the edge of the shell is level to the height of the liquid portion of the egg (this is to increase the working space).
13. For 48-hr embryos, place the filter paper donut over the embryo so that the embryo is in the middle of the donut. For all ages of embryos, place a few small drops of formalin on the embryo and wait a few minutes.

    The formalin helps to firm up the tissues and makes the embryo easier to handle.

14. Using small dissecting scissors, clip around the donut. For 72- and 96-hr embryos, clip around the outermost edges of the vasculature so that that the vasculature comes out with the embryo. Try to keep the vasculature intact so that it can be evaluated later for the pattern of blood vessel formation.
15. Gently insert the metal scooper underneath the donut and/or embryo and carefully lift up, clipping any pieces of membrane missed in the initial clipping. Place the donut and/or embryo into a Petri dish filled with PBS-azide.

16. Gently wash off any excess yolk clinging to the embryo, using a blunt probe or blunt forceps. Verify that the embryo is in the center of the donut or vasculature, and then use forceps, the metal scooper, or a silanized, fire-polished, wide-bore pipet to transfer the embryo to the appropriately labeled vial containing 10% formalin.

Label vials and lids with egg ID number, age, date, and any other relevant information. Since formalin can wash off permanent marker ink, label the vial itself, cover the label with labeling tape, and then label the tape. The tape protects the markings on the vial, which acts as a back-up label.

HANDLING HATCHLINGS

BASIC PROTOCOL 3

Requirements for housing and sacrificing live animals will vary from facility to facility, as well as endpoints collected by each researcher. In general, the authors recommend following the guidelines below for most teratogenicity studies involving hatchling birds.

Collect data

1. Always record the date and time of pipping (when the chick first pecks through the shell) and the date and time of hatching.

   The time between pipping and hatching can indicate the overall vigor of the chick.

2. Once the chicks have hatched, record any obvious physical and behavioral abnormalities.

3. Record the weight and crown-rump length of each chick. If doing necropsies, record the weight of the yolk sac to obtain a yolk-free body weight.

House and mark chicks

4. If no independent measurements will be made on each chick, separate chicks by dose.

5. If independent measurements will be made on each chick, mark each individual chick with either a leg or wing band or with non-toxic, permanent marking pens or paint applied to the feathers on the back and/or the head.

   Using different marker colors can indicate the dose and the number of marks can indicate the bird number. Chicks from different doses can be housed together as long as each chick is marked.

SACRIFICING CHICKS

SUPPORT PROTOCOL 1

There are three common methods for sacrificing, and the choice of which method to use will be determined, in part, by how the organs and blood must be treated for the experiment. For histology, the best method is intracardial superfusion with fixative (Method A). For larger animals, the arteries can be the route of entry of the superfusion fluids. Somewhat less optimal but still acceptable for small animals is decapitation with rapid immersion fixation (Method B). When the requirement is for blood collection, decapitation is preferred. When the requirement is for collection of fresh organ tissue, the authors' preferred method is decapitation. Some researchers choose to use CO_2 asphyxiation. This method is not recommended as it is, by far, the least humane, producing clearly panicked chicks. The net result will be a highly stressed and frightened chick with elevated corticosteroid blood levels, with all the concomitant biochemical stress changes. The 30 sec to several minutes it takes for the chicks to expire is more than sufficient to allow biochemical stress changes to occur.

Materials

Chicks
Sodium pentobarbitol (Somnotol or equivalent; see recipe)
Phosphate-buffered saline (PBS; see recipe)
0.75% avian saline (see recipe)
Fixative (heparin; see recipe)
Blood collection vial, i.e., heparinized or EDTA-treated vacutainer tube

Scalpel
Large shears (e.g., sewing shears)

Method A: Intracardial perfusion

1a. Pre-dose the chick with sodium pentobarbitol (Somnotol) injected i.m. or i.p. Wait until the chick is unresponsive to a wing or toe pinch. Stroking the chick before injection and during the wait will keep it warm and less stressed.

2a. Pin the chick down, wings spread-out, on a dissection board with fluid collection capability (a baking dish filled with paraffin works very well).

3a. Open the thoracic cavity by cutting below the rib cage, then up along the center of the rib cage, and bending the rib cage back out of the way.

4a. Use two fluids: first use a phosphate-buffered saline such as 0.75% avian saline, and then use a fixative. Use a three-way valve to switch between the solutions. Make sure there is no air in the perfusion lines or the perfusion needle. For gravity-fed perfusion (slow and more protective of tissue microarchitecture), hang the apparatus from ~2 to 3 feet above the chick.

5a. At the start of the perfusion, insert the tip of the needle into the chick's left ventricle (your right when looking down at the chick), keeping the needle parallel to the medial ventricular wall. Immediately after starting the drip, cut the chick's right atrium to allow the blood to drain and prevent back pressure in the tissues, which can damage the microarchitecture. Run the phosphate-buffered saline first until the fluids run clear (usually ~1 to 1.5 ml/g body weight), then switch to the fixative, running at least 1 to 1.5 ml/g body weight through.

A well-fixed chick will be stiff and the neck will remain rigid.

6a. Post fix the chick at 4°C in at least 2 ml fixative per gram of body weight, changing the post-fix after 48 hr.

Method B: Decapitation

1b. Keep the chick warm and unstressed until sacrifice.

2b. Using two people, with one person holding the chick and the other holding scissors (large sewing shears work best), cut off the head.

This works best if the person holding the chick tucks the legs and wings into the cupped hand holding the chick so that they do not get inadvertently snipped and if the person doing the cutting gently pulls on the head to stretch out the neck to obtain a precise cut.

3b. Quickly catch the trunk blood (if doing blood collection) as it flows out of the neck into an appropriate blood collection vial, i.e., heparinized or EDTA-treated vacutainer tube.

4b. Dissect out the most time-critical organs first, such as the brain and the liver. The dissection can be done on ice to slow tissue degradation.

5b. Immersion fix all tissues to be archived for histology. Rapid freeze tissues for biochemistry.

TREATMENT OF ORGANS

The treatment of organs from the chicks will depend on the endpoints collected by each researcher. For example, certain types of histological protocols require fixation of organs in different solutions and neurological, immunological, and enzymatic protocols often require immediate fixing or freezing of organs or sera. It is the duty of the researcher to follow the procedures dictated by the ultimate endpoint.

REAGENTS AND SOLUTIONS

Use Milli-Q-purified water or equivalent in all recipes and protocol steps. For common stock solutions, see ***APPENDIX 2A****; for suppliers, see* ***SUPPLIERS APPENDIX****.*

Avian saline, 0.75%

Dissolve 7.5 g NaCl in 900 ml distilled water. Once dissolved, bring final solution up to 1 liter using a graduated cylinder or volumetric flask. Store up to several months at room temperature in a pre-cleaned or sterilized glass bottle. Check for mold growth before use for solutions older than a few weeks. Saline used with live tissues should be freshly made or stored at 4°C for no longer than a few days.

Heparin (for perfusions)

Dissolve 0.5 ml heparin in 100 ml PBS (see recipe). Make fresh before each set of perfusions.

Phosphate buffer, 0.1 M (pH 7.4)

Mix 3240 ml of 0.2 M dibasic phosphate stock solution (see recipe), 760 ml of 0.2 M monobasic phosphate stock solution (see recipe), and 4 liters distilled water. Check the pH before adding the final 4 liters of distilled water. Adjust as necessary using the appropriate monobasic or dibasic phosphate stocks. Store up to 1 year at room temperature, following the same guidelines for dead/live tissue as for the dibasic and monobasic stock solutions.

Phosphate buffer–dibasic stock solution, 0.2 M

Dissolve 113.56 g Na_2HPO_4 (mol. wt. 141.96 anhydrous) in 2 liters of distilled water on a stir plate. Once dissolved, bring final solution up to 4 liters using a graduated cylinder or volumetric flask. Store up to 1 year at room temperature if only used with dead tissue. Replace after a few weeks if used with live tissue. Discard solution if there is any evidence of mold growth.

Phosphate buffer–monobasic stock solution, 0.2 M

Dissolve 27.5 g $NaH_2PO_4 \cdot H_2O$ (mol. wt. 137.99) in 900 ml of distilled water on a stir plate. Once dissolved, bring final solution up to 1 liter using a graduated cylinder or volumetric flask. Store up to 1 year at room temperature, following the same guidelines for dead/live tissue as for the dibasic stock solution.

Phosphate-buffered saline (PBS)

Dissolve 60 g NaCl in 8 liters of 0.1 M phosphate buffer (see recipe). Store up to 1 year at room temperature, following the same guidelines for dead/live tissue as for the stock solutions.

Phosphate buffered saline with azide (PBS-azide)

Dissolve 0.5 g sodium azide (Caution: water reactive) in 8 liters of PBS (see recipe). Store up to 1 year at room temperature.

Povidone iodine, 20%

Mix 200 ml povidone iodine (available in most drugstores) with 800 ml distilled water. Store indefinitely at room temperature. This solution can be re-used. Replace when it looks dirty, usually after ~300 eggs or when it is used up. Store the used solution separate from the fresh solution.

Sodium pentobarbitol (Somnotol)

Use 0.05 to 0.07 ml/40 to 50 g hatchling chick. Use directly from the stock bottle (65 mg/ml Somnotol stock). Store up to 1 year at room temperature.

COMMENTARY

Background Information

Description of the early embryo assay

The Early Embryo Assay (EEA) is a short-term (<5 day) bioassay used for analysis of teratogenic effects in chicken (and other avian) embryos. The EEA consists of exposing eggs to a contaminant from the start of incubation, either via maternal deposition, or injection into the yolk or the airsac. Following an appropriate incubation time, embryos are evaluated considering the effects of the toxicant on normal growth and development, and on the induction of gross abnormalities (teratogenic changes). The embryos are evaluated at various developmentally relevant time points during the period of early organogenesis. The time points chosen for evaluation are based on preliminary data that pinpoints the early developmental processes that are most likely to be affected by that toxicant or mixtures of toxicants and that identifies the time pattern for the development of the chosen species being evaluated. For 2,3,7,8-tetrachlorodibenzo-*p*-dioxin (TCDD) and the related polychlorinated biphenyls, for example, the optimal time points for embryonic evaluation are after 48, 72 and 96 hr of incubation for the chicken embryo. For other avian species, the researcher must determine the chronological age appropriate for the developmental endpoint under study. This may take some practice given that chronological age does not always equal developmental age.

After the incubation is stopped, the embryo is sacrificed by fixation with, e.g., 10% neutral-buffered formalin, removed from the egg, and evaluated in two ways. First, the embryo is developmentally staged using a stereo microscope. For each age of embryo, each tissue or organ undergoing change at that time is assessed according to its degree of development. These tissues and organs are termed "developmental indicators" and are relevant to each specific embryonic age (see Table 13.4.1). For avian embryos, the growth and development are characterized according to Hamburger and Hamilton staging (Hamburger and Hamilton, 1951). For other classes of vertebrates, a similarly detailed developmental characterization reference would be used. Next, each embryo is assessed for gross visible abnormalities of the individual tissues and organs, and of the embryo as a whole. Overall developmental delays are noted in this step. Finally, the results are evaluated statistically by dose or site to ascertain relative effects of the contaminant exposure on the growth and morphometry of each indicator tissue and organ. Abnormalities are assessed strictly by percent of observed embryos and degree affected, while the stages of each organ and the overall stage ranges observed in each embryo are compared quantitatively. All embryos exposed to a contaminant (either in the wild, at a contaminated site, or in the laboratory) are compared to "control" embryos either taken from a relatively uncontaminated reference site, or injected in the laboratory with the vehicle alone.

Benefits of the early embryo assay

By examining the embryo early, during the process of organogenesis, it may be determined whether critical stages and which stages in the process of early development are being affected, providing more clues to potential mechanisms of developmental toxic action. Furthermore, identifying the specific developmental processes that are affected enables one to utilize the developing database of information about molecular processes that control development. Thus, if it were known, e.g., that a specific gene was expressed just as somites begin to form, and a particular contaminant was documented to affect early somite formation, then an examination of whether that gene was affected by that contaminant could be undertaken. Identifying an array of such contaminant-affected genes could lead to development

Table 13.4.1 Major Developmental Indicator Organs for Embryonic Day 2 (E2), Embryonic Day 3 (E3), and Embryonic Day 4 (E4) Chicken Embryos

E2	E3	E4
Somites	Somites in tail	Somites in tail
Heart	Heart	Curvature
Curvature	Curvature	Visceral arches
Eyes	Visceral arches	Eyes

	Amnion	

of a suite of relatively contaminant-specific biomarker assays for developmental toxicity.

The early embryo assay has several cost and procedural benefits. The costs of collection of eggs from a sampling site can be substantial, but because the incubation is undertaken in the laboratory, the costs of subsequent trips to the sampling site are saved. Trained observers are able to analyze embryos in a period of time comparable to a necropsy analysis, especially if a well-characterized suite of abnormalities is known to occur for a given toxic agent (15 to 25 min per embryo). The eggs are relatively easy to obtain for many species of birds. Time of collection to the end of the assay (incubation of the eggs) is relatively short (up to 5 days), and sacrifice is relatively quick (on an order of minutes per embryo). Preliminary experiments using a number of different toxicants, as well as preliminary field studies examining embryos exposed to different contaminants in the field, indicate that the pattern of abnormalities observed for each toxicant is to some degree characteristic, although certain abnormalities (such as delays in heart folding or somite abnormalities) appear in embryos exposed to any one of several contaminants (Henshel et al., 1996). For example, characteristic abnormalities associated with TCDD and similarly-acting planar polychlorinated biphenyls (PCBs) in early embryonic chickens include delays in heart folding, delayed or ill-defined brain development, twisting of the embryo just below the level of the heart, asymmetric somites, and abnormal mandibular arches (Henshel, 1993; Henshel et al., 1993). Once the specific abnormalities or suite of abnormalities have been documented and shown to be consistent among species, it would be relatively straightforward for a trained technician to screen the embryos. In addition, if previously unidentified abnormalities occur, it might be possible to infer that a previously unidentified compound is present at that site.

Differences between the early embryo assay and the chick embryo screening test (CHEST)

The Chick Embryo Screening Test (CHEST) assay has been used for some time (Jelinek and Marhan, 1994; Davies and Freeman, 1995) to screen for the teratogenic potential of toxicants. The CHEST assay, however, is distinctly different from the EEA. The CHEST assay is not as portable to the field because exposure conditions are not the same as for chemicals deposited by the mother into the yolk, and ultimately does not have the same potential for development of teratogenicity and development-related biomarkers. Where the EEA begins exposure at the start of incubation, mimicking maternal deposition, the CHEST assay embryos are exposed sometime during the early phases of organogenesis, usually on embryonic (incubation) day 4 [E4], but sometimes on days 2 [E2] or 3 [E3] of incubation. Where the embryos used in the EEA are examined early, during organogenesis, the CHEST

embryos are examined late in development, usually around day 18 of incubation. One benefit of using the CHEST assay compared to the EEA is that it does examine the chick embryos relatively late in development. This enables the evaluation of which observed abnormalities have the potential to be life threatening. However, even more information would be obtained by allowing the chicks to hatch. This would provide information about hatching success as well as about teratogenic changes and growth anomalies evident at the end of the incubation period.

The first problem with using the CHEST assay for any monitoring program carried out by a large number of people in many different places is that the CHEST assay does not have a consistent protocol for exposure. This is a problem because inconsistent results might be observed with embryos exposed on different incubation days, depending on the toxicant being used. Second, exposure to the toxicant during organogenesis rather than from the start of incubation misses all effects manifested during the early embryo formation and early organogenesis phases of development, both of which are very sensitive to disturbance. Third, it is very difficult to inject the yolk of embryos past the first day of incubation since the yolk liquifies and disturbance to the liquified yolk increases the risks of experiment-induced egg mortality. Thus, one loses a critical exposure route (via the yolk) and this is the route that could be the best mimic of natural (in the wild) exposure conditions.

Differences between the early embryo assay and classical field evaluation of teratogenesis

Classical teratogenic evaluation of field-exposed egg-laying animals has consisted of evaluating both the live hatchlings and the dead embryos for gross abnormalities. This can provide clear indications of teratogenic effects, similar to the CHEST assay. However, information is often lost from the early dead embryos as they are often very decomposed by the time of evaluation. Thus, if a contaminant does affect early development, and causes a lethal deformation, it may not be easy to determine the specific developmental processes affected if the embryos are just detectable as "early dead but decomposed." Stopping incubation earlier in development allows the assessor to detect early, potentially more sensitive deformations in examinable embryos. In addition, early embryos may be more sensitive since the early embryo is the most sensitive period in embryonic development for non-specific effects. Some toxicants, such as heavy metals that affect migration in the developing nervous system (Henshel et al., 1996) or TCDD-related compounds that may specifically affect developmental control mechanisms (Henshel et al., 1993) induce effects that are best detected in the early embryo. If only hatching or reproductive success is examined, this precludes detection of physiological stresses that may have occurred during development. These physiological stresses can decrease organismal viability or vitality. The EEA allows for the detection of these early changes.

Benefits of using the early embryo assay in teratogenic monitoring

The early embryo assay provides the potential for applying reliable and sensitive teratogenic evaluation techniques to field monitoring. In conjunction with assessment of other critical parameters, such as reproductive success, teratogenic monitoring of viable and late dead hatchlings, assessment of behavioral neurotoxicity and immunotoxicity, enzyme activity and plasma hormone levels, this combined series of biomarkers will provide a relatively complete picture about the sub-lethal homeostatic mechanisms essential to survival of any individual. The EEA allows a glimpse into potentially serious, but otherwise hard to detect, early teratogenic changes, and may provide a database upon which new developmentally relevant biochemical or molecular biomarkers may be developed. Taking freshly laid eggs is not likely to impact nesting behavior, especially if one or two eggs are left in the nest. Some species, if sufficiently disturbed, will often build or locate a new nest and begin laying again. If taken to excess, this process could deplete the energy and nutrition stores of the laying female. Therefore, care should be taken not to remove too many eggs from any given nest. However, if the appropriate ages for study have been predetermined, as few as one to two embryos per nest can provide sufficient information within a colony-wide (>10 nests) study. For maximal knowledge, the authors suggest also having some method by which to evaluate exposure in at least one of the eggs from each nest sampled. Once, however, a significant knowledge base has been established regarding the relative species sensitivity and chemical sensitivities for early embryos compared to older embryos and hatchlings, the EEA may some day be considered sufficient for

identifying potential contamination problems at the screening level. Furthermore, development of this knowledge base will help future field researchers as they interpret the "decomposed" early embryos found within unhatched eggs. By studying the early embryos, there is the potential to identify the underlying mechanism of specific abnormalities that would not be identifiable in either unhatched embryos or viable hatchlings.

Additionally, since the EEA evaluates teratogenicity in embryos early in development, animal welfare certification for research projects are not difficult to obtain. Young embryos in ovo are not treated as "animals" under the National Institutes of Health animal care regulations.

Transferability to other species, including non-avian species

The EEA may be used with any species provided the basic patterns of early embryonic growth and development have been characterized in that species and verified in field collected and relatively uncontaminated specimens. The authors have found, however, that the relative rate of growth of a given species may be slower than the "standard" species. In this assay, chicken is the standard species; swallows follow a different pattern of development during some periods of development. Thus, whatever species is used, the researcher must first characterize the basic developmental rate for that species under the incubation conditions to be used in the experiment.

Critical Parameters

Study design

The most critical issue when running toxicological experiments with chicken embryos is the study design. Two factors are critical: ensuring sufficient power to evaluate the effect and ensuring that the study design enables within experiment quality controls. In order to decide the sample size for an experiment, most toxicologists follow established parameters for a "good experiment." These parameters might be 200 rats per dose per gender per age for a cancer study, or maybe 50 rats per dose per gender for an acute toxicological assessment. Using this type of thinking, standard practice tends to say that 20 eggs per dose per timing endpoint is ideal for most experiments, 15 eggs per dose per time is sufficient for most experiments, and 10 eggs per dose per timing endpoint is acceptable for a scoping or preliminary study. The problem with teratological studies is that some teratological endpoints have a very low frequency of occurring, even under what might otherwise be "ideal" inducing conditions. For example, long experience with cormorants and terns of the Great Lakes led Jim Ludwig to determine that the rate of cross-billed hatchlings occurring in even the most contaminated areas was ~0.4%, or four cross-bills observed per 1000 hatchlings assessed (Ludwig et al., 1996). At that rate of occurrence, should embryos ever develop cross-bills within a laboratory dosing study, the incidence would be so low that one could almost never be sure that the abnormalities were due to the injected toxicant.

A good study design can enable one to interpret an experiment with an across-dose mortality rate. A poor study design would leave such an experiment without recourse. There are three major parameters that must be included in the study design that goes beyond the obvious issues related to the power of the design (such as the number of eggs injected per dose and the number of doses tested).

1. *Controls*. Beyond all other types of experiments, it is critical to include both vehicle controls and non-injected controls in every group of eggs placed in the incubator. The vehicle controls are the usual controls for the toxicants injected. The non-injected eggs control for the eggs themselves (inherent viability, storage factors, handling effects, and incubator conditions). It is important to remember to treat these non-injected eggs the same as the injected eggs so that the only difference between the non-injected eggs and the other eggs is that the non-injected eggs do not receive the vehicle of the agent under study. Similarly, if the eggs are being sacrificed at more than one time point, the non-injected control eggs must also be sacrificed at each of the timed endpoints. Thus, one needs to include a set of non-injected eggs for each sacrifice time point.

2. *Batches.* Eggs come from multiple hens, which can introduce some variability, both due to factors related to the hen (age, stress levels, health) and the environment (climate and immediate temperature, time after laying and before collection, handling and storage). Thus, it is best to inject and incubate eggs in batches that include some of the sample from each dose group and each control group. To ensure intra-batch standardization and the ability to carry out a statistical quality assurance check, it is best to include at least three eggs in each dose group (and control groups) in each injection/in-

cubation batch. Five per dose group is an even better number. Then, in order to increase the net sample size for the final dose group analysis, one must set at least 3 to 4 batches of eggs for each experiment. This allows the researcher to check for consistency in eggs and incubation conditions over time. This also means that if there is a problem during the incubation period, one only has to reinject and reincubate a portion of the whole experiment, not the entire experimental set. If one were to incubate by dose group, one glitch could destroy a complete dose group, and there might not be any way to be sure that the problem was the incubation conditions and not the toxicant at that dose.

3. *Randomization*. Several factors need to be randomized. Placement of the eggs within an incubator should be randomized to minimize the possibility that a temperature gradient within the incubator differentially affects whole dosed sets of the experiment. Other factors requiring randomization include placement of eggs into dose groups, the order in which embryos are sacrificed to randomize the amount of time an embryo is at room temperature before sacrifice, and the order in which embryos are analyzed (to avoid analyzing all of one dose group at a time).

4. *Volume of injection.* Embryo mortality may result by injecting too much material (even saline) into the airsac or even the yolk. A general rule of thumb, based on preliminary experiments, is that no more than 50 µl of an oily substance, and 100 µl of an aqueous substance should be injected into the air sac. These are absolute maximum volumes for the average 50- to 60-g egg. The apparent problem is that the oil coats the embryo and causes anoxic effects. To prevent this problem, standard practice in the authors' laboratory for oil-based toxicants is to keep the volume of injection to 0.1 µl/g egg. This keeps the injection volumes well-below the 25 µl cut-off that seems to maximize egg viability. DeWitt (unpub. observ.) compared the effects of corn oil injected into the eggs at 0.1 µl/g egg and 1 µl/g egg. There was a significant difference (P = 0.005) in egg viability at these volumes (4 to 5 µl total oil versus 40 to 50 µl oil total).

5. *Vehicle/diluent.* The vehicle chosen must clearly be determined by the toxicant's solubility. However, it is important to remember that the vehicle may itself have effects on developing embryos, and the vehicle may have an impact on the relative toxicity of the toxicant in question. Several common vehicles are questionably non-toxic. Vehicles that have been used in embryos include acetone, DMSO, dioxane, as well as a number of vegetable oils, water, and saline. According to Walker (1967), some of the vehicles (such as formaldehyde and acetone) may interact with the yolk, binding the toxicant into the yolk and making it unavailable to the embryo. In this case, injecting a yolk-binding solvent vehicle into the yolk will artificially decrease the apparent toxicity of the toxicant being tested. Oils injected into the yolk will stay in a droplet and rise up under the embryo, affecting toxicant availability. Some investigators add an emulsifier, such as lecithin, to the oil. In this case, the oil emulsion spreads out under the outer member of the yolk. In this case, the embryo may take in less toxicant emulsion at a time, spread out over a longer period of time (Brunstrom and Darnerud, 1983). Some of the vegetable oils contain high enough concentrations of natural estrogenic compounds to cause masculinization of the brain or feminization of the brain or body, depending on the timing of the injection (Casanova et al., 1999). Use of such vehicles could affect a measurement endpoint. As discussed above, the choice of vehicle also affects the possible volume that may be injected. The other factor to balance against the vehicle to be used is where the researcher wants to inject the toxicant: into the yolk, the air sac, or the albumin. The yolk contains the most fat. The albumen is water-based, but the embryo does not start to "eat" the albumin until more than halfway through incubation, whereas the yolk starts to be liquified and taken up by the embryo within 1 or 2 days of the start of incubation. In summary, it is important to test the vehicle itself and evaluate both inherent toxicity, and how it interacts with the part of the egg it is injected into.

Timing issues

Timing considerations play a role both for the injection and for the sacrifice.

1. *Timing of injection/co-injection*. The embryo will start to develop as soon as the egg is incubated, even somewhat at room temperature. A number of researchers (Hoffman and Ramm, 1972a,b; Hoffman, 1975; Hoffman and Campbell, 1978; Brunstrom, 1983, 1988; Brunstrom and Darnerud, 1983; Brunstrom and Lund, 1988; Powell et al., 1996a,b; Grasman and Whitacre, 2001; Fox and Grasman, 1999) prefer to start incubating the egg first, then injecting the toxicant at embryonic day 3 or 4. This way, researchers can candle the eggs prior to injection and cull out any eggs that do not

seem to be developing normally. The problem with this approach is that the nervous system is the first system to start developing, followed closely by the heart and vasculature. If the toxicant affects the nervous system during that very early organizing phase of development, it is important that the toxicant be present during that phase in order to observe these effects. TCDD, for example, induces effects on embryos that can be detected by 48 hr of incubation. Timed experiments that evaluated heart abnormalities that occurred in chicken hatchlings injected as embryos on day 0 versus day 4 of incubation showed that the heart abnormalities were much less severe, and some abnormalities were absent (e.g., split aortic arch) in the hatchlings that were only exposed from embryonic day 4 onward (Noel and Henshel, 1996). If the researcher chooses to inject preincubated embryos, they must be aware that they may well have missed very early effects.

2. *Timing of sacrifice.* The nervous system, for example, develops in an ordered way, rostral to caudal, with a series of interdependent changes that occur at characteristic developmental stages (Purves and Lichtman, 1985). One must therefore choose the embryological endpoints with an awareness of what is supposed to happen prior to that point in development. One must also determine whether the resultant toxicological effect would be permanent or transient and adjust sacrifice ages appropriately.

Troubleshooting

Problems with chicken embryo studies often derive from several prime sources: (a) the uninjected eggs; (b) incubation conditions; (c) injection technique, volume and diluent; and (d) improper study design.

The non-injected eggs

Eggs that have been mishandled (often during shipping), allowed to overheat sometime prior to incubation, or allowed to chill at too low a temperature, will have poor viability. So long as the study design ensures that all batches of eggs include some non-injected controls, this will be evident from the cross-dose decrease in viability. In general, a 70% to 80% cross-dose or control viability is acceptable, but an 85% to 95% control viability is preferred. Consistent batch viabilities of ≤75% indicates that the eggs are being stressed or mishandled, or that the hens are reaching the end of their useful laying life. Eggs that are stored for too long also begin to lose viability. To ensure that storage is not a factor in the authors' results, eggs are held at 55°F for no more than 3 to 5 days, with 1 to 2 days being the preferred storage time. By 1 week, viability may decrease. By 2 weeks, viability is clearly affected. Any longer than 2 weeks and viability continues to decrease steadily. This change in viability will partially vary with the freshness of the eggs when put into storage, and partially depend on the storage conditions (temperature and humidity). Each laboratory should test the storage versus viability function for themselves with each new supplier or new brood of hens that provide the eggs.

Incubation conditions

Incubation conditions are critical. A slight change in incubation temperature, for example, can significantly affect the rate of embryonic development. Two degrees change of incubation temperature can result in significantly reduced viability and embryonic deformation (see detailed tables in Romanoff and Romanoff, 1972). Humidity that is too low will stress the embryo, reduce growth rate, and decrease the embryo's ability to rotate within the shell. This direct unchanging physical contact can produce gross malformations. Extended dryness may result in the death of the embryo or an embryo so weakened that it can not pip or fully hatch. Humidity that is much too high can result in excess fluid inside the shell. In this case, the excess fluid can actually drown the embryo if the humidity excess is severe. (This is less often seen with chicken embryos than with some other avian embryos. This has been seen, for example, with cormorants.) Incubation conditions need to be monitored. It is highly recommended to make sure the incubator is holding a steady temperature for at least 24 hr after being started before putting any eggs in to incubate. Thus, prior to initiating a new experiment, it is always a good idea to incubate a set of non-injected eggs and to sacrifice them at specific pre-chosen points throughout development in order to establish the growth-rate curve for the specific incubation conditions (temperature and humidity) that will be used.

Anticipated Results

The types of results will clearly depend on the study design and the endpoints chosen for analysis. In a classic toxicological experiment, with multiple doses used, two possible results may be seen for any given endpoint. First, there may be a classic dose-response curve at which there is an increase in the rate or intensity of the endpoint with increased dose applied. Many

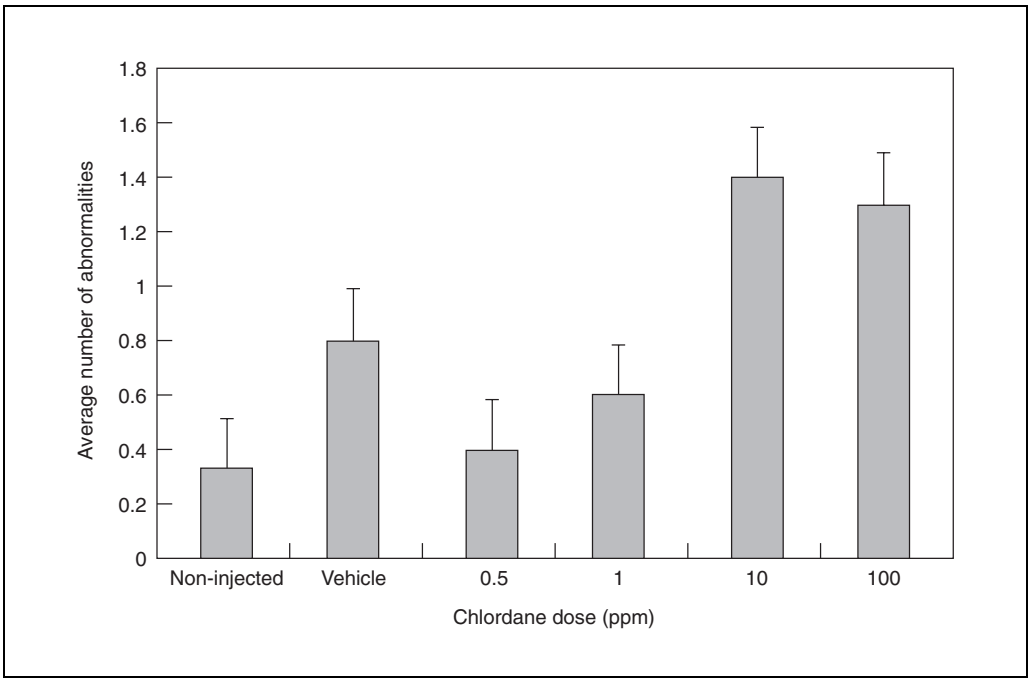

Figure 13.4.1 Average number of abnormalities in 48-hr-old domestic chicken embryos (*Gallus gallus*) exposed to technical-grade chlordane (parts per million) in ovo. Abnormalites included underdeveloped overall for age, underdeveloped organs for stage of embryo, constricted heart, asymmetric somites, abnormal spine, abnormal turning of head, and constriction of optic vesicles.

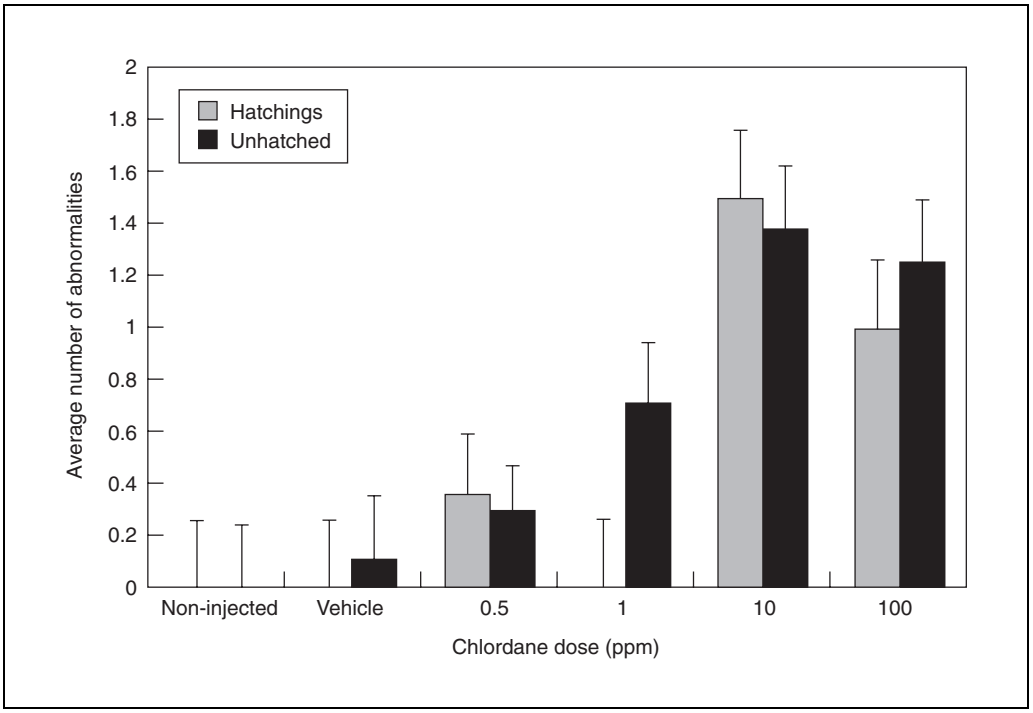

Figure 13.4.2 Average number of abnormalities in domestic hatchling or dead-at-pipping chickens (*Gallus gallus*) exposed to technical-grade chlordane (parts per million) throughout development in ovo. Abnormalites included edema, curled toes, and small size for age.

abnormalities, however, seem to occur at a higher frequency in the dosed populations, but may not occur in a pattern that matches ever-increasing frequency with ever-increasing dose.

One would say that most malformations should never occur. However, given the detectable rate of unexplained birth defects in human infants, it is clear that unexplained gross malformations do occur. This happens in chicken embryo experiments as well. The fact that some gross abnormalities occur across all doses and controls and incubators in only sporadic batches of eggs indicates to us that the most common cause relates to the handling of the eggs prior to arrival in the authors' laboratory.

Given the potential for non-specific gross malformations being induced by handling, incubation conditions, errors made during the injection process, or by other not clearly defined factors, the researcher must realize that periodically one of many gross malformations (e.g., slow developmental rate, hematomas, or generalized bleeding, twisting of the tail) may occur. These are not normally developing embryos, but the cause of the abnormality may be unclear, and may not be due to the toxicant being tested. Study designs that incorporate appropriate controls will enable the researcher to interpret the results. Study designs that lack the appropriate controls will result in difficult-to-interpret results if any of these abnormalities occur.

The following information in this section illustrates an example of the early embryo assay and a lethality study (LD50) designed to explore the teratogenic effects of chlordane, an organochlorine insecticide.

Basic Protocols 1 to 3

Eggs obtained from the Purdue University Poultry Unit (Purdue University Animal Sciences Research Farms) were prepared as directed in Basic Protocol 1, steps 1 to 5, in four different batches for the early embryo assay and in one batch for the lethality study. Technical grade chlordane (CAS number 57-74-9, Ultra-Scientific) was mixed with a safflower oil vehicle so that 0.1 µl per gram of egg resulted in either 0.5, 1, 10, or 100 parts per million concentration. Controls received the safflower oil alone or no injection at all. Doses were the same for both the early embryo assay and the LD50 study. Injection and incubation procedures followed Basic Protocol 1, steps 8 to 16.

Incubation for the early embryo assay eggs was stopped at either 48 or 96 hr of incubation. The LD50 eggs were taken to hatch unless candling revealed death, in which case the eggs were opened and the embryos were removed, aged, and assessed for external abnormalities (see Basic Protocol 1, step 16). Early embryos were removed from eggs as per Basic Protocol 2, steps 6 to 16. Hatchling chicks were examined for external abnormalities, weighed, measured, and sacrificed via decapitation (see Basic Protocol 3, Method B). Sera were collected from trunk blood that was spun in a microcentrifuge for 15 min and immediately snap frozen at −80°C. Brains were immediately removed and immersion-fixed in 10% neutral-buffered formalin. Livers were removed, weighed, and cut in half, with one half immersed in formalin and the other half immersed in glycerol and snap frozen at −80°C. See Figures 13.4.1 and 13.4.2 for results.

Time Considerations

One benefit of working with the avian embryo is that, if time is a factor for the researcher, the researcher can often choose a different endpoint or earlier stage to evaluate. Thus, the early embryo assay uses early stages of tissue development to evaluate (after 48 to 96 hr of incubation in general), reducing the total time for generation of embryos to evaluate to one 5-day week. Certain endpoints, however, are determined by the developmental timing of the embryo and cannot be changed by evaluating a slightly younger stage. Myelination, for example, starts by embryonic day 13 in the chicken spinal cord. This is much earlier than in the mammalian embryos, in which myelination generally begins postnatally. In the chicken embryo, however, myelination continues steadily over the course of embryonic days 13 through 16. Then just before day 17 myelination progresses in a burst so that by embryonic day 17, the chicken embryo spinal cord is almost as well-myelinated as the spinal cord of the hatchling chicken (21 days).

In Vivo Assessment of Prenatal Developmental Toxicity in Rodents

Developmental toxicity is defined as any adverse effect on the developing organism that may result from toxicant exposure prior to conception, during prenatal development, or postnatally to the time of sexual maturation. There are four major manifestations of developmental toxicity: (1) death, (2) structural abnormality, (3) altered growth, and (4) functional deficits (EPA, 1991). This unit describes two basic approaches for testing chemicals (or conditions) for their potential to cause prenatal developmental toxicity in rats and mice. Both protocols are similar in that they involve treatment of pregnant animals, followed by an evaluation of the prenatally exposed litters. The protocols differ, however, in the methodology used to evaluate the litters. In the first approach (see Basic Protocol 1), referred to as a Segment II study, the evaluation of the progeny focuses on the external, skeletal, and soft-tissue morphology of the full-term fetus. In the second basic approach (see Basic Protocol 2), often referred to as the Chernoff/Kavlock assay, the evaluation of the progeny focuses on the postnatal growth and viability of the neonates. This protocol is useful as a developmental toxicity screen and is effective in prioritizing chemicals for Segment II testing.

SEGMENT II STUDY

BASIC PROTOCOL 1

This is the standard test for developmental toxicity in rodents, and it is consistent with governmental guidelines for prenatal developmental toxicity testing (ICH, 1994; EPA, 1998b; OECD, 2000). The following Basic Protocol is presented as an overview of the study design; methodological details are provided in the ensuing Support Protocols: (1) performing cesarean sections (Support Protocol 1), (2) examination of apparently nongravid uteri (Support Protocol 2), (3) examination of fetal visceral specimens (Support Protocol 3), (4) preparation of fetal skeletal specimens (Support Protocol 4), (5) examination of fetal skeletal specimens (Support Protocol 5), and (6) statistical analysis and interpretation of the data (Support Protocol 6).

Materials

Young adult (e.g., 60- to 90-day-old) timed-pregnant rats or mice of any strain with high fecundity

Test substance

Bodian's solution (see recipe) or Bouin's solution (see recipe)

4% (w/v) NaCl

Additional reagents and equipment for care and handling of rodents (e.g., Coligan et al., 2003), cesarean section (Support Protocol 1), examination of apparently nongravid uteri (Support Protocol 2), examination of fetal visceral specimens (Support Protocol 3), preparation of fetal skeletal specimens (Support Protocol 4), and examination of fetal skeletal specimens (Support Protocol 5), and data analysis and interpretation (Support Protocol 6)

Treat and observe dams during gestation

1. Obtain timed-pregnant animals prior to gestation day (GD) 6.

   The day upon which a copulatory plug or vaginal sperm is found is designated gestation day (GD) 0.

Contributed by Michael G. Narotsky and Robert J. Kavlock

Current Protocols in Toxicology (2003) 13.5.1-13.5.25

2. Weigh the animals prior to treatment (if possible, at least 1 day prior to treatment initiation) for group assignment. Assign the animals to treatment groups using procedures that provide comparable weight distributions in all groups (see, e.g., Narotsky et al., 1997).

   Information on housing, handling, and identification of experimental rodents is available in Coligan et al. (2003).

3. Treat the animals with the test substance by a relevant route (typically by gavage) at least once per day from the point of implantation to the day prior to scheduled caesarean section.

   Rats should generally be treated on GD 6 to 20, and mice on GD 6 to 17. Animals may be dosed more frequently than once per day if this is deemed appropriate based on pharmacokinetic data.

4. Record maternal body weights and food consumption at ≤3-day intervals throughout the treatment period.

   The authors recommend recording body weights daily throughout the treatment period and 1 day after the last treatment.

5. Observe the animals for clinical signs of maternal toxicity throughout the study period. Note changes, e.g., in skin, pelage, eyes, mucous membranes, breathing, behavior, or excreta. Generally, examine the animals immediately after dosing, ~1 hr later (or when maximum effects might be anticipated), and again prior to the end of the working day.

Perform cesarean sections

6. Using a method approved by the Institutional Animal Care and Use Committee (also see AVMA, 2001), euthanize the rats on GD 21 and mice on GD 18 (to avoid losses due to early deliveries, it may be necessary to euthanize the animals 1 day earlier, i.e., on GD 20 for rats and GD 17 for mice). Weigh the gravid uterus. Deliver the litters by cesarean section. Count and classify each implantation site. Weigh and examine each live fetus for external alterations. Maintain the identity of each fetus throughout all examinations. For maternal rats, count the number of corpora lutea.

   The abovementioned procedures are described in Support Protocol 1.

7. Examine apparently nongravid uteri for resorption sites (see Support Protocol 2).

8. Preserve approximately one-half of the live fetuses of each litter in Bodian's (or Bouin's) solution for subsequent visceral examination (see Support Protocol 3).

9. Place the remaining live fetuses in 4% NaCl for subsequent preparation of skeletal specimens (see Support Protocol 4).

Examine fetal specimens

10. Examine visceral specimens for alterations (see Support Protocol 3).

11. Examine skeletal specimens for alterations (see Support Protocol 5).

Analyze and interpret data

12. Prepare data for statistical analysis. If not captured automatically during data collection, enter the data into a computerized format for subsequent data processing.

13. Statistically analyze the data using appropriate methods (see Support Protocol 6).

14. Summarize the data by preparing group summary tables and graphical presentations of the data (see Support Protocol 6).

15. Evaluate the data and draw conclusions regarding maternal and developmental toxicity of the test article (see Support Protocol 6).

CHERNOFF/KAVLOCK ASSAY

BASIC PROTOCOL 2

This is generally considered a screening assay for developmental toxicity. For most intents and purposes, the preparturition steps are identical to the methods used in a Segment II study.

Materials

Young adult (e.g., 60- to 90-day-old) timed-pregnant rats or mice of any strain with high fecundity

Test substance

Additional reagents and equipment for care and handling of rodents (e.g., Coligan et al., 2003) and examination of apparently nongravid uteri (Support Protocol 2)

Treat and observe dams during gestation

1. Obtain timed-pregnant animals prior to gestation day (GD) 6.

   The day upon which a copulatory plug or vaginal sperm is found is designated gestation day (GD) 0.

2. Weigh the animals prior to treatment (if possible, at least 1 day prior to treatment initiation) for group assignment. Assign the animals to treatment groups using procedures that provide comparable weight distributions in all groups (see, e.g., Narotsky et al., 1997).

   Information on housing, handling, and identification of experimental rodents is available in Coligan et al. (2003).

3. Treat the dams with the test substance by a relevant route (typically by gavage) on GD 6 to GD 20 (for rats) or GD 6 to GD 17 (for mice).

4. Record maternal body weights and food consumption daily throughout the treatment period and 1 day after the final treatment.

5. Observe the animals for clinical signs of maternal toxicity throughout the study period. Note changes, e.g., in skin, pelage, eyes, mucous membranes, breathing, behavior, or excreta. Generally, examine the animals immediately after dosing, ~1 hr later (or when maximum effects might be anticipated), and again prior to the end of the working day.

Examine the dams for parturition

6. After GD 20 (for rats) or GD 18 (for mice) determine observe the dams periodically for signs of parturition, while disturbing the dams as little as possible. Check the dams at the end of the working day on GD 20 (rats) or 18 (mice) and more frequently on the next 2 days. Continue periodic checking of any apparently gravid dams that have not delivered after this period.

7. For each dam, when vaginal bleeding or pup(s) are first observed, record the date (or gestation day), time, and one of the following descriptions of the status of parturition:

"Blood only" (vaginal bleeding, but no pups)
"One pup, in progress" (two or more pups delivered, but parturition not yet completed)
"Completed."

Also record any findings of prolonged labor or dystocia.

Examine the litters

8. Examine the litters on postnatal day 1 (PD 1).

   PD 1 corresponds to GD 22 regardless of the day of parturition. Alternatively, some laboratories define PD 1 as the day on which parturition was completed.

9. For each litter, record the approximate time of the PD 1 examination.
10. Place the dam in a holding cage and collect the pups. Carefully examine the cage bedding to find any buried pups.
11. Examine each pup. Record the weight (to the nearest 0.1 g), sex, and any external alterations observed. On PD 1, note the presence or absence of an abdominal milk band: i.e., milk in the stomach visible through the neonate's abdominal wall.

    In studies where sex differentiation may be affected, quantitation of the anogenital distance may be warranted.

12. Euthanize any moribund or malformed live pups that are not expected to survive using methods approved by the Institutional Animal Care and Use Committee (also see AVMA, 2001). Based on gross external findings, preserve and examine each specimen using appropriate methods to best evaluate possible visceral or skeletal defects (see, e.g., Support Protocols 3 to 5).
13. Preserve and examine any intact dead pups as deemed appropriate.
14. Return the live pups and then the dam to their home cage.
15. Examine the litters on PD 6, repeating steps 10 to 14.
16. After the PD 6 examinations, euthanize the pups in a manner approved by the Institutional Animal Care and Use Committee (also see AVMA, 2001). As deemed appropriate, re-examine/dissect select pups to confirm in-life examination findings (e.g., microphthalmia). Carcasses may be discarded.

Examine the uterus

17. Euthanize the adult females in a manner approved by the Institutional Animal Care and Use Committee (also see AVMA, 2001). Excise the dam's uterus and press the uterus between the outer surfaces of two petri dishes. Count the implantation sites while viewing the uterus against a light source.
18. For apparently nongravid females, stain and examine the uterus as described in Support Protocol 2.

SUPPORT PROTOCOL 1

CESAREAN SECTIONS

This protocol, performed as part of the Segment II study (see Basic Protocol 1), describes the procedures used to examine the uterus, deliver and examine the full-term fetuses, and designate the fetuses for subsequent examinations.

Materials

Mouse or rat from Segment II study (see Basic Protocol 1)
Physiological saline: 0.9% (w/v) NaCl
4% (w/v) NaCl
Bodian's solution (see recipe)

Surgical instruments
Dissecting microscope
Weigh boats (or petri dishes)
24- or 48-well plates
Absorbent paper and/or cardboard trays
18-well polystyrene trays (Flambeau Products Corp.)
Dry-erase marking pen (or equivalent)
Solvent-resistant specimen jars
Dissecting microscope

Additional reagents and equipment for care and handling of rodents (e.g., Coligan et al., 2003) and examination of apparently nongravid uteri (Support Protocol 2)

Examine uterine contents in situ

1. Euthanize the dam according to methods approved by the Institutional Animal Care and Use Committee (also see AVMA, 2001), and open the abdominal body wall.

2. Without incising the uterine wall, examine the uterine contents and classify each implantation site as one of the following.

    a. Metrial gland only
    b. Metrial gland plus placenta
    c. Macerated fetus
    d. Dead fetus (without areas of resorption)
    e. Live fetus (responds to tactile stimuli).

    Record the sequence of implantation sites in a systematic manner (e.g., right to left, or cervix to ovary) for each uterine horn.

Remove and weigh the gravid uterus and examine nongravid uteri

3. Excise the uterus, leaving the left ovary attached to the uterus (to distinguish the right and left horns in step 6); excise the right ovary separately, being careful to leave part of the right oviduct attached to the uterus to minimize the chance of uterine rupture. Place the tissues in petri dishes or weigh boats. Examine the carcass, especially known target organs of toxicity, for gross lesions, and record any findings.

4. Weigh the gravid uterus (with left ovary attached) to the nearest 0.1 g.

5. If the uterus appears nongravid, examine as in Support Protocol 2.

Remove ovaries for subsequent counting of corpora lutea

6. If the uterus is gravid, lay it flat on absorbent paper, noting the right and left horns as indicated by the attached (left) ovary. For rats, remove the left ovary (with some of the oviduct attached) and store with the right ovary in physiological saline for subsequent counting of the corpora lutea. Place ovaries from the same dam in the same well of a 24- or 48-well plate and label with the dam number.

Remove fetuses from uterus and examine externally

7. Open the uterus (the authors recommend using curved, blunt-tipped scissors) and confirm/correct implantation designations (see step 2). Remove each live fetus from

the uterus and, maintaining their intrauterine sequence (i.e., position within the uterus), place on absorbent paper.

8. For each live fetus, record the individual fetal weight (to the nearest 0.1 g).

9. Examine each live fetus externally for alterations. Proceed in an orderly manner to scrutinize the entire fetus, including the head (shape, pinnae, eyes, eyelids, snout, jaw, nares, lip), skin, tail, back, ventral wall, genitalia, limbs, feet, and digits (it is unnecessary to open the mouth to examine the palate at this time, since the palate will be more easily examined during the skeletal and visceral examinations). Photographically document findings as deemed appropriate.

10. Examine the external genitalia and record the sex of each fetus. Determine the sex by noting the anogenital distance (longer for males).

Designate fetuses for skeletal/visceral examination

11. Euthanize the fetuses using a method approved by the Institutional Animal Care and Use Committee. For example, inject sodium pentobarbital (~200 mg/kg) intraperitoneally.

    Protocols for euthanasia of rodents, including the pentobarbital method, are provided in AVMA (2001) and Coligan et al. (2003).

12. Systematically, and in a nonbiased manner, select approximately one-half of the fetuses from each litter for skeletal examination. For example, select alternate fetuses for skeletal examination starting with the first fetus (closest to the right ovary) in even-numbered dams and the second fetus in odd-numbered dams.

13. Place fetuses that were selected for skeletal examination in 4% NaCl. Maintaining the intrauterine sequence, place each skeletally designated fetus in a well of an 18-well plastic tray. Use a different tray for each litter.

    See Support Protocol 4 for further preparation of the skeletal specimens.

14. Individually identify each of the remaining fetuses by marking the back with a dry-erase marker (or similar ink that is resistant to Bodian's solution). Snip some skin off of the back (avoiding the identification marking) to enhance penetration of the fixative and place in a solvent-resistant specimen jar with Bodian's solution for subsequent visceral examination.

    All viscerally designated fetuses may be fixed in the same jar; the amount of fixative should be ~10 times the tissue mass being preserved (i.e., 10 ml fixative per 1 g tissue). Alternatively, place fetuses in individual compartments of a solvent-resistant tray. See Support Protocol 3 for subsequent examination of the visceral specimens.

Count the corpora lutea

15. For rats, examine the ovaries with the aid of a dissecting microscope and record the total number of corpora lutea for each dam (the ovaries and oviducts may be discarded after examination). Place any ovaries that are not examined by the end of the working day in physiological saline and refrigerate.

    For mice, the authors do not recommend counting the corpora lutea; in this species, the corpora lutea rupture easily, yielding unreliable counts (Taylor, 1986).

EXAMINATION OF APPARENTLY NONGRAVID UTERI

This method describes the procedure for staining resorption sites in rodent uteri. The procedure is used on apparently nongravid uteri to detect or confirm cases of full-litter resorption in both the Segment II and Chernoff/Kavlock protocols.

CAUTION: Due to the stench of ammonium sulfide, all work with this chemical should be conducted in a fume hood.

Materials

Uteri (see Basic Protocols 1 and 2 and Support Protocol 1)
2% (w/v) ammonium sulfide (see recipe)

Surgical instruments
Petri dishes
6-well tissue culture plate (or similar container)
Sealable specimen bags

1. Excise the uterus.
2. Press the uterus between the outer surfaces of two petri dishes and count the implantation sites while viewing the uterus against a light source.
3. Place the uterus in a compartment of a 6-well tissue culture plate for staining. Label the plate with the dam number and record the number of implantation sites.
4. Put ~5 ml of 2% ammonium sulfide solution into each uterus-containing well.
5. After at ≥15 min, but preferably after 1 to 4 hr, examine each uterus for darkly stained implantation sites. Press the uterus between two petri dishes to facilitate the examination (Fig. 13.5.1).
6. Record the number of positively stained implantation sites.
7. After all uteri are examined, seal them in a specimen bag and dispose of them.

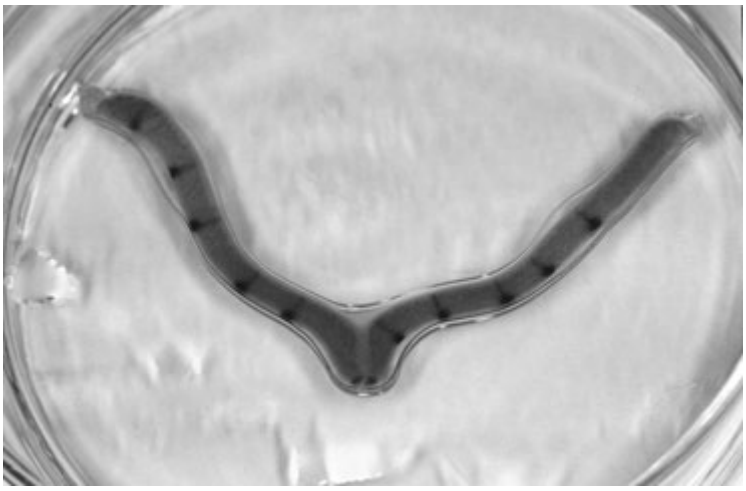

Figure 13.5.1 A rat uterus stained with 2% ammonium sulfide and viewed between two glass pretri dishes. Five stained resorption sites are visible for each uterine horn.

EXAMINATION OF FETAL VISCERAL SPECIMENS

A variety of methods may be used to examine Segment II specimens (see Basic Protocol 1) for soft-tissue defects. The following describes an examination procedure with fixed specimens. Except for examination of the brain, this procedure can be easily applied to fresh specimens.

NOTE: Since the examination involves dissection of tissues, it often precludes subsequent re-examination of many findings; thus, it is important to photographically document findings as deemed appropriate.

NOTE: When recording findings, use terminology consistent with that recommended by the International Federation of Teratology Societies Committee on Harmonization of Terminology in Developmental Toxicology (Wise et al., 1997).

Materials

Fetal specimens (see Basic Protocol 1 and Support Protocol 1) in Bodian's solution
Bodian's solution (see recipe) or Bouin's solution (see recipe)
Thymol crystals

Dissecting microscope
Dissection instruments including:
- Forceps
- Iris scissors
- Ultramicrodissection scissors
- Razor blades (or scalpels)

Air-tight vials (e.g., scintillation vials)

Vent specimen and examine externally

1. Maintaining litter identification, transfer specimens from Bodian's solution to an open container of tap water under a fume hood. After the specimen has sunk, i.e., when most of the fixative fumes have dissipated, remove the specimen for examination.
2. Examine each specimen externally for alterations of the head (i.e., general shape, pinnae, eyes, eyelids, jaw, nares, and lip), as well as the skin, tail, back, ventral wall, limbs, feet, and digits.
3. Section the specimen through the mouth (just below the pinnae) and the abdomen (leaving the diaphragm intact) yielding three portions: the head, forequarters, and hindquarters.

Examine the head

4. Remove the tongue and examine the palate for a cleft. Also examine the rugae for irregularities.
5. Make transverse sections perpendicular to the mouth and through the nasal passages, eyes, and the greatest diameter of the skull. In addition, make a mid-sagittal section through the hindbrain portion of the specimen.

   The mid-sagittal section need not go entirely through the specimen; the two halves may remain "hinged" with connective tissue.

6. Examine the head sections with particular attention to the nasal passages and septum, palate and rugae, eyes, lenses, retinae, and ventricles of the brain.

7. Score the dilation of the lateral ventricles:

   0 = essentially none
   1 = slight
   2 = moderate
   3 = severe.

Examine the forequarters

8. Examine the liver for color and texture. Carefully remove it, leaving the diaphragm intact.
9. Examine the diaphragm for herniation.
10. Cut through the length of the sternum and expose the thoracic cavity.
11. Remove the thymus with forceps and examine the major blood vessels; in particular, note the presence of the innominate artery.
12. Examine the trachea and esophagus by moving a forceps tip between the two from the larynx to the heart. In particular, note any fistulas and the right-left orientation.
13. Examine the lungs for size, lobation, and right-left orientation.
14. Examine the heart for size and orientation.
15. Section the heart perpendicular to the ventricular septum (Wilson, 1965) or use ultramicrodissection scissors to cut along the pulmonary artery and right ventricle, and then along the aorta and left ventricle (Stuckhardt and Poppe, 1984).
16. Examine the ventricular septum and valves.
17. Examine the front feet.

Examine the hindquarters

18. Carefully remove the digestive viscera and spleen and note any signs of intra-abdominal hemorrhage.
19. Examine the viscera for an accessory spleen or lobule at the caudate end of the spleen.
20. Examine the urinary bladder and the genitalia. Record the sex of the fetus; note if the external genitalia do not correspond with the internal genitalia.
21. Examine the kidneys for size and position. If the anterior tip of the left kidney is below the level of the hilus of the right kidney, or if the posterior tip of the right kidney is above the level of the hilus of the left kidney, note the kidneys as offset. If the anterior tip of the left kidney is anterior to the anterior tip of the right kidney note the kidneys as offset.
22. Gently remove the mesentery covering the ureters, then score the widest dilation of each ureter:

    0 = normal
    1 = slight
    2 = moderate
    3 = severe.

23. Section each kidney transversely through the hilus and score the dilation of the renal pelvis and the size of the papilla:

    0 = papilla intact, no dilation
    1 = papilla reduced
    2 = papilla nearly absent
    3 = papilla absent.

24. Examine the hind feet.

Store the specimen

25. Place the sections of each specimen in an *air-tight* vial for storage and tap water (with thymol crystals) sufficient to cover the tissues. Unless alterations were noted, the lower jaw and abdominal viscera (except for the urinary tract and genitalia) may be discarded. Label the vial/cap with the litter and fetus numbers of the specimen. Store indefinitely at room temperature.

SUPPORT PROTOCOL 4

PREPARATION OF FETAL SKELETAL SPECIMENS

In this protocol, the cesarean-delivered fetuses are skinned, eviscerated, and double-stained for skeletal examination. The bones are stained with alizarin red S, and the cartilage is stained with Alcian blue.

CAUTION: 95% ethanol is flammable. Store specimen trays containing 95% ethanol in a fire-safety cabinet.

Materials

Fetuses (see Basic Protocol 1 and Support Protocol 1)
4% NaCl
95% (or 100%) and 70% ethanol
150 mg/liter Alcian blue (see recipe)
1% (w/v) potassium hydroxide (KOH; see recipe)
25 mg/liter Alizarin red S (see recipe)
1:1 (v/v) glycerol/70% ethanol solution (see recipe)
2:2:1 (v/v/v) glycerol/70% ethanol/benzyl alcohol solution (see recipe)

Dissecting instruments including forceps and iris scissors
18-well polystyrene trays (Flambeau Products Corp.)
Flexible screen
Colored tape and marking pen

1. After the fetuses have been removed from the uterus, weighed, sexed, examined for external alterations, and euthanized (see Support Protocol 1), place the specimens in 4% NaCl for ~1 to 4 hr.

2. Eviscerate the fetus and completely remove the skin. Use particular care when removing skin from the extremities. Remove the thoracic and abdominal viscera as well as the subcutaneous fat between the scapulae and along the back of the neck. Be careful not to damage the skeleton. Upon completion of this step, place the fetus in a tray with 95% ethanol. Store trays with 95% ethanol in a fire-safety cabinet.

    Generally, the authors recommend that the eyes remain in situ.

3. Leave the fetuses in 95% ethanol for at least 1 day and stain according to the following schedule. To retain the specimens in their assigned cells, place a sheet of flexible screen under the lid of the tray while pouring off the solutions.

Day 1: Afternoon: Transfer the specimens to alcian blue solution. Leave overnight.
Day 2: Morning: Transfer the specimens to fresh 95% ethanol for destaining/rinsing.
Day 2: Afternoon: Transfer to 1% KOH. Leave overnight.
Day 3: Morning: Transfer to solution of alizarin red S (25 mg/l) in 1% KOH.
Day 4: Morning: Transfer to solution of 1:1 glycerol/70% ethanol.

4. If the specimens are overstained on the morning of Day 4, destain in a solution of 2:2:1 70% ethanol/glycerol/benzyl alcohol for 1 day, then transfer to 1:1 glycerol/70% ethanol.

EXAMINATION OF FETAL SKELETAL SPECIMENS

SUPPORT PROTOCOL 5

After the skeletal specimens have been prepared (Support Protocol 4), they are examined using the following protocol.

Materials

Stained fetal specimen in 1:1 glycerol/70% ethanol (Support Protocol 4)
1:1 (v/v) glycerol/70% ethanol solution (see recipe)
Glycerol

Shallow transparent dish (e.g., ashtray or petri dish)
Forceps
Dissecting microscope with base illumination
Specimen containers (e.g., jars, trays, and vials)

Prepare the specimen

1. Place the specimen in a shallow transparent dish. To minimize glare, submerge the specimen in 1:1 glycerol/70% ethanol (i.e., the solution in which the specimen is stored at the end of Support Protocol 4). Use forceps to facilitate manipulation of the specimens.

2. Examine the specimen using a dissecting microscope with a below-stage light source. Note, in particular, the anatomical features mentioned in the steps below; however, do not limit the recording of findings to these items.

   As needed, consult atlases of normal (Yasuda and Yuki, 1996; Menegola et al., 2001) and abnormal (IFTS, see Internet Resources) skeletal morphology.

   When recording findings, use terminology consistent with that recommended by the International Federation of Teratology Societies Committee on Harmonization of Terminology in Developmental Toxicology (Wise et al., 1997).

Examine the head

3. Examine the mandible and orbits for size and position.

4. Note the ossification of the calvaria.

   Reduced ossification is indicated by a discrete boundary between degrees of ossification.

5. Examine the anterior region of the suture between the frontal bones for the (normal) absence of an "interfrontal bone" and score:

   0 = absent
   1 = barely visible (with normal magnification)
   2 = readily visible
   3 = severely enlarged.

6. Score the size of the anterior fontanel (and the separation between the parietals):

   0 = minimal
   1 = slight (most typical for GD 20 rat fetuses)
   2 = moderate
   3 = severe.

7. Score the ossification of the supraoccipital:

   0 = >90% ossified
   1 = 50% to 90% ossified
   2 = >0 and <50% ossified
   3 = completely unossified.

8. Score the ossification of the hyoid:

   0 = ossified (normal)
   1 = reduced ossification
   2 = completely unossified.

9. Score palate closure. If necessary, break the mandibles for easier viewing:

   0 = palatal shelves (virtually) touching
   1 = gap between palatal shelves
   2 = cleft palate.

Examine the sternum

10. Identify by number (1 for manubrium, 6 for xyphoid) any sternebrae that are affected in the following categories: unossified; small, reduced ossification, or unilaterally ossified; bilobed or bipartite; offset. In addition, indicate the presence of an extra sternebra and identify any sternebrae that are fused and whether or not the fusion is associated with offsetting.
11. Designate a sternebra that is misaligned by at least one-half the sternebra's length as "offset." Also indicate if offsetting is due to deficient ossification.
12. If fusion between two (or more) sternebrae is present, indicate the sternebrae involved. If the fusion is associated with misalignment (i.e., offsetting), indicate this (e.g., "FO:3&4" indicates that sternebrae 3 and 4 are fused due to some offsetting of one or both sternebrae). Otherwise, "fused" indicates that the fusion was not associated with offsetting sternebrae (e.g., "FU:3&4").
13. Count the number of intact sternocostal connections. Note if there are fewer (or more) than seven intact costal cartilages on each side connecting the ribs to the sternum.

Examine the ribs

14. Examine the ribs, noting any fusions, bifurcations, or irregularities in shape (e.g., wavy) or ossification.
15. Note the presence (and side) of any cervical ribs. In addition, indicate if a cervical rib articulates with a vertebra other than C7.
16. If wavy ribs are predominant on the affected side(s), it is not necessary to identify each affected rib. For other findings, e.g., fused, specify the ribs involved.
17. Count the ribs on each side. Indicate the number of ribs if other than 13.
18. Classify the length of the last rib relative to the adjacent rib:

    Focal = rudimentary rib with no length
    Short = with length, but less than half the length of the adjacent rib
    Long = less than half the length of the adjacent rib.

Examine the vertebrae

19. Examine the vertebrae, noting the shape and ossification of the centra and arches.
20. Record the numbers of centra that are bilobed and bipartite.
21. Except for unossified, bilobed, and bipartite centra, describe any findings with respect to the specific vertebra (e.g., S1 or sacral-1) and the side (right, left, or both) affected. For the purposes of identification, designate a vertebra associated with a 14th thoracic/lumbar rib as L1.
22. Count the cervical vertebrae (and check for cervical ribs, see above). Count the number of presacral vertebrae (normally 26); indicate if other than 26. Examine the lumbosacral junction and indicate if this is asymmetrical; i.e., a vertebra shows lumbar characteristics on one side and sacral characteristics on the other side.
23. Count and record the number of ossified cervical vertebral centra.
24. Count and record the number of unossified thoracolumbosacral vertebral centra.
25. Count and record the number of ossified caudal vertebrae. Begin the count after the fourth sacral vertebra. For fetuses with a hybrid vertebra (see above), count the hybrid as the first sacral vertebra.

Examine the girdles, long bones, and feet

26. Examine the girdles and long bones. Note instances of unossified pubis, or reduced ossification of the pubis.
27. Examine the feet for any fused or misshapen structures. For each foot, record the numbers of ossified metacarpals/metatarsals and proximal phalanges.

Store the specimen

28. When ready for final storage, transfer the specimens to glycerol (with a few crystals of thymol to prevent mold growth). Store indefinitely at room temperature.

ANALYSIS AND INTERPRETATION OF DATA

SUPPORT PROTOCOL 6

This protocol addresses statistical considerations and data-interpretation issues that are especially pertinent to the Segment II and Chernoff/Kavlock studies. This is not intended to be comprehensive, but to present general concepts and references.

Materials

Statistical software (e.g., SAS, GraphPad InStat, BenchMark Dose Software)

Compile the data

1. If not already captured automatically into an electronic format at the time of data collection, enter the data into a computerized format such as an ASCII file or a spreadsheet.

   For developmental data, use the litter (not the fetus or pup) as the basic experimental unit for statistical analysis. The number of offspring is inappropriate as the sample size, since litter mates are not biologically independent from each other (Gad and Weil, 1989).

2. In the study's database, identify each female (and litter) according to its treatment group, survival, and pregnancy outcome (live litter, resorbed litter, or not pregnant). Also, identify dams with only one implantation site.
3. For each treatment group, tally the number of females that died, were not pregnant, or had only one implantation site. Exclude these females from subsequent analyses.

Calculate descriptive statistics

4. For continuous data (e.g., body weights) and counts (number of implantation sites), calculate descriptive statistics (mean ± standard error) for each treatment group. See Tables 13.5.1 and 13.5.2 for listings of endpoints.

5. For dichotomous or categorical data (e.g., male-female, live-dead-resorbed, affected-normal) calculate the percentage for each litter, then calculate the mean ± SE of the litter values.

   Determine the number and percentage of dams with full-litter resorption.

   For gestation lengths, determine the number and percentage of females delivering on each gestation day.

   For fetal-examination data, determine the incidences (number of litters per group, and each group's mean ± SE of the litter percentages) for each distinct finding, as well as for categories of related findings. Categorize findings based on syndrome, organ system, and etiology, as well as severity. For example, determine the incidence of "dilated urinary tract" as well as of each of the included findings of hydronephrosis, dilated renal pelvis, and dilated ureter.

6. Tabulate the group data.

7. Graphically represent the data as appropriate using, e.g., line graphs or bar graphs.

Calculate inferential statistics

8. Conduct appropriate inferential statistical tests (e.g., analysis of variance) to identify endpoints with significant differences between groups (Burg and Hardin, 1987; Gad and Weil, 1989; Kimmel and Price, 1990) Use appropriate multicomparison techniques (e.g., Tukey's method, least squares means, or Dunnett's test) to identify treatment groups that are significantly different from the control group.

   For gestation lengths, the authors recommend using the nonparametric Kruskall-Wallis test—i.e., rank the gestation lengths by the time and stage (just started, in progress, complete) that parturition was observed, and conduct an analysis of variance on the ranks.

   Use one-tailed tests for endpoints pertaining to survival (e.g., prenatal loss, postnatal loss).

   Analyze fetal-examination data for each distinct finding, as well as for categories of related findings (see Step 5).

   For fetal-examination findings with severity indicators (e.g., the score for the dilation of the renal pelvis), analyze incidences at each increasing level of severity (i.e., slight + moderate + severe; moderate + severe; severe).

   Use litter size as a covariate in the analysis of fetal or pup weight.

   Use the number of implantation sites as a covariate in the analysis of litter size.

   Use the number of corpora lutea as a covariate in the analysis of implantation sites.

9. Identify data points that are significantly different from controls on tables and graphs.

Interpret the data

10. Assess maternal toxicity according to the key endpoints, which include weight gain, food consumption, and clinical observations. Determine the dose levels associated with maternal toxicity and its relative severity.

    For clinical observations (e.g., behavioral changes), consider their time of onset, duration, frequency, and severity.

    For body weight data, especially consider weight gains early in the treatment period (e.g., GD 6 to 7), i.e., before the growth of the uterine contents will contribute notably to the

Table 13.5.1 Endpoints in Segment II Studies

Source of data	Endpoint
Maternal	Body weight (each time point)
	Weight gain (each interval, but especially early in treatment period)
	Extrauterine weight gain[a]
	Food consumption (each interval)
Cesarean section	*Number per dam of:*
	Corpora lutea (not for mice)
	Implantation sites
	Live fetuses
	Dead fetuses
	Resorption sites (each type, and total)
	Non-live implantation sites (dead fetuses + resorption sites)
	Percent per litter of:
	Preimplantation loss [100 × (corpora lutea – implants) ÷ corpora lutea]
	Postimplantation loss [100 × (implants – live fetuses) ÷ implants]
	Live males (or females) [100 × male fetuses ÷ live fetuses]
Fetal examinations	*For each type of examination (external, visceral, and skeletal):*
	No. of affected fetuses per litter (for each abnormality)
	Percent affected fetuses per litter [affected ÷ examined]
	No. of litters affected (litter with at least one affected fetus)
	Percent litters affected [affected litters ÷ examined litters]

[a]Extrauterine weight gain = (last gestational weight) – (pre-treatment body weight) – (gravid uterine weight).

Table 13.5.2 Endpoints in Chernoff/Kavlock Assays

Source of data	Endpoint
Maternal	Body weight (each time point)
	Weight gain (each interval, but especially early in treatment period)
	Extrauterine weight gain[a]
	Food consumption
	Gestation length
Developmental	*Number per litter of:*
	Implantation sites
	Live pups on PD 1
	Live pups on PD 6
	Live male (or female) pups
	Affected pups (e.g., with a specific abnormality, such as tail defect)
	Percent per litter of:
	Prenatal loss [100 × (implants – live pups) ÷ implants]
	Postnatal loss [100 × (live PD 1 pups – live PD 6 pups) ÷ live PD 1 pups]
	Male (or female) pups [100 × live males ÷ live pups]
	Affected pups [100 × affected live pups ÷ live pups]

[a]Extrauterine weight gain = (last gestational weight) – (pre-treatment body weight) – (PD1 live-litter weight).

weight of the dam. Differences in weight gain later in gestation may reflect developmental, rather than maternal, toxicity.

Assess developmental toxicity as a function of maternal toxicity for each litter. For example, was there correlation between endpoints of maternal toxicity (e.g., maternal body weight loss) and developmental toxicity (e.g., reduced fetal weight)?

11. Assess developmental toxicity. Endpoints are listed in Tables 13.5.1 and 13.5.2.

    For Segment II studies, especially consider postimplantation loss, fetal weight, and fetal-examination findings.

    For Chernoff/Kavlock assays, especially consider gestation length, prenatal loss, postnatal loss, pup weight (PD 1 and 6), and pup-examination findings.

    Consider competing outcomes. For example, a high resorption rate may preclude detection of malformations, as susceptible conceptuses may resorb before reaching full term.

    Subjectively compare the data with historical control data (Haseman et al., 1984; EPA, 1991; Kimmel and Price, 1990). Consider the current controls to be representative of the species if the data are within the 95% confidence interval, rather than the extremes, of the historical data (Kimmel and Price, 1990).

12. Calculate the benchmark dose (EPA, 1995, 2000) for each endpoint affected by treatment. Use, for example, BenchMark Dose Software (see Internet Resources) to facilitate the calculations.

13. Enter the control data into a database of historical control data. Note any changes in laboratory procedure that may affect the data in this study as compared to previous studies.

REAGENTS AND SOLUTIONS

Use deionized, distilled water in all recipes and protocol steps. For common stock solutions, see ***APPENDIX 2A****; for suppliers, see* ***SUPPLIERS APPENDIX****.*

Alcian blue, 150 mg/liter

3.0 g Alcian blue 8GX (e.g., Acros Organics)
16 liters 95% ethanol
4 liters glacial acetic acid
Store at room temperature; discard if Alcian blue precipitates

CAUTION: *A fume hood should be used when working with the alcohols, aldehydes, or acetic acid. Ethanol solutions at concentrations greater than 70% are flammable; use appropriate precautions (e.g., metal containers or fire-safety cabinets).*

Alizarin red S, 25 mg/liter

500 mg Alizarin red S (e.g., Acros Organics)
20 liters 1% (w/v) potassium hydroxide (see recipe)
Store up to 6 months at room temperature, protected from light.

Ammonium sulfide, 2% (w/v)

Take 1 part 20% (w/v) ammonium sulfide (purchased, e.g., from Sigma) and add sufficient water for a total of 10 parts. Prepare fresh for each use.

Bodian's solution

950 ml glacial acetic acid
380 ml formaldehyde *or* 950 ml 10% formalin
14.4 liter 95% ethanol

continued

3270 ml tap or distilled water if formaldehyde is used *or* 2700 ml if 10% formalin is used
Store indefinitely at room temperature

CAUTION: *A fume hood should be used when working with the alcohols, aldehydes, or acetic acid. Ethanol solutions at concentrations greater than 70% are flammable; use appropriate precautions (e.g., metal containers or fire-safety cabinets).*

Bouin's solution

3000 ml saturated aqueous picric acid
1000 ml formaldehyde
200 ml glacial acetic acid
Store indefinitely at room temperature

CAUTION: *Dry picric acid is explosive and is sensitive to percussion and friction. Store picric acid powder in water; ensure that the water level is always above the powder. If picric acid crystals form at screw cap, apply water prior to removing cap. A fume hood should be used when working with aldehydes or acetic acid.*

Glycerol/70% ethanol, 1:1 (v/v)

1 part 70% ethanol
1 part glycerol

Store at room temperature; solution may be reused if not too dark.

CAUTION: *A fume hood should be used when working with the alcohols, aldehydes, or acetic acid. Ethanol solutions at concentrations greater than 70% are flammable; use appropriate precautions (e.g., metal containers or fire-safety cabinets).*

Glycerol/70% ethanol/benzyl alcohol, 2:2:1 (v/v/v)

2 parts 70% ethanol
2 parts glycerol
1 part benzyl alcohol
Store at room temperature; solution may be reused if not too dark; may become too alkaline after several uses

CAUTION: *A fume hood should be used when working with the alcohols, aldehydes, or acetic acid. Ethanol solutions at concentrations greater than 70% are flammable; use appropriate precautions (e.g., metal containers or fire-safety cabinets).*

Potassium hydroxide, 1% (w/v)

200 g potassium hydroxide (KOH)
20 liters distilled water
Store up to 6 months at room temperature

COMMENTARY

Background Information

The Segment II study was first promulgated in 1966 by the Food and Drug Administration (FDA, 1966) as part of a three-segment series of studies intended to test for toxic effects on fertility (Segment I), developmental toxicity (Segment II), and effects on parturition and lactation (Segment III). Since then, the Segment II study has been harmonized across international governmental regulatory agencies (ICH, 1994) and has undergone several enhancements (e.g., a longer treatment period, staining of cartilage in skeletal specimens), but remains much the same in basic study design.

The Chernoff/Kavlock assay was first developed in 1982 (Chernoff and Kavlock, 1982) as a preliminary screening assay in mice. Modifications to the protocol have been incorporated here, in EPA testing guidelines (EPA, 1996), and elsewhere (Hardin, 1987; Kavlock et al., 1987; Wickramaratne, 1987). As a screen, it is very useful in prioritizing potentially toxic agents for testing by the more rigorous (and costlier) Segment II protocol (Hardin, 1987; Hardin et al., 1987a,b; Kavlock et al., 1987; Seidenberg and Becker, 1987; Wickramaratne, 1987; Moore et al., 1995). Compared to the Segment II protocol, the Chernoff/Kavlock as-

say is less costly and requires considerably less technical expertise. Although the Chernoff/Kavlock protocol does not detect skeletal or visceral alterations, it is important to note that it can detect other adverse effects that a Segment II protocol cannot. Because of the postnatal component of the screening protocol, it can detect changes to other endpoints that are indicative of developmental toxicity, such as functional deficits (Lau et al., 2001), morphological changes that develop postnatally (Wier et al., 1987), and changes in gestation length (Rands et al., 1982; Narotsky et al., 1994; Narotsky and Kavlock, 1995; Narotsky et al., 2001).

Generally, these protocols detect three of the four major manifestations of developmental toxicity—i.e., they can identify agents that cause death, structural abnormalities, or growth deficits, but they are limited in their ability to identify agents that cause functional deficits. Protocols with longer postnatal assessments, including those focused on developmental neurotoxicity (EPA, 1998a) or multigeneration studies (EPA, 1998c) are generally more effective at detecting functional deficits.

It should be noted that many important aspects of both the Segment II and Chernoff/Kavlock protocols are beyond the scope of this unit and are not addressed in detail here. See published guidelines for further information regarding Good Laboratory Practices (FDA, 1997), the choice of species and strain, number of animals per group, dose selection, number and spacing of dose levels (EPA, 1991; ICH, 1994; EPA, 1998b), route and frequency of administration (ICH, 1994; EPA, 1998b), animal husbandry (ILAR, 1996), euthanasia methods (AVMA, 2001), and risk assessment (EPA, 1991). The guidelines on risk assessment (EPA, 1991) address several important issues regarding data interpretation, including the usage of historical control data and the relationship between maternal and developmental toxicity. In addition, other authors have provided excellent references regarding important issues in developmental toxicity testing, such as dermal absorption studies (Kimmel and Francis, 1990), and statistical analyses (Burg and Hardin, 1987; Gad and Weil, 1989; Kimmel and Price, 1990).

Critical Parameters and Troubleshooting

A variety of methods may be used to examine visceral specimens for soft-tissue defects. The methods generally fall into two categories: the Wilson free-hand razor section technique (Wilson, 1965; Barrow and Taylor, 1969; Wilson, 1973; Weber and Weber, 1991) and the microdissection technique (Nishimura, 1974; Staples, 1977; Stuckhardt and Poppe, 1984). Both techniques are effective in detecting visceral defects; however, with adequate training, the Wilson sectioning method has been suggested to be more sensitive at detecting certain cardiac defects (Christ et al., 1991). The Wilson method must be performed on specimens fixed in Bouin's or Bodian's solution. The head is best examined with the Wilson method. Although labor-intensive, microdissection is preferably conducted with fresh specimens; this is also compatible with subsequent skeletal examination of the carcass. Alternatively, to accommodate a smaller workforce, the specimens may be fixed at the time of cesarean section,

Table 13.5.3 Example of Data Summary for a Segment II Study with Rats[a]

Dose (mg/kg/day)	0	100	200	400
No. of dams	19	13	19	15
Dams with full-litter loss	0	0	0	1
Mean ± SE per dam

allowing either microdissection or sectioning of the preserved specimens.

Although some regulatory guidelines suggest categorizing fetal examination findings as malformations or variations, or categorizing based on severity (major malformations, minor malformations) it should be noted that there is no generally accepted classification of malformations and variations. Furthermore, there is no scientific justification for using such classification. Instead (or in addition), the authors recommend categorizing findings based on syndrome, organ system, and etiology.

When conducting developmental toxicity studies, it is essential to have high pregnancy rates in the test animals. Pregnant animals can be obtained by breeding them in the test facility, or by purchasing timed-pregnant animals from an animal supplier. The latter approach allows some scheduling flexibility in that a larger number of test animals can be bred on the same day. However, disadvantages of buying timed-pregnant animals include the fact that the animals are subject to the stress of shipping during the preimplantation period of pregnancy (possibly contributing to low pregnancy rates) and that a quarantine period may be impossible, in addition to the increased cost.

Anticipated Results

Uterine findings

Table 13.5.3 presents an example of uterine-findings data from a Segment II study (Narotsky et al., 1994). In this example, no significant differences between groups were noted for the numbers of corpora lutea, implantation sites, or live fetuses. More importantly, the values for pre- and post-implantation loss were also comparable between groups. The values for fetal weight, however, indicated significant dose-related reductions at dosages of 200 and 400 mg/kg. Therefore, based on the fetal weight data, the test agent in this example was developmentally toxic at 200 and 400 mg/kg. On the basis of this study alone, it is unclear whether the isolated case of full-litter resorption at 400 mg/kg was treatment-related.

Skeletal findings

An example of findings from fetal skeletal examinations in a Segment II study (Narotsky et al., 1994) is presented in Table 13.5.4. Findings consistent with delayed development at dosages of 200 and 400 mg/kg include reductions in ossification (e.g., of the calvaria, hyoid, supraoccipital, sternebrae, metacarpals, phalanges, and caudal vertebrae) and an increased fontanel score. Findings indicating a toxic, and

[b]Adjusted for weight of live litter on PD 1.

[c]Includes one dam that died at term and two that died during lactation.

dose-related, effect on the development of the axial skeleton include lumbar ribs at dosages of 200 and 400 mg/kg, extra cervical ribs, extra (>26) presacral vertebrae, and rib and vertebral malformations at dosages of 400 mg/kg. Although the incidences of rib and vertebral malformations (fusion, duplication, misarticulation) did not reach statistical significance, they were attributed to treatment.

Visceral findings

Table 13.5.5 gives an example of fetal visceral examination findings in a Segment II study (Narotsky et al., 1994). Significant, dose-related increased incidences of dilated renal pelvis (also reflected by kidney scores) indicated a toxic effect at 200 and 400 mg/kg. Sporadic, non-dose-related malformations (ventricular septal defect, microphthalmia, micrognathia, cleft palate) were not attributed to treatment.

Chernoff/Kavlock assay

An example of a data summary from a Chernoff/Kavlock assay (Narotsky et al., 1995) is presented in Table 13.5.6. In this example, dose-related maternal toxicity at 9 and 12 mg/kg was evidenced by adjusted gestational weight gains (weight gain from GD 6 to 20, minus the live PD 1 litter weight). Maternal toxicity is also evident at 12 mg/kg, as indicated by significant weight losses early in the treatment period (GD 6 to 8) and by maternal deaths at term and during lactation (see footnote to Table 13.5.6). Developmental toxicity was evidenced by significantly increased postnatal loss at both 9 and 12 mg/kg dosages. Although pup weights were unaffected at dosages of 9 mg/kg, reduced pup weights at 6.8 and 12 mg/kg were attributed to treatment. Therefore, in this example, maternal toxicity was evident at 9 and 12 mg/kg; whereas developmental toxicity was evident at 6.8, 9, and 12 mg/kg. Pups with eye defects (anophthalmia or microphthalmia) occurred in one litter in each of the 6.8- and 12-mg/kg groups; based on this study alone, it was unclear whether this finding was treatment related.

Time Consideration

Typically, the in-life phase of a Segment II study (see Basic Protocol 1) or a Chernoff/Kavlock assay (see Basic Protocol 2) is ~3 to 5 weeks for mice and ~4 to 6 weeks for rats, depending on the time required to obtain sufficient mated animals for the study. The number of mated animals obtained on a given day should not exceed the number of animals that the available workforce can accommodate in one day, particularly for labor-intensive tasks such as cesarean sections. The time required to complete the cesarean sections (see Support Protocol 1) in a Segment II study may range from 1 day to 2 weeks, depending on the time required to obtain sufficient mated animals for the study. Examinations of apparently nongravid uteri (see Support Protocol 2) are done in conjunction with cesarean sections as well as Chernoff/Kavlock assays and generally require <1 hr on a given day. Preparation of fetal skeletal specimens (see Support Protocol 4) requires a minimum of 7 days; however, the ethanol fixation period is typically extended until a Monday or Tuesday so that the succeeding steps can be completed during a standard work week. The time required to complete the examinations of fetal visceral (see Support Protocol 3) and fetal skeletal specimens (see Support Protocol 5) may range from weeks to months, and is dependent on the number of specimens, the extent of the fetal abnormalities, the data-recording system, and the size and skill of the workforce.

Organ Culture of Midfacial Tissue and Secondary Palate

Palatogenesis presents an interesting model for many of the processes involved in morphogenesis in the embryo. The formation of the secondary palate requires neural crest cell migration, interaction of the palatal cells with the surrounding extracellular matrix, interaction and signaling between epithelial and mesenchymal cells, adhesion and fusion of morphological structures—which also involves cell death and transformation of cells from epithelial to mesenchymal phenotypes—and finally, differentiation into bone and stratified oral and ciliated nasal epithelia. A number of culture models are used to study these processes, including whole embryo culture, mesenchymal and micromass cell cultures, epithelial cell culture, and palatal organ culture (Tyler and Pratt 1980; Thesleff, 1981; Ferguson et al., 1984; Whitby, 1987; Pisano and Greene, 2000). A suspension palatal organ culture technique is described in this unit.

The suspension palatal organ culture method requires dissection of embryonic midfacial tissues, including the maxillary arch and secondary palatal shelves, and suspension of these "explants" in culture medium. Normal processes of palatogenesis occur during the culture period, including palatal shelf growth, elevation, and fusion. The suspension palatal organ culture model provides a tool for studies of mechanisms of normal and abnormal palatogenesis, and has applications for developmental biology and toxicology.

SUBMERGED PALATAL ORGAN CULTURE OF MOUSE MIDFACIAL TISSUES

BASIC PROTOCOL

This palatal organ culture protocol supports the outgrowth, elevation, and fusion of secondary palatal shelves. This protocol describes the dissection of the embryonic craniofacial tissue and preparation of culture medium. It specifies the gas mixtures and equipment required, the schedules for refreshing medium and gases, and the basic criteria for evaluation of the results. Modifications to the Basic Protocol are required to culture embryonic rat midfacial tissues (see Alternate Protocol). Modifications are also recommended to improve the growth and fusion of the palatal shelves (some species and strains may require adjustments to the basic model) and to support responsiveness to specific test agents (e.g., in some situations, supplementation of medium with serum may be necessary).

NOTE: All protocols using live animals must first be reviewed and approved by an Institutional Animal Care and Use Committee (IACUC) and must follow officially approved procedures for the care and use of laboratory animals.

NOTE: All solutions and equipment coming into contact with tissues to be cultured must be sterile and aseptic technique should be used accordingly. Filtration to sterilize the final solutions is performed in the laminar flow hood. Sterile media, supplements, and treatments are combined prior to culture in the laminar flow hood using sterile equipment and aseptic technique. Collection of fetuses from the dam may be performed at the laboratory bench; however, dissection of fetal tissues to be cultured, the transfer to culture flasks, and gas addition to the flasks should all occur in the laminar flow hood. All subsequent medium or gas exchanges, and any interim examination of cultures must occur in the laminar flow hood.

Current Protocols in Toxicology (2003) 13.6.1-13.6.11

Materials

Supplemented custom-modified Biggers BGJ medium (see recipe)
Dimethylsulfoxide (DMSO)
Chemical to be tested
Penicillin/streptomycin solution: 10,000 U penicillin G with 10 mg streptomycin/ml
Medical gas mixture tank of 50% O_2, 5% CO_2, 45% N_2
70% ethanol
Phosphate-buffered saline (PBS; see recipe)
Time-mated, gestation day (GD) 12 pregnant female mice (mated overnight, next morning plug-positive, confirmed mating = GD 0)

Rocker platform with adjustable tilt rate (side-to-side motion) to fit in incubator
37°C culture incubator
25-cm^2 (75-cm^2 for rat) tissue-culture flasks with tight-fitting caps (e.g., 70-ml capacity, Corning)
0.2-µm syringe filters
1-, 5-, and 10-ml syringes
Two-stage gas regulator, suitable for use with pressurized oxygen
Laminar flow hood (must be operable with door open or have ports for microscopes)
Disposable 1-ml plastic transfer pipets with bulbs, sterile
Dissecting stereo microscope(s)
Fiber-optic illuminator(s)
Gauze pads
Dissection pad (cut a black rubber stopper, size no.12 or other suitable dark rubber pad, horizontally to provide ½-in. height, sterilized by storing in a beaker of 70% ethanol)
60-mm petri dishes
Dumont forceps no. 5, stainless steel (at least 2 pairs, have extra on hand and be aware that these points are easily damaged even in routine use)
3-in. Vannas ultra-microscissors straight (Roboz Surgical or equivalent spring-loaded iridectomy scissors with very fine small blades)
Disposable no. 11 scalpels
5-in. micro-dissecting spatula (Roboz or equivalent)
4-in. dissecting forceps serrated, curved
4¼-in. curved, blunt-tip microdissecting scissors
4-in. curved, sharp-tip microdissecting scissors
5-in. straight hemostatic forceps, delicate, flat mosquito jaw (Roboz or equivalent)
Vacuum flask and vacuum hose
5-, 10-, and 25-ml disposable pipets, sterile
Vacuum pipettor

Prepare for culture

1. At least 24 hr prior to culture setup, place the rocker apparatus in the incubator and turn on, then adjust rate to provide ~15 tilts per min (left side up, moves down, and returns to original up position = 1 tilt).

   The motor will increase the temperature of the incubator chamber. Check after operation for several hours and adjust incubator temperature controls to maintain 37°C with the rocker on. Leave rocker on until completion of culture period.

2. Measure 9 ml of supplemented custom-modified Biggers BGJ medium for each 25-cm^2 flask to be prepared in step 7 into a sterile tube of appropriate volume.

   One tube will be prepared for each control and treated group.

3. Prepare 1000× stock solutions in DMSO of chemical to be tested and sterilize by filtration (for small volumes, use a syringe and 0.2-µm low-volume syringe filter).
4. Add 1 µl DMSO solvent per milliliter of supplemented custom-modified Biggers BGJ medium into the tube corresponding to the control-group flask (0.1% DMSO final).
5. Add 1 µl of the 1000× treatment stock solution of the chemical of interest per milliliter of supplemented custom-modified Biggers BGJ medium into each tube corresponding to each treated-group flask.
6. Add 5 µl penicillin/streptomycin solution per milliliter of supplemented custom-modified Biggers BGJ medium into each tube (final concentration = 50 µg streptomycin/ml and 50 U penicillin/ml).
7. Label 25-cm^2 culture flasks and transfer 9 ml of control or treated medium from each tube to its corresponding flask.

Set up for gas delivery

8. Connect the two-stage regulator to the medical gas mixture tank of 50% O_2, 5% CO_2, and 45% N_2.
9. Attach plastic tubing to the outflow valve of the regulator and position the open end of the gas tubing in the laminar flow hood.
10. Attach a sterile 0.2-µm syringe filter to the end of the gas tubing.
11. Cut the bulb off a sterile, disposable 1-ml plastic transfer pipet and attach the tapered 4-in. long pipet stem to the outflow side of the 0.2-µm syringe filter connected to the gas tubing.
12. Adjust gas flow on the regulator and direct a stream of gas through the tubing, filter, and pipet stem into the flask.

    The gas flow rate should be sufficient to agitate the medium.

13. Flush the air from the flask by streaming gas for 10 to 15 sec, replacing all the air with the gas mixture. Withdraw the pipet and immediately cap the flask tightly.
14. Place flasks horizontally on a raised platform inside the laminar flow hood workspace. Loosen cap but leave it resting over flask opening. Place several flasks at a time on the rack. If possible, have one flask of each treatment on the rack, as this permits loading of tissues from each litter across a block of treatment groups.

    Elevating the neck of the flask makes it easier to place tissues inside the flask. A test tube rack works well as a platform.

Prepare dissection area and tools

15. Place dissecting microscope(s) and fiber-optic illuminator(s) in laminar flow hood.
16. Place sterile gauze pads adjacent to microscope, on stage/platform and have additional gauze pads available in a convenient position in the hood.
17. Place dissection rubber pad on gauze, cover with another gauze pad, and soak gauze with 70% ethanol to sterilize.
18. Place the following dissecting instruments on gauze on each side of microscope in the laminar flow hood, cover with additional gauze, and soak with 70% ethanol to sterilize: Dumont forceps no. 5, spring-loaded iridectomy scissors with very fine small scissor blades (3-in. Vannas ultra-micro scissors, straight, for mouse), disposable no. 11 scalpels, and 5-in. micro-dissecting spatula.

19. Prepare a clean, absorbent paper–covered station to sacrifice the dam.
20. Add 2 to 3 ml sterile PBS to petri dishes (1 dish per litter) and place on ice.
21. Add 70% ethanol to small beaker and place dissection instruments in beaker: 4-in. serrated, curved dissecting forceps; 4¼-in. curved, blunt-tip microdissecting scissors; 4-in. curved, sharp-tip microdissecting scissors; and 5-in. straight hemostatic forceps.

Sacrifice dam and remove uterus and conceptuses

22. Euthanize time-mated (GD 12) pregnant female mice by CO_2 asphyxiation and/or cervical dislocation, according to methods approved by the Institutional Animal Care and Use Committee.

    Donovan and Brown (1995) describes the abovementioned euthanasia procedures in detail.

23. Place dam on its back and soak abdomen with 70% ethanol. Grip and lift abdominal skin with dissecting forceps, then with sharp-tip dissecting scissors, cut through skin and muscle.
24. Continue to open the abdomen through the diaphragm and rib cage. Cut lateral to midline to expose abdominal organs fully.
25. Moving the other organs aside, grip the cervical region at the base of the uterine horns and cut through the cervical tissue. As the uterine horns are raised, use the scissors to strip excess fat away from the uterus.
26. With the forceps, lift the uterus free from the abdomen and, if needed, cut at the site of each ovary to release. Place the intact uterus with contents on gauze pads.

Remove embryos from uterus

27. Clamp the tip of one uterine horn with the hemostatic forceps and lock forceps closed by engaging the clips on the handles.
28. With forceps, extend and slightly stretch the uterine horns to a linear position on the gauze, holding one end with the hemostat and the other with the forceps.
29. Use the blunt-tip dissecting scissors to open the uterus at the end furthest away from the hemostat clamp. Insert the blunt tip into the incision in the uterus near a conceptus and cut the uterine wall, cutting towards the hemostat-clamped end.
30. Cut on the other side of the cervix to open the second uterine horn.

    With practice, this method allows a rapid opening of the uterus, which exposes all of the conceptuses with yolk sac, extra embryonic membranes, and fluids intact.

31. Gently remove the conceptuses, individually, by sliding the curved forceps beneath the conceptus between the placenta and uterine wall, lifting the intact conceptus, and placing it into the PBS in the petri dish. Keep the dish covered as much of the time as possible.

    A second pair of forceps will be helpful to hold the uterus down while pinching off each conceptus.

32. After all conceptuses are transferred to the dish, place on ice, and move to the laminar flow hood for the dissection of fetal tissues.

    The petri dishes on ice can be kept just outside the hood.

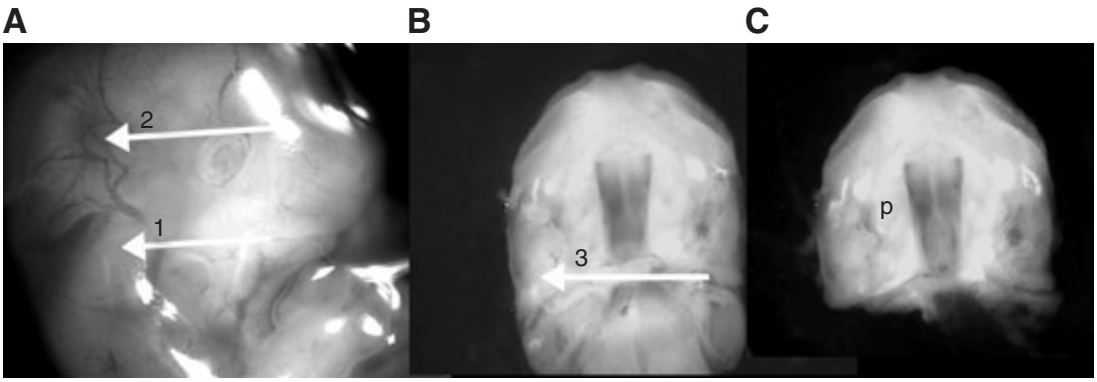

Figure 13.6.1 The gestation day 12 mouse head (plug day = 0) is shown before dissection for palatal organ culture. (**A**) The first incision is made as shown for arrow 1 through the oral cavity to separate mandible from head. The second incision is shown along arrow 2 to remove the upper cranial tissue. (**B**) After turning the midface over, exposing the palatal shelves, a final cut is made as indicated by arrow 3 to remove remaining hindbrain tissues. (**C**) The resulting midfacial region is placed in culture. The letter p indicates a palatal shelf.

Dissect mid-craniofacial region

33. Place the petri dish in the hood to open and remove one embryo at a time. Place the embryo on the black rubber platform.
34. Use two Dumont forceps to remove yolk sac, amnion, and placenta.
35. Use the Vannas ultra-microscissors to cut off the mandible and top of the head (see Fig. 13.6.1A). Insert one blade of the microscissors into the oral cavity and the other blade across the outside of the face, cut to separate the mandible and neck from the upper head.

    Forceps placed at the back of the head can be used to brace or hold head in position during the cut.

36. Make a second cut at the level of the eye to remove the upper brain tissues. Push the other tissues aside and turn the midface over, exposing the palatal shelves.
37. Trim off excess tissues and remove hindbrain tissue with a scalpel by cutting at the level of the posterior palatal shelves (see Fig. 13.6.1B).

    If any mandible, tongue, or hindbrain remains, trim off. Eyes will remain on the final midfacial explant that is now ready to transfer to the culture flask (see Fig. 13.6.1C).

38. Transfer midfacial explant by sliding a dissection spatula under the explant, pressing down on the rubber mat to assist in pickup. Open cap of flask (from step 14) and insert the spatula until it touches the medium and the tissue floats off the spatula.
39. Continue to dissect embryos from the litter until completed, or up to 30 to 35 min. Discard any embryos that are not processed within this period of time.
40. Distribute embryos from each litter across the treatment groups/flasks by placing several flasks on the platform to receive tissues in sequence as the dissections occur. Put up to four tissue samples per flask.
41. Continue to sacrifice dams as needed. After 1 hr of dissections, or when all flasks are loaded with tissues (if completed in <1 hr), flush each flask with the gas mixture as in step 13 (10 to 15 sec gas flow in each flask) and cap tightly.
42. Place flasks on the rocker platform in the 37°C incubator.

    If necessary, continue collecting tissues and repeat steps above for up to 3 to 4 hr.

Change culture medium and exchange gas

43. Replace medium and flush flasks with the gas mixture 24 hr after set up and each 24 hr thereafter.

    In most cases, the treatments are also included with the fresh medium.

44. Prewarm the supplemented custom-modified Biggers BGJ medium with DMSO solvent or treatment and penicillin/streptomycin added (as in steps 2 to 6) complete in a 37°C water bath.

45. Remove medium from flask by pouring into a beaker or by suction (keep tissues inside flask).

    For removal by suction, prepare a vacuum flask to trap the medium as it is removed. Cut a sterile, disposable transfer pipet and attach it to the end of the vacuum hose to provide a clean suction tip to place into each culture flask. Replace the pipet between treatments, if not between each flask. Although several flasks can be processed before replacing medium, try not leave tissues for more than a few minutes without medium in the flasks.

46. Pipet 9 ml fresh prewarmed medium into each flask.

47. Flush each flask with the gas mixture as in step 13 and replace on the rocker in the 37°C incubator.

    Cultures can be maintained 4 to 5 days or until palatal fusion occurs. Palatogenesis schedule and thus duration of culture depends on strain of mice chosen for cultures.

Evaluate tissue

48. At intervals during culture and at the end of culture, examine the explants under a dissecting microscope to track progress of palatal elevation and fusion.

    Palates that are attached cannot be separated even by gentle pulling with Dumont forceps on the primary palatal edges. A palatal seam will remain intact and the adjacent tissue will tear if sufficient force is used.

ALTERNATE PROTOCOL

SUBMERGED PALATAL ORGAN CULTURE OF RAT MIDFACIAL TISSUES

Rat strains differ in their requirements for successful fusion of the palates in culture. Fisher 344 rats perform well under the same conditions as the mice (four explants in 9 ml of medium for 4 to 5 days). Sprague-Dawley and CR/Lewis rats require larger, 75-cm^2 flasks with 50 ml of medium, where each flask can hold up to ten explants. The equipment, supplies, and reagents required are the same as for mouse, with the exceptions noted below. The protocol for preparation of the cultures is also the same as for mouse except as noted.

Additional Materials *(also see Basic Protocol)*

Time-mated, gestation day (GD) 14 rats (mated overnight, next morning plug-positive, confirmed mating = GD 0)

75-cm^2 tissue-culture flasks, canted-neck plug seal (caps must form gas-tight seal, no ventilated filter caps)

Vannas ultra-microscissors (spring-loaded iridectomy scissors), with slightly larger blades than used for mouse

For rat palatal organ cultures, supplemented Biggers BGJ medium (prepared as described for mouse cultures; see recipe) is supplemented with 1×10^{-11} M all-trans retinoic acid. The CR/Lewis rat palates also have a higher percentage of explants fuse if the gas is changed on day 4 to 95% O_2, 5% CO_2 and the flasks are flushed with the gas in the morning and late afternoon on day 4. Tissues are scored the next morning (day 5).

REAGENTS AND SOLUTIONS

Use Milli-Q purified water or equivalent in all recipes and protocol steps. For common stock solutions, see ***APPENDIX 2A****; for suppliers, see* ***SUPPLIERS APPENDIX****.*

All-trans retinoic acid, 1×10^{-2} M

Dissolve 3 mg retinoic acid (RA) per milliliter of filtered DMSO (final 1×10^{-2} M). Dispense into 0.1-ml aliquots into amber vials. Protect from light, store up to 1 year at −80°C.

Dilute stock with DMSO in serial dilutions as required for treatments or as a supplement to medium. Add 1 µl RA/ml medium (DMSO = 0.1%).

Apo-transferrin, 10 mg/ml

Dissolve 20 mg apo-transferrin in 2 ml sterile, distilled water. Dispense into 200-µl aliquots per 1.5-ml sterile tube. Store 10 mg/ml stock up to 1 year at −20°C.

Custom-modified Biggers BGJ medium, 1×

Reconstitute a 5-liter powder package of modified Biggers BGJ medium (see Table 13.6.1 for composition; the custom medium is supplied by Irvine Scientific) per supplier's instructions for a final concentration of 1× by adding powdered medium slowly to 4 liters distilled, deionized water with stirring. Add 14 g sodium bicarbonate and bring up to 5 liters with distilled, deionized water. Check pH (pH 7.0 to 7.5) and osmolarity (265 to 300 mOs/kg). Filter sterilize using 0.2-µm nylon or cellulose acetate filters. Store liquid medium up to 6 months at 4°C.

Bottle filter systems and autoclaved sterile glass bottles or filter units with 500-ml or 1-liter plastic storage flasks can be used for sterilization and storage.

Supplemented custom-modified Biggers BGJ Medium: Prior to use, measure 100 ml of 1× custom-modified Biggers BGJ medium with sterile graduated cylinder and

continued

Table 13.6.1 Custom-Modified Biggers BGJ Formulation[a] (with L-Glutamine 150 mg/ml, without $NaHCO_3$)

Ingredient	mg/liter	Ingredient	mg/liter
Sodium chloride	6400	*p*-Aminobenzoic acid	1.5
Potassium chloride	425	Ascorbic acid	150
Glucose (dextrose) anhydrous	4400	Nicotinic acid amide	15
Calcium lactate·$5H_2O$	600	Phenol red, Na salt	17.04
L-Arginine HCl	70	Thiamine HCl	3
L-Cysteine HCl·H_2O	135	α-Tocopherol phosphate, 2Na	0.75
L-Glutamine	150	Potassium phosphate, monobasic KH_2PO_4	113
L-Histidine HCl·H_2O	150	Magnesium sulfate, anhydrous $MgSO_4$	161.17
L-Isoleucine	23	Choline chloride	38
L-Leucine	40	Folic acid	0.15
L-Lysine HCl	225	Inositol	0.15
L-Methionine	40	Riboflavin	0.15
L-Phenylalanine	40	Vitamin B-12	0.03
L-Threonine	60	D-Biotin	0.15
L-Tryptophan	30	Pantothenic acid, Ca salt	0.15
L-Tyrosine 2Na·$2H_2O$	43.25	Pyridoxal HCl	0.15
L-Valine	50		

[a]Adapted from Shiota et al., 1990. The custom-modified Bigger BGJ formulation is supplied by Irvine Scientific.

pour into sterile plastic flask. Add 15 mg L-glutamine, cap flask tightly, and mix by inversion. Add 600 mg bovine serum albumin per milliliter of medium, cap flask tightly, and mix by gentle inversion. Filter sterilize supplemented medium using 0.2-µm nylon or cellulose acetate filters. Store up to 2 weeks at 4°C.

Additional supplements for the culture medium can include the following (also see Critical Parameters and Troubleshooting):

5 µl/ml sodium L-ascorbate solution (final 50 µg/ml; see recipe)
1% (v/v) fetal bovine serum (50% stock, 20 µl/ml medium; see recipe)
1 µl/ml sodium selenite solution (final 10 ng/ml; see recipe)
1 µl/ml apo-transferrin (final 10 µg/ml; see recipe)
L-Glutamine can be increased four times the normal level
All-trans retinoic acid (final 1×10^{-11} M; see recipe)

Fetal bovine serum, 50%

Dilute 1:1 (v/v) FBS with custom-modified Biggers BGJ medium (not supplemented, see recipe). Dispense into 3- to 5-ml aliquots per tube. Filter sterilize using 0.2-µm nylon or cellulose acetate filters. Store ≥1 year at −20°C.

Phosphate-buffered saline (PBS)

Calibrate a 4- to 6-liter Erlenmeyer flask by measuring 4 liters water with a graduated cylinder and add to flask, mark the 4-liter level on the side of the flask, and decant the water.

Add 3 liters distilled water to the Erlenmeyer flask. Weigh and add to water the following while stirring with a magnetic stir bar:
35.04 g NaCl
1.38 g $NaH_2PO{\cdot}H_2O$ (monobasic)
8.04 g $Na_2HPO_4{\cdot}7H_2O$ (dibasic)
Add distilled H_2O up to the 4-liter mark
Adjust pH to 7.4 with 1 N NaOH
Filter sterilize with a 0.2-µm filter and store in sterile 500-ml flasks ≥1 year at 4°C

Sodium L-ascorbate

Dissolve 200 mg sodium L-ascorbate in 20 ml sterile, distilled water
Dispense into 1-ml aliquots per 1.5-ml sterile tube
Store 10 mg/ml stock ≥1 year at −20°C

Sodium selenite

Dissolve 5 mg sodium selenite in 5 ml sterile, distilled water
Dilute 1:100 to give 10 µg/ml stock
Dispense 10 µg/ml solution into 1-ml aliquots per 1.5-ml sterile tube
Store aliquots ≥1 year at −20°C

COMMENTARY

Background Information

Clefts of the secondary palate are among the most frequent birth defects in live-born human infants. Across the United States in 1997, a compilation of data from states with birth defects monitoring programs (National Birth Defects Prevention Network, 1997) showed the incidence of cleft palate without cleft lip to range from 2.01 to 14.2 per 10,000 live births. Thus, the formation of the secondary palate and the mechanism for induction of cleft palate has been the focus of extensive research. Palatogenesis also presents an interesting model for many of the processes involved in morphogenesis in the embryo.

Several palatal organ and cell culture methods have been developed and some are discussed in review and overview articles (Thesleff, 1981; Whitby, 1987; Pisano and Greene, 2000). The major palatal organ culture

models include a model in which the palatal shelves are isolated and cultured on a membrane support (Tyler and Koch, 1975; Ferguson et al., 1984) and a model in which the midfacial region, including the maxillary arch, is submerged in medium in a culture flask (Lewis et al., 1980; Shiota et al., 1990; Abbott and Buckalew, 1992; Al-Obaidi et al., 1995). The system in which the palatal shelves are supported on a membrane above the medium, a Trowell-like palatal organ culture, requires skill to dissect and orient the palatal shelves. This method also requires organ culture dishes with a chamber to support the grids and membranes. Although successfully applied by many investigators in studies of chick, alligator, mouse, rat, and human secondary palatal shelves, this approach is not described in this unit (Ferguson et al., 1984; Abbott and Pratt 1987a,b; Abbott and Birnbaum, 1990, 1991).

The culture technique described here (see Basic Protocol) is the submerged culture of the entire midfacial region. This method can be performed with relatively standard culture equipment and supplies and is simpler to perform than the supported organ cultures. This model also offers several advantages over the membrane-supported palatal culture system as it permits the palatal shelves to grow, elevate, and fuse in the culture medium. The protocol presented here is a modification of a method initially described by Shiota et al. (1990). The modifications include simplifying the dissection and performing the culture in disposable flasks on a rocker platform, as well as suggesting adjustments to the culture medium supplementation, volume, and schedule for replacing medium as needed for each species, strain, or test agent. These modifications facilitated the performance of large studies and were successfully applied to mouse, rat, or human specimens (Abbott and Buckalew, 1992; Abbott et al., 1993, 1994, 1996, 1998, 1999; Shuey et al., 1994).

Critical Parameters and Troubleshooting

Developmental staging and schedule for tissue collection

Mice can be mated overnight and checked for sperm plug the next morning, which is designated GD 0. The palatal shelves appear as outgrowths of the maxillary arch between GD 11 and 11.5. The palatal shelves should be clearly visible on GD 12 (Theiler stage 20 or Carnegie stage 17) and should be vertical in orientation. A similar developmental stage for rats is found on GD 14. Be aware that different strains of mice (and even the same strain in different breeding colonies) may differ by as much as 6 to 12 hr in developmental staging. Confirm the best time for collecting tissues from the animals being used.

Maintaining tissue integrity

The embryos need to be removed from the uterus as quickly as possible. They remain in the best condition for up to 30 min on ice in PBS if the membranes and placenta stay attached. This leaves the circulatory system as intact as possible, with little or no blood loss from the conceptus before dissection. Any embryos that have ruptured yolk sac vasculature or are separated from the placenta should be dissected first. The petri dish is kept on ice to retain integrity of tissues as long as possible. The amount of time that passes between sacrifice of the dam and completed dissection of the tissues will also affect the quality of the cultures. Optimal outcomes are obtained when each litter requires <20 min to process and the cultures are completed and placed in the incubators within 1 to 2 hr after sacrifice of the first dam. Longer processing times may also produce good outcomes, but larger experiments require attention to the schedule and may need two experienced researchers. With practice, two skilled researchers can prepare 80 to 90 explants for culture in ~1 hr. It is not recommended to use any embryos that are on ice >30 min.

Factors affecting rate of palatal fusion in control cultures

A number of factors can affect the numbers of explants that fuse by the end of the culture period. Obviously, the control cultures need to be maintained long enough to permit fusion of most or all of the explants. Initially, it may be desirable to allow some flasks to remain in culture, observing daily, until all explants are fused or until no additional fusion events occur. This will define the duration required for the optimal control fusion rates. There are other factors that affect the numbers or rate of palatal fusion and some of these can be manipulated to improve the outcome. These variables include the size and number of explants per container, the volume of medium, and the vessel selected for the cultures (roller bottle versus flask). The limiting factors that are common for all of these variables are likely to be the availability of nutrients and, probably even more of

a determinant, the oxygenation of the medium. The authors' observations during variations of these factors were that too many explants, too low a medium volume, too small a vessel, and infrequent medium or gas exchanges all resulted in poor growth and fusion. In experiments, the flasks produced better results than roller bottles, and changing medium and gas daily was an improvement relative to less frequent exchanges (although every other day may be sufficient for some cultures). However, each of these variables can be manipulated as required to optimize cultures for specific strains and species.

Issues related to prevention of contamination

Bacterial and fungal contamination are generally a result of poor sterile technique and can be avoided by careful decontamination of all surfaces and instruments, and use of sterilized reagents. Filter sterilization should always be done with 0.2-μm pore size filters. All glassware should be covered with aluminum foil and autoclaved with indicator tape to show that effective levels of sterilization temperatures and times were attained. All equipment, instruments, and hood and incubator surfaces should be routinely decontaminated and sterilized with 70% ethanol. Perform as many of the procedures as possible in a laminar flow hood. Wear gloves and change them whenever there is a chance that the surfaces are contaminated. Even the water bath that is used to warm the medium needs to be as clean as possible. Once contamination occurs, all the areas used for preparing and incubating the cultures need to be thoroughly decontaminated. Awareness and vigilance to prevent contamination are far better than solving the problem after contamination occurs.

Customizing medium formulation with optional supplements

Palatal shelves have normal development and fuse in the standard control medium without addition of the optional supplements. However, depending on the test compound, additional supplements may be required to provide responses to a toxicant that are similar to those observed after an in utero exposure. This seems to depend on the mechanism of action of the compound, as the secondary palatal shelves elevate and fuse in absence of these additives. Caution should be exercised with supplements to assure that normal palatal processes occur in the presence of the additives. Excess fetal bovine serum (>1%) can interfere with palatal fusion. Be aware that each new lot of serum, even if it is from the same supplier, needs to be tested in the model to confirm that it supports normal development.

Anticipated Results

The palatal shelves of the mouse craniofacial explants elevate and contact and fuse during the 4 to 5 days of culture. In experiments with CD1 mice, the incidence of fusion after 4 days in culture was 93% (i.e., 93% of all explants were completely fused). The remaining 7% of explants showed at least partial fusion after 4 days in culture. C57BL/6N mice exhibited similar results and responded to various teratogenic exposures (e.g., all-trans retinoic acid, 5-fluorouracil, methanol, ethanol, 2,3,7,8-tetrachlorodibenzo-*p*-dioxin, dexamethasone, hydrocortisone) with failure to fuse.

The outcomes for rat palatal shelves depended on the strain of rat. F344 rat explants cultured for 5 days adhered and 82% had fused palatal shelves. Sprague-Dawley and CR/Lewis rat palates needed larger flasks, more medium, and supplementation with low levels of retinoic acid. However, 80% of these palates fused if additional gas exchanges and higher oxygen were administered on the fourth day of culture.

Time Considerations

The preparations on the day of culture prior to sacrifice and tissue collection can require 1 to 1.5 hr depending on the experience of the operator and the scale of the experiment. The amount of time required for the sacrifice and dissections will be dependent on the number of flasks required for that experiment. Plan 3 to 4 hr (all morning or all afternoon) to conduct a typical experiment as outlined below. Generally, allow 15 min per litter. A typical experimental design includes 3 flasks (12 tissues) per treatment group. Allow four tissues per flask—for C57 strains, estimate an average of eight fetuses per litter; CD1 mice and most strains of rats will average ten or more embryos per litter. Thus, a control and three concentration levels of a treatment will require 12 flasks and 48 embryonic dissections from six litters. After initial setup, the subsequent medium and gas exchange for the flasks requires ~1 hr or less each day. Evaluating the tissues under the dissecting microscope generally does not require more than a few minutes per flask and subsequent fixation and/or processing of the

specimens will depend on the objectives of the study.

Overview of Behavioral Teratology

Four decades ago, a growing awareness of the potential central nervous system toxicity of many chemicals present in the environment led to extensive regulatory activity by governmental agencies in various countries, aimed at protecting populations from exposure to noxious agents. As a result, screening chemicals for possible neurotoxicity became mandatory. Among the analyses to be carried out in the neurotoxic hazard identification, behavioral teratology studies were recommended (WHO, 1986).

The discipline of behavioral teratology is based on the study of behavior as a powerful tool to identify and disentangle noxious effects of compounds known or suspected to be potentially neurotoxic early during development (Bignami, 1996; Cuomo et al., 1996; Kulig et al., 1996). Indeed, because behavior is the ultimate output of the brain, behavioral assessments can provide critical information on the noxious action exerted by selected chemicals—information that is different from, and complementary to, the information provided by neurochemical, cellular, and histological evaluations. In particular, behavioral assessments allow one to investigate the integrity of a number of brain processes, helping to identify selected structural and/or functional alterations. A large number of behavioral protocols are available that are rapid, simple, quantitative, easily replicable, and reliable as indices of brain dysfunction.

In the 1970s, the approach of classical neurotoxicology and neuroteratology, based exclusively on neuropathological and neurochemical analyses, shifted to a more comprehensive strategy that also included the study of behavioral parameters. The work by Joan M. Spyker on the deleterious effects on behavior of developmental exposure to methylmercury is considered the starting point of behavioral teratology (Spyker, 1975). This work takes into account important considerations on the use of behavioral analysis for risk assessment, providing useful working hypotheses concerning the significance and the nature of the behavioral effects observed.

The development of the discipline of behavioral toxicology and teratology has been marked by problems and difficulties concerning specific theoretical and methodological issues. For example, the concept of compensatory processes, which may or may not counterbalance and thus mask the adverse effects produced by exposure to a given noxious compound, should be carefully taken into account in order to minimize the risk of false negatives. Due to inadequate knowledge of several developmental events, most of the compensatory phenomena are not easily predicted and involve complex reorganizational processes that may occur at the neuroanatomical, neurochemical, or behavioral level. Since the development of diverse neural and behavioral systems is differentially timed, the ontogenetic analysis can represent a powerful strategy to investigate the effects of administering selected compounds on different brain functions prior to the occurrence of possible compensatory events. In fact, the literature provides examples that illustrate how selected developmental brain manipulations can induce transient phenotypic consequences that are not detectable later on, after compensatory events at a functional level have taken place (Ricceri et al., 1997, 1999).

From a methodological viewpoint, a controversial issue that characterized the initial phases of development of behavioral toxicology and teratology arose because most investigators were not aware of the importance of taking into account the litter effect, which is due to the nonindependence among observations taken on littermates. This nonindependence stems from the fact that pups tend to be more similar to each other within each litter than between litters, due to genetic and/or environmental/experiential factors (Alleva et al., 1985; Buelke-Sam et al., 1985; Chiarotti et al., 1987). Specifically, the litter, rather than the individual, represents the appropriate statistical unit in the data analysis. While parametric statistical methods generally allow one to easily manage the litter effect, particularly by mixed-model ANOVA designs, the nonparametric ones, which have to be applied when the distribution of the response variable does not respect the parametric assumptions, do not allow one to manage such an effect when working with complex experimental designs (for further considerations and for solutions aimed at minimizing the loss of statistical power, see Marascuilo and McSweeney, 1971; Winer, 1971; Chiarotti and Sparks, 2002).

BASIC CONSIDERATIONS IN BEHAVIORAL TERATOLOGY

Animal Species

Laboratory rodents are the animal species most commonly used in behavioral teratology studies. This is because using mice and rats provides numerous advantages: (1) ease of breeding and short gestation period, (2) large litter size (outbred mouse strains, such as Swiss CD-1, produce as many as 16 to 18 pups), (3) low maintenance costs due mainly to their relatively small size, (4) the availability of extensive background information on mouse and rat physiology and behavior, and (5) the fact that the mouse is the only species with a wide variety of inbred and noninbred strains that have specific characteristics and are easily amenable to genetic manipulations.

Primate species are also used in toxicology and teratology studies. Primates provide a major advantage compared to rodents: their high cognitive functions and their behavioral competencies, which are close to those of humans, make primates a highly appropriate model for selected in-depth analyses of potential human behavioral dysfunction due to exposure to neurotoxicants. However, both ethical considerations and cost suggest that the use of primates in scientific research should be strictly limited to cases in which a given problem cannot be solved otherwise. In fact, on the basis of primate physiology and behavior, it is supposed that these animal species are much more susceptible than others to psychophysical pain and stress.

The Ethological Perspective in Behavioral Studies

As Charles Darwin pointed out in his book *The Expression of Emotions in Man and Animals*, published in 1872, each species has evolved a species-specific behavioral repertoire shaped by its unique evolutionary history (Darwin, 1872). As a consequence, distinct species may react differently to the same stimulus or may manifest different behavioral displays as a response to the same internal drive (Crews, 1997; Katz and Harris-Warrick, 1999). Thus, the study of behavioral patterns of a given species should be carried out with consideration toward the ecoethological constraints that shaped them, since these can provide the appropriate contextual information for an accurate interpretation (Kamil and Mauldin, 1988; Martin and Bateson, 1993). This point is central to the ethological perspective in the study of behavior and should be carefully kept in mind in designing experiments as well as in interpreting data.

In order to score endpoints representative of specific behavioral competencies, experimental designs should be based on the manipulation of stimuli having a marked ecoethological relevance in the natural habitat for the species under investigation (Kamil and Mauldin, 1988; Alleva et al., 1995; Capone et al., 2002). Indeed, such relevance will determine the efficacy of the test. For instance, it has been shown that in a classical conditioning-avoidance paradigm, selected stimuli can be promptly paired, but others need repeated trials or prevent learning altogether. Rats can learn with a single trial to associate food with a nausea-inducing substance, thus developing a powerful conditioned aversion, but they require many trials to learn to avoid food associated with an electric foot shock. The relevance of this difference appears evident when considering the adaptive value of learning that allows rats to avoid eating a food that previously made them sick (Garcia and Koelling, 1966).

The wide use of animal models in neurotoxicology and teratology studies raises several issues concerning the comparison of selected behavioral responses between different species and the appropriate evaluation of the clinical relevance of behavioral alterations found in experimental models (Alleva and Sorace, 2000; Cenci et al., 2002; Watase and Zoghbi, 2003). Also in this case, the ethological perspective is an essential factor in reaching significant and reliable conclusions. For instance, in the study of behavior in animal models, the analysis of human-like symptoms in animals should be based primarily on a reasonable expectation of functional similarity of the displayed behavioral strategy, rather than on one of behavior equivalency. The crucial point is not whether a mouse would show a given behavioral impairment, but, rather, how a behavioral impairment would manifest itself in a mouse (Gerlai and Clayton, 1999; Cenci et al., 2002). Ethological studies have provided detailed descriptions of the mouse behavioral repertoire that allow an accurate analysis aimed at identifying deficits in specific behavioral abilities (Martin and Bateson, 1993; Alleva et al., 1995; Crusio and Gerlai, 1999; Crawley, 2000; Branchi and Ricceri, 2002).

Assessment of Multiple Behavioral Endpoints that Encompass Diverse Behavioral Competencies

It should be kept in mind that each behavior is a part of a complex repertoire. As a consequence, a selected behavioral competency cannot be correctly assessed without investigating different endpoints, since distinct behavioral competencies may influence each other in generating a selected behavioral response. For example, the performance of a mouse in a learning test is clearly related to its learning abilities, but a variety of other nonassociative factors, including emotional as well as stimulus and response factors, may exert an influence as great as or even greater than that of associative factors (Wolfer et al., 1998; van der Staay, 2000). Their performance in a plus-maze test is related to both their activity and their anxiety levels (Rodgers and Johnson, 1995; File, 2001). Furthermore, in order to exhaustively describe the rodent behavioral phenotype, a multitier strategy, comprising different levels of behavioral testing characterized by an increasing complexity of the responses scored, should be applied (Crawley, 2003). The lower tiers comprise the assessment of such simple behavioral and functional responses as reflexes, postures, motor coordination, and sensory abilities, among others. The higher tiers require a more complex behavioral approach, including testing of attention, anxiety, and learning and memory, which leads to a higher burden of appropriate controls aimed at avoiding erroneous inferences (e.g., confounding changes in associative and nonassociative functions in the case of learning and memory studies). This strategy allows one to exclude, or, on the contrary, to confirm, that impairments found in complex experimental situations may be due to deficits in simple physiological or behavioral functions, such as changes in response modulation or altered sensitivity to either signaling or reinforcing stimuli (Bignami, 1996; Rogers et al., 1997; Crawley, 2003).

Appropriate Test Strategies Should Be Applied at Each Age Phase

Mice and rats are altricial rodents: pups are born in a highly immature condition, with eyes and ears closed, after a short pregnancy (gestation lasts around 20 days, depending on the species and strain). At birth, they are able to crawl, to attach themselves to a nipple, and to suckle, yet they need close body contact with the mother because they are not able to thermoregulate. Several reflexes and behavioral responses appear at successive postnatal steps in parallel with somatic changes, progressively expanding pup sensory and motor capabilities (Bignami, 1996; Crawley, 2000). The subsequent, more complete behavioral repertoire increases the ability of the pup to procure food and fluid, especially after eye opening, which occurs around the end of the second postnatal week (Scott, 1953; Fox, 1965). The time of onset of selected somatic changes and the time of first appearance and subsequent complete maturation of various reflexes and responses show a remarkable regularity, providing effective tools to assess possible neurobehavioral developmental alterations (Bignami, 1996).

Thus, when exploiting behavioral studies during the first phases of development, Patrick Bateson's cardinal view of neurobehavioral development in mammals as a process akin to the metamorphosis of a caterpillar into a butterfly (Bateson, 1981), should be taken into account.

Mice Versus Rats: Species Differences Matter

The rat, in particular the *Rattus norvegicus* species, has been used in research since the mid-1800s (Sharp and La Regina, 1998). Since then, considerable knowledge on rat physiology and behavior has been produced, making this species historically the one most commonly used in the study of behavior. More recently, the mouse has been more and more extensively used in neurotoxicity and teratology studies, because of its smaller size and lower maintenance costs and because, among mammals, the mouse is the most amenable to genetic manipulations. As a consequence, many of the behavioral tests originally developed for rats began to be modified for use in mouse studies. However, in this process, the different species-specific competencies of rats and mice have not always received adequate consideration (Whishaw, 1995; Whishaw and Tomie, 1996; Frick et al., 2000). The natural habitats of the two species show important differences; for instance, while rats live in subterranean burrows near water, e.g., on river banks, mice do not. An ecological niche rich in water has allowed the rat to develop a high competency in coping with situations that require swimming. This issue has been elegantly pointed out by experiments showing that mice can learn water-based tasks but that their learning performance is quite inferior to

that of the rat (Whishaw, 1995); however, this difference is reduced when selected parameters of the experimental setting, such as pool size (Frick et al., 2000; van der Staay, 2000) and height of the pool walls (Carman and Mactutus, 2001), are appropriately modified. By contrast, the spatial learning abilities of the two species are similar when compared in dry-land mazes, such as the radial-arm maze (Whishaw and Tomie, 1996; *UNIT 11.3*). Still other factors having an ecoethological relevance may differently influence rat and mouse performances in a water maze (*UNIT 11.3*). For example, the differences in their respective predator-avoidance responses have been hypothesized to affect strategies for crossing open spaces and thus for reaching the platform (Schenk, 1987). This strengthens the notion that the learning abilities of the two species are essentially similar, except for the influence of experimental variables related to differences in their respective ecoethological characteristics (Kamil and Mauldin, 1988; Martin and Bateson, 1993).

Nonethological factors may deeply modulate animal performance in a learning test. For example, the water-based tests expose animals to cold water for a few minutes, and mice, unlike rats, can become severely hypothermic during such exposure. Thus, when testing mice in these experimental paradigms, temperature monitoring is crucial to control for this confounding factor (Iivonen et al., 2003).

These considerations should not preclude the use of tests developed for rats in mouse studies, or vice versa, but tests should be modified according to the species-specific competencies of the species under study, and the possible interference in behavioral performances arising from this process should be rigorously taken into account.

The exploitation of several rodent and nonrodent species such as gerbils, marmots, or voles in teratology and neurotoxicology studies represents a potentially important asset. Precocial–type species, such as guinea pigs or spiny mice (*Acomys cahirinus*), may provide important insights into the effects of neurotoxicant exposure at early postnatal phases, when newborns are already quite similar to adults (Pintor et al., 1986; D'Udine and Alleva, 1988). In fact, to obtain a better characterization of the complex ontogenic profile of developing humans, a comparative approach using more than two species, including precocials and altricials, is crucial to avoid biased species- or family-specific observations. The case of thalidomide is a telling example of the inadequacy of studies carried out using only a single mammalian species to identify and prevent possible adverse effects on developing humans.

Pharmacological Challenges

The use of psychoactive drugs that act on specific neurotransmitter systems represents a further useful addition to the assessment of the functional state of such systems during development. Drug challenges, such as by compounds modulating synaptic efficacy (i.e., receptor agonists and antagonists), may unmask neurobehavioral alterations not detectable under baseline testing conditions. They also can provide critical cues to the identification of changes in selected neural systems during development. For example, the use of challenges with both a monoaminergic agent (amphetamine) and a muscarinic blocker (scopolamine) at selected postnatal ages after prenatal exposure of mice to a benzodiazepine (oxazepam), showed a delay in the development of monoaminergic, but not cholinergic systems regulating locomotor activity (Alleva et al., 1985). By contrast, the use of a scopolamine challenge made it possible to show an accelerated maturation of cholinergic regulatory systems in mice neonatally treated with nerve growth factor (Calamandrei et al., 1991).

Ethical Aspects

A last, but not less important, aspect of studying behavior from the ethological perspective is that ethologically refined experimental designs meet the requirements of animal welfare, reducing the suffering of laboratory animals by taking care of their ethological needs, at least partially. This point is in line with the requirement of refinement of experimental procedures expressed by Russell and Burch (1959) in their classic book *The Principle of Humane Experimental Techniques*, a milestone in the field of improving laboratory animal well-being. It is worthy of notice that a direct consequence of the enhanced psychophysical welfare of experimental subjects is a more reliable behavioral response pattern, improving data quality (Vitale and Alleva, 1999; Alleva and Vitale, 2000). Moreover, the combination of an ecoethological approach with a progressive refinement of statistical methods can also contribute to reducing the number of animals used without reducing the power of behavioral analysis.

Statistical Analysis of Behavioral Data

The statistical analysis of behavioral data follows the collection and checking of data, and is aimed at assessing the effect of treatments on the observed behaviors. In the following, the author will briefly describe different behavioral tests and the response variables collected in each test, to introduce the statistical methods for the analysis of such variables. A more detailed description of the tests and of the response variables can be found in specific units of *Current Protocols in Toxicology*. The most specialized statistical terms appearing in this unit are defined under Specialized Statistical Terms, below.

When available for the analysis of a particular behavioral test, different statistical approaches to behavioral data will be described. These are often not redundant, yielding different kinds of information, and resulting in the refinement of behavioral research (Chiarotti and Puopolo, 2000). The different approaches can be characterized by different degrees of complexity which, if present, will be highlighted in each specific paragraph. For a synthetical description of the aim and characteristics of the different statistical methods that can be used for the analysis of each behavioral test data, see Table 13.8.2 at the end of this unit.

SPECIALIZED STATISTICAL TERMS

Between-Subject, Within-Subject, and Repeated Measures Factors

The between-subject factor is a factor that includes two or more levels, each of them randomly assigned to one group of independent statistical units (e.g., mice, rats, monkeys). Units in each final group are independent of each other and independent with respect to all units belonging to the other final groups.

The within-subject factor is a factor that includes two or more levels, each of them assigned to one of two or more correlated groups of independent statistical units (e.g., mice, rats, monkeys). This means that units in each final group are independent of each other, while each unit in a final group is correlated to one unit in any other final group.

The repeated measures factor is a factor that includes two or more levels, each of them assigned to each statistical unit. This means that each statistical unit is repeatedly tested under all levels of the repeated measures factor.

Normality

The assumption of normality implies that the distribution of the variable to be analyzed by parametric tests (see Statistical Tests for the Analysis of Behavioral Data, below) is normal in the population from which units (or blocks of units) are sampled. The normal distribution is a continuous frequency distribution of infinite range having a single mode (unimodal). It is characterized by two parameters: skewness and kurtosis.

Skewness describes the asymmetry of a distribution. It is equal to 0 for unimodal symmetrical distributions, such as the normal distribution, whereas it is negative for unimodal distributions with a longer left tail (towards lower values of the variable) and positive for distributions with a longer right tail (towards higher values).

Kurtosis describes the steepness of the unimodal frequency curve toward the mode. Usually, the kurtosis index is centered so that it is equal to 0 in normal distributions. Distributions with a positive, zero, and negative kurtosis index are referred to, respectively, as "leptokurtic" (heavy-tailed), "mesokurtic," and "platykurtic" (light-tailed).

Contributed by Flavia Chiarotti
Current Protocols in Toxicology (2005) 13.8.1-13.8.29

The normality assumption also states that the treatments administered to the statistical units in the different subgroups do not affect the shape of the distribution of the variable and that only the mean value of the variable changes among subgroups.

Homoscedasticity (Homogeneity of Variance)

Homoscedasticity refers to the homogeneity of variance among the independent groups being compared. In experimental designs including between-subject factors, homoscedasticity must be evaluated by comparing variances among the groups based on factor levels. When more data are collected on each statistical unit (within-subject or repeated measures factors), the data in each block (corresponding to within-subject factor levels) or in each unit (corresponding to repeated measures) should first be averaged before testing for homoscedasticity.

Sphericity

The sphericity assumption states that the variances of the differences between paired observations are equal across all groups in the sampled population. A simpler yet stricter condition is that referred to as "compound symmetry," which is met when, in the variance-covariance matrix of the sampled population, all of the variances are equal and all of the covariances are equal, although the covariances are not necessarily equal to the variances. This means that the data collected on statistical units under different conditions (corresponding to different levels of the within-subject factor or to different repeated measures) must be equally related to each other with the same correlation coefficient, ρ. Compound symmetry is sufficient, yet not necessary, for ensuring the validity of the F ratio under the general null hypothesis of no treatment effect. The F ratio is the test statistic in the parametric ANOVA. In particular, it is computed as the ratio between the variance of the effect under assessment and the variance of the error term. This ratio follows an F distribution if all the assumptions upon which the test relies are met. In other words, if compound symmetry is satisfied, then sphericity is also satisfied, but if compound symmetry is not satisfied, then sphericity must still be evaluated.

BASIC PROTOCOL 1

FOX BATTERY TEST

The Fox battery test is a battery of tests that characterize maturation of a set of sensorimotor functions, behavioral traits, and learning abilities from birth to weaning, initially developed for the assessment of behavioral ontogeny of house mice (Fox, 1965). Three main problems arise in analyzing data from a Fox battery test. First, the original response variables are ordinal scores, representing successive developmental stages achieved by the experimental subjects. Specifically, for each item, four well defined stages of mouse development can be recognized and scored: (i) absence of response (score 0); (ii) initial appearance of response (score 1); (iii) evident response (score 2); and (iv) full response (score 3). Thus, the range of data is so narrow (scale from 0 to 3) that data distribution cannot be considered as continuous. Therefore, neither parametric nor nonparametric tests can be applied, because the former require that data be normally distributed, and the latter cannot manage the large number of equal values (ties) coming from the narrow range of scores.

Second, for a better evaluation of the effect of treatments (in a broad sense) on the ontogeny of behavior, littermates receive, when possible, different treatments (obviously, under some conditions, this is very difficult or even impossible, as in the case of treatments that must be administered prenatally). Splitting litters into different treatment groups allows one to reduce at most the confounding effect of the genetic variability between litters, which would affect the assessment of treatment effect if whole litters were assigned to the same treatment group. Furthermore, littermates are tested repeatedly over days to

monitor the behavioral development. From a statistical point of view, this results in experimental designs including litters as the random blocking factor, treatments as the fixed factor within litters, and postnatal days (PNDs) as the fixed repeated measures on individual subjects. Therefore, it is not appropriate to use methods that assume the independence of observations, such as the χ^2 test, frequently performed to assess the different distribution of the scores among treatment groups day-by-day.

Finally, score profiles are expected to be monotonically nondecreasing, but sometimes they may present regressions—i.e., the score a subject achieves one day may be lower than the score achieved on the day before. This can be due to the particular situation in which the subject is at the time of testing (e.g., digestion, sleep, or even boredom), which can affect its capability and promptness in responding to stimuli.

Two solutions can be adopted to analyze Fox battery test data, as described, respectively, in steps 1a to 6a and 1b to 4b, below.

Analysis of a synthetical measure of the score profile

1a. Convert the original scores for each subject in each component of the test battery from multiple (repeated observations over time for each subject) to single (one observation per subject), by computing a synthetical measure.

To do this, different strategies can be adopted, as outlined below. Each of them presents both pros and cons.

i. For each component of the test battery, choose a particular score (usually scores 2 or 3) as adult-like response or full appearance of a somatic feature, and register the first day when the subject attains a score equal to or greater than that (for the sake of brevity, in the following this will be called first day of adult-like responding).

To choose the abovementioned threshold score, the score profile in the period of testing, collected on subjects in the control group, must be considered. Specifically, a good choice for the threshold is a score that control subjects are likely to present some days after the beginning and before the end of the testing period.

Pro: If the threshold is appropriately chosen, it is possible to detect anticipations or delays of the full response, which can be attributed to the treatment(s) under study.

Con: If the threshold score is not set at the maximum score (e.g., at score 2), it is impossible to distinguish between subjects attaining the full response with different scores (e.g., with score 2 or score 3) on the same day of testing. Moreover, subjects attaining the full response on the same day of testing with the same score, but presenting different score profiles before and/or after the attainment of the full response, will be considered equivalent.

ii. For each component of the test battery, compute the area under the curve generated by the repeated scores.

Pro: The whole score profile is considered in computing this synthetical measure. Subjects attaining the full response at the same day of test with the same score, but presenting different score profiles before and/or after the attainment of the full response, will be given different synthetical measures.

Con: Different score profiles, even in the presence of different first days of adult-like responding, can result in the same synthetical measure.

2a. Check the normality of the distribution of transformed synthetical data in each subgroup of subjects, using the Shapiro-Wilk test or the Kolmogorov-Smirnov test, Lilliefors modification (Armitage et al., 2002; Chiarotti, 2004). If the normality assumption is respected, proceed to step 3a; otherwise go to step 5a.

3a. Compare variances among subgroups using the Levene test or the Bartlett test (Armitage et al., 2002; Chiarotti, 2004). If variances are homogeneous, proceed to step 4a; otherwise go to step 5a.

4a. Perform, on the transformed synthetical data, the parametric tests for the comparison among groups appropriate for the modified experimental design (Edwards, 1985; Wilcox, 1987; Winer et al., 1991). Go to step 6a.

Remember that if the design includes repeated measures taken on the subjects, appropriate correction in case of violation of the sphericity assumption must be adopted, such as Greenhouse-Geisser or Huynh-Feldt corrections (Winer et al., 1991; Armitage et al., 2002; Chiarotti, 2004).

5a. Perform, on the transformed synthetical data, the nonparametric tests for the comparison among groups appropriate for the modified experimental design (Marascuilo and McSweeney, 1977; Brunner et al., 2002). Go to step 6a.

Note that the most commonly used statistical packages do not include nonparametric methods for the analysis of experimental designs with between-subject and within-subject or repeated measures factors. Therefore, to perform the suggested analysis, one must have access to an ad hoc software application and to the knowhow necessary for its use.

6a. Present the results (see Presentation of Results, below).

Analysis of the whole score profile by survival curves

1b. Choose the score to be considered as response, i.e., the score after which the subject that attained it will be ignored in the analysis; that score will be considered as *death*. Register, for each subject, the time from the first day of observation until the first day when the subject attains a score equal to or greater than the response; that time will be considered as *time to death*.

Subjects that do not reach the abovementioned score will be considered as censored, and will be given a time equal to the span of observation (follow-up time).

2b. Analyze *survival* data using methods such as the Kaplan-Meier survival analysis or the Cox proportional hazards model (Armitage et al., 2002).

The Kaplan-Meier survival analysis method allows one to compare survival times among two or more independent groups and to take into account at most one stratification variable. The Cox proportional hazards model method allows one to assess the independent effect on survival of more fixed or time-dependent covariates.

3b. Repeat the survival analysis using different scores as response.

It is important to note that repeated analyses on the same data can result in an increase in the probability of type I error, and that appropriate corrections (such as the Bonferroni correction; Armitage et al., 2002) should be adopted.

Pro: The described methods allow one to take into account the whole score profile.

Con: The described methods have been developed for independent data, and correlated data (such as those resulting from littermates assigned to different treatment groups) cannot be managed easily.

More complex methods can deal with survival data organized in different stages, taking into account the successive survival times in each consecutive stage. Unfortunately, these are more difficult to manage, and many of the most common statistical software applications do not perform such methods. Therefore, unless one has access to the more specialized software applications and to the knowhow necessary for their use, it may be advisable to refer to the kind of analysis suggested above in steps 1b to 3b.

4b. Present the results (see Presentation of Results, below).

ULTRASOUND VOCALIZATIONS TEST

Ultrasound vocalizations are emitted by pups in response to various conditions, such as maternal separation, low-temperature isolation, tactile stimulation, or olfactory stimulation. These vocalizations stimulate prompt expression of maternal behavior.

The response variable in the ultrasound vocalizations test (Hofer et al., 2001) is the number of calls emitted by the pups under various experimental conditions (between- or within-subject factor, according to the experimental design adopted).

For a more sophisticated analysis, vocalizations can be characterized according to the frequency modulation and the duration of the acoustic signal (sound category), as evidenced by the spectrographic analysis of calls. Moreover, ultrasound can be classified according to different frequency bands. Each vocalization is then defined by a specific sound category and frequency band. Therefore, the number of calls emitted by the pup in each sound category/frequency band combination can be considered as repeated measures on the pup.

The statistical analysis of the response variable *number of calls* passes through the following steps.

1. Check the normality of the distribution of data in each subgroup of subjects using the Shapiro-Wilk test or the Kolmogorov-Smirnov test, Lilliefors modification (Armitage et al., 2002; Chiarotti, 2004). If the normality assumption is respected, proceed to step 2; otherwise go to step 4.
2. Compare variances among subgroups using the Levene test or the Bartlett test (Armitage et al., 2002; Chiarotti, 2004). If variances are homogeneous, proceed to step 3; otherwise go to step 4.
3. Perform the parametric tests for the comparison among groups appropriate for the experimental design adopted (Edwards, 1985; Wilcox, 1987; Winer et al., 1991). Go to step 7.

   Remember that if the design includes repeated measures taken on the subjects, appropriate correction in case of violation of the sphericity assumption must be adopted, such as Greenhouse-Geisser or Huynh-Feldt corrections (Winer et al., 1991; Armitage et al., 2002; Chiarotti, 2004).

4. Consider the experimental design. If it is rather simple—i.e., no limits for the between-subject factors (treatments) and at most two levels for each repeated measures factor (days, trials)—go to step 5; otherwise go to step 6.
5. Analyze the profile on the consecutive days of testing and trials using a nonparametric test for the comparison among groups, choosing the test appropriate for the experimental design adopted—including between-subject factor(s) and repeated measures factor (days, trials) (Marascuilo and McSweeney, 1977; Brunner et al., 2002). Go to step 7.

   Remember that the most commonly used statistical packages do not include nonparametric methods for the analysis of experimental designs with between-subject and within-subject or repeated measures factors. Therefore, to perform the suggested analysis, one must have access to an ad hoc software application and to the knowhow necessary for its use.

6. Transform the original data for *number of calls* using the appropriate normalizing transformation, which must be applied separately on each observation (Edwards, 1985; Armitage et al., 2002).

Remember that the appropriate transformation must be chosen on the basis of some knowledge with regard to the theoretical and empirical distributions of data (i.e., the distributions of data in the population and in the observed samples, respectively). Note that non-normality of the UV response variable usually results from too small a number of calls under final conditions, which suggests a Poisson distribution of data. Thus, the square-root transformation is the most appropriate for normalizing data distribution. After the transformation, go back to step 1. Note that persistent violations of the assumptions of normality and homogeneity of variance after the transformation of data indicate that the performed transformation was not appropriate.

7. Present the results (see Presentation of Results, below).

BASIC PROTOCOL 3

PASSIVE AVOIDANCE TEST

Usually, in the passive avoidance test, the experimental subjects undergo repeated trials until they reach the criterion (which is, commonly, suppressing the spontaneous response for two consecutive trials), or, in case they do not reach the criterion, until they undergo the predetermined maximum number of trials. The first phase of learning (acquisition) is usually followed by an interval, and then subjects undergo one single retest trial to assess the long-term memory (memory retention).

Different kinds of data can be collected in a passive avoidance test, namely (1) number of trials to reach the criterion, (2) latency profile in the repeated trials of the learning phase, and (3) latency to step-through in the retest trial.

All the response variables are characterized by the presence of a cutoff that limits the range of values the response variable can take. In particular, latencies longer than the cutoff value are commonly arbitrarily given the cutoff value. This value is also used in the learning phase to complete the latency profile for the trials following the attainment of the criterion (usually, these trials are not performed). For all this, data usually do not follow a normal distribution. Thus, parametric methods, which use statistics based on the quantitative value of the different observations, are inappropriate.

Different solutions can be adopted for the analysis of the various response variables.

Number of trials to reach the criterion

This variable can be subjected to two different analyses as described in steps 1a to 6a and 1b to 4b, respectively.

Tests for the comparison among groups (most frequently used)

1a. Check for the presence of cutoff values. If they are present, go to step 5a; otherwise go to step 2a.

2a. Check the normality of the distribution of data using the Shapiro-Wilk test or the Kolmogorov-Smirnov test, Lilliefors modification (Armitage et al., 2002; Chiarotti, 2004). If data are normally distributed, go to step 3a; otherwise go to step 5a.

3a. Compare variances among subgroups of subjects using the Levene or the Bartlett test (Armitage et al., 2002; Chiarotti, 2004). If variances are homogeneous, go to step 4a; otherwise go to step 5a.

4a. Perform a parametric test for the comparison among groups, choosing the test appropriate for the experimental design adopted (Edwards, 1985; Wilcox, 1987; Winer et al., 1991). Go to step 6a.

5a. Perform nonparametric tests for the comparison among groups, choosing the test appropriate for the experimental design adopted (Marascuilo and McSweeney, 1977; Brunner et al., 2002). Go to step 6a.

6a. Present the results (see Presentation of Results, below).

Survival analysis (less commonly used)

1b. Set the status of the subject equal to *dead* if the subject has reached the criterion within the maximum number of trials, or *censored*, if not.

2b. Set the survival time equal to the number of trials to reach the criterion (if the subject is dead) or to the maximum number of trials (if the subject is censored).

3b. Perform the Kaplan-Meier survival analysis (Armitage et al., 2002) on these data, using *treatment(s)* as grouping variable(s).

4b. Present the results (see Presentation of Results, below).

Latency profile in the repeated trials

If the experimental subject reaches the criterion during the acquisition phase before undergoing the maximum number of trials, it is usually given the maximum latency for the remaining trials. The latency profile is then strongly affected by the limits arbitrarily set by the researcher. For this reason, parametric methods are frequently not appropriate for the analysis of this kind of data. On the other hand, nonparametric methods taking into account between-subject and repeated measures factors at the same time are not available in the most commonly used statistical packages.

1c. Convert the whole latency profile into a single response variable, using one of the two following methods.

i. Calculating the median latency value.
ii. Calculating the area under the latency curve.

2c. Analyze the single response variable using tests for the comparison among groups. To do this, follow the instructions given for the variable *number of trials to reach the criterion* (see steps 1a to 5a).

3c. Present the results (see Presentation of Results, below).

Latency to step-through in the retest trial

Subjects that have learned the task in the acquisition phase usually show memory of the task in the retest trial, unless the administered treatments interfere with memory processes. For this reason, latency in the retest trial is often affected by the presence of cutoff values which, together with the non-normality of the distribution common to most latency variables, make parametric tests not suitable for the statistical analysis. Therefore, nonparametric tests for the comparison among groups are usually the best choice, as described in steps 1d to 6d.

1d. Check for the presence of cutoff values. If they are present, go to step 5d; otherwise go to step 2d.

2d. Check the normality of the distribution of data, using the Shapiro-Wilk test or the Kolmogorov-Smirnov test, Lilliefors modification (Armitage et al., 2002; Chiarotti, 2004). If data are normally distributed, go to step 3d; otherwise go to step 5d.

3d. Compare variances among subgroups of subjects, using the Levene or the Bartlett test (Armitage et al., 2002; Chiarotti, 2004). If variances are homogeneous, go to step 4d, otherwise go to step 5d.

4d. Perform a parametric test for the comparison among groups, choosing the test appropriate for the experimental design adopted (Edwards, 1985; Wilcox, 1987; Winer et al., 1991). Go to step 6d.

5d. Perform nonparametric tests for the comparison among groups, choosing the test appropriate for the experimental design adopted (Marascuilo and McSweeney, 1977; Brunner et al., 2002). Go to step 6d.

6d. Present the results (see Presentation of Results, below).

BASIC PROTOCOL 4

MORRIS WATER MAZE TEST

Usually, the Morris water maze test consists of an acquisition phase (learning) followed by a probe trial (retention). The acquisition phase lasts for a larger number of days, and on each day of testing, the experimental subjects undergo repeated trials, spaced by an intertrial interval. The probe trial is commonly conducted after a period (minutes) from the completion of the last training trial, on the last day of the acquisition phase. For more details, see *UNIT 11.3*.

The duration of the acquisition phase (number of days, number of trials on each day, maximum duration of each trial, and intertrial interval), the duration of the period before the probe trial, and the duration of the probe trial itself are predetermined by the experimenter. These constitute the cutoffs for the different response variables that can be collected in the test.

The response variables that are collected in the acquisition phase are: (1) latency profile to reach the platform; (2) mean velocity, in the repeated days and trials within days; (3) path length, in the repeated days and trials within days; (4) time spent in the peripheral annular area close to the wall (thigmotaxis), in the repeated days and trials within days.

The response variables that are collected in the probe trial are: (1) crossings of acquisition quadrant; and (2) total time spent in the acquisition quadrant.

Latency profile to reach the platform

Usually, if the experimental subject does not find the platform within the allotted time, the experimenter manually places it onto the platform and lets it stay there for a predetermined period (seconds). The latency profile is then strongly affected by the limits arbitrarily set by the researcher. For this reason, as with passive avoidance data, the latency profile to reach the platform cannot be appropriately analyzed using parametric methods. On the other hand, nonparametric methods that take into account, at the same time, between-subject and repeated measures factors (days, trials) with more than two levels each are not available in the most common statistical packages. Therefore, proceed as follows.

1a. Convert the latency profile in each day of testing into a single response variable, using one of the two following methods.

i. Calculating the median latency value.
ii. Calculating the area under the latency curve.

2a. Check the normality of the distribution of data using the Shapiro-Wilk test or the Kolmogorov-Smirnov test, Lilliefors modification (Armitage et al., 2002; Chiarotti, 2004). If data are normally distributed, go to step 3a; otherwise go to step 5a.

3a. Compare variances among subgroups of subjects using the Levene or the Bartlett test (Armitage et al., 2002; Chiarotti, 2004). If variances are homogeneous, go to step 4a; otherwise go to step 5a.

4a. Analyze the profile on the consecutive days of testing using a parametric test for the comparison among groups, choosing the test appropriate for the experimental design adopted, including between-subject factor(s) and the repeated measures factor (days) (Edwards, 1985; Wilcox, 1987; Winer et al., 1991). Go to step 6a.

5a. Analyze the profile in the consecutive days of testing using a nonparametric test for the comparison among groups, choosing the test appropriate for the experimental design adopted (Marascuilo and McSweeney, 1977; Brunner et al., 2002). Go to step 6a.

Remember that the most commonly used statistical packages do not include nonparametric methods for the analysis of experimental designs with between-subject and within-subject or repeated measures factors. Therefore, to perform the suggested analysis, one must have access to an ad hoc software application and to the knowhow necessary for its use.

6a. Present the results (see Presentation of Results, below).

Mean velocity and path length in the repeated days and trials within days

These quantitative variables are unbounded, in that no arbitrary cutoffs are set by the experimenter. To analyze these variables, proceed as follows.

1b. Check the normality of the distribution of data using the Shapiro-Wilk test or the Kolmogorov-Smirnov test, Lilliefors modification (Armitage et al., 2002; Chiarotti, 2004). If data are normally distributed, go to step 2b, otherwise go to step 4b.

2b. Compare variances among subgroups of subjects using the Levene or the Bartlett test (Armitage et al., 2002; Chiarotti, 2004). If variances are homogeneous, go to step 3b, otherwise go to step 4b.

3b. Analyze the profile on the consecutive days of testing and trials using a parametric test for the comparison among groups, choosing the test appropriate for the experimental design adopted, including between-subject factor(s) and repeated measures factor (days and trials) (Edwards, 1985; Wilcox, 1987; Winer et al., 1991). Go to step 7b.

4b. Consider the experimental design. If it is rather simple—i.e., no limits for the between-subject factors (treatments), two levels at most for each repeated measures factor (days and trials)—go to step 5b; otherwise go to step 6b.

5b. Analyze the profile on the consecutive days of testing and trials using a nonparametric test for the comparison among groups, choosing the test appropriate for the experimental design adopted, including between-subject factor(s) and repeated measures factor (days and trials) (Marascuilo and McSweeney, 1977; Brunner et al., 2002). Go to step 7b.

Remember that the most commonly used statistical packages do not include nonparametric methods for the analysis of experimental designs with between-subject and within-subject or repeated measures factors. Therefore, to perform the suggested analysis, one must have access to an ad hoc software application and to the knowhow necessary for its use.

6b. Transform data using the appropriate normalizing transformation, which must be applied separately on each observation (Edwards, 1985; Armitage et al., 2002). After the transformation, go back to step 1b.

Remember that the appropriate transformation must be chosen on the basis of some knowledge with regard to the theoretical and empirical distributions of data (i.e., the distributions of data in the population and in the observed samples, respectively). Usually, square-root transformation is appropriate if data means and standard deviations in each treatment group are proportional, while logarithmic transformation is appropriate

in the case of strongly asymmetrical distribution, with a long upper tail. Note that persistent violation of the assumptions of normality and homogeneity of variance after the transformation of data indicate that the transformation performed was not appropriate.

7b. Present the results (see Presentation of Results, below).

Time spent in the peripheral annular area close to the wall (thigmotaxis) in the repeated days and trials within days

This quantitative variable rarely reaches the cutoff value, except when the experimental subject remains in the peripheral annular area close to the wall for the whole duration of the trial, predetermined by the experimenter. Therefore, follow the instructions given for the variables mean velocity and path length (see steps 1b to 7b).

Crossings of acquisition quadrant

This quantitative variable is superiorly unbounded. Indeed, the higher limit of this variable derives from both the predetermined duration of the probe trial (equal for all subjects) and the maximum swimming velocity that the experimental subjects can reach (different among subjects), and thus it varies from subject to subject. Therefore, follow the instructions given for the variables mean velocity and path length (steps 1b to 7b).

Total time spent in the acquisition quadrant

This quantitative variable rarely reaches the cutoff value, except when the experimental subject remains in the acquisition quadrant for the whole duration of the probe trial, predetermined by the experimenter. Therefore, follow the instructions given for variables mean velocity and path length (steps 1b to 7b).

BASIC PROTOCOL 5

SPATIAL OPEN FIELD TEST

The spatial open field test usually consists in seven repeated sessions, during which animals are put in an open-field arena. In session 1 the arena is empty; in sessions 2 to 4, four different plastic objects are placed in the arena; in sessions 5 and 6 two of these objects are displaced; in session 7, one of the objects is replaced by an unfamiliar one.

Response variables in the spatial open field test can be assigned to two main categories: *general* behaviors, such as rearing, wall rearing, grooming, top rearing, and locomotor activity (crossings), which are recorded during all sessions; and behaviors *specifically directed* towards the objects, such as object contacts, which are recorded only in the sessions when objects are presented to subjects.

For both categories, data recorded are frequencies and, in some cases, durations of behaviors—i.e., data are quantitative. Therefore, to analyze these variables, proceed as follows.

Univariate methods

1a. Check the normality of the distribution of data using the Shapiro-Wilk test or the Kolmogorov-Smirnov test, Lilliefors modification (Armitage et al., 2002; Chiarotti, 2004). If data are normally distributed, go to step 2a; otherwise go to step 4a.

2a. Compare variances among subgroups of subjects using the Levene or the Bartlett test (Armitage et al., 2002; Chiarotti, 2004). If variances are homogeneous, go to step 3a; otherwise go to step 4a.

3a. Analyze the profile on the consecutive days of testing and trials using a parametric test for comparison among groups, choosing the test appropriate for the experimental design adopted, including between-subject factor(s) and repeated measures factor (days and trials) (Edwards, 1985; Wilcox, 1987; Winer et al., 1991). Go to step 7a.

4a. Consider the experimental design: if it is rather simple—no limits for the between-subject factors (treatments), two levels at most for each repeated measures factor (days and trials)—go to step 5a; otherwise go to step 6a.

5a. Analyze the profile on the consecutive days of testing and trials using a nonparametric test for comparison among groups, choosing the test appropriate for the experimental design adopted, including between-subject factor(s) and repeated measures factor (sessions and, in case, blocks of minutes) (Marascuilo and McSweeney, 1977; Brunner et al., 2002). Go to step 7a.

Remember that the most commonly used statistical packages do not include nonparametric methods for the analysis of experimental designs with between-subject and within-subject or repeated measures factors. Therefore, to perform the suggested analysis, one must have access to an ad hoc software application and the knowhow necessary for its use.

6a. Transform data using the appropriate normalizing transformation, which must be applied separately on each observation (Edwards, 1985; Armitage et al., 2002). After the transformation, go back to step 1a.

Remember that the appropriate transformation must be chosen on the basis of some knowledge with regard to the theoretical and empirical distributions of data (i.e., the distributions of data in the population and in the observed samples, respectively). Usually, square-root transformation is appropriate if data means and standard deviations in each treatment group are proportional, while logarithmic transformation is appropriate in the case of strongly asymmetrical distribution, with a long upper tail. Note that the persistent violation of the assumptions of normality and homogeneity of variance after the transformation of data, indicate that the performed transformation was not appropriate.

7a. Present the results (see Presentation of Results, below).

Multivariate methods

1b. When many behavioral categories are collected at the same time in order to take into account the correlation among them, perform a principal component analysis (PCA) on all quantitative observations (Jackson, 1991; Armitage et al., 2002).

The statistical unit for PCA is the subject at a session. For example, if there are two levels of treatment (vehicle and drug), with 10 subjects per treatment level (for a total of 20 subjects), and 7 sessions, the resulting number of statistical units for PCA will be $2 \times 10 \times 7 = 140$. On each statistical unit, all different behaviors are recorded, making up the data set to be analyzed by PCA.

2b. Extract PCA factors and consider only the subset of factors having an eigenvalue (corresponding to the variance of the original data explained by that factor) ≥ 1.

3b. Check the cumulative proportion of variance in data space explained by that subset of factors.

Note that PCA is effective in parsimoniously describing a set of continuous, interrelated variables when the number of subset factors is much lower (i.e., <50%) than the number of the original variables and the cumulative proportion of explained variance is sufficiently large (i.e., $>0.67 = 67\%$).

4b. To interpret the subset factors, look at the correlations between them and the original variables, given by the unrotated factor loadings.

As a rule of thumb, a correlation between the original variable x and the factor $z > 0.5$ (or < -0.5) indicates that the factor z is affected by the original variable x. Lower correlations denote that the variable is less important in influencing the factor.

5b. Collect the estimated factor scores for each statistical unit on each subset factor.

6b. Analyze the factor scores, separately for each subset factor, with a parametric test for the comparison among groups, choosing the test appropriate for the experimental design adopted.

In this example, the design includes treatment as between-subject factor, subjects as random blocking factor nested under treatment, and sessions as repeated measures factors (Edwards, 1985; Wilcox, 1987; Winer et al., 1991).

7b. Present the results (see Presentation of Results, below).

BASIC PROTOCOL 6

MATERNAL BEHAVIOR ASSESSMENT

The maternal behavior assessment usually consists in the recording of dams' behavior in the presence of their offspring. For more details, see *UNIT 13.9*.

The response variables can be assigned to two main categories: (1) maternal behavior observed in the *home cage*, such as retrieval, nursing (arched-back, blanket, passive), pup care (licking, anogenital licking, stepping), dam self-care (self-grooming, eating, drinking), and other (digging, rearing, moving, resting, standing out of nest); and (2) maternal behavior in a *novel cage*, including retrieving and standing on nest, nursing, licking, digging, and self-grooming.

Methods for the analysis of maternal behavior data depend on type of data. Steps are presented for dichotomous variables which are scored as either 0 or 1, as well as for quantitative variables (also see *UNIT 13.9*).

For dichotomous variables

Original data are recorded using the instantaneous sampling; thus, they are dichotomous scores (0/1). In particular, score 0 is assigned when the behavior is not shown in the interval (seconds) of observation, while score 1 is assigned when the behavior is performed. Instantaneous sampling is repeated more times (at least eight times, preferably) at each time point; time points (hours) are repeated (usually five times) for all days of testing (days). Such data can be (1) maintained as dichotomous scores, or (2) transformed into a quantitative variable. This choice influences the methods that can be adopted for the statistical analysis.

Maintain dichotomous scores

1a. Convert the original dichotomous scores (0/1), relative to each instantaneous sample, into an overall dichotomous score (0/1, absence/presence of the behavior) relative to each time point (hour) of observation.

2a. Analyze the variable using a stepwise forward logistic regression (LR) analysis (Hosmer and Lemeshow, 2000).

In particular, the dichotomous variable (0/1) is the dependent variable in the LR model, while treatments (categorical), hours, and days of observation (continuous) are the putative explanatory variables.

Observations repeated on the same animals over days and hours are related to (dependent on) each other; this dependency must be taken into account by specifying groups (clusters) of dependent observations on animals.

3a. Present the results (see Presentation of Results, below).

Transform dichotomous scores into quantitative variables

1b. Transform the original dichotomous scores (0/1), relative to each instantaneous sample, into a quantitative variable, adding the original scores over the instantaneous sampes within each time point.

These observations (one per time point) will range from 0 (behavior never shown) to the maximum number of instantaneous samples within the time point (e.g., 8).

2b. Analyze quantitative data using univariate (steps 3c to 9c) and/or multivariate methods (steps 3d to 9d).

Univariate methods

3c. Check the normality of the distribution of data using the Shapiro-Wilk test or the Kolmogorov-Smirnov test, Lilliefors modification (Armitage et al., 2002; Chiarotti, 2004). If data are normally distributed, go to step 4c; otherwise go to step 6c.

4c. Compare variances among subgroups of subjects using the Levene or the Bartlett test (Armitage et al., 2002; Chiarotti, 2004). If variances are homogeneous, go to step 5c; otherwise go to step 6c.

5c. Analyze the profile on the consecutive days and hours of testing using a parametric test for the comparison among groups, choosing the test appropriate for the experimental design adopted, including between-subject factor(s) and repeated measures factor (days, hours) (Edwards, 1985; Wilcox, 1987; Winer et al., 1991). Go to step 9c.

6c. Consider the experimental design. If it is rather simple—i.e., no limits for the between-subject factors (treatments), two levels at most for each repeated measures factor (days, hours)—go to step 7c; otherwise go to step 8c.

7c. Analyze the profile on the consecutive days of testing and trials using a nonparametric test for the comparison among groups, choosing the test appropriate for the experimental design adopted, including between-subject factor(s) and repeated measures factor (days, hours) (Marascuilo and McSweeney, 1977; Brunner et al., 2002). Go to step 9c.

Remember that the most commonly used statistical packages do not include nonparametric methods for the analysis of experimental designs with between-subject and within-subject or repeated measures factors. Therefore, to perform the suggested analysis, one must have access to an ad hoc software application and to the knowhow necessary for its use.

8c. Transform data using the appropriate normalizing transformation, which must be applied separately on each observation (Edwards, 1985; Armitage et al., 2002). After the transformation, go back to step 3c.

Remember that the appropriate transformation must be chosen on the basis of some knowledge with regard to the theoretical and empirical distributions of data (i.e., the distributions of data in the population and in the observed samples, respectively). Usually, square-root transformation is appropriate if data means and standard deviations in each treatment group are proportional, while logarithmic transformation is appropriate in the case of strongly asymmetrical distribution, with a long upper tail. Note that the persistent violations of the assumptions of normality and homogeneity of variance after the transformation of data indicate that the performed transformation was not appropriate.

9c. Present the results (see Presentation of Results, below).

Multivariate methods

3d. Perform a principal component analysis (PCA) on all quantitative observations (Jackson, 1991; Armitage et al., 2002).

The statistical unit for PCA is the subject at a given day and time point (hour) of observation. For example, if there are two levels of treatment (vehicle and drug), 10 subjects per treatment level (for a total of 20 subjects), 13 days of observation, and 5 time points per day (65 repeated observations on each subject), the resulting number of statistical units for PCA will be $2 \times 10 \times 13 \times 5 = 1300$. On each statistical unit, all different behaviors are recorded, making up the data set to be analyzed by PCA.

4d. Extract PCA factors and consider only the subset of factors having an eigenvalue (corresponding to the variance of the original data explained by that factor) ≥ 1.

5d. Check the cumulative proportion of variance in data space explained by that subset of factors.

Note that PCA is effective in parsimoniously describing a set of continuous, interrelated variables when the number of subset factors is much lower (i.e., <50%) than the number of the original variables, and the cumulative proportion of explained variance is sufficiently large (i.e., $>0.67 = 67\%$).

6d. To interpret the subset factors, look at the correlations between them and the original variables, given by the unrotated factor loadings.

As a rule of thumb, a correlation between the original variable x and the factor $z > 0.5$ (or < -0.5) indicates that the factor z is affected by the original variable x. Lower correlations denote that the variable is less important in influencing the factor.

7d. Collect the estimated factor scores for each statistical unit on each subset factor.

8d. Analyze the factor scores, separately for each subset factor, with a parametric test for the comparison among groups, choosing the test appropriate for the experimental design adopted.

In this example, the design includes treatment as between-subject factor, subjects as random blocking factor nested under treatment, and days and hours as repeated measures factors (Edwards, 1985; Wilcox, 1987; Winer et al., 1991).

9d. Present the results (see Presentation of Results, below).

For quantitative variables

As regards retrieving and standing on nest (*UNIT 13.9*), the observed response variable is the latency to perform the behavior. As concerns nursing, licking, digging, and self-grooming, the observed response variables are the number of 30-sec intervals when the behaviors are performed during the course of the whole test (which commonly lasts 30 min). For this reason, variables are quantitative, ranging from 0 to the maximum number of intervals (e.g., 60). For all variables, the experimental design does not include repeated measures factors, i.e., it is usually simple. Therefore, to analyze these variables proceed as follows.

Tests for the comparison among groups (most frequently used)

1e. Check for the presence of observations equal to the cutoff value. If they are absent, go to step 2e, otherwise go to step 5e.

2e. Check the normality of the distribution of data using the Shapiro-Wilk test or the Kolmogorov-Smirnov test, Lilliefors modification (Armitage et al., 2002; Chiarotti, 2004). If data are normally distributed, go to step 3e; otherwise go to step 5e.

3e. Compare variances among subgroups of subjects using the Levene or the Bartlett test (Armitage et al., 2002; Chiarotti, 2004). If variances are homogeneous, go to step 4e; otherwise go to step 5e.

4e. Perform a parametric test for the comparison among groups (Edwards, 1985; Wilcox, 1987; Winer et al., 1991). Go to step 6e.

5e. Perform a nonparametric test for the comparison among groups (Marascuilo and McSweeney, 1977; Brunner et al., 2002). Go to step 6e.

6e. Present the results (see Presentation of Results, below).

Survival analysis

In addition to the analysis described in steps 1e to 6e, retreiving latency can be subjected to a survival analysis (Kaplan-Meier), which allows one to take into account the competition between mutually exclusive responses. Indeed, when the mother is slow in retreiving the pups, they can spontaneously huddle, thus creating a nest area before the mother can do it herself. In this case, the mother's response must be considered as censored (censored 1) at the time of pups' huddling, since she is no longer able to perform the selected behavior. Finally, the mother must also be considered as censored (censored 2) if neither retrieving nor huddling is observed before the cutoff time.

1f. Set the status of the subject equal to *dead* if the subject has performed the behavior, or *censored* if not (whatever the cause).

2f. Set the survival time equal to the latency to perform the behavior, if the subject is *dead*. If the subject is *censored 1*, set the survival time equal to the time of pups' huddling. If the subject is *censored 2*, set the survival time equal to the cutoff time.

3f. Perform the Kaplan-Meier survival analysis (Armitage et al., 2002) on these data using *treatment(s)* as grouping variable(s).

4f. Present the results (see Presentation of Results, below).

STATISTICAL TESTS FOR THE ANALYSIS OF BEHAVIORAL DATA

Different tests can be used to analyze behavioral data, depending on the experimental design adopted and the response variable. Tests have already been mentioned that must be used to check the assumption upon which the parametric tests rely (Shapiro-Wilk test or Kolmogorov-Smirnov test, Lilliefors modification for the normality assumption; Levene test or Bartlett test for the homogeneity of variance; Greenhouse-Geisser or Huynh-Feldt corrections for the sphericity assumption; Bonferroni correction for multiple comparisons). In addition, mention has been made of the Kaplan-Meier survival analysis, the Cox proportional hazards model, the principal component analysis (Armitage et al., 2002), and logistic regression (Hosmer and Lemeshow, 2000), which, under some conditions, can be used to test behavioral data. On the contrary, no specific mention has been made of the tests for comparison among groups regarding the measures of location. For this reason, a very brief description of such tests, either parametric or nonparametric, will be given below.

Details on all mentioned tests will not given here, because that would go beyond the aim of this unit. However, a deeper insight into statistics for the health and social sciences can be obtained from statistical textbooks (Marascuilo and McSweeney, 1977; Edwards, 1985; Winer et al., 1991; Armitage et al., 2002; Brunner et al., 2002). Finally, remember that statistical software applications are now available for all personal computers; therefore, what is important is to be able to choose the appropriate method and to appropriately describe the experimental design, rather than to know all the calculations involved in performing the tests.

Tests for the Comparison Among Groups

Parametric tests

This category of tests requires that some assumptions be respected in order to make test results reliable. Two of them are common to all parametric tests, specifically: (1) independence of observations within each final subgroup; (2) normality of the distribution of data in each subgroup. Other assumptions depend on the specific test being performed.

Student t test for two independent groups

This is the test most frequently used to compare two groups of independent subjects in cases where a single observation is available for each subject (i.e., no repeated measures). Subjects are either randomly assigned to one of two groups according to the treatment administered by the experimenter (e.g., vehicle and drug), or randomly selected by the experimenter from the population of subjects presenting one of the two modalities of the characteristic under investigation (e.g., males and females).

This test is based on the following additional assumptions: (3) independence of the observations between the two groups, and (4) homogeneity of variance between the two groups. It is important to note that the *t* test is robust against slight violations of the assumptions of normality and homogeneity of variance. Variances in the two groups can be compared, using, for example, the Bartlett, Fisher F, Cochran, or Levene test. If the variances are significantly different, tests for separate variances must be applied (e.g., Welch *t* test, Brown-Forsythe test), which are usually more conservative than the Student *t* test.

Student t test for two dependent groups (Paired t test)

This is the test most frequently used to compare two groups of correlated statistical units. In particular, *n* pairs of correlated observations are collected, coming either from *n* pairs of related subjects (e.g., littermates, one tested after the administration of vehicle and the other after the administration of drug), or from *n* subjects, each tested under both conditions (vehicle and drug), with the order of treatment administration being randomly assigned to each subject. No additional assumptions are required for this test. The paired *t* test is robust against slight violations of the normality assumption.

Analysis of variance (ANOVA)

ANOVA is a very useful method that allows one to assess the significance of the difference among two or more groups of subjects (i.e., the significance of the effect of one *treatment* factor with two or more levels). Moreover, factorial ANOVA allows one to assess the significance of the effect of more treatment factors, each with two or more levels, together with their interaction(s). For example, if male and female mice are treated with vehicle or drug, the experimental design includes four subgroups coming from the combination of sex and treatment, i.e., control males, drug males, control females, drug females. In this situation, it is possible to test the main effect of drug, the main effect of sex, and the interaction of drug and sex.

When performing the ANOVA, particular care must be put into model selection. The ANOVA model depends on the experimental design. There are three main types of experimental designs: (1) completely randomized designs, (2) randomized block designs, and (3) split-plot designs.

Completely randomized designs (CRD). In this situation, subjects belonging to the different subgroups under comparison, corresponding to the different levels or combinations of levels of the factor(s) under study, are independent within each subgroup and among subgroups. The factor or factors under study are called between-subject factor(s) or grouping factor(s).

Randomized block designs (RBD). In this case, subjects belonging to the different subgroups under comparison are independent within each subgroup and dependent among subgroups. Subgroups correspond to the different levels or combinations of levels of the factor(s) under study, which are referred to as *conditions* in the following discussion. As in the case of the paired *t* test, this situation can derive from (1) one group of subjects, or (2) more groups of related subjects (e.g., littermates). In the former case, each subject is tested under all different conditions, while in the latter case, within each group, subjects are assigned to different conditions, one subject per condition. The factor(s) under study is(are) called within-subject factor(s) or repeated measures factor(s).

Split-plot designs. Split-plot designs are a combination of CRD and RBD. A random sample of blocks (e.g., litters), each consisting of more than one subject (e.g., littermates), is extracted from a population. The blocks are randomly assigned to one out of two or more conditions, treatments or combinations of treatments—i.e., between-subject factor(s). The units within each block are randomly assigned to different treatments or to combinations of treatments—i.e., within-subject factor(s)—or are evaluated at different times—i.e., repeated measures. Between-subject, within-subject, and repeated measure factors are usually fixed-effect factors, whereas blocks and units are random-effect factors.

Nonparametric tests

This category of tests generally relies on the following assumptions: (1) independence of observations within each final subgroup, and (2) continuity of the response variable in the sampled population. The latter implies that equal observations (ties) should be unlikely. Anyway, even though a variable is continuous in theory, all measurements must be made on a discrete scale; thus equal observations can occur more frequently than expected. Usually, the first step in nonparametric tests is the transformation of the original observations into ranks. Equal observations are commonly transformed into equal ranks, corresponding to the mean of the ranks that would have been assigned to the equal observations had they been different. In the presence of ties, appropriate corrections for the test statistic must be adopted. This holds true for all tests that will be described in the following paragraphs.

Mann-Whitney U test for two independent groups

This test is the nonparametric counterpart of the Student *t* test for two independent groups. It is designed to test the hypothesis of equality of the underlying distributions. Compared to the *t* test, the *U* test has an asymptotic efficiency equal to 95.5% when the assumptions for the *t* test are respected. This means that the *U* test is almost as powerful as the *t* test in detecting differences between two independent groups, and is therefore a good alternative to the *t* test when the latter cannot be performed because of violation of the assumptions. Note that the minimum total size required by the *U* test to detect differences between the two groups under comparison is $n = 7$ (i.e., at least 2 versus 5 observations) for the one-sided test, or $n = 10$ (i.e., at least 2 versus 8 observations) for the two-sided test.

Wilcoxon test for two dependent groups

This test is the most famous nonparametric counterpart of the Student *t* test for two dependent groups. It is based on the differences between paired observations, which are transformed into ranks for successive computations. The test assumes the continuity of the distribution of such differences. This implies that differences equal to 0 are unlikely. Unfortunately, as measured observations are necessarily discrete, differences equal to 0 are more frequent than expected. Usually, such differences are dropped (this is the option adopted in most statistical software applications), reducing the effective sample size.

Note that the minimum effective sample size required by the Wilcoxon matched-pair test to detect differences between the paired groups under comparison is $n = 5$ for the one-sided test, or $n = 6$ for the two-sided test.

Kruskal-Wallis analysis of variance for independent groups

This is the nonparametric countepart of the parametric ANOVA for CRD (see above). It is designed to test the hypothesis of equality of the underlying distributions among the groups based on the different levels of one between-subject factor. Compared to parametric ANOVA, the Kruskal-Wallis ANOVA has an asymptotic efficiency equal to 95.5%, when the assumptions for the parametric ANOVA are respected. If the response variable follows a non-normal distribution, the efficiency of Kruskal-Wallis ANOVA is always greater than or equal to 86% (and it can exceed 100%, e.g., in case of uniform or exponential distributions). Kruskal-Wallis ANOVA is not too sensitive to differences in spread and shape of data distribution (thus it is not too affected by violation of normality and homogeneity of variance assumptions), while it is most sensitive to differences in centers (such as means and medians, or other indexes of location).

When the experimental design includes more than one factor (e.g., two factors, sex and treatment, with two levels each, four final subgroups), the main effects of the different factors and their interaction can be assessed by using χ^2 partitioning. This method can give the exact partitioning of the overall Kruskal-Wallis χ^2 only in the case of balanced designs, i.e., when sample sizes are equal in all final subgroups. Unfortunately, this method is not available in the most common statistical software applications.

Friedman analysis of variance for dependent groups

This is the nonparametric countepart of the parametric ANOVA for RBD. It allows one to test the hypothesis of equality of the underlying distributions among the groups, based on the different levels of one within-subject factor, against the alternative hypothesis of difference in centers (such as means and medians, or other indexes of location). Compared to parametric ANOVA, when the assumptions required by this method are respected, the Friedman ANOVA has an asymptotic relative efficiency $E = 3K/[\pi(K + 1)]$, where K is the number of groups under comparison. As it can be noted, the asymptotic relative efficiency increases as K increases, ranging from the minimum of 63.7% (when $K = 2$) to 95.5% (when K is exceptionally large).

When the experimental design includes more than one factor (e.g., two factors, day and trial, with 5 and 10 levels respectively, 50 final subgroups), the main effects of the different factors and their interaction can be assessed by using the χ^2 partitioning. This method gives the exact partitioning of the overall Friedman χ^2, when the design is balanced, i.e., when sample sizes are equal in all final subgroups (this is the usual situation, since unbalancing can derive only from missing values). Unfortunately, the χ^2 partitioning is not available in the most common statistical software applications.

Nonparametric ANOVA for split-plot designs

Data from split-plot designs cannot be analyzed using nonparametric ANOVA, unless each within-subject or repeated measures factor has only two levels. In this situation, it is possible to assess the significance of the interaction of between-subject factor(s) with within-subject factor(s) by performing the Kruskal-Wallis ANOVA, with the between-subject factor as the grouping variable, on the difference between the two levels of the within-subject factor. Unfortunately, this analysis can not be directly performed using the most common statistical software applications.

PRESENTATION OF RESULTS

Tables and figures can be used to present the results of statistical analyses. In particular, to synthesize qualitative data, use *absolute* and *percent frequencies* in the different categories of each variable. On the contrary, for quantitative data, use the appropriate indexes of location (*mean*) and variability (*variance*, *standard deviation*, *standard error*). When the distribution of data is markedly asymmetrical (presence of outliers or of cutoff values), it is preferable to use *median* and *range*, *interquartile range*, or *median absolute deviation* (Armitage et al., 2002).

In addition, when a logistic regression has been performed, present odds ratios (ORs) with the corresponding confidence interval (CI). Commonly, the 95% CI is used (Hosmer and Lemeshow, 2000).

Similarly, for Kaplan-Meier survival analysis, present the cumulative incidence (that is, the incidence of subjects achieving the response) at a given time since the beginning of observation, with the corresponding 95% CI.

Finally, remember to report the test statistics with pertinent degrees of freedom and the exact significance levels. Reporting significances as $p < 0.05$, or $p =$ ns is absolutely discouraged, except for multiple comparison tests.

In preparing tables, follow a few main rules.

1. Subdivide complex tables into two or more simpler tables.
2. Put all necessary information in the title and in legend of the table (e.g., measurement units for the variables, explanation of symbols, marginal and overall totals, denominators for computation of percentages).
3. Clearly state the source of data (if not original).

Follow the same rules in preparing figures. In addition, pay attention to the maximum number of different curves and symbols that can be managed in one figure. It has to be noted that, when reporting results of statistical analyses in figures, the significance of the comparison of two groups can be presented using asterisks, the number or type of which depends on the significance level, e.g, * = 0.05, ** = 0.01 and *** = 0.001. Different types of graphics can be used to present data, depending on the statistical method used for data analysis (Table 13.8.1). The following discussion briefly describes bar charts, box and whisker plots, histograms, Kaplan-Meier cumulative incidence curves, line diagrams, and PCA graphs (Jackson, 1991; Armitage, 2002).

Bar chart

Similar to the histogram (and frequently mistaken for it), this graphical method is very useful in the case of quantitative variables with normal or symmetrical distribution. It allows one to show the distribution of one quantitative variable for different levels of other variable(s)—i.e., grouping factor(s). The height of each rectangle is equal to the mean of the variable in the corresponding group, while the upper whisker is equal to the standard deviation (or the standard error) in the same group. For an example, see Figure 13.8.1.

Box and whisker plot

This presentation is very useful in case of quantitative variables with non-normal or asymmetrical distribution. It makes it possible to synthesize one quantitative variable (outcome) for different levels of other variable(s), i.e., grouping factor(s), by presenting some measures of location and variability. Boxes cover the interquartile range and are

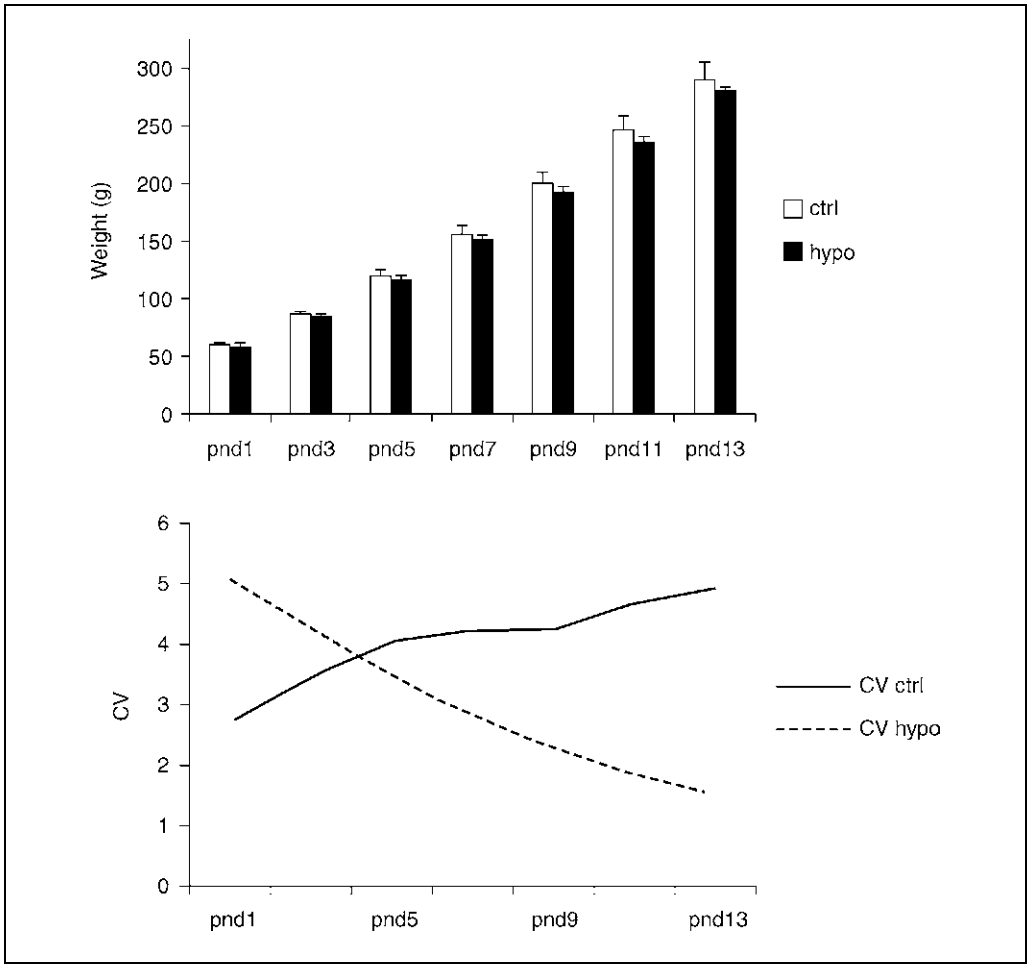

Figure 13.8.1 (**A**) Example of a bar chart. Results of parametric analysis of variance performed on litters' weight for the comparison between hypoxic (hypo) and control (ctrl) dams, every 2 days from postnatal day (pnd) 1 to pnd 13 (7 recordings). The mean litter weight is reported, with vertical bars representing standard error of mean. (**B**) The coefficient of variation (CV; i.e., the standard deviation divided by the group mean) has been plotted against PND to show the increase in this measure occurring in control litters, compared to those whose mothers had undergone hypoxia immediately after birth. Reprinted from *Neurotoxicology and Teratology*, Vol. 25, Cirulli et al. (2003). Long-term effects of acute perinatal asphyxia on rat maternal behavior, p. 575, Copyright 2003, with permission from Elsevier.

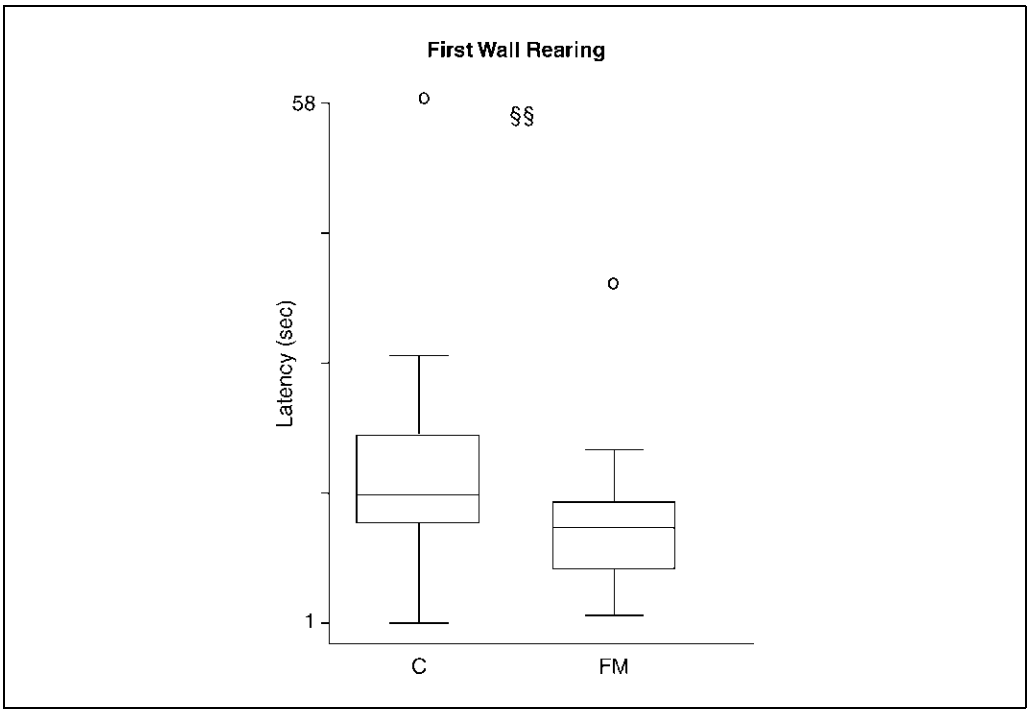

Figure 13.8.2 Example of box and whisker plot. Results of nonparametric Kruskal-Wallis analysis of variance for the comparison between two groups of CD-1 mice, one exposed to millipede aversive odor (FM) and the other to vehicle odor (C). In the figure, a box and whisker plot of latency of first wall rearing recorded in mice during the hot-plate test, performed after 15 min of exposure to the stimulus object, are reported. The line in the middle of the box represents the median. Box covers interquartile range (IQ); whiskers extend to upper and lower adjacent values. Upper value is defined as largest data point less than or equal to $x_{[75]} + (1.5 \times \text{IQ})$. Lower value is defined as smallest data point greater than or equal to $x_{[25]} - (1.5 \times \text{IQ})$. Outliers (points more extreme than the adjacent values) are represented by the letter "o." The symbol §§ represents $p < 0.001$. Reprinted from *Brain Research Bulletin*, Vol. 58(2), Capone et al. (2002). A new easy accessible and low-cost method for screening olfactory sensitivity in mice: Behavioural and nociceptive response in male and female CD-1 mice upon exposure to millipede aversive odour, p. 201, Copyright 2002, with permission from Elsevier.

divided by the median; whiskers extend to the range or some other measure of dispersion (e.g., percentile range). Observations that fall out of the whiskers represent outliers. The presence of more outliers in one direction than in the other implies asymmetry in the distribution of data. For an example, see Figure 13.8.2.

Histogram

A histogram allows one to show the frequency distribution in the different classes of a categorized quantitative variable or of a qualitative variable. Rectangles whose areas are proportional to the class frequencies are drawn on portions of the *x* axis, the width of each portion representing the class interval of the variable. In case of qualitative variables, the height of each rectangle is proportional to the frequency in the corresponding class.

Kaplan-Meier cumulative incidence curve

This graphical method allows one to represent the increase over time of the cumulative incidence of subjects showing the response. When the survival analysis is performed on behavioral developmental data, the curve represents the cumulative proportion of subjects achieving the developmental stage chosen as response. More cumulative incidence curves (one per treatment group) can be represented in one figure, using different symbols

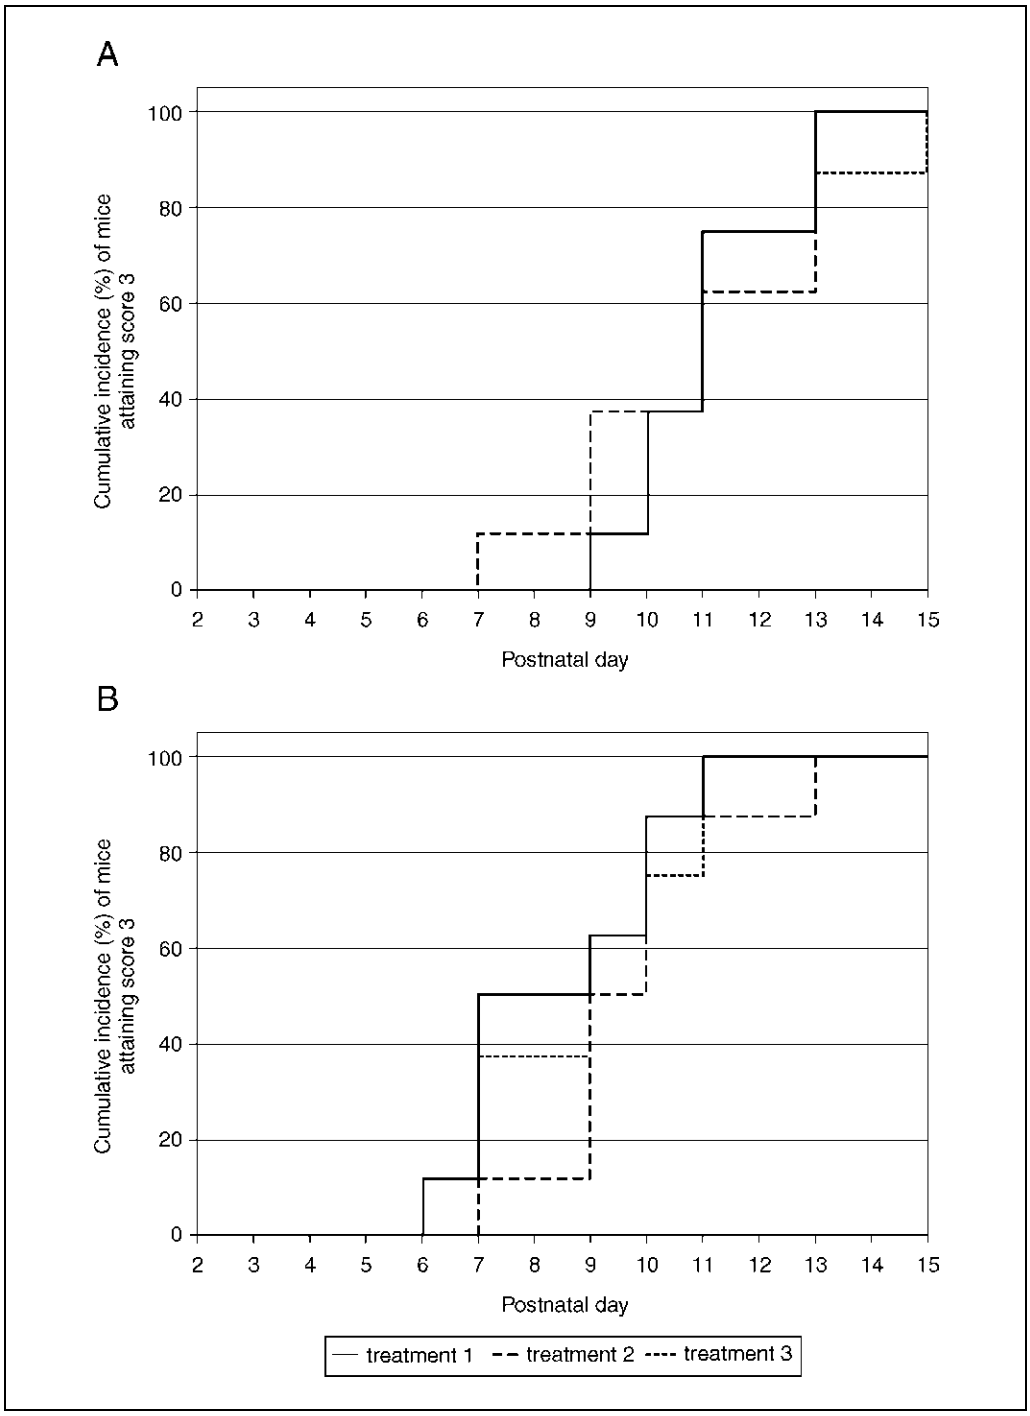

Figure 13.8.3 *(continues on next page)* Example of Kaplan-Meier cumulative incidence curve. Results of the Kaplan-Meier survival analysis performed on the swift righting score collected at postnatal days 2 to 11 and 13 to 15 on male and female mice, born from primiparous or multiparous dams, undergoing three different treatments (1, 2, and 3). (**A**) Female mice born from primiparous dams; (**B**) female mice born from multiparous dams; (**C**) male mice born from primiparous dams; (**D**) male mice born from multiparous dams. The swift righting behavior was considered as adult-like at score 3; thus that score was considered as *death*. The first day when the subject attained a score equal to 3 was considered as *time to death*. Subjects that did not reach that score were considered as *censored*, and were assigned a time equal to the span of observation (*follow-up time* = 15 days). Sex was considered as stratifying variable, while combinations of parity and treatment were considered as grouping variable (6 levels). A significant difference was observed among the six groups within each stratum ($p<0.0005$ for all tests for the comparison of survival curves). F. Chiarotti and D. Santucci (unpub. observ.).

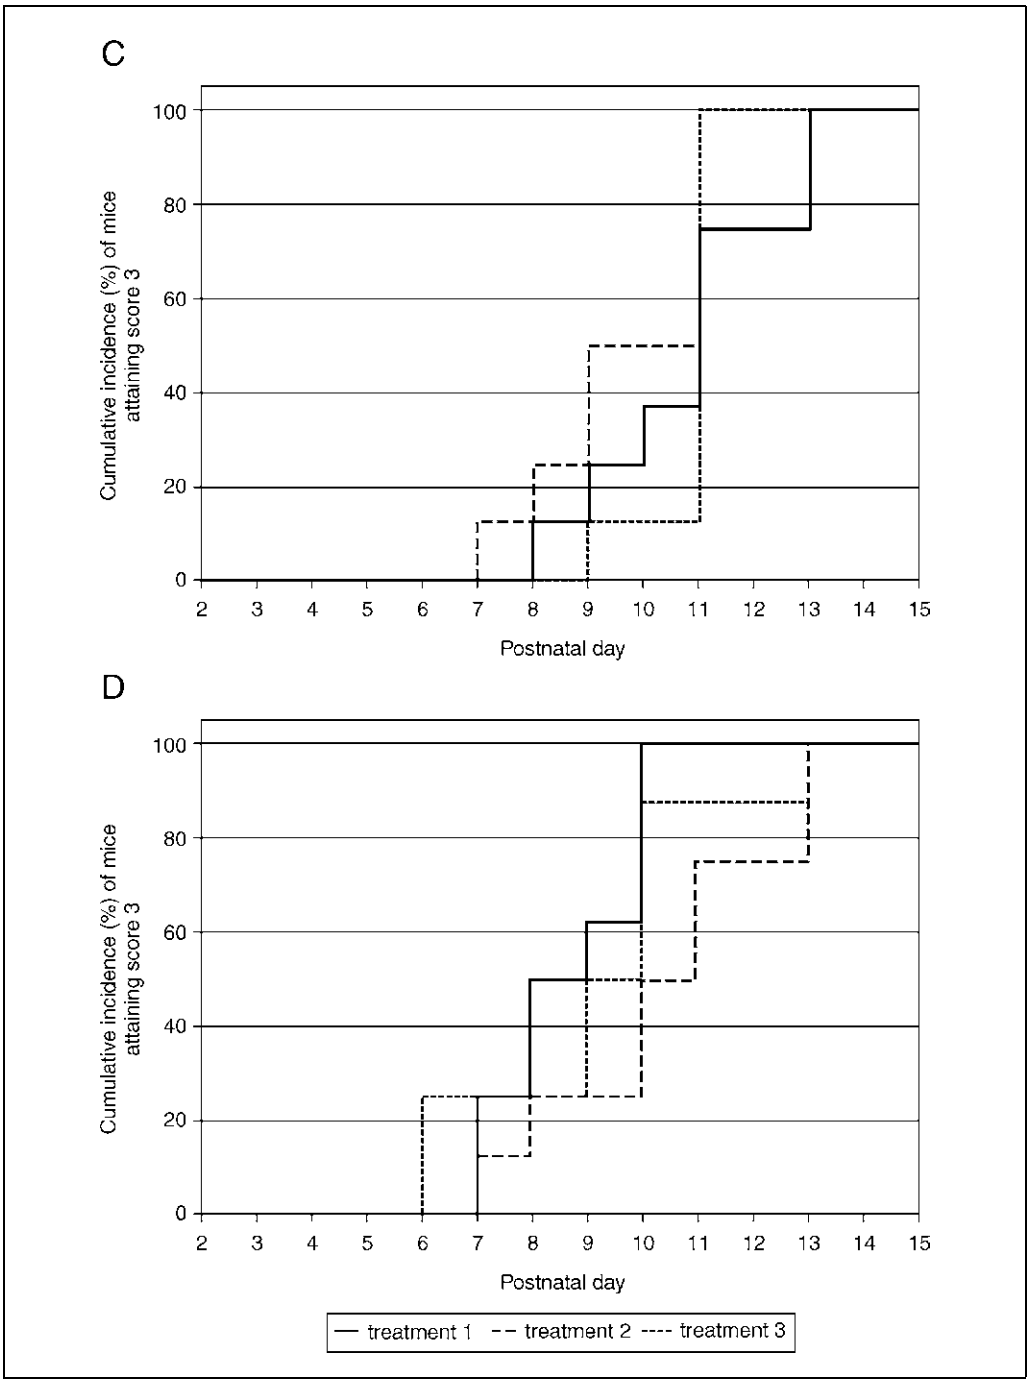

Figure 13.8.3 *(continued)*

to distinguish among different treatment groups. Sometimes the survival curves are presented, showing the decrease over time of the survival of subjects free from event. For an example, see Figure 13.8.3.

Line diagram

This technique allows one to represent data that have been collected over a period of time or over increasing doses of a drug. Mean values of the response variable are plotted as dots, and these are connected by lines showing the trend (increase, decrease or no change) over time or over doses. More curves can be presented in the same figure, one per subgroup, based on one or more between-subject factor(s). This helps to visualize

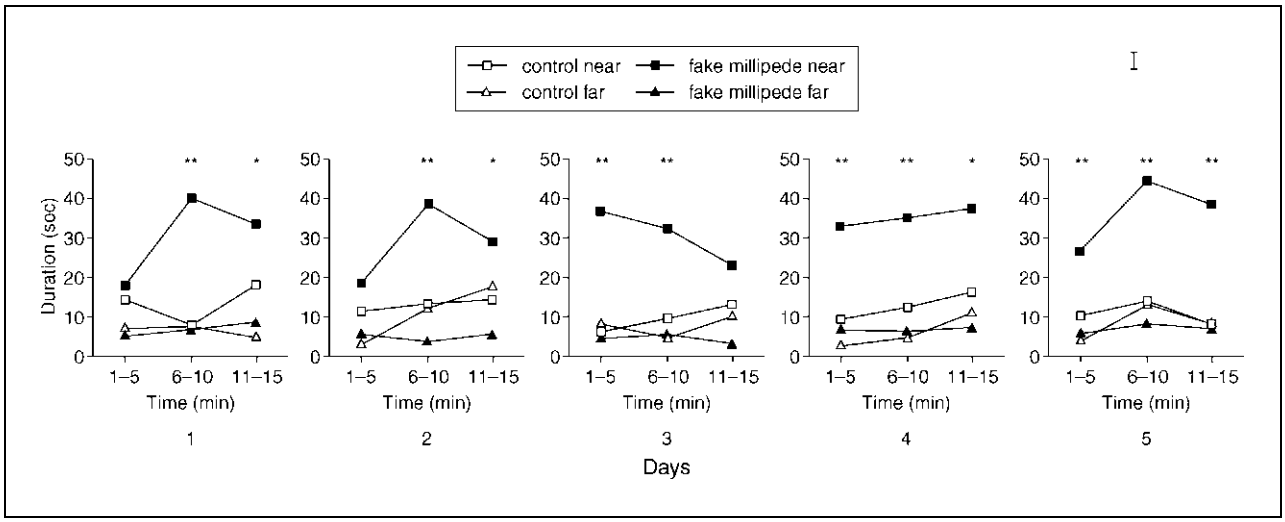

Figure 13.8.4 Example of line diagram. Results of parametric analysis of variance performed on the duration of bar holding behavior for the comparison between two groups of CD-1 mice, exposed either to millipede aversive odor (FM) or to vehicle odor (C). For each mouse, the behavior was recorded for 5 consecutive days, 15 min (3 blocks of 5 min each) per day. The behavior displayed near to the stimulus object was distinguished from the behavior displayed far from the stimulus object. In the figure, mean durations of the nonavoidance response of bar holding throghout the 5 days of testing are reported. Vertical bar on the right-hand side of the figure indicates pooled standard error of mean. This represents the best estimator of the standard error, based on more degrees of freedom, under the hypothesis of homogeneity of variance. It is computed as the square root of the ratio between the error term in the ANOVA (i.e., mean square of the residual appropriate for the assessment of the effect represented in the figure) and the number of observations contributing to each mean reported in the figure. Reprinted from *Brain Research Bulletin*, Vol. 58(2), Capone et al. (2002). A new easy accessible and low-cost method for screening olfactory sensitivity in mice: Behavioural and nociceptive response in male and female CD-1 mice upon exposure to millipede aversive odour, p. 197, Copyright 2002, with permission from Elsevier.

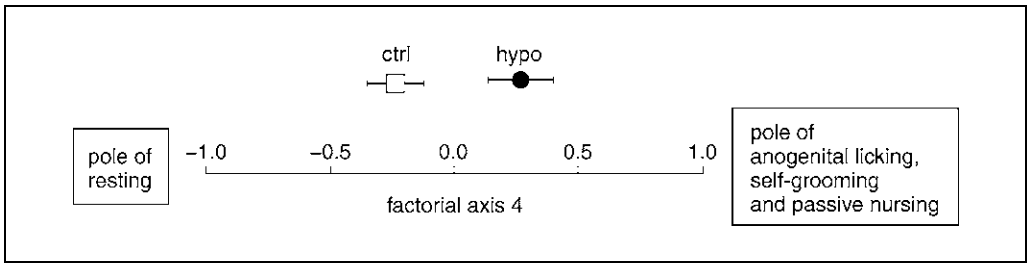

Figure 13.8.5 Example of PCA graph. Results of principal component analysis performed on maternal behavior of hypoxic and control dams, observed in the home cage. Factorial axis 4. Mean (SEM) coordinates of individuals as a function of postnatal treatment. ctrl = controls, $n = 6$; hypo = hypoxic, $n = 7$. Perinatal hypoxia affected animal's spread across the axis, increasing the probability of finding hypoxic subjects on the positive side ($p = 0.0169$). Reprinted from *Neurotoxicology and Teratology*, Vol. 25, Cirulli et al. (2003). Long-term effects of acute perinatal asphyxia on rat maternal behavior, p. 574, Copyright 2003, with permission from Elsevier.

the effect of the between-subject factor(s) on the trend over time or over doses. For an example, see Figure 13.8.4.

PCA graph

For the presentation of PCA results, monodimensional (*x* diagram) or bidimensional (*xy* diagram) graphs can be used. The graphical representation must be limited to those PCA factors that can be easily interpreted in terms of the original variables and allow a significant discrimination among the experimental groups. Each PCA factor is represented on one axis, ranging from −1 to +1. The original variables inversely correlated with

a PCA factor are reported near the negative pole of the axis representing that factor, while variables directly correlated to the factor appear near the positive pole. Along the axis, the mean values (dots) and the standard deviations (bars) relative to the subgroups differing for that PCA factor must be reported. For an example, see Figure 13.8.5.

CHAPTER 14
Hepatotoxicology

INTRODUCTION

The liver is a frequent target for chemically induced injury. This injury is manifested by a number of toxic endpoints and is detectable at levels of organization from the molecular to the gross anatomical. The significance of the liver in toxic action has several roots. First, with the possible exception of the skin, it is the largest organ in the mammalian body. Second, most xenobiotics enter the body via the gastrointestinal tract and, after absorption, are transported directly to the liver via the hepatic portal vein, making the liver the first organ perfused by chemicals absorbed by the gut. Third is the high concentration of xenobiotic-metabolizing enzymes (XMEs), particularly isoforms of cytochrome P450 (CYP). These enzymes, while primarily involved in detoxication also carry out many activation reactions, the products of which may cause hepatotoxicity or toxicity in other organ systems after being distributed throughout the body.

Because XMEs, and particularly CYP isoforms, have broad overlapping substrate specificities and because xenobiotics may serve as substrates, inhibitors and/or inducers of these enzymes, they are a common locus for toxic interactions between different xenobiotics. Thus the liver, with its high content of XMEs, is an important site for drug and other chemical interactions.

The number of toxic endpoints observed in liver is large and includes fatty liver, cell necrosis, apoptosis, cholestasis, cirrhosis, hepatitis and carcinogenesis. Similarly the range of hepatoxicants is large, including clinical drugs, drugs of abuse, industrial solvents and biologicals, the latter including both plant and fungal metabolites.

Hepatoxicity has been investigated at all levels of organization from the molecular, through the subcellular and cellular to liver slices and the isolated, perfused liver. This wide variety of causes, mechanisms and effects will form the overall basis of this chapter, starting with additional details of the importance and role of this organ in toxic action in the overview of hepatotoxicity (*UNIT 14.1*) and continuing with a most important technique, that for the isolation of hepatocytes (*UNIT 14.2*). *UNIT 14.3* describes the preparation and use of a small animal model for liver dysfunction caused by hemorrhagic shock. Blood loss continues to be a leading cause of death in many countries. About half of the victims survive the initial early death phase only to succumb later to organ failure, of which liver failure is the most important. This unit describes a rat model for such liver failure, a model needed to carry out the studies essential for clinical amelioration of this serious problem.

UNIT 14.5, on the measurement of hepatobiliary transport, describes methods for collecting bile from anesthetized mice and rats, carrying out isolated perfused rat liver studies and studies using isolating plasma membrane vesicles from the basolateral and canalicular domains of rat liver.

Overview of Hepatotoxicity

Hepatotoxicity is a collection of diverse toxic responses defined by target tissue—in this case, the liver—as opposed to other subdivisions of toxicology that are based upon a specific type of toxic effect or functional endpoint. As such, no battery of liver-specific testing protocols exists; rather, hepatotoxicity of a chemical is usually detected during acute or repeat-dose testing protocols or in clinical medicine as alterations in liver-specific serum parameters. Liver, because of its relative abundance and ease of cell dispersal, has long been a favorite tissue of biochemists and cell biologists. Thus, a rich background exists for the study of how toxicant interactions at the molecular level adversely affect liver cell function. Many of the methods for assessing generalized cellular and genetic toxic responses, xenobiotic metabolism, and regulation of glutathione homeostasis are especially pertinent here and are readily applied to cells of the liver.

FREQUENCY OF CHEMICALLY INDUCED HEPATOTOXICITY

Liver is a frequent target tissue of chemical toxicity. To illustrate the magnitude of liver susceptibility to adverse chemical effects for this overview, entries from the Environmental Protection Agency's Integrated Risk Information System (IRIS) database (see Internet Resources) were reviewed for hepatotoxic effects. For brevity, this exercise was limited to IRIS chemicals for which there are sufficient data to establish chronic oral reference doses (RfDs; i.e., estimates of human oral exposure levels that pose negligible risk of deleterious effects) and noncancer endpoints. From a total of 355 such chemicals, 141 (39%) show some evidence of hepatotoxicity. For 71% of these, hepatotoxicity is a critical effect (i.e., an adverse effect that occurs dose dependently at the lowest dosage in the most sensitive species and, thus, is used to establish the RfD).

To estimate exposure potential, those IRIS hepatotoxicants manufactured or imported at quantities of >1 million pounds per year, the so-called high production volume (HPV) chemicals, were identified (see Internet Resources). The IRIS hepatotoxicants that would be expected to pose a higher risk would then be those HPV chemicals with greater potencies as indicated by low liver "lowest observed adverse effect levels" (LOAELs). Of the 46 IRIS hepatotoxicants that are HPV chemicals, 12 have liver LOAELs ≤10 mg/kg/day, approximately one-fifth the human daily intake by weight of table salt. Most familiar among these are the industrial solvent carbon tetrachloride, herbicide 2,4-dichlorophenoxyacetic acid (2,4-D), munitions ingredient 2,4-dinitrotoluene, previous fuel additive tetraethyl lead, and plastic monomer vinyl chloride.

Also evident from this exercise is the predominance of pesticides (57%) among the IRIS hepatotoxicants. This results, in part, from the availability of large amounts of information from the comprehensive toxicity testing required for their registration. Of the IRIS pesticide hepatotoxicants with liver LOAELs ≤10 mg/kg/day, 44% are currently registered for use, while 14% are no longer registered or have severely restricted use (e.g., γ-hexachlorocyclohexane). Although banned, the latter are persistent organochlorine compounds, such as dichlorodiphenyltrichloroethane (DDT), mirex, and dieldrin, that have bioaccumulated during their earlier use such that toxicity of their residues is still of concern. Mandated reporting requirements have also enabled inclusion of a considerable number of industrial hepatotoxicants in the IRIS database. An important consideration apparent from the analysis of industrial chemicals is that the LOAELs for hepatotoxic effects of the phthalates, HPV chemicals used for manufacture of plastics, are relatively high; all are >400 mg/kg/day, except for di(2-ethylhexyl)phthalate (DEHP; LOAEL = 19 mg/kg/day).

Pharmaceuticals such as estrogenic and androgenic steroids, anesthetic halothane, retinoid acitretin, antiviral fialuridine, analgesic bromfenac, antidiabetic troglitazone, and others (Zimmerman, 1998) have exhibited hepatotoxic effects in humans, but since these substances are not found in the environment, they are not listed in the IRIS database. Although these serve as highly visible examples, the overall prevalence of chemical hepatotoxicity among pharmaceuticals relative to other chemical classes is difficult to estimate without a readily accessible, comprehensive database of animal toxicity tests. Further, when judging risks of pharmaceuticals, higher LOAELs have relevance because humans are purposely exposed, but the risk for

Contributed by Sharon A. Meyer
Current Protocols in Toxicology (2001) 14.1.1-14.1.6

hepatotoxicity must be weighed against the benefit of therapeutic effect.

Hepatotoxicity can be modified by several factors. Aggravation of hepatotoxicity from chemical-chemical interactions is of concern during concurrent therapies and environmental exposures to mixtures. Simultaneous exposures can result in competition for metabolic and excretory pathway components and thus alter toxicokinetics, whereas sequential exposures can cause induction or inhibition of molecular mediators of toxic effects. Lifestyle factors also have the potential to increase risk of hepatotoxicity. In particular, the most serious health hazard from chronic ethanol consumption is liver fibrosis, while adverse interactive effects have been noted with acetaminophen (Slattery et al., 1996). Importantly, the severity and incidence of adverse effects of chemicals on the liver can be expected to increase with the projected rise in prevalence of confounding viral hepatitis in the general U.S. population.

LIVER FUNCTION IN SUSCEPTIBILITY TO HEPATOTOXICANT TARGETING

The liver is the first internal organ to receive nutrients absorbed from the diet because its blood supply is directly connected to the intestines via the portal vein. Efferent venous blood from the intestine mixes with arterial blood upon entry into the hepatic sinusoids, the specialized capillary beds of the liver, which are fed by terminal branches of both the portal vein and hepatic artery. Although advantageous for hepatic coordination of endogenous metabolite homeostasis with newly absorbed material, this routing makes liver especially susceptible to disposition of orally administered xenobiotics. Liver parenchymal cells, the hepatocytes, are also instrumental in processing the excretory products of catabolism and their secretion by energy-dependent transporters localized to the canalicular region of the plasma membrane. Canalicular membranes from adjacent hepatocytes align to form conduits that empty into periportal bile ductules. Movement of biliary components from hepatocytes into bile ductules, and eventually their secretion into the duodenum, establishes a pathway for enterohepatic circulation of materials upon reabsorption into the portal circulation. Enterohepatic circulation not only provides a means for recovery of important nutrients and symbiotic metabolism by enteric microbes, but also increases the susceptibility of liver to toxicants by decreasing their rate of clearance.

Hepatocytes comprise ~70% of the cellular population of the liver and are the site of key anabolic reactions contributing to regulation of systemic carbohydrates, lipids, and proteins. For example, provision of systemic glucose for consumption by obligate consumers like the brain is largely dependent upon gluconeogenic activity of hepatocytes. Enzymes necessary for conversion of nonglucose energy sources to gluconeogenic precursors, such as the amino acid transaminases, are in such abundance that their leakage can be detected in the circulation and used as a surrogate indicator of hepatocyte damage. As a result of their high synthetic activity, hepatocytes are especially susceptible to effects of antimetabolites and metabolite depletion. Metabolism of lipid triglycerides and fatty acids requires substantial hepatocyte energy expenditure and thus accounts for the frequent occurrence of lipid accumulation in toxicant-exposed liver.

Other liver cell types include epithelial cells that line bile ductules and Kupffer cells, the largest reservoir of macrophages in the body. Kupffer cells are dispersed within the sinusoids and perform a major role in the liver inflammatory response through secretion of cytokines (Jaeschke et al., 1996). These function through sinusoidal endothelial cells to recruit circulating lymphocytes to damaged liver and initiate chemically induced hepatitis. Ito cells, or fat-storing cells, are a minor population that resides in the space between sinusoidal endothelial cells and hepatocytes. These cells are the site of storage of liver retinoids and can also be activated by Kupffer cell cytokines to synthesize collagen. As such, they are major cellular mediators of liver fibrosis and cirrhosis.

Hepatocytes exhibit heterogeneity depending upon their position along the sinusoid. Several sinusoids radiate from a single terminal hepatic venule or central vein, the efferent terminus of the capillary bed, and thus define a structural unit called the liver lobule. Microscopically, the lobule appears as a hexagon centered upon the central vein with alternate vertices defined by portal triads, distinct regions that contain the preterminal branches of the portal vein, hepatic artery, and bile duct. Hepatocytes are aligned in cords that run parallel with the sinusoids. Those hepatocytes nearest the central vein, the centrilobular hepatocytes, are functionally different from the periportal hepatocytes at the lobule perimeter due, in part, to the microenvironments established by oxygen and nutrient gradients that exist across the sinusoidal length (Gupta, et al.,

1999). A second classification scheme groups hepatocytes according to their relative distance from the terminal branches of the afferent vasculature. The resulting functional unit, called the acinus, defines those hepatocytes closest to the portal tract and central vein as zones 1 and 3, respectively, while those intervening in zone 2 are nearly equivalent to midlobular hepatocytes.

Hepatocyte heterogeneity can impart positional specificity to chemically induced liver injury. Sublobular regions of injury are typically defined pathologically as centrilobular or periportal (i.e., surrounding the central veins or portal tracts), while a small number of hepatotoxicants selectively damage the midlobular hepatocytes. The amount of sublobular area involved in response to a given hepatotoxicant is somewhat plastic, and depends upon dose and functional state of the liver. This sublobular pattern of injury can provide important information about the severity and mechanisms of hepatotoxicity.

Hepatocytes are physiologically specialized to metabolize xenobiotics, and metabolic activity is regulated to match functional load. Liver is rich in activities of oxidative Phase I and conjugative Phase II enzymes, for which methodology has been described elsewhere in this book (see Chapter 4). Sequential activities of these enzymes yield water-soluble metabolite conjugates of hydrophobic xenobiotics that are substrates of hepatocyte canalicular transporters. However, Phase II activities can apparently become rate limiting because unconjugated, oxidized metabolites can accumulate upon exposure to high doses of xenobiotics. Induction of cytochrome P450 enzymes, which are localized to centrilobular hepatocytes, can also lead to imbalance between Phase I and II activities and consequential production of reactive metabolites. Binding of cytochrome-P450-derived reactive metabolites to various cellular macromolecules can deleteriously affect protein function and form antigenic sites that result in localized centrilobular hepatocellular degeneration. Examples of methods for detection of protein adduction and lobular localization are presented in *UNIT 2.3*. Nucleophilic sites of nucleic acids are also susceptible to reactive metabolite adduction, which can lead to cytotoxicity and mutagenicity from the formation of cleavage sites in the polyphosphoribose strand or from promutagenic sites at modified bases. These lesions can be detected with protocols described elsewhere (see Chapter 3). Elevated cytochrome P450 activity can also lead to production of oxidative stress through leakage of reactive oxygen species from uncoupled partial reactions. Methods useful for assessment of cellular oxidative damage have been presented in *UNITS 2.4, 3.2, 7.3, 9.2, 9.3 & 9.6*.

TYPES OF TOXIC RESPONSES OF LIVER AND THEIR ASSESSMENT

A multitude of hepatic responses follows exposure to a chemical and precedes overt toxicity. The challenge for the toxicologist is to distinguish those that are intermediates leading to adverse endpoints from those that are beneficial adaptive responses. A classic example is whether the frequently observed increase in weight of chemically treated liver has toxicological significance. This response is often accompanied by increased hepatocyte size (hepatocellular hypertrophy), induction of xenobiotic metabolizing enzymes, and proliferation of associated intracellular organelles. Although these are undoubtedly adaptive responses to facilitate xenobiotic clearance, they are often a prelude to hepatotoxicity at higher dosages or following longer exposures. Of the hepatotoxicants in the IRIS database, 50% elicit an increased liver weight and/or hepatocellular hypertrophy in addition to definitive pathological indicators of hepatotoxicity or elevated serum liver enzymes. Thus, although a response may not be obviously causal to an adverse effect, its association with adverse effects of more severe exposures may be of some predictive value. The ability to make this distinction becomes more daunting as greater numbers of molecular changes are being associated with known hepatotoxicants with the application of highly efficient differential techniques.

For acute exposures, the benchmark adverse effect for toxicity is necrosis as recognized pathologically. Because cellular necrosis is accompanied by leakage of cellular contents, their detection in serum is commonly used as a noninvasive surrogate. The serum enzyme included in clinical chemistry panels most indicative of hepatocellular necrosis is alanine aminotransferase (ALT; also called serum glutamate pyruvate transaminase, SGPT). Aspartate aminotransferase (AST; also called serum glutamate oxaloacetate transaminase, SGOT) is also used, but is less specific. Sorbitol dehydrogenase (SDH) is another specific indicator of hepatocellular damage and is frequently used experimentally. Adverse hepatocellular changes that can precede overt necrosis include

fatty degeneration (steatosis), vacuolation, and deposition of various pigmented material, such as ferric heme in the hemosiderosis often seen with aryl amines (e.g., *N*,*N*-dimethylaniline) and nitroaromatics (e.g., 2,4,6-trinitrotoluene, TNT). Modest lymphocyte infiltration also usually accompanies hepatocyte degeneration and becomes pronounced with overt necrosis. Methods for histopathological and serum liver enzyme assessments will be presented in a future unit.

Impairment of bile formation (cholestasis), as a result of either hepatocyte or bile duct epithelial dysfunction, can be recognized histologically from bile deposits within canaliculi or bile ductules. Elevated alkaline phosphatase activity and bilirubin in serum also indicate cholestasis. A specific functional test for bile formation involves measurement of the clearance rate of intravenously administered bromosulfophthalene, an organic acid that is rapidly and specifically taken up by hepatocytes, conjugated, and pumped by a canalicular transporter into bile (Tennant, 1999). Direct measurement of bile flow can be monitored experimentally upon surgical cannulation of the common bile duct with subsequent administration of chemical to the intact animal or into the infusate of the isolated, perfused liver preparation. The functional integrity of the canalicular space between hepatocytes of isolated couplets and in a collagen sandwich configuration in culture (Liu et al., 1999) allows study of molecular targets of chemicals that induce hepatocellular cholestasis, such as the antipsychotic drug chlorpromazine.

Although forms of hepatocellular necrosis, steatosis, and cholestasis may also be associated with chronic exposure to hepatotoxic chemicals, fibrosis—or its more progressed form, cirrhosis—and neoplasia are more characteristic of long-term treatment. Fibrosis results from excess synthesis of extracellular matrix materials, especially collagen, by activated Ito cells. This material is deposited in the space between sinusoidal endothelial cells and hepatocytes and can be detected histologically with specific stains. Excess extracellular matrix in this perisinusoidal space can retard uptake of material from the sinusoidal fluid, a necessity for efficient hepatocyte regulation of systemic metabolites and first-pass metabolism of orally absorbed xenobiotics. Cirrhosis results when fibrosis becomes so severe that dense connective tissue bands encompass macroscopic nodular regions of liver.

The primary hepatotoxic chemical that causes cirrhosis in humans is ethanol. Early experimental models for ethanol-induced hepatotoxicity were limited by the rat's natural aversion to alcohol. Although these pair-fed, liquid-diet protocols have been instrumental for delineating effects of ethanol on induction of metabolic enzymes and interactions with other hepatotoxicants, they only achieved the less severe effect of fatty liver associated with subtoxic dosages. A more recent model in which ethanol is administered via an indwelling, intragastric feeding tube replicates the more severe alcoholic liver disease seen in humans and will be an essential tool for determining mechanistic aspects of ethanol-induced fibrosis. Recent studies with this model have emphasized the importance of Kupffer cells and free radicals as mediators of hepatotoxicity from chronic ethanol exposure (Thurman et al., 1999).

Rodent liver is often a site of chemically induced carcinogenesis observed in the two-year bioassay (Chhabra et al., 1990). Rat liver is a well-established model for the study of multistage chemical carcinogenesis. Specificity for the individual stages of initiation and promotion has been demonstrated for a variety of chemicals and has contributed to the mechanistic understanding of critical events necessary for each stage. As with other multistage models, initiation in rat liver has been shown to result from chemical modification of DNA and subsequent mutation. Compared to other models, however, rat liver has been especially informative about events associated with promotion because one of the earliest tumor precursor lesions is discernible in this system. These lesions, the altered hepatocyte foci (AHF), are small aggregates of hepatocytes distinguished by tinctoral staining and enzyme expression patterns that are also shared with subsequent neoplasias. Each AHF is presumed to be the clonal expansion of a single initiated cell; thus, information about rate of initiation and growth potential of initiated cells can be derived from AHF counts and morphometric analyses. Studies on differential properties of focal hepatocytes relative to those of surrounding liver have clearly demonstrated a role for chemical tumor promoters in creating an imbalance in cell proliferation and loss through programmed cell death (apoptosis; *UNIT 2.2*). In addition to their value for mechanistic studies, the development of these focal lesions within a relatively short treatment period (~4 months) has enabled the

development of an efficient screening assay for nongenotoxic hepatocarcinogens (Dragan et al., 1991).

An important etiological factor of human hepatocarcinogenesis is infection with hepadna viruses. Animal models that closely mimic this disease include transgenic mouse models and naturally occurring infected species, such as the woodchuck *(Marmota mona*x). These models have been valuable for understanding mechanistic aspects of virally induced carcinogenesis (Rogler et al., 1995) and evaluating efficacy of antiviral therapeutics. They also promise to be excellent experimental tools for study of viral interactions with chemicals that produce noncancerous forms of hepatotoxicity (Cullen and Marion, 1996).

CONCLUSION

This overview has presented some of the salient features of liver biology and physiology that provide the basis for a variety of experimental tools used for the study of chemical hepatotoxicity. An important protocol unit, to follow, details procedures to conduct the histopathological and clinical chemistry assessments that yield definitive evidence for adverse chemical effects on the liver. Additional units will focus on more mechanistic and functional aspects of hepatotoxicology and will present liver-specific protocols that address these types of issues. Once questions about a chemical's hepatotoxicity focus on the molecular level, these also can be approached with methods presented in units of Chapters 2, 3, 4, and 6. Collectively, these and future contributions to *Current Protocols in Toxicology* provide a wide assortment of experimental tools for the study of many of the diverse responses of the liver to toxicants (for additional background, see Arias et al., 1994).

Preparation of Hepatocytes

Recent advances in laboratory procedures have made it a common practice to investigate the metabolism of new chemical entities (NCEs) and candidate drugs by various in vitro biological systems. In many instances, the in vivo metabolism of xenobiotics may increase or decrease a drug's toxicity or mutagenicity, and such metabolism may represent the underlying basis of clinically significant drug-drug interactions. Intact primary hepatocytes are one of the in vitro systems used for investigating drug metabolism and toxicity and for evaluating the in vivo disposition of drugs and other xenobiotics. In contrast to subcellular fractions, intact hepatocytes contain both Phase I (oxidative) and Phase II (conjugative) enzymes that are present in various organelles (e.g., microsomes, cytosol, mitochondria) together with the required cofactors (e.g., NADPH, uridine diphosphate-glucuronic acid, 3′-phosphoadenosine-5′-phosphosulfate). Accordingly, isolated hepatocytes provide an in vitro system for studying the integrated metabolism of drugs and other xenobiotics.

Intact viable hepatocytes can be isolated from the liver tissue of a wide variety of laboratory animals as well as from nontransplantable human livers (i.e., those donated for research). Briefly, liver tissue is perfused by a two-step collagenase digestion. The first perfusion buffer (PB-1), containing ethylene glycol-bis(β-aminoethylether)-*N*,*N*,*N*′,*N*′-tetraacetic acid (EGTA), depletes the liver of interstitial calcium and weakens epithelial cell-cell adhesion, which facilitates enzymatic digestion. The second perfusion buffer (PB-2) contains collagenase, which digests intercellular collagen required for cell-cell adhesion; this eventually leads to the complete digestion of cell-cell contacts.

In the case of laboratory animals, the best results are obtained when the liver perfusion is performed in situ during a nonrecoverable surgery (see Basic Protocol). Direct cannulation of the hepatic portal vein in an anesthetized animal allows for delivery of perfusion buffers directly into the encapsulated liver, resulting in increased perfusion efficiency and therefore greater hepatocyte yield. For previously excised livers or liver tissue (see Alternate Protocol), blood is removed by purging with a balanced salt solution, and the tissue is perfused and digested by cannulation of one or more blood vessels. Following perfusion, hepatocytes are released from the digested liver into a complete medium containing serum and hormonal supplements. Viable cells are then isolated by low-speed centrifugation and separated from dead cells through the use of a colloidal suspension of polyvinylpyrrolidone (PVP)–coated silica (Percoll). Finally, isolated viable hepatocytes are washed with fresh medium, resuspended in incubation medium, and dispensed into incubation vessels. Alternatively, hepatocytes can also be cryopreserved (see Support Protocol), although this may be associated with the loss of some hepatocellular functions, especially in the case of human hepatocytes.

CAUTION: Organs obtained from some laboratory animals and human donors may harbor infectious agents, which represent biological hazards. Take precautions to protect laboratory personnel with proper immunizations against these infectious agents as well as personal protective equipment including eye protection, gloves, and, if necessary, face masks. If possible, conduct all hepatocyte isolation steps in a Biosafety class II containment hood. Additionally, dispose of all potential biohazardous waste in a manner consistent with local laws and regulations.

NOTE: All protocols using live animals must first be reviewed and approved by an Institutional Animal Care and Use Committee (IACUC) and must follow officially approved procedures for the care and use of laboratory animals. Procedures involving the use of human-derived organs and tissues may require Institutional Review Board (IRB) approval by the Human Subjects Committee.

Contributed by Daniel R. Mudra and Andrew Parkinson

Current Protocols in Toxicology (2001) 14.2.1-14.2.13

NOTE: All solutions and equipment coming into contact with living cells must be sterile and aseptic technique should be used accordingly

NOTE: All culture incubations should be performed in a humidified 37°C, 5% CO_2 incubator unless otherwise specified.

BASIC PROTOCOL

IN SITU PERFUSION OF LABORATORY ANIMAL LIVER TO ISOLATE INTACT HEPATOCYTES

Perfusion during nonsurvival surgery is typically performed on small laboratory animals, such as mice or rats, and consistently yields a high number of viable hepatocytes. Direct cannulation of the portal vein in an anesthetized animal takes advantage of the dilated hepatic vascular system, thereby increasing the overall efficiency of the perfusion. This requires that the technician use a number of surgical techniques and that the animal be anesthetized (under a surgical plane) but alive during the initial part of the perfusion. Maintenance of aseptic technique, including the use of sterilized surgical instruments, is essential to minimize the risk of bacterial contamination of the resulting hepatocyte preparation.

Primary hepatocytes should be suspended in a hormone-supplemented complete medium and isolated by low-speed centrifugation. The percentage of viable cells in the preparation is improved through the prudent use of Percoll (Sigma-Aldrich). If possible, it is best to perform hepatocyte isolation steps in a biosafety containment hood. This will protect the analyst from undue exposure to potential biohazards as well as protect the hepatocyte suspension from possible microbial contamination.

Materials

Laboratory animal
50 mg/ml sodium pentobarbital dissolved in 5:4:1 (v/v/v) water/propylene glycol/alcohol (e.g., Nembutal, Abbott Laboratories)
Iodine surgical scrub (e.g., Betadine)
70% (v/v) ethanol
PBS (*APPENDIX 2A*), sterile
PB-1 (see recipe), sterile and oxygenated
Collagenase
PB-2 (see recipe), sterile and oxygenated
$DMEM^+$ (see recipe)
0.04% (w/v) trypan blue
90% (v/v) isotonic Percoll (Sigma-Aldrich) in PBS (*APPENDIX 2A*), store at 2° to 8°C
Culture medium (application specific)

Surgical tray
Gauze pads
Scalpel
Surgical sutures
Perfusion apparatus, including perfusion line, peristaltic pump, and oxygen source (see Fig. 14.2.1)
16-G surgical catheter
Surgical forceps
Surgical scissors, sterile
100-mesh nylon net or cheesecloth, sterile
Vacuum aspirator

Additional reagents and equipment for counting cells with a hemacytometer (*APPENDIX 3B*)

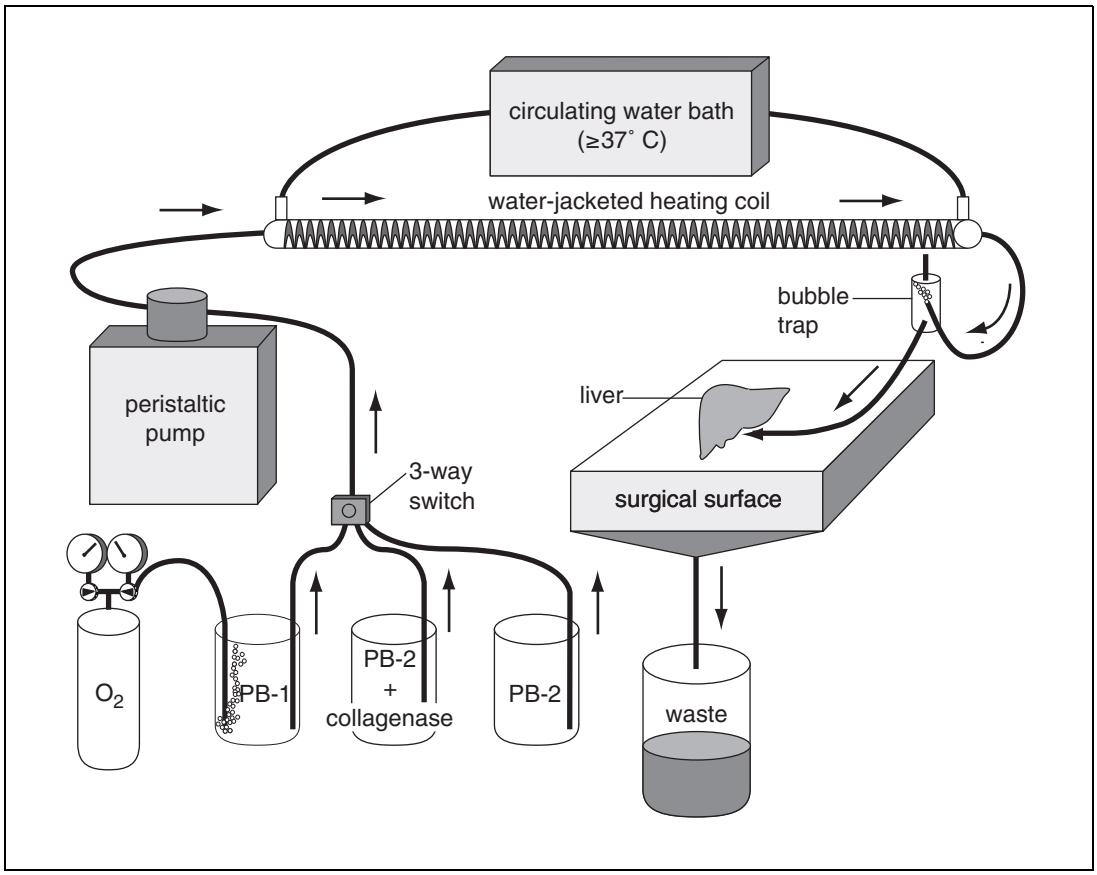

Figure 14.2.1 An example of a laboratory perfusion apparatus. This setup consists of a peristaltic pump, a heat source and a heat transfer device to maintain perfusate at 37° to 39°C, an in-line bubble trap to prevent large amounts of air from entering the liver, a carbogen (95% O_2/5% CO_2) source, and an adequate surgical procedure area. PB-1 and PB-2 are perfusion buffer 1 and 2, respectively.

Prepare animal for surgery

1. Anesthetize a laboratory animal with an appropriate dose of 50 mg/ml sodium pentobarbital.

   For most small laboratory animals (e.g., rats weighing 200 to 300 g), an intraperitoneal injection at ~60 mg/kg is sufficient to induce an anesthetic surgical plane. For larger animals (e.g., dog), the infusion of an anticoagulant before organ harvest should be considered, and a licensed veterinarian should be consulted for the appropriate surgical procedure.

2. Place animal on a surgical tray and cleanse the abdominal area with a gauze pad soaked in an iodine surgical scrub, followed by a scrub with a gauze pad soaked with 70% ethanol.

Cannulate portal vein

3. Use surgical scissors to make an initial incision through the skin and muscle wall proximal to the pubis (marked "a" in Fig. 14.2.2).

4. Cut through the abdominal skin and muscle wall with a curving incision from point "a" up to the rib cage (point "b" in Fig. 14.2.2).

   Do not cut into the diaphragm or any portion of the intestine.

5. Pull the abdominal skin and muscle above the thoracic cavity to expose the abdominal organs.

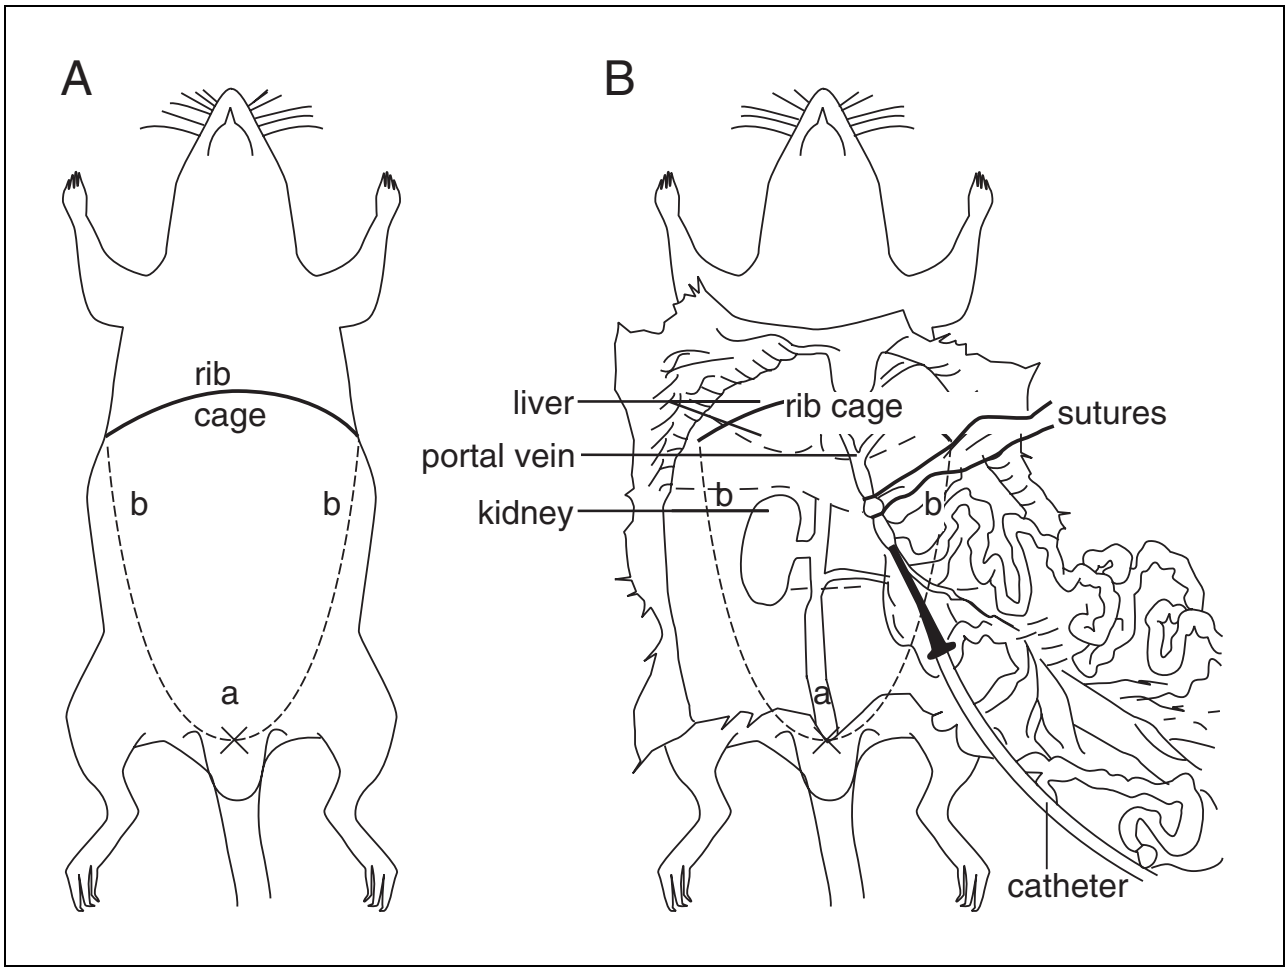

Figure 14.2.2 An example of surgical incisions on a laboratory rodent to expose the abdominal cavity. (**A**) Ventral view of an animal, with head (anterior) at the top. Each bilateral incision begins (×) at the pubis (a). The incision path follows the dotted line, up through the abdomen (b), ending at the anterior border of the rib cage as indicated. (**B**) Dissected view with intestines removed and showing positions of sutures and catheter.

6. Move the intestines from the abdominal cavity to the animal's left side using a gauze pad soaked with sterile PBS.

   If necessary, position the lobes of the liver so that the portal vein is easily accessible.

7. Place two surgical sutures loosely around the portal vein, but do not tighten.

   Blood must continue to flow through the portal vein at this time.

8. Set the peristaltic pump of a perfusion apparatus to deliver a slow drip (between 1 and 10 ml/min) of sterile oxygenated PB-1.

   Perfusion of livers for the purpose of hepatocyte isolation requires sustained perfusion of the organ at a relatively constant flow rate of 35 to 50 ml/min. Figure 14.2.1 shows one example of a perfusion system. Regardless of the source of the apparatus and its components, the assembled perfuser must provide variable flow rates, prevent air from entering the hepatic vascular system, provide a means of oxygenating the perfusion buffers, and maintain a constant perfusate temperature. For best results, all surfaces and the perfusion tubing should be cleaned with 70% (v/v) ethanol before and after each use. Before the perfusion is begun, all ethanol must be removed from the perfusion lines and replaced with PB-1.

9. Insert a 16-G surgical catheter, with the bevel of the needle facing up, into the portal vein distal to the sutures.

The size of the catheter may vary based on the size of the animal. For example, perfusion of a mouse liver may require a 22-G catheter, while perfusion of a guinea pig liver may require a 12-G catheter.

10. Provide gentle pressure to push the cannula forward, but not through, the vessel wall, so that the top portion is now proximal to both surgical sutures.

    Retrograde bleeding should now be observed at the base of the cannula.

11. Remove needle, leaving the cannula in the portal vein, and tighten sutures to secure the cannula.

Perfuse liver

12. Attach the perfusion line to the base of the cannula and immediately cut the inferior vena cava distal to the right kidney.

    The cut should be performed immediately after attachment of the perfusion line as pressure will quickly build within the liver and inferior vena cava.

13. Slowly increase the flow rate on the perfusion apparatus to between 35 and 50 ml/min.
14. Make a cut in the animal's diaphragm to expose the thoracic cavity, ceasing the animal's respiration.
15. Continue perfusion with PB-1 for 10 to 15 min.
16. Add collagenase to PB-2 at a final concentration of ~90 U/ml.

    Various categories of collagenase (e.g., Type I, Type IV.) are available from commercial vendors. Preparations may vary in activity based on the ratio of active enzyme content to contaminating proteases. The authors have found that Types I and IV collagenase (exceeding 500 U/mg) are most effective for the digestion of rat and human liver tissue. Each laboratory should determine which preparation of collagenase yields the best results for specific experimental conditions and animal species.

17. Switch perfusion apparatus to deliver oxygenated PB-2 containing collagenase. Continue perfusion for 10 to 20 min.
18. Switch perfusion apparatus to deliver oxygenated PB-2 without collagenase. Continue perfusion for 3 to 5 min.
19. Slowly decrease the flow rate (30 sec to 1 min) on the perfusion apparatus to stop the perfusion.

    During the course of the perfusion, no air should enter the liver via the perfusion lines. Air forced into the hepatic vascular system will dramatically decrease the viable cell yield.

Excise digested liver

20. Remove cannula from the portal vein and lift animal by the rib cage with surgical forceps, allowing the liver to fall forward.

    The digested liver is very soft and should be handled with care. The liver tissue should not be grasped directly with the forceps, rather grasp the surrounding vasculature or transport the liver using a surgical spatula.

21. Cut the connective tissue surrounding the liver, remove the liver from the abdominal cavity, and place it in a sterile container for processing.

    Do not cut any portion of the intestine, as this may expose the liver to intestinal flora that may contaminate the resulting hepatocyte preparation.

Process digested liver

22. Dispense DMEM$^+$ onto the digested liver such that 75% to 100% of the tissue is covered with medium.

23. Release hepatocytes into the surrounding medium by tearing Glisson's capsule (the outer membrane) using sterile surgical scissors.

    Depending on the efficiency of tissue digestion, it may be necessary to manually cut the tissue into fine pieces, thus releasing the hepatocytes into the medium. Scissors may be employed for this purpose.

24. Filter suspension using a sterile 100-mesh nylon net or, for suspensions ≥300 ml, a dual layer of sterile cheesecloth.
25. Divide filtered suspension among several sterile 50-ml centrifuge tubes.
26. Centrifuge 3 (±1) min in a low-speed centrifuge at 40 to 60 × *g*, room temperature.
27. Use a vacuum aspirator to remove supernatant fraction, add 5 to 10 ml DMEM$^+$ to each cell pellet, and gently resuspend cells. Pool cell suspensions.
28. Prepare an 8:1:1 (v/v/v) dilution of PBS/0.04% trypan blue/cell suspension (typically 50 to 100 µl of the homogeneous suspension) and count hepatocytes (*APPENDIX 3B*).

    Trypan blue is taken up by dead cells and excluded by live ones, thus allowing determination of percent viability and total cell counts.

29. Add 90% isotonic Percoll according to Table 14.2.1 and gently mix by inversion. Divide among sterile 50-ml centrifuge tubes, as needed, so that no tube contains >5 ml suspension.

Isolate cells

30. Centrifuge 5 (±1) min at room temperature according to Table 14.2.1.
31. Discard supernatant fraction by aspiration, add 5 to 10 ml DMEM$^+$ to each cell pellet, and gently resuspend.
32. Combine all remaining cells into one tube, if possible.

    The cell pellet in one 50-ml centrifuge tube must not be >10 ml.

33. Centrifuge 3 (±1) min at 40 to 60 × *g*, room temperature.
34. Discard supernatant fraction by aspiration, add a small volume of culture medium (e.g., 1 ml medium per milliliter of cell pellet), and gently resuspend.

    The culture medium may vary based on the application.

35. Combine cell suspension into one vessel.
36. Prepare an 8:1:1 (v/v/v) dilution of PBS/0.04% trypan blue/cell suspension and count hepatocytes (*APPENDIX 3B*).
37. Dilute cells with culture medium to the desired concentration and set up drug metabolism studies (see Table 14.2.2) or cryopreserve cells (see Support Protocol).

Table 14.2.1 Experimental Conditions for Percoll Centrifugation of Hepatocytes from Various Species

Species	% Percoll in DMEM$^+$	Centrifugation (× *g*)
Rat, mouse, dog	45%	60-80
Monkey	25%	40-60
Human	20-25%[a]	40-60

[a]Percoll concentration may be decreased if human hepatocytes contain high levels of intracellular fat (see Table 14.2.3).

Table 14.2.2 Recommended Experimental Conditions for Xenobiotic Metabolism Experiments

Experimental condition	Recommendation
Incubation time and medium	≤2 hr in balanced salt (e.g., Hank's, Kreb's) ≤6 hr in complete medium (e.g., DMEM+, Waymouth's, William's E)[a]
Hepatocyte concentration	1×10^6 viable cells/ml
Incubation volume	50-100 µl in 96-well plate 250 µl in 24-well plate 1.0 ml in 20-ml scintillation vial
Incubation conditions	37°C, 95% relative humidity, 95% air/5% CO_2, nonshaking incubator
To start incubations	Place multiwell plates on ice (4°C) until incubations are to be started. Enzymatic reactions will begin when cell suspensions are placed at 37°C.
To stop incubations	Place cell suspensions at or below −70°C or add an equal volume of stop reagent (e.g., concentrated acid, organic solvent).

[a]Typically it is not recommended to incubate hepatocytes in a suspension culture for >6 hr.

PERFUSION OF A PREVIOUSLY EXCISED LIVER

ALTERNATE PROTOCOL

Perfusion of a previously excised liver is typically useful for the perfusion of livers from large laboratory animals (e.g., dog, monkey) or nontransplantable human livers donated for research. This procedure can be performed on a whole liver or on a portion of a liver with a single cut face and encapsulated by Glisson's capsule. Typically, the best results are obtained when the liver is preperfused with an organ preservation solution—for example, University of Wisconsin (UW) solution (Jamieson et al., 1988)—and stored on wet ice during its transport to the laboratory. These steps will help to minimize organ damage and loss of cell viability during cold-ischemic transport. As a general rule, perfusion of an excised liver should be performed within 24 to 36 hr after harvest.

Additional Materials *(also see Basic Protocol)*

Previously excised liver
Plastic cannulas from surgical catheters (or equivalent)
Medical adhesive (e.g., Loctite 4013; Loctite)

1. If possible, insert a single perfusion line (e.g., perfuser tubing) into the portal vein and/or the hepatic artery of a previously excised liver. Secure the inserted tubing using silk sutures, umbilical tape, or medical adhesive. In the case of a cut portion of a liver, use a surgical catheter to access the portal vein. Use up to four catheters and attach each to a branch of the perfusion tubing.
2. Seal any remaining vessels on the face of the liver with medical adhesive and allow adhesive to set for the time indicated by the manufacturer.

   For best results, apply a sufficient amount of medical adhesive to seal all cut portions of the liver. This will increase the internal vascular pressure, leading to increased perfusion efficiency.

3. Start the peristaltic pump of the perfuser to deliver a slow flow rate of sterile, oxygenated PB-1 and gradually increase to between 100 and 600 ml/min. Maintain perfusion for 10 to 15 min.
4. Add collagenase (~90 U/ml) to PB-2 (see Basic Protocol, step 16).
5. Switch perfusion apparatus to deliver oxygenated PB-2 containing collagenase and perfuse 10 to 20 min.

   The waste collected here may be recirculated through the perfusion apparatus.
6. Switch perfusion apparatus to deliver oxygenated PB-2 without collagenase. Continue perfusion for 3 to 5 min.
7. Slowly decrease the flow rate on the perfusion apparatus to stop the perfusion.
8. Place the digested liver in a sterile container and isolate cells (see Basic Protocol, steps 22 to 37).

SUPPORT PROTOCOL

CRYOPRESERVATION OF HEPATOCYTES

As an alternative to the immediate use of isolated hepatocytes, the cells may be cryopreserved and stored in the vapor phase of liquid nitrogen for later use. Cryopreserved hepatocytes can be thawed and reisolated for use in integrated drug metabolism studies. Yields after thawing may vary among species, although cryopreserved hepatocytes have been shown to retain most hepatocellular functions such as active drug-metabolizing enzymes (Guillouzo et al., 1999; Li et al., 1999; Madan et al., 1999).

Additional Materials *(also see Basic Protocol)*

Isolated hepatocytes (see Basic Protocol; see Alternate Protocol)
Fetal bovine serum (FBS), heat-inactivated (*APPENDIX 3B*)
Dimethyl sulfoxide (DMSO)

Hepatocyte storage vials (must withstand −196°C)
Microprocessor-controlled programmable freezing chamber (e.g., model 1010; Forma Scientific) with thermometer
Liquid nitrogen storage unit

Prepare hepatocytes

1. Centrifuge isolated hepatocytes 3 (±1) min at 40 to 60 × *g*, room temperature.
2. Discard supernatant fraction by aspiration with a vacuum aspirator.
3. Add a sufficient volume of FBS to bring concentration to 11×10^6 viable cells/ml (as determined in Basic Protocol, step 36) and gently resuspend cell pellet.

   Although a cell concentration of 10×10^6 viable cells/ml is recommended for most applications, optimal cell concentrations may differ for specific species or applications.
4. Slowly add DMSO dropwise to a final concentration of 10% (v/v) and mix cell suspension by gentle inversion.

Prepare storage vials

5. Divide the homogenous mixture into aliquots in hepatocyte storage vials.
6. Cryopreserve hepatocytes in a microprocessor-controlled programmable freezing chamber according to the following stepwise freezing program. Use a temperature probe to measure the temperature of a sample containing only FBS and 10% (v/v) DMSO.

Cool −1°C/min until sample reaches −4°C
Cool −25°C/min until chamber reaches −25°C (sample temperature should be approximately −8° to −10°C)
Warm 15°C/min until chamber reaches −12°C
Cool −1°C/min until chamber reaches −40°C
Cool −10°C/min until chamber reaches −90°C
Hold −90°C until sample reaches −90°C.

7. Transfer vials to a liquid nitrogen storage unit.

The vial used to measure sample temperature should be discarded. For best results store the vials in the vapor phase at or below −145°C.

Thaw hepatocytes

8. Remove one or more vials of cryopreserved hepatocytes from the liquid nitrogen storage unit.
9. Place in a 37°C shaking water bath until sample is partially thawed and can be poured from the vial.
10. Gently pour thawed hepatocytes into a sterile 50-ml centrifuge tube containing 28.2 ml $DMEM^+$ and 11.8 ml of 90% isotonic Percoll.
11. Add $DMEM^+$ to obtain a final concentration of 21.5% (v/v) Percoll.
12. Centrifuge hepatocytes 5 (±1) min at room temperature according to Table 14.2.1.

Prepare cell suspension

13. Count cells as described (see Basic Protocol, steps 27 to 28).
14. Combine all remaining cells into one tube, if possible.

The cell pellet in one 50-ml centrifuge tube must not be >10 ml.

15. Prepare final suspension as described (see Basic Protocol, steps 33 to 37) and immediately deliver cells to a suspension culture containing the investigative substrate.

It is thought that cryopreserved hepatocytes may have an infinite storage life when maintained at ultra-cold temperatures (liquid nitrogen). However, rigorous studies into the long-term storage of cryopreserved hepatocytes are incomplete, and it is recommended that each laboratory monitor cell yield and viability in preparations over time.

REAGENTS AND SOLUTIONS

Use Milli-Q-purified water or equivalent (0.22-μm filtered with a resistivity ≥14 MΩ cm) in all recipes and protocol steps. Filter sterilize (0.22-μm filter) all solutions prepared with nonsterile components at the time of preparation. For common stock solutions, see ***APPENDIX 2A****; for suppliers, see* ***SUPPLIERS APPENDIX****.*

Perfusion buffer 1 (PB-1)

To ~1.8 liters water add:
13.8 g NaCl (final 118 mM)
0.7 g KCl (final 4.7 mM)
0.33 g KH_2PO_4 (final 1.2 mM)
4.2 g $NaHCO_3$ (final 25 mM)
2.0 g glucose (final 5.5 mM)
0.4 g EGTA (final 0.5 mM)

continued

Adjust to pH 7.4 with NaOH or HCl as needed
H_2O to 2 liters
Sterilize with a 0.22-μm filter
Store up to 6 months at 4°C

Perfusion buffer 2 (PB-2)

Prepare as for PB-1 (see recipe), but replace EGTA with:
4 ml 1.0 M $CaCl_2$ (final 2.0 mM)
2.4 ml 1.0 M $MgSO_4$ (final 1.2 mM)
Store up to 6 months at 4°C

Supplemented Dulbecco's modified Eagle medium (DMEM$^+$)

Two packages (13.4 g/package) DMEM without phenol red (Life Technologies)
7.4 g $NaHCO_3$ (final 44 mM)
20 ml 200 mM GlutaMAX-1 (Life Technologies; final 2 mM)
20 ml 10 mM MEM non-essential amino acids solution (MEM-NEAA, Life Technologies; final 0.1 mM)
25 ml heat-inactivated fetal bovine serum (FBS; *APPENDIX 3B*; final 5%, v/v)
781 μl 4 mg/ml insulin (final 6.25 μg/ml)
5 ml penicillin/streptomycin (100× stock: 5000 U/ml penicillin, 5000 μg/ml streptomycin)
50 μl 10 mM dexamethasone in dimethyl sulfoxide (final 1 μM dexamethasone)

Dissolve DMEM in ~1.8 liters water. Add $NaHCO_3$, GlutaMAX-1, and MEM-NEAA. Adjust pH to 7.4 with NaOH or HCl, as needed, and adjust final volume to 2 liters with water. Filter sterilize and store up to 6 months at 4°C. Before use, add FBS, insulin, penicillin/streptomycin, and dexamethasone to 500 ml medium. Store up to 1 month at 4°C.

NOTE: *DMEM and DMEM$^+$ are light sensitive and should be stored in a dark environment.*

COMMENTARY

Background Information

Recent advances have made it increasingly common to conduct experiments designed to predict the in vivo metabolism and disposition of drugs and other xenobiotics. A variety of in vitro systems has been developed to conduct these experiments. In order of increasing complexity, these are: recombinant enzymes, liver microsomes (and other subcellular fractions), postmitochondrial fraction (S9), immortalized cell lines, primary hepatocytes, and liver slices (Parkinson, 1996b; Parkinson et al., 1997). Intact primary hepatocytes offer several advantages over other in vitro systems. However, they also present unique challenges that must be considered in an experimental design.

Isolated primary hepatocytes can be obtained from various laboratory animals, as well as from nontransplantable human livers (i.e., those donated for research). The perfusion process described in this unit is based on the methods described by Berry and Friend (1969), Seglen (1976), Quistroff et al. (1989), and LeCluyse et al. (1996a,b). This process yields viable hepatocytes suitable for drug metabolism studies. The process of hepatocyte isolation includes several measures and precautions to maintain viability and hepatocellular function.

Hepatocytes have inherent characteristics that should be considered when determining their suitability for drug metabolism studies. Compared with precision-cut liver slices, isolated hepatocytes have been shown to exhibit greater rates of testosterone oxidation, 7-ethoxycoumarin O-deethylation, and 1-chloro-2,4-dinitrobenzene (CDNB) conjugation with glutathione (Ekins et al., 1995). The lower metabolic rates observed in liver slices are most likely due to a low rate of substrate and nutrient diffusion through the multiple layers of hepatocytes, which is not a problem with isolated hepatocytes.

Intact hepatocytes provide a complex biological system in which substrates are subject to metabolism by a variety of enzymes either simultaneously or sequentially. These enzymes include, but are not limited to, cytochrome

P450 enzymes (CYPs; Seddon et al., 1989; Bayliss et al., 1994) as well as sulfotransferases (STs), UDP-glucuronosyltransferases (UGTs), and glutathione *S*-transferases (GSTs; Ekins et al., 1995). This abundance of active enzymes must be considered when analyzing data obtained from hepatocyte incubations. For example, consider that a primary oxidative metabolite of interest may be rapidly glucuronidated, thereby making the oxidative metabolite nondetectable by the standard analytical method. In cases such as this, it may be desirable to reduce the incubation time or to enzymatically deconjugate metabolites (e.g., with β-glucuronidase and/or sulfatase). Furthermore, some preparations of human hepatocytes may fail to convert a substrate to a metabolite known to be formed by pooled human liver microsomes. One possible cause of this negative result is that the hepatocyte preparation is from a donor who lacked the enzyme responsible for forming the metabolite. Several drug-metabolizing enzymes are known to be polymorphically expressed (Parkinson, 1996a), and the use of individual (i.e., nonpooled) hepatocyte samples may at times result in negative metabolic results.

Finally, hepatocytes offer a unique in vitro system to study a compound's toxicological effects. Analysis of intracellular toxicological markers such as ATP levels, heat shock–protein content, rate of mitochondrial respiration, or enzyme levels in the surrounding medium—for example, lactate dehydrogenase (LDH), alanine aminotransferase (ALT), and aspartate aminotransferase (AST)—will allow for a rapid estimate of an NCE's hepatotoxic effects. Measurement of trypan blue uptake over the course of the incubation may provide insight into the possible toxic effects of the substrate. There is also growing interest in the use of microarrays to screen for changes in gene expression in order to evaluate the potential hepatotoxicity of a chemical.

Critical Parameters and Troubleshooting

It is important that hepatocytes be isolated in a medium containing the synthetic glucocorticoid dexamethasone, which maintains liver-specific functions (e.g., albumin synthesis), supports organized arrangement of the cytoskeleton, and alleviates the loss in protein synthesis typically observed in the first 24 hr after isolation (LeCluyse et al., 1996b). It is also important to note that efforts should be made to maintain high cell viability during drug metabolism studies. Typically, the initial isolation of hepatocytes may yield a preparation that is made up of only 50% to 70% viable hepatocytes. This percent viability can be greatly enhanced by centrifugation with an isotonic mixture of the PVP-coated silica, Percoll. It is important to note that apoptotic and ruptured hepatocytes are likely to be metabolically incompetent, as the cofactors necessary for drug metabolism have been diluted into the surrounding medium. Additionally, an overabundance of nonviable hepatocytes present in an incubation mixture may increase the levels of lysosomes and autolytic enzymes in the surrounding medium, thereby leading to a more rapid decline in cell viability and substrate metabolism. For these reasons, it is prudent to make efforts to increase the overall cell viability in the hepatocyte preparation.

Table 14.2.3 lists possible problems and recommended solutions that may be encountered during the hepatocyte isolation procedure. Remember that in the case of human hepatocyte isolation—and in the case of some laboratory animals (e.g., monkey)—disease and environmental factors may cause dramatic differences in the efficiency of tissue digestion and overall hepatocyte yield.

Additional problems may be encountered during hepatocyte incubations. Experimental designs may vary for numerous reasons including species specificity, the compound under investigation, and the forthcoming analytical method. Table 14.2.2 provides a brief outline of several considerations and recommendations for designing drug metabolism experiments with hepatocytes.

Anticipated Results

The percent viability of the final hepatocyte preparation will typically be ≥70% (with higher viability typically observed in preparations of rat hepatocytes). The number of hepatocytes obtained per gram of liver tissue will vary depending on the species.

Time Considerations

The perfusion procedures described in the Basic Protocol and Alternate Protocol require ~1 to 1.5 hr to complete (this does not include solution preparation, laboratory setup, or apparatus cleaning). The hepatocyte isolation procedure described in the Basic Protocol requires ~2 hr. Additional time is required once hepatocyte incubations are initiated; incubation times may range from 10 min (Zomorodi et al., 1995) to 6 hr; see Table 14.2.2. The cryopreservation

Table 14.2.3 Troubleshooting Guide for Preparation of Hepatocytes for Xenobiotic Metabolism Studies

Problem	Critical parameters and recommended measures
Difficulty in placing surgical sutures around portal vein	In laboratory rats there is typically a space in the fat tissue surrounding the portal vein. Use a pair of curved forceps to help locate this space and provide a means to thread the surgical suture around the vein.
Initial perfusion does not remove all blood (clotting is evident)	Gently pull cannula away from liver, being careful to leave it in the portal vein.
	Increase perfusion flow rate.
Poor liver digestion and low cell yield	Catheter may not be inserted properly. It is important to obtain good flow into the portal vein. Be sure catheter needle has not poked a hole in the vein, allowing perfusion buffer to leak out before reaching liver.
	Increase purity of collagenase. Utilize a collagenase high in enzymatic purity (in U/mg). Low enzyme purity is caused by proteases that will impede digestion and decrease hepatocyte viability.
	Be sure no air has entered the perfusion line.
Initial centrifugation does not yield many cells, but many cells are in supernatant	Dilute cell suspension to a point where cells efficiently pellet at a low-speed centrifugation (see Table 14.2.1). As a general rule, do not exceed 5-ml cell pellets in each 50-ml centrifuge tube.
Cell buildup at the top of the supernatant after Percoll separation	This is normal. The buildup contains mostly dead cells that are meant to be removed from the hepatocyte preparation.
No cell pellet after Percoll centrifugation	Increase centrifugation speed or time slightly.
	Decrease Percoll content. In the case of hepatocytes from human and some laboratory animals, the cells may contain high levels of intracellular fat (visible with a microscope at 100×), which will decrease the efficiency of the Percoll separation.
Percent viability is no better after Percoll centrifugation than before	Increase Percoll concentration and recentrifuge.
	When aspirating supernatant, be sure to aspirate off dead cells on top of the supernatant. If this layer is not carefully removed, the cells will be integrated with the viable cell pellet, minimizing the effectiveness of the Percoll separation.
Trypan blue count does not accurately reflect hepatocyte density	Obtain an aliquot from a homogeneous cell suspension. Any settling of the hepatocytes may lead to an errant trypan-blue count, which will lead to inaccurate cell numbers added to each hepatocyte incubation.
Cell yield is high although viability is quite low	Decrease time of perfusion with collagenase. Collagenase can be toxic to hepatocytes.
	Select a collagenase with higher purity (U/mg).
	Be sure the temperature of the perfusate is maintained between 37° and 39°C during perfusion. This is the temperature range where collagenase is most active.
	Improve hepatocyte handling techniques. Hepatocytes must be handled gently during cell isolation to avoid physical trauma to the cell membranes.
	In the case of human liver, organ damage occurring prior to perfusion may result in isolation of nonviable hepatocytes. Trypan-blue exclusion performed before Percoll centrifugation will provide initial viability information that may aid in determining the health of the original liver.

procedure requires ~1.5 hr including the stepwise freezing procedure.

Small Animal Models of Hemorrhagic Shock–Induced Liver Dysfunction

Blood loss and ensuing circulatory failure continues to be the leading cause of death between the ages of 1 and 45 in most western countries. About one half of the deaths result from rapid exsanguination or severe central nervous trauma within 1 hr of injury. Although progress has been made with respect to early resuscitation of trauma victims, depression/disturbances of cellular functions propagate the development of multiple organ failure and sepsis, the leading course of late death in the intensive care unit. Hepatocellular dysfunction is a key feature of the pathophysiological sequelae of trauma/hemorrhage in patients surviving the first hours and hemorrhagic hypotension has been widely used as a model for indirect liver injury in the critically ill. At least two phases of hepatic dysfunction can be distinguished: an early injury characterized by ischemia/reperfusion of the pericentral region of the liver acinus with enzyme leakage and development of acute "pericentral necrosis" and a late injury resulting from an inflammatory reaction ("ischemic hepatitis"), which is heralded by a rise in serum bilirubin (Hawker, 1991).

This unit describes a low-flow ischemia model of the liver due to hemorrhagic hypotension (see Basic Protocol) that can be used to produce a reproducible and graded injury to the pericentral region of the acinus, which is critical for metabolism of xenobiotics. This protocol allows for measurement of cardiac output and regional flow (see Support Protocol 1) and requires specially prepared tubing (see Support Protocol 2).

INDUCING HEMORRHAGIC SHOCK

BASIC PROTOCOL

Small animal models of hemorrhagic shock with or without resuscitation can be subdivided based on the physiological end point to define the severity of the ischemic insult as well as the use of anesthetics and/or heparin or infliction of a concomitant trauma (Chaudry et al., 1993). The following protocol describes an anesthetized, nonheparinized rat model of reversible hemorrhagic shock without concomitant trauma where the ischemic insult is defined by maintenance of a fixed mean arterial blood pressure over a given period of time. In addition, a resuscitation protocol is described, which restores central and liver regional hemodynamics while moderate hemodilution is tolerated similar to the current clinical standards (Bauer et al., 1996).

Materials

Male Sprague-Dawley rats (≥250 g body weight)
Sodium pentobarbital
Disinfectant
Ringers solution (see recipe)
Citrate-phosphate-dextrose solution; aseptically filtered (see recipe): suggested anticoagulant/whole blood ratio is 1.4:10; store at 4° to 8°C

Animal clippers
Heating pad
Rectal temperature probe (e.g., Thermistor 8402-20, Cole-Parmer Instrument)
Sterile surgical instruments
Polyethylene tubing (0.58-mm i.d., 0.96-mm o.d.; Intramedic PE 50, Becton Dickinson Primary Care Diagnostics), TDMAC coated (see Support Protocol 2)
Pressure transducer and data acquisition system
5-ml sterile disposable syringes

Current Protocols in Toxicology (2002) 14.3.1-14.3.8

Induce anesthesia and prepare for surgery

1. Withhold food from animals for 12 hr prior to surgery, but allow ad lib access to water.
2. Induce general anesthesia by intraperitoneal injection of 50 mg pentobarbital/kg body weight.

   This protocol has been standardized for male Sprague-Dawley rats since there is sexual dimorphism with respect to susceptibility to ischemic injury of the liver. Since hepatic glutathione levels and intravascular volume are important determinants of bleed-out volume and hepatocellular susceptibility to redox injury, pellet food is withheld for 12 hr prior to onset of the experiment, while animals are allowed free access to water. Surgery must be performed at defined times (7:00 to 8:00 a.m.) due to the circadian profile of hepatocellular glutathione content.

3. Shave neck and apply disinfectant prior to surgical incision.
4. Place animals on a 38°C heating pad to maintain body temperature at 36° to 37°C. Monitor the body temperature using a rectal probe.

   Body temperature is an important determinant of ischemic injury.

5. Perform a tracheotomy to ensure a patent airway and allow the animal to breathe ambient air.

   The tubing should be as wide as possible to avoid airway obstruction and should not be longer than 2 cm to avoid increase in dead space. Spontaneous breathing is recommended since positive pressure ventilation will impair hepatic venous drainage and splanchnic blood flow. If artificial ventilation is required, neuromuscular blockade should be achieved with a long acting nondepolarizing neuromuscular blocking agent (e.g., 0.1 mg/kg pancuronium bromide, Sigma).

6. Cannulate the right jugular vein, the left carotid artery, or a femoral artery using polyethylene tubing (PE 50).

   To avoid clotting use PE tubing that is coated with tridodecylmethylammonium heparinate (TDMAC, see Support Protocol 2). If two arteries need to be cannulated, e.g., for insertion of a thermistor-tipped probe allowing measurement of cardiac output and invasive blood pressure reading/blood withdrawal, a carotid and a femoral artery can be used. In this case, the thermistor-tipped probe is inserted through the carotid artery and must be advanced to the aortic root, while the arterial line is placed into the femoral artery. Never cannulate two carotid arteries since bilateral ligation of the carotid arteries in combination with hemorrhagic hypotension induces brain ischemia and respiratory arrest.

7. Start a constant infusion of an isotonic Ringers solution (10 ml/kg/hr) immediately after establishing venous access to compensate for evaporative losses during surgery. Continue this infusion in time-matched sham-operated animals for the whole experiment. Measure the arterial blood pressure continuously by connecting the arterial line to a pressure transducer.

Induce hemorrhagic shock and resuscite

8. After a stabilization period of 15 min and recording of baseline hemodynamics, induce hemorrhagic hypotension by blood removal via the arterial line, collecting shed blood in 5-ml syringes containing citrate-phosphate-dextrose solution to avoid clotting.

   The required shed blood volume to achieve a mean arterial pressure (MAP) of 35 to 40 mmHg is ~2 to 2.5 ml/100 g body weight. The target pressure should be achieved within 5 min.

   The use of heparin as the anticoagulant for shed blood storage should be avoided since heparin has a substantial protective effect in this model.

9. Maintain target MAP by withdrawal of small amounts of blood (0.2 to 0.4 ml) during the early ("compensatory") phase of hemorrhage or by reinfusion of saline during the late ("decompensatory") phase.

10. Resuscitate by retransfusion of 60% of shed blood over 20 min and three times the shed blood volume of Ringers solution over 2 hr.

If the hemorrhagic hypotension is limited to 60 to 90 min, a complete recovery of central and liver regional hemodynamics can be achieved with this protocol ("reversible shock"). Longer periods may result in irreversible shock. However, even with restoration of (supra-) normal central hemodynamics, some degree of microvascular failure of the sinusoids will ensue.

MEASUREMENT OF CARDIAC OUTPUT AND REGIONAL FLOW

SUPPORT PROTOCOL 1

If measurement of cardiac output is required (for most experimental conditions this is optional), it can be achieved by the transpulmonary dilution technique (Bauer et al., 1996).

A bolus of 0.1 ml cold physiological saline is injected into the central venous line and cardiac output can be calculated from the area under the curve of the temperature reading of the thermistor tip (thermistor tip catheter, Columbus Instruments) placed in the aortic arch according to the Fick principle (e.g., on a cardiac output computer, Cardiomax II, Columbus Instruments). Although techniques using microspheres allow accurate measurements of systemic and liver regional hemodynamics (Hauptman et al., 1989; Chaudry et al., 1993; Van Oosterhout et al., 1998), the use of the thermodilution technique has the advantage that it allows repeated measurements of cardiac output. The thermodilution technique yields somewhat higher cardiac output values than other techniques due to the heat loss of the injectate from the vascular system and should therefore be reported as percent of baseline.

If measurements of regional blood flow are required, this can be achieved in the rat for most organs, including both inflows of the liver, by ultrasonic flow probes placed around the feeding vessels, e.g., hepatic artery and portal vein (T206, small animal flow meter, Transonic; Bauer et al., 1996; D'Almeida et al., 1996). In addition, high resolution intravital microscopy can be used to directly assess sinusoidal perfusion and hepatocellular mitochondrial redox state, since the sinusoid is an important site of blood flow regulation (Clemens and Zhang, 1999). While the latter technique is fairly sophisticated and requires expensive equipment, a simple method to assess microvascular perfusion and hepatocellular clearance capacity has been described using in vivo indocyanine green (ICG) clearance. After a bolus injection, plasma concentrations of ICG are measured and the maximum rate of ICG clearance (V_{max}) and Michaelis-Menten constant (K_m) are calculated (Hauptman et al., 1989; Chaudry et al., 1993).

COATING OF POLYETHYLENE TUBING WITH TDMAC

SUPPORT PROTOCOL 2

To prevent clotting, tridodecylmethylammonium (TDMAC) heparinate is used to coat the inner surface of polyethylene tubing.

CAUTION: TDMAC heparinate is highly toxic; see Material Safety Data Sheets for guidelines regarding handling, storage, and disposal. TDMAC heparinate is highly flammable, keep container tightly closed.

Materials

2% (w/w) solution (~1000 USP U/ml) TDMAC-heparin
(tridodecylmethylammonium heparinate; Polysciences)
Source of constant nitrogen flow

1. Coat the inner surface of the polyethylene tubing by refluxing in a 2% TDMAC-heparin solution.
2. Incubate 2 to 3 hr at 40° to 50°C.
3. Remove TDMAC-heparin by blowing a dry stream of nitrogen for 20 min through the tubing.
4. Air dry 1 to 3 hr at room temperature.
5. After drying, autoclave coated tubing.

REAGENTS AND SOLUTIONS

*Use Milli-Q-purified water or equivalent in all recipes and protocol steps. For common stock solutions, see **APPENDIX 2A**; for suppliers, see **SUPPLIERS APPENDIX**.*

Citrate-phosphate-dextrose solution, pH 5.6

0.327 g citric acid monohydrate
2.63 g sodium citrate dihydrate
2.32 g anhydrous glucose in injection-grade water
Bring to 100.0 ml; filter sterilize
Store up to 1 week at 4°C
Osmolality: 438 mOsmol/kg

Ringers solution

147 mM NaCl
4 mM KCl
2.3 mM $CaCl_2$
For 1 liter:
8.6 g NaCl
0.3 g KCl
0.33 g $CaCl_2$ in injection-grade water
Bring to 1000.0 ml
Filter sterilize or autoclave before use
Store up to 4 weeks at room temperature

COMMENTARY

Background Information

Various models of hypovolemic shock have been described since the original report by Penfield (1919) of a fixed-pressure model of hemorrhagic hypotension.

These models differ primarily with respect to the physiological endpoint to define the degree of injury. While fixed-pressure (as described above) or fixed-volume (i.e., defined by the amount of blood removed) models are easily used in small animal preparations, more sophisticated models, e.g., directly assessing oxygen debt, are restricted to large animals such as dogs or sheep.

The described model of hemorrhagic shock-induced injury to the pericentral region of the liver acinus allows for the infliction of a graded and defined dysfunction of those parenchymal cells of the liver primarily responsible for metabolism of xenobiotics. This dysfunction can be easily assessed by measuring clearance of drugs, such as indocyanine green (Hauptman et al., 1989; Chaudry et al., 1993). Moreover, the impact of therapeutic agents can be studied in a model closely mimicking the pathophysiology of many surgical conditions associated with development of secondary liver dysfunction.

Table 14.3.1 Typical Measurements Obtained from Hemorrhagic and Sham-Operated Animals[a,b]

Measurement	Baseline	End of shock	5 hr resuscitation
Mean arterial pressure [mmHg]	117.3 ± 5.44 (119 ± 4.33)	38.9 ± 0.50 (105.3 ± 3.23)	100.9 ± 4.35 (98.0 ± 4.98)
Heart rate [min^{-1}]	367.2 ± 8.98 (376.0 ± 11.45)	358.8 ± 19.05 (386.0 ± 16.22)	398.4 ± 15.05 (354.0 ± 8.63)
Cardiac output [% of baseline]	100.0 (100.0)	36.0 ± 3.59 (104.0 ± 4.02)	109.1 ± 6.08 (114.2 ± 5.93)
Hepatic arterial blood flow [ml/min]	3.4 ± 0.66 (3.4 ± 0.66)	0.7 ± 0.12 (3.1 ± 0.48)	2.5 ± 0.42 (2.4 ± 0.37)
Portal venous blood flow [ml/min]	19.5 ± 2.88 (19.5 ± 2.88)	7.0 ± 1.16 (17.8 ± 2.23)	18.8 ± 1.98 (15.9 ± 1.24)
pH	7.38 ± 0.01 (7.38 ± 0.02)	7.26 ± 0.02 (7.39 ± 0.02)	7.45 ± 0.01 (7.42 ± 0.01)
pO_2 [mmHg]	80.7 ± 5.47 (73.2 ± 4.68)	100.7 ± 18.07 (74.3 ± 5.10)	84.1 ± 3.49 (83.0 ± 3.69)
pCO_2 [mmHg]	51.6 ± 2.43 (49.4 ± 1.96)	34.0 ± 2.46 (41.9 ± 8.12)	40.5 ± 1.68 (40.9 ± 1.07)
Base excess [mmol/liter]	3.5 ± 0.85 (2.6 ± 0.99)	−11.8 ± 1.14 (3.5 ± 0.64)	2.8 ± 0.39 (1.5 ± 0.75)
Hemoglobin [g/100 ml]	12.71 ± 0.34 (12.35 ± 0.38)	8.72 ± 0.41 (11.38 ± 0.36)	9.87 ± 0.36 (11.58 ± 0.32)
White blood count [$\times 10_3/\mu l$]	7.05 ± 0.72 (8.16 ± 1.08)	3.57 ± 0.53 (5.43 ± 0.61)	7.17 ± 0.57 (7.52 ± 0.32)
Platelets [$\times 10_3/\mu l$]	1016.1 ± 18.05 (980.3 ± 52.17)	764.4 ± 42.71 (965.4 ± 56.67)	952.1 ± 32.67 (1020.8 ± 40.72)
α-Glutathione-*S*-transferase [μg/liter]	43.2 ± 10.33 (33.2 ± 3.79)	n.d. n.d.	557.4 ± 175.00 (61.7 ± 33.51)

[a]Data are mean ± SEM for 6 independent, individual experiments for each time point and treatment: baseline, end of shock, and after 5 hr of resuscitation; data in parentheses are obtained from time-matched sham-operated animals.

[b]Abbreviations: n.d. = not determined.

The molecular sequelae of hemorrhage and resuscitation include the activation of redox-sensitive transcription factors (most notably heat shock factor and activator protein-1) and dependent gene products such as heat shock protein 70 or heme oxygenase-1.

Critical Parameters and Troubleshooting

The amount of ischemic injury in the described model will vary with duration of hemorrhagic hypotension, the blood pressure maintained during the period of hemorrhagic hypotension, and as a function of variables affecting oxygen consumption, such as body temperature and plane of anesthesia. The liver glutathione content is a critical determinant for hepatocellular injury. The best single predictor to assess ischemic tissue injury and systemic oxygen debt is the base deficit. Repeated measurements of base deficit during hemorrhagic hypotension can help to define the degree of global ischemic injury.

Anticipated Results

Table 14.3.1 summarizes systemic and liver hemodynamics, gas exchange, acid-base status, and hepatocellular injury with the described model of reversible shock (1 hr of hemorrhagic hypotension at 35 to 40 mmHg). Values in parentheses indicate data obtained in sham-operated time-matched controls.

Figure 14.3.1 illustrates the differential expression pattern and time course of the redox-sensitive transcription factors activator protein (AP)-1 and nuclear factor (NF) κB as assessed by electrophoretic mobility shift assay. While the described model of hemorrhage and resus-

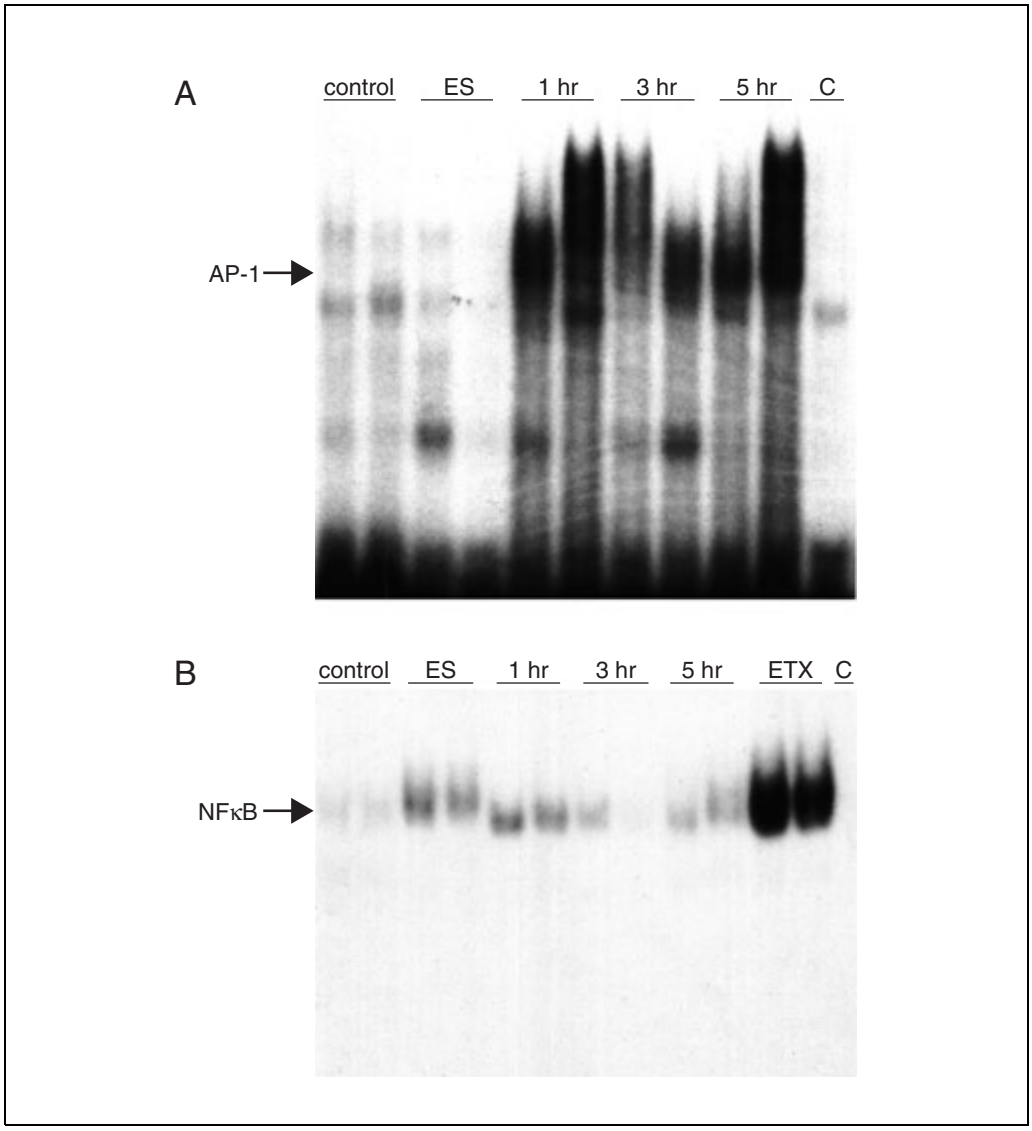

Figure 14.3.1 Differential expression of AP-1 (**A**) and NFκB (**B**) in animals subjected to hemorrhage. ES: end of hemorrhagic hypotension; 1 hr: 1 hr after onset of resuscitation; 3 hr: 3 hr after onset of resuscitation; 5 hr: 5 hr after onset of resuscitation. (**B**) ETX: NFκB binding activity in nuclear protein extracts obtained from 2 animals injected with *E. coli* endotoxin (1 mg/kg body weight) 6 hr prior to preparation of nuclear protein (positive control).

citation is a strong activator of AP-1 binding activity, only a faint activation of NFκB is observed.

Figure 14.3.2 shows the differential expression pattern and time course of transcripts encoding typical stress proteins, i.e., heme oxygenase-1, the heat shock protein hsp 70, and the acute phase reactant β-fibrinogen, as assessed by northern blot hybridization.

While hemorrhagic shock is a faint inducer of the acute phase reactant β-fibrinogen, a strong induction of the heat shock proteins hsp 32 (heme oxygenase-1) and hsp 70 over sham operated controls is associated with resuscitation from hemorrhage. The induction of hsp 70 in this model is typically biphasic with an early moderate and a late substantial increase in steady state transcripts (Fig. 14.3.2). Inter-animal variability associated with the model correlates with time course and degree of pericentral injury.

Time Considerations

The time required to perform the surgical instrumentation for hemodynamic measurements will vary depending on the parameters studied: standard tracheotomy and cannulation of a central venous and an arterial line can be achieved in <15 min while placement of transit-time ultrasound flow probes may be time-consuming and requires experience. Significant changes in hepatocellular function (e.g.,

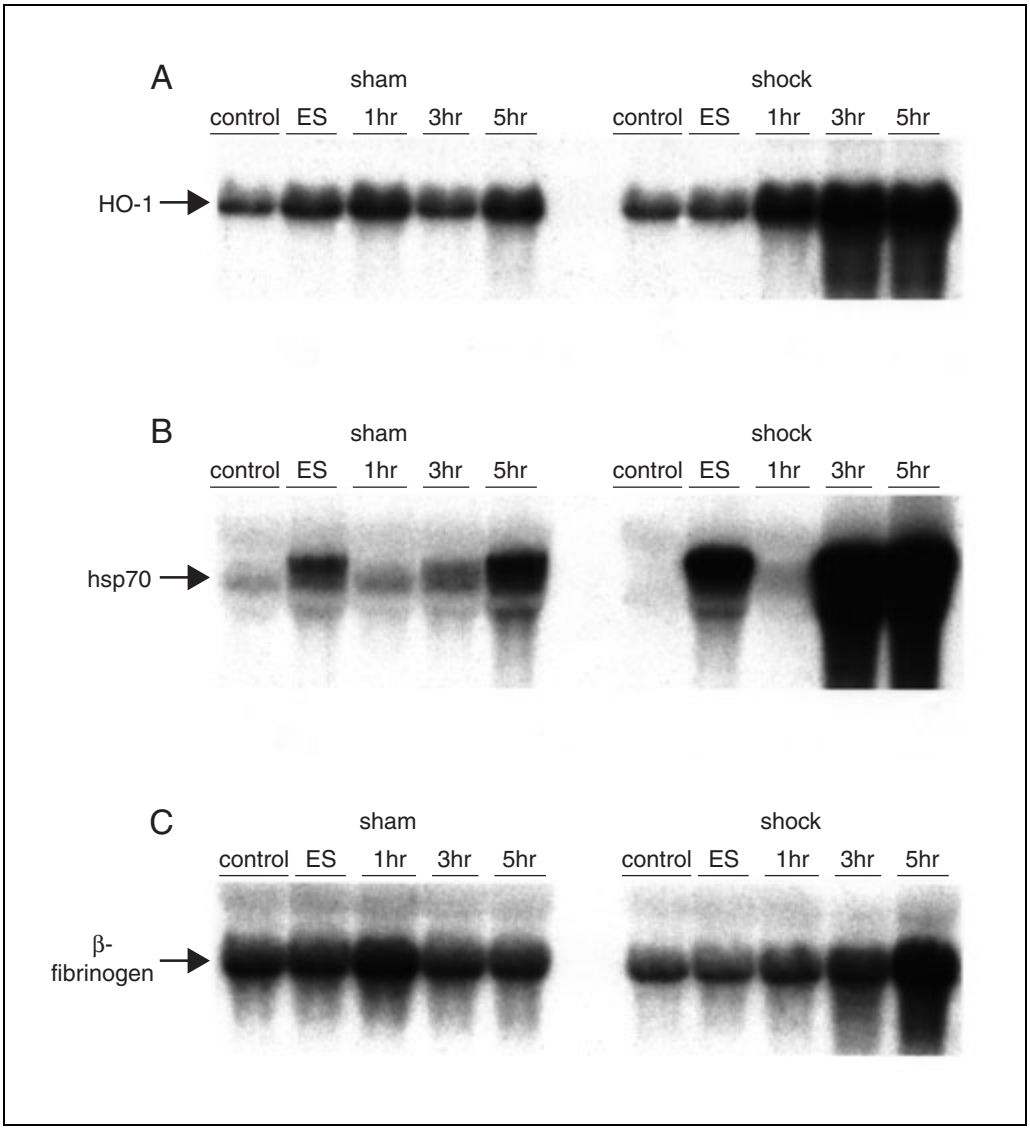

Figure 14.3.2 Differential expression of Heme oxygenase 1 (**A**), heat shock protein 70 (**B**), and β-fibrinogen (**C**) in animals subjected to hemorrhage. Left panels: samples obtained from sham-operated time-matched controls without hemorrhage; right panels: samples obtained from animals subjected to hemorrhagic hypotension (1 hr, 40 mmHg) and subsequent fluid resuscitation. ES: end of hemorrhagic hypotension; 1 hr: 1 hr after onset of resuscitation; 3 hr: 3 hr after onset of resuscitation; 5 hr: 5 hr after onset of resuscitation.

alterations in clearance capacity for ICG) and activation of transcription factors occur already during hemorrhagic hypotension or early upon resuscitation while expression of stress proteins as well as influx of inflammatory cells may require several hours (see Figs. 14.3.1 and 14.3.2).

Isolation of Liver Kupffer Cells

Kupffer cells (KCs), which are derived from the monocyte and macrophage cell lineage, are the resident macrophages of the liver. Though KCs make up <5% of the liver's volume, they represent ~80% of the total fixed macrophage population in the body. They play a major role in physiological processes as well as in the pathogenesis of several liver diseases.

To prepare pure cultures of parenchymal cells (PCs) and nonparenchymal cells (NPCs) including KCs for biochemical and cell physiological studies, several isolation methods have been recommended. The technique described in this unit is a simple and rapid procedure focusing on the isolation of KCs. The goal is to isolate large amounts of pure, viable, and functional cells without changing physiological properties or destroying components of the cytoplasmic membrane.

The isolation method can be used for rat (average size of 200 to 250 g) and mouse (average size of 20 to 25 g). The procedure is very similar for both rodents, and any methodological differences in the isolation of KCs from rats or mice will be explained as annotations to the individual steps. In general, the main text describes the procedure and amounts used for one rat liver.

The method described in the Basic Protocol will provide viable KCs in large amounts, which can be used for further investigations. It is based on collagenase perfusion of the liver, isopycnic sedimentation in Percoll, and selective adherence of the cells in culture. The protocol is subdivided into six main parts (animal preparation, operation procedures, liver perfusion, centrifugation, cell counting and viability check, and inoculation and culture).

The method is normally used to isolate NPCs (Kupffer and stellate cells) and PCs. Because of the authors' focus on KC isolation, only passing mention is made about the PCs and the stellate cells in the individual steps. Please see appropriate protocols for further handling of these cell fractions (Smedsrød and Pertoft, 1985).

NOTE: All solutions and equipment coming into contact with living cells must be sterile, and aseptic technique should be used accordingly.

NOTE: All culture incubations should be performed in a humidified 37°C, 5% CO_2 incubator unless otherwise specified.

Materials

Rat
50 mg/ml Nembutal sodium solution (Abbott Laboratories)
100% (v/v) ethanol
CMF-HBSS (see recipe), 37°C
0.02% (w/v) collagenase type IV in HBSS (see recipe), made fresh
PBS (see recipe)
HBSS (see recipe)
50%/25% two-step Percoll gradient (see recipe) in 50-ml conical centrifuge tubes
0.4% (w/v) trypan blue solution (Sigma)
RPMI medium 1640 (Life Technologies) containing 1× antibiotic and antimycotic solution (Sigma) and 10% (v/v) fetal bovine serum (FBS; Life Technologies)

Current Protocols in Toxicology (2002) 14.4.1-14.4.12

1/2-cc insulin syringe
Shaver
Surgical tools (sterile), including:
  Scissors
  Forceps
Pins or dots, sterile
Sterile threads (~15 to 20 cm long)
20-G catheter
Perfusion system that allows regulation of the flow rate
Petri dishes, sterile
Nylon gauze (50-μm mesh width), sterile
50-ml conical centrifuge tubes
Large-capacity centrifuge with adjustable brake, swing-out rotor, and speed up to $2000 \times g$, 4°C
Glass or plastic coverslips or tissue culture dishes, sterile

Additional reagents and equipment for counting cells with a hemacytometer and determining viability using trypan blue exclusion (*APPENDIX 3B*)

Prepare animal

1. Weigh a rat.

   Alternatively, a mouse can be used.

   The animal should always be held by the neck. If the experimenter is not experienced in handling animals, a special covered glove (rat glove) should be worn to protect from bites.

2. Anesthetize the animal using a 50-mg/ml Nembutal sodium solution injected intraperitoneally using a 1/2-cc insulin syringe (50 mg Nembutal/kg body weight).

   Either the lower right or left abdominal quadrant makes a good intraperitoneal injection point (Fig. 14.4.1A).

   The syringe should be aspirated to make certain that the needle did not enter a blood vessel.

3. Use a shaver to shave the whole abdomen and lower thorax of the animal.

4. Secure the animal to the workstation by taping its legs and sterilize its abdomen and thorax with 100% ethanol (Fig. 14.4.1A). Confirm that the animal is well anesthetized and is breathing regularly.

   The operation should be performed at a clean workstation under sufficient light. All tools (e.g., scissors, forceps, perfusion system, glass bottles, culture tubes) need to be sterilized before use.

Operate

5. Use a pair of scissors to open the abdomen by making a median incision 1 to 2 cm above the hind legs, and continuing up to the sternum. Make sure that the diaphragm is intact. Proceed with one horizontal incision on each side ending at the rib cage. Use forceps to reflect the flaps consisting of skin and muscle layers toward the head and secure them using pins or dots (Fig. 14.4.1B).

   If the isolation of KCs from more then one animal is planned, the authors recommend performing the operations successively. An alternative would be to perform the first isolation through step 20, place the supernatant on ice, carry out the second isolation up to step 20, and then finish both preparations simultaneously from step 21.

6. Pass a sterile thread under the inferior vena cava (IVC) at a level just below the liver and ligate loosely (Fig. 14.4.1C).

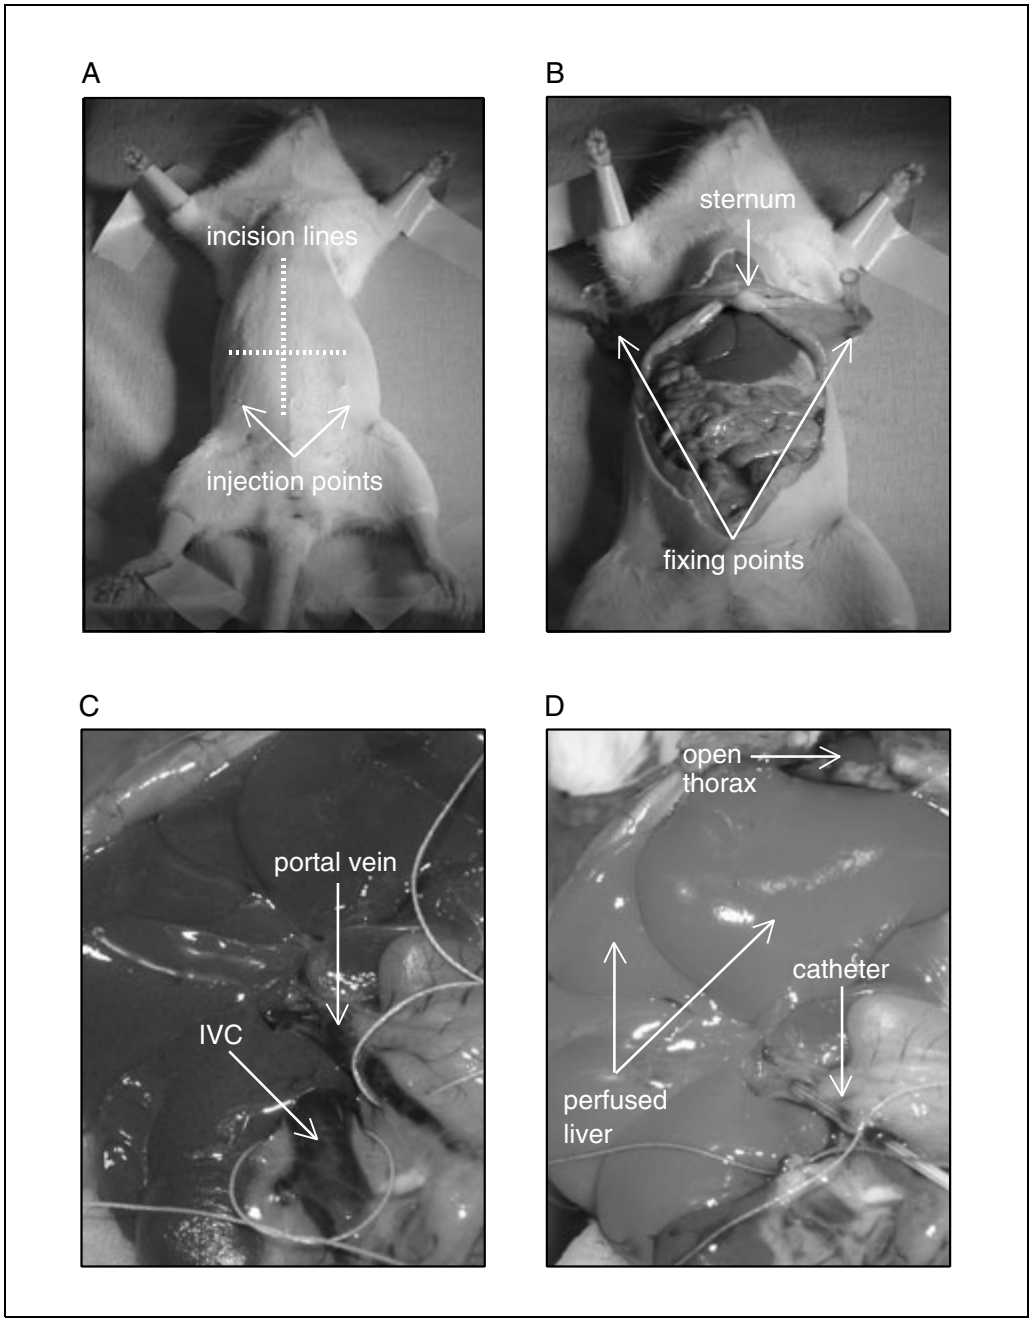

Figure 14.4.1 Animal preparation and operation procedure. (**A**) Orientation and securing of the animal to the workstation. Recommended incision lines and intraperitoneal injection points are indicated. (**B**) Opened abdomen after median and horizontal incisions. (**C**) Loosely tied threads around the inferior vena cava (IVC) and portal vein. (**D**) Perfused liver after cutting the IVC and the abdominal artery and opening the thorax. The catheter is placed in the portal vein, fixed with a thread, and the IVC is ligated. *This black and white facsimile of the figure is intended only as a placeholder; for full-color version of figure go to http://www.currentprotocols.com/colorfigures.*

7. Pass a sterile thread under the portal vein and ligate loosely (Fig. 14.4.1C).
8. Insert a 20-G catheter into the portal vein, ligate the thread tightly around the portal vein to secure the catheter, and connect a perfusion system that includes prewarmed CMF-HBSS to the catheter (Fig. 14.4.1D).

   For a mouse, a 24-G catheter is used.

   The perfusion system and catheter must be free of air. The CMF-HBSS used for the perfusion should be kept at 37°C in a water bath during the procedure.

Perfuse liver

9. Begin perfusing at a rate of 20 ml/min and cut the distal part of the IVC below the ligature and the abdominal artery to make an overflow and get the blood out of the vascular system.

   For a mouse, the IVC is cut just before the perfusion system is connected to the catheter. This is done to prevent pressure damage in the liver as a result of the small blood volume in mice. The perfusion rate is 8 ml/min.

10. Open the thorax and cut the heart.
11. Ligate the thread tightly around the IVC under the liver (Fig. 14.4.1D) and continue perfusion for 10 min.

    For a mouse, the perfusion is continued for 3 min.

    At this point the entire liver should be perfused (as indicated by a change in color from dark to light brown).

12. Change the perfusion solution to 0.02% collagenase type IV in HBSS and perfuse 10 min at a rate of 20 ml/min (200 ml total volume).

    For a mouse, 0.03% to 0.04% collagenase type IV in HBSS is perfused for 4 min at a rate of 5 ml/min (20 ml total volume).

    When the solutions are changed, a constant flow should be maintained and air must not get into the system.

    Including enzymatic digestion during the liver perfusion will yield cells that are free of desmosomes and tight junctions, which loosens cellular attachments to the extracellular matrix.

13. Remove the liver from the animal, rinse it briefly with PBS to get rid of any blood on the outside, place it in a sterile petri dish, and cover it with ~50 ml of 0.02% collagenase type IV in HBSS.

    When removing the liver, the gut must not be cut or punctured, which would release endotoxins or bacteria into the liver homogenate.

14. Gently tease the liver with forceps until it is in solution.
15. Filter the cell suspension through sterile nylon gauze to remove undigested tissue and connective tissue.
16. Transfer the filtered cell suspension to two 50-ml conical centrifuge tubes and fill them with HBSS.

Centrifuge suspensions

17. Centrifuge suspensions 3 min at 70 × *g*, 4°C (maximal brake).

    For a mouse, the suspension is centrifuged 3 min at 35 × g.

    All steps between the centrifugations are performed in 50-ml tubes that are placed on ice.

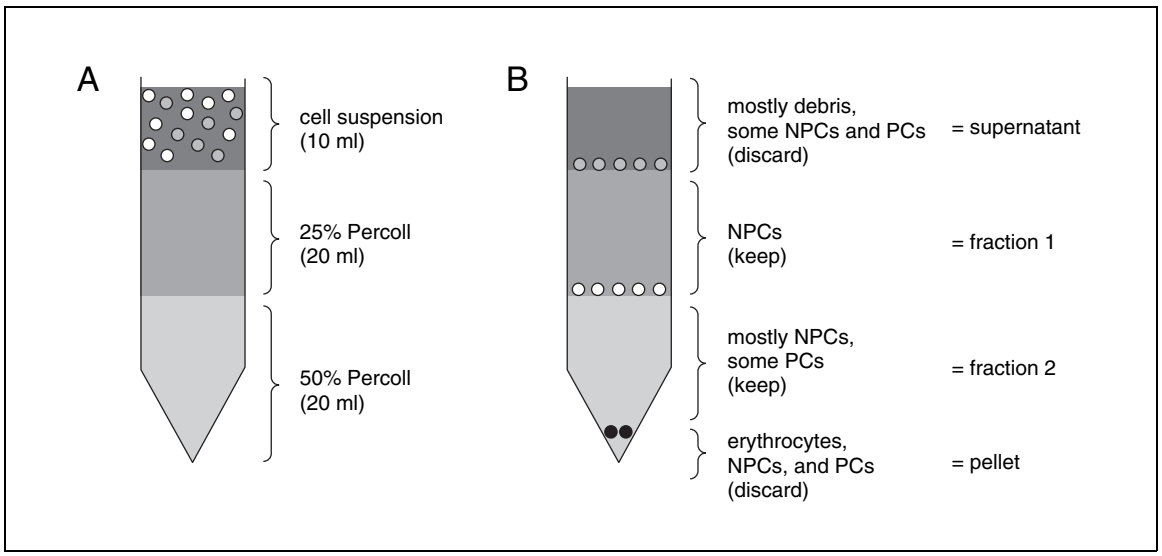

Figure 14.4.2 Isopycnic (gradient) centrifugation with Percoll. (**A**) The cell suspension, including mostly nonparenchymal cells (NPCs), is placed on a 50%/25% two-step Percoll gradient before centrifugation. (**B**) After centrifugation, the cells are separated into four fractions; fraction 1 has the highest concentration of Kupffer cells. PC, parenchymal cell.

18. Transfer supernatants to clean 50-ml tubes and place on ice. Resuspend pellets by filling tubes with HBSS to 50 ml.

    The supernatant contains mainly NPCs (Kupffer and stellate cells), whereas the pellet contains mainly PCs (mostly hepatocytes). If hepatocytes need to be collected, these pellets (and also those from step 19) can be used with an appropriate protocol (Smedsrød and Pertoft, 1985).

19. Centrifuge resuspended pellets 3 min at 70 × *g*, 4°C (maximal brake). Transfer supernatants to clean 50-ml tubes, place on ice, and discard pellets.

    For a mouse, centrifuge 3 min at 25 × g, 4°C (maximal brake). Keep the supernatant and resuspend the pellet again in HBSS. Centrifuge the resuspended pellet 3 min at 20 × g, 4°C (maximal brake).

    The additional centrifuge steps with the resuspended pellet are performed to separate the PC and NPC fractions as completely as possible.

20. Fill both supernatant tubes (steps 18 and 19) to 50 ml with HBSS if needed.

    For a mouse, all three supernatant tubes (from the three centrifugation steps) should be filled.

21. Centrifuge tubes 7 min at 650 × *g*, 4°C (maximal brake).

    The pellet contains mostly Kupffer and stellate cells and some PCs, erythrocytes, and cell debris.

22. Discard supernatants and resuspend pellets in 10 ml HBSS per tube by gently pipetting.

23. Carefully layer cell suspension from each tube onto a 50%/25% two-step Percoll gradient in a 50-ml conical centrifuge tube. Try to avoid mixing the cell suspension with the upper Percoll layer (Fig. 14.4.2A).

24. Centrifuge tubes 15 min at 1800 × *g*, 4°C (brake off).

25. Carefully remove upper layer (supernatant) from each tube and discard. Collect middle layers (fractions 1 and 2) of both tubes together into one new 50-ml tube and fill tube with HBSS (Fig. 14.4.2B). Discard pellets.

    The cells are distributed into four distinct zones in the gradient (Fig. 14.4.2B). The upper zone (supernatant) includes material that did not penetrate the upper Percoll cushion (mainly debris, damaged cells, and a few viable NPCs). The intermediate zones (fractions 1 and 2) contain mainly purified NPCs. The pellet consists of erythrocytes, NPCs, and PCs.

    If stellate cells need to be purified, fraction 1 alone should be collected using an appropriate protocol (Smedsrød and Pertoft, 1985).

26. Centrifuge pooled middle layers 7 min at 650 × *g*, 4°C (maximal brake).

27. Discard supernatant and resuspend pellet in 5 ml HBSS with gentle pipetting.

    For a mouse, the pellet should be resuspended in 1 ml HBSS.

    The actual HBSS volume in which the pellet is suspended, which will depend on the subsequent experiments that the investigator will carry out, should be determined by further experimentation.

Count cells and check viability

28. Mix 10 µl KC solution (step 27) and 10 µl of 0.4% trypan blue solution in a tube by gently pipetting.

29. Use 10 µl of the mixture to determine cell number and viability (*APPENDIX 3B*). Also check the purity (e.g., KCs, hepatocytes, bacteria, cell debris) of the cells (Fig. 14.4.3A).

    This is only a crude measure of purity and viability. Normally, assessment of cell purity requires morphological, biochemical, histochemical, or immunohistochemical methods to identify specific cells of interest. Because of difficulties identifying KCs after isolation (depending on the investigator's level of experience), cell-specific cytochemical assays (peroxidase, acid phosphatase) and morphological techniques (India ink or colloidal carbon phagocytosis) are often used. A simple method to identify KCs and exclude other cells morphologically (by light and fluorescence microscope) is to observe the uptake of latex beads in the cells (Shaw et al., 1984; Fig. 14.4.3B).

    The easiest technique for assessing cell viability is the trypan blue exclusion method (Fig. 14.4.3A). Other choices for determining cell yield and viability depend on the available time and equipment (e.g., electronic Coulter counters, channelyzers) but are usually impractical because of the cost of these instruments.

Inoculate cultures

30. Plate cells at an appropriate density on glass or plastic coverslips or tissue culture dishes and culture them in RPMI medium 1640 containing 1× antibiotic and antimycotic solution and 10% FBS for 15 min at 37°C.

    The number of cells plated will depend on the size of the coverslip or dish and on the subsequent experiments. In general, 0.5 to 50 × 10^6 cells per dish is appropriate.

    The final concentrations of the antibiotics and antimycotic are 100 U/ml penicillin G, 100 µg/ml streptomycin sulfate, and 0.25 µg/ml amphotericin B.

31. Remove nonadherent cells by replacing the culture medium.

    To obtain a pure monolayer culture of KCs, an incubation time of 15 min was chosen based on the selective adherence (i.e., attachment and spreading) of KCs to glass or plastic surfaces.

32. Culture cells for an appropriate period (usually ≥24 hr) prior to experiments.

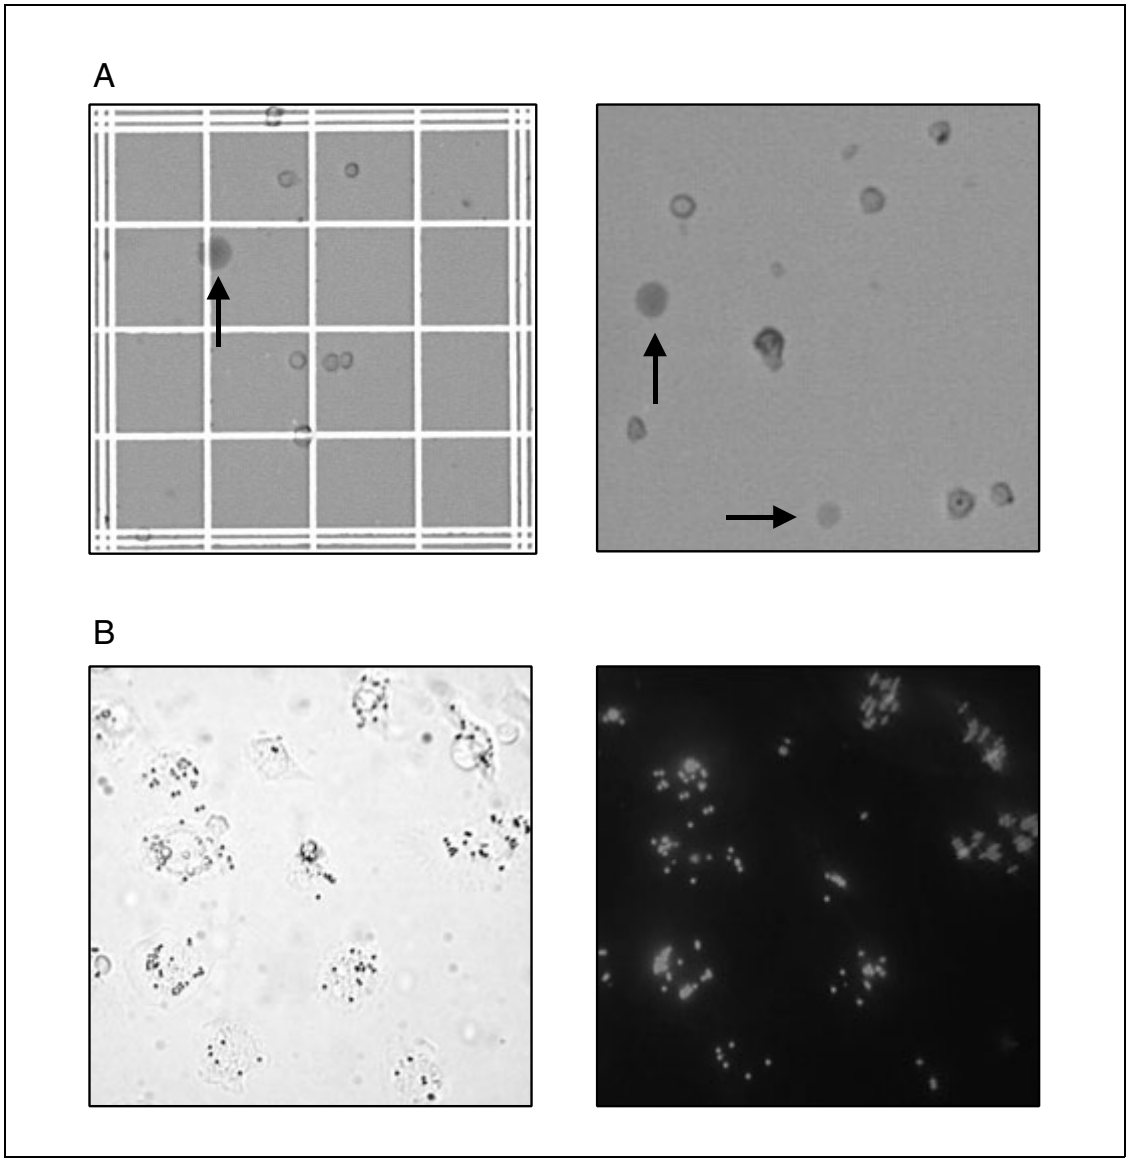

Figure 14.4.3 Assessment of Kupffer cell (KC) purity and viability. (**A**) Cell count on a hemacytometer by trypan blue exclusion (viability check). Arrows in left and right panels indicate excluded cells (blue cells). (**B**) Purity check by the uptake of latex beads in KCs. Left panel is with and right panel is without a green filter, which shows the uptake of latex beads by their fluorescence. *This black and white facsimile of the figure is intended only as a placeholder; for full-color version of figure go to http://www.currentprotocols.com/colorfigures.*

REAGENTS AND SOLUTIONS

*Use Milli-Q-purified water or equivalent in all recipes and protocol steps. For common stock solutions, see **APPENDIX 2A**; for suppliers, see **SUPPLIERS APPENDIX**.*

Ca^{2+}- and Mg^{2+}-free Hanks' balanced salt solution (CMF-HBSS)

Make up HBSS (see recipe) without $MgSO_4 \cdot 7H_2O$ and $CaCl_2 \cdot 7H_2O$. Add 0.19 g EGTA (0.5 mM final). Adjust the pH to 7.2 at room temperature with 1 M NaOH or 1 M HCl. Filter sterilize using 0.22-µm filters and store up to 3 months at 4°C.

For convenience, a 10× CMF-HBSS stock (without sodium bicarbonate, EGTA, pH adjustment, and filtration) can be made.

Hanks' balanced salt solution (HBSS)

8 g NaCl (138 mM final)
0.4 g KCl (5.4 mM final)
0.091 g $Na_2HPO_4 \cdot 7H_2O$ (0.3 mM final)
0.06 g KH_2PO_4 (0.4 mM final)
1 g dextrose (5.6 mM final)
0.2 g $MgSO_4 \cdot 7H_2O$ (0.8 mM final)
0.185 g $CaCl_2 \cdot 7H_2O$ (1.26 mM final)
0.35 g $NaHCO_3$ (4 mM final)
Add H_2O to 1 liter
Adjust pH to 7.4 at room temperature with 1 M NaOH or 1 M HCl
Filter sterilize using 0.22-μm filters
Store up to 3 months at 4°C

A 10× HBSS stock (without sodium bicarbonate, pH adjustment, and filtration) can be made.

Percoll solution, 50%

Dissolve 0.35 g $NaHCO_3$ (4 mM final) in 400 ml water and add 500 ml of 100% Percoll (Amersham Pharmacia Biotech) and 100 ml of 10× HBSS (see recipe; final density ~1.065 g/ml). Adjust pH to 7.4 at room temperature with 1 M NaOH or 1 M HCl. Filter sterilize using 0.22-μm filters and store up to 1 month at 4°C.

Percoll solution, 25%

For 20 ml, add 10 ml of 50% Percoll solution (see recipe) and 10 ml HBSS (final density ~1.037 g/ml). Always make fresh.

Phosphate-buffered saline (PBS)

8 g NaCl (138 mM final)
0.2 g KCl (2.7 mM final)
2.17 g $Na_2HPO_4 \cdot 7H_2O$ (8.1 mM final)
0.2 g KH_2PO_4 (1.5 mM final)
Add H_2O to 1 liter
Adjust pH to 7.4 at room temperature with 1 M NaOH or 1 M HCl
Filter sterilize using 0.22-μm filters
Store up to 3 months at 4°C

Two-step Percoll gradient, 50%/25%

In a 50-ml conical centrifuge tube, carefully layer 20 ml of 50% (v/v) Percoll solution (see recipe) under 20 ml of 25% (v/v) Percoll solution (see recipe). Always make fresh.

COMMENTARY

Background Information

Kupffer cells (KCs) are macrophages that reside in the hepatic sinusoids, predominantly in periportal regions of the liver, and are usually attached to endothelial cells. They show receptor-mediated, nonspecific endocytotic activity, which is important for the uptake of foreign particles, mainly microorganisms and bacterial endotoxins. The first morphological observations pointing to this specific cell type date back to the work of Wedl (1854), and a few years later to that of Eberth (1867). In 1876, Karl von Kupffer published the first general description of this phagocytic, reticuloendothelial cell, which was later named after him (Kupffer, 1876). Since then, much work has been done to explain and characterize the specific properties and functions of these cells (Jones and Summerfield, 1988; Wake et al., 1989).

KCs can be activated by numerous agents including γ-interferon, platelet-activating factor (PAF), and endotoxins. Their response to these factors includes the release of physiologically active substances such as eicosanoids, inflammatory cytokines—interleukin 1 (IL-1), interleukin 6 (IL-6), tumor necrosis factor α

(TNF-α)—transforming growth factor β (TGF-β), interferon α and β, lysosomal enzymes, and free-radical species that participate in inflammation, immune responses, and modulation of hepatocyte metabolism. The factors released by activated KCs interact with other cell types leading to specific responses such as synthesis of acute-phase proteins, glucose production, vasoconstriction, apoptosis, cell proliferation, and even tissue injury. These factors participate in hepatic injury seen in sepsis, obstructive jaundice, transplantation, endotoxin shock, alcoholic liver disease, and other types of toxicant-induced liver injury.

Over the years, several methods have been introduced and modified to purify both parenchymal and nonparenchymal cells (Alpini et al., 1994). It would be beyond the scope of this unit to give a complete overview of the advantages and disadvantages of all isolation methods for liver cells including KCs. Summaries of the most significant methods are, however, provided (for further information, see references).

To produce a cell suspension from the liver, mechanical (Branster and Morton, 1957) and enzymatic (Alpini et al., 1989) dissociation techniques have been used. Collagenase has become widely used for the enzymatic digestion of the liver, more so than other proteolytic enzymes such as pronase and trypsin. Moreover, other approaches such as immunoaffinity (Munthe-Kaas et al., 1975), selective attachment (Smedsrød and Pertoft, 1985), sorting of fluorescence-labeled cells (Morin et al., 1984), selective cytotoxicity (Alpini et al., 1989), free-flow electrophoresis (Miller et al., 1983), and centrifugal techniques have been used to purify liver cells. In fact, cell separation of a specific subpopulation is best accomplished with a combination of these methods.

The most commonly used approaches to purify cells are centrifugal techniques including counterflow elutriation (Zahlten et al., 1978) and isopycnic (Smedsrød and Pertoft, 1985), velocity, and isokinetic gradient centrifugation (Brouwer et al., 1984). These methods are based on the properties of cell size or cell density. They vary in complexity and require expensive equipment. Finding the most appropriate protocol consequently depends on the general scientific approach (e.g., investigation of one specific cell type or comparison of liver cell subpopulations) and the availability of time and equipment.

To isolate KCs, enzymatic digestion with collagenase and/or pronase (Munthe-Kaas et al., 1975) by perfusion or by direct incubation with minced liver tissue (Branster and Morton, 1957) is often used. Because certain receptors at the cell surface are destroyed by pronase and reappear only after a period of cultivation, these isolated cells can be less useful in studies of physiological processes even though the method isolates KCs in high yields. Therefore, low-temperature isolation techniques (Praaning-Van Dalen et al., 1982) are combined to reduce damage to certain cell membrane proteins.

The purification of KCs is commonly performed with methods based on cell size or density, such as isopycnic centrifugation through gradient materials including Ficoll, metrizamide (Zahlten et al., 1978), Nycodenz (Blomhoff et al., 1984), Stractan (Friedman and Roll, 1987), or Percoll (Smedsrød et al., 1985). They vary in their ease of preparation (e.g., the Stractan method is complicated), length of storage (e.g., Ficoll is unstable once made up), viscosity, osmolarity, range of usable density, cell toxicity, and cost (e.g., Ficoll is expensive). The gradient centrifugations are normally followed by counterflow elutriation (which requires special rotors and centrifuges) and/or selective attachment methods. For completion, other isolation techniques use selective preloading of KC lysosomes (e.g., with Jectofer, Zymosan, Triton WR 1339, or colloidal carbon) to alter cell density. Two other methods are injection with colloidal iron in vivo followed by magnetic separation (Rous and Beard, 1934) and enterotoxin treatment (Blomhoff et al., 1984) to selectively disrupt hepatocytes.

The isolation method described in this unit is based on the protocol by Smedsrød and Pertoft (1985) with slight modification to focus on KCs. It was originally designed as a rapid method for mass isolation of functionally intact hepatocytes and reticuloendothelial cells (stellate and Kupffer cells) from a single rat liver. Nonrecirculating collagenase perfusion is used to digest the liver, providing a cell suspension with reduced alterations in cell membrane composition and greater functional activity than have been observed with mechanical dispersion techniques or with other proteolytic enzymes like pronase. The perfusion is followed by isopycnic sedimentation in Percoll and selective attachment to purify the KCs. The advantages of performing the centrifugation with Percoll (which is composed of colloidal silica coated with polyvinylpyrrolidone and has a density of 1.130 g/ml), as opposed to other commercially available gradient materials, are

Table 14.4.1 Kupffer Cell Isolation Troubleshooting Guide[a]

Problem	Possible cause	Solution
Low animal survival before liver perfusion	Nembutal concentration too high	Weigh the animal and, if necessary, lower the Nembutal concentration (normally, 50 mg/kg body weight is used).
	Nembutal injected into a blood vessel	Aspirate to make sure that needle is intraperitoneal (Fig. 14.4.1A shows injection points).
Incomplete liver perfusion	Air in perfusion system or liver	Avoid air bubbles during portal vein cannulation.
		When changing perfusion solutions, do not let air get into the system (use an air bubble trap).
	Blood clots in the liver	Perfuse liver with recommended flow rate and make sure that the flow is constant (if necessary use heparin).
Incomplete digestion of liver	Insufficient collagenase concentration	Adjust amount of collagenase (see Critical Parameters and Troubleshooting).
	Too short perfusion time	Perfuse liver for recommended time (10 min each for CMF-HBSS and collagenase in HBSS).
	Incomplete liver perfusion	See above.
Insufficient cell separation during isopycnic (gradient) centrifugation	Percoll layers not intact before centrifugation	Avoid mixing either the two Percoll layers or the cell suspension and the upper Percoll layer (Fig. 14.4.2A).
	Incomplete cell sedimentation in Percoll after centrifugation	Check settings of the centrifuge (speed and temperature). The brake must be off.
Reduced yields of KCs	Contamination by microbes	Make sure that all buffers and solutions are sterile and store as indicated.
		All tools (including perfusion system) need to be cleaned or sterilized before use.
	Reduced number of viable KCs	Keep liver moist during the perfusion.
		After removing liver from the animal, tease liver very gently into solution.
		Try different lots of collagenase (if necessary, reduce the amount used).
	Reduced plating and culturing efficiency	Plate isolated KCs on glass or plastic surfaces (e.g., tissue culture dishes) and, if necessary, increase time until first medium change (time required for attachment and spreading).
		Change medium only at the appropriate times.
	Incomplete liver perfusion, digestion of the liver, or cell separation during isopycnic (gradient) centrifugation	See above.
Contamination of KCs with other liver cells	Too long attachment and spreading time	Decrease time between plating KCs and first medium change (normally 15-30 min).
	Insufficient cell separation during isopycnic (gradient) centrifugation	After gradient centrifugation, keep only fractions 1 and 2 and discard supernatant and pellet.

[a]Abbreviations: CMF-HBSS, Ca^{2+}- and Mg^{2+}-free Hanks' balanced salt solution; KC, Kupffer cell.

its relatively low cost and stable storage properties, not to mention the easy preparation of the Percoll solutions. Finally, a purified KC population is cultured based on the selective substrate attachment properties of these cells to plastic or glass surfaces.

The main disadvantage of the method is that other techniques can sometimes yield higher numbers of isolated cells (see Anticipated Results). However, the simplicity (e.g., no special equipment necessary), rapidity, and relatively low cost of the procedure, as well as the possibility of isolating different cell types from one animal for comparisons, clearly indicate the benefits of this method.

Critical Parameters and Troubleshooting

To prevent any kind of contamination, the protocol should be performed under sterile conditions. This includes not only sterilizing surgical tools and other equipment (e.g., glass bottles, culture dishes, perfusion system) but also confirming that solutions have not been stored longer than suggested (see Reagents and Solutions) and are free of any obvious contamination.

Another critical parameter in the isolation process is the protease used for the enzymatic digestion of the liver. Collagenase shows a great variation in enzymatic activity and specificity. Several different lots of collagenase (from different vendors and even among lots from the same vendor) may need to be tested to determine which lot best provides the anticipated result. If different lots of collagenase with different enzyme activities are used, the final collagenase concentration in HBSS for the liver perfusion may need to be adjusted.

Potential problems related to this isolation method and their causes and solutions are included in Table 14.4.1.

Anticipated Results

The final number of isolated KCs is dependent on the rodent, the specific strain, and the pretreatment of the animal (e.g., in some fibrosis or necrosis models, there will be fewer cells than in control animals). In general, the number of KCs isolated in the described method is 8 (± 1.5) $\times 10^6$ cells/g liver (purity ≥95%) for rats and 7.5 (± 1.5) $\times 10^6$ cells/g liver (purity ≥95%) for mice. The recovery rate of KCs is ~29% for rats and ~27% for mice based on the estimated number of 27 (± 3) $\times 10^6$ KCs/g liver. The yields are similar to those achieved with other procedures (Knook and Sleyster, 1976). The actual number of KCs maintained in culture can vary depending on the plating efficiency and the number of times the medium is changed. A reduction of ≤50% is possible.

Time Considerations

The estimated time for each part of the protocol is as follows:

Animal preparation: ~15 min
Operation: ~10 min
Liver perfusion: ~30 min
Centrifugation: ~45 min
Cell counting: ~10 min
Cell culture (until first medium change): ~30 min

Taken together, a total time of ~2.5 to 3 hr for the isolation of KCs should be estimated per animal.

Measurement of Hepatobiliary Transport

The liver is remarkably efficient at removing a multitude of compounds from circulating blood plasma and metabolizing, storing, and/or excreting these compounds and their metabolites into bile or back into the bloodstream (Boyer, 1986). Hepatobiliary transport of endogenous and exogenous compounds is mediated by the coordinated action of multiple transport systems present at the basolateral (sinusoidal) and apical (canalicular) membrane domains of hepatocytes. Over the past few years, many of these transporters have been characterized at the cellular and molecular levels, and these data have provided important insight into the normal physiology of bile formation, the pathophysiology of hepatic disorders, and the processes that mediate xenobiotic elimination and disposition (Borst and Elferink, 2002; Kato et al., 2002; Hagenbuch and Meier, 2003; Trauner and Boyer, 2003).

Several experimental model systems have been used to study hepatobiliary functions, including isolated membrane vesicles, cell lines, primary hepatocytes, and liver slices (Brandon et al., 2003). The most direct method for examining biliary excretory function, however, is to collect bile via the common bile duct in anesthetized animals or in the perfused liver. Analysis of bile volume (flow rate), pH, osmolarity, and chemical and protein composition provides invaluable information about hepatocellular function and the ability of the liver to clear toxic chemicals. Moreover, identification of drug or xenobiotic metabolites in bile provides direct evidence for the involvement of specific enzymes and transporters in their metabolism and hepatobiliary elimination.

Although bile sampling in intact animals provides the most direct information about hepatobiliary transport processes, this approach does have some drawbacks: it is often difficult to analyze and regulate blood plasma concentration of a compound or its metabolites in the whole animal, and metabolism by other organs often complicates interpretation of results. For these reasons, the isolated perfused liver model has been used extensively for studying hepatobiliary function.

The versatility of the perfused rat liver model, as well as the fact that the isolated organ remains functional for extended periods, has made it a favorite system for addressing many questions in different research areas. For toxicology, this model provides a direct means for assessing the role of the liver in the metabolism, bioactivation, toxicity, and elimination of drugs and xenobiotics. Chemicals may be added in precise amounts to the perfusate, and metabolites may be sampled directly in bile or perfusate. Hepatocellular function and viability may be addressed directly in the intact organ, thus revealing interactions among the different cell types (e.g., Kupffer cells, stellate cells, sinusoidal endothelial cells, cholangiocytes, and hepatocytes), as well as the involvement and sensitivity of cells located in different acinar zones of the liver lobule.

Because bile cannot be sampled at its primary site of formation (the bile canaliculus), the specific processes that mediate membrane transport of organic and inorganic molecules into bile have been difficult to identify and characterize using perfused liver or in vivo models. Even though chemical analysis of bile collected from the common bile duct provides some insight into these processes, it cannot directly define the events that take place on the hepatocyte canalicular plasma membrane. A solution to this dilemma was provided by the development of techniques to isolate plasma membrane vesicles that are enriched in either canalicular or basolateral membrane domains (Evans, 1969; Long et al., 1969; Meier et al., 1984). These isolated membrane subfractions are useful for establishing the localization of enzymes, receptors, channels, pumps, and transporters on

the different plasma membrane domains, for functionally characterizing these membrane proteins, and for examining the interaction of toxic chemicals with these processes.

This unit describes basic methods for collecting bile from anesthetized mice and rats (see Basic Protocol 1), carrying out isolated perfused rat liver studies (see Basic Protocol 2), and simultaneously isolating plasma membrane vesicles derived from the basolateral and canalicular domains of rat liver (see Basic Protocol 3).

NOTE: All protocols using live animals must first be reviewed and approved by an Institutional Animal Care and Use Committee (IACUC) and must follow officially approved procedures for the care and use of laboratory animals.

BASIC PROTOCOL 1

BILE COLLECTION IN ANESTHETIZED RATS AND MICE

This protocol is suitable for short-term bile collection in anesthetized rats or mice (<3 hr), but this time interval can be extended by several hours if supplemental fluids are given to replenish the volume lost by exhalation, evaporation, and bile collection.

Materials

Rat or mouse
50 mg/ml pentobarbital sodium

Flexible temperature probe (rectal probe; e.g., Yellow Springs Instrument)
Thermostat-controlled heat lamp or heat pad
Surgical instruments, sterile, including:
  Scalpel or blunt-end scissors
  Hemostats
  Forceps, fine
  Iridectomy scissors (i.e., fine, sharp-pointed scissors)
Suture, size 3-0
PE-10 tubing (polyethylene tubing), ≥10 cm long with beveled end (e.g., Clay Adams)
Surgical clamps, optional
1-ml microcentrifuge tubes

1. Weigh a rat or mouse and anesthetize with 50 mg/ml pentobarbital sodium (55 mg/kg, intraperitoneally). Place the animal on its back with the head oriented away from the surgeon. Monitor body temperature continuously with a flexible temperature probe and maintain it at 37°C by use of a thermostat-controlled heat lamp or heat pad. Administer additional anesthetic intraperitoneally as required throughout the experiment (~15 to 20 mg/kg every hr).

   Additional fluid is not normally required for bile collections of ≤3 hr. For longer experiments, dilute saline or glucose solutions can be administered intravenously or intraperitoneally.

2. Use a scalpel or blunt-end scissors to make a midline incision in the abdomen that extends downward from the symphysis pubis (~2 cm in length in mice and 4 cm in rats). Cut skin first and then muscle layer. Hold the two flaps open to the side with hemostats.

   By staying in the midline, bleeding is minimized.

To cannulate bile duct in rats

3a. Pull out the duodenum, find the bile duct, and, using fine forceps, isolate the bile duct from the surrounding connective tissue. Isolate a bile duct segment that is within 3 cm of the liver. Do not sever any pancreatic ducts when isolating the bile duct.

4a. Put a double suture around the bile duct (a 30-cm segment of 3-0 suture folded in half), cut the suture at the mid-point, and, using one of the two pieces, loosely tie the distal suture near the end of the bile duct.

5a. Using fine iridectomy scissors, make a nick in the bile duct at a 45° angle and insert the beveled end of a length of PE-10 tubing to within 1 cm of the liver. Tie down both sutures.

The PE-10 tubing should be ≥10 cm long to help divert the bile into a collection vessel. It is helpful to put a mark near the beveled end of the PE-10 tubing with an indelible marker, as this makes it easier to visualize the end of the tube within the bile duct.

6a. Close the muscle layer first and then the skin layer with surgical clamps or suture, being careful not to twist or bend the bile duct or cannula.

Twisting or bending the duct or cannula will obstruct bile flow.

7a. Collect bile in tared 1-ml microcentrifuge tubes at 15-min intervals, or more frequently if desired.

Bile flow rates are expected to be from 4 to 8 ml/hr/kg body weight, or about 0.25 to 0.5 ml/15 min/250 g rat.

To cannulate bile duct in mice

3b. Follow the procedure described for rats (steps 3a to 6a), except ligate the cystic duct to exclude the gallbladder and stretch the PE-10 tubing to make a smaller tube that can be inserted into the relatively small bile duct of the mouse.

The PE-10 tubing should be pulled gently with both hands until it begins elongating. It is then cut at a 45° angle at the stretched end. The goal is to reduce the outer (and inner) diameter to about one-half of its original size while being careful not to completely collapse the inner pore of the tubing.

Stretching the PE-10 tubing is also appropriate for cannulating the bile duct of a weanling rat.

4b. Collect bile in tared 1-ml microcentrifuge tubes at 15-min intervals, or more frequently if desired.

Bile flow rates are expected to be from 4 to 8 ml/hr/kg body weight, or about 0.25 to 0.5 ml/15 min/250 g rat.

PREPARING AN ISOLATED PERFUSED RAT LIVER

BASIC PROTOCOL 2

Liver perfusion is a versatile technique, both technically and in terms of the questions that may be addressed (Miller, 1973). (1) Livers may be perfused in situ or may be isolated and perfused away from the rest of the animal. For short perfusions (<1 hr), in situ perfusion may be acceptable, but for longer perfusions it is usually necessary to isolate the liver into a relatively clean environment in which temperature and humidity can be more readily controlled. (2) The perfusate may be passed only once through the liver (i.e., single-pass perfusion) or may be recirculated. Single-pass perfusions are technically easier to perform and allow a constant delivery of drugs or nutrients to the liver, but they can be expensive depending on the composition of the perfusion medium. Single-pass perfusions also tend to deplete the liver of certain factors that are continuously released

into the sinusoidal circulation, and this may be detrimental to hepatic function. Conversely, toxic metabolites may accumulate in perfusate solutions that are recirculated, and this may also be detrimental. (3) Perfusate can be passed in the normal direction (inflow through the portal vein) or in a retrograde direction, via the hepatic vein. (4) Both the portal vein and hepatic artery may be cannulated for perfusion, although perfusion through the portal vein is adequate for most studies (Miller, 1973). (5) There are also many choices of perfusate media, ranging from simple salt solution (e.g., Krebs-Henseleit buffer) to perfluorocarbon emulsions or whole blood.

This protocol describes the isolated perfusion of rat livers using recirculating Krebs-Henseleit (KH) buffer, although other buffers or approaches may be substituted with only minor modifications. This protocol is modeled after that described by Miller (1973). In brief, the bile duct, portal vein, and thoracic vena cava are cannulated, the liver is placed on a 10-cm petri dish with a 1-cm hole cut in the middle to allow the venous outflow to drain downward, this petri dish is put in a heated Plexiglas chamber, and the liver is perfused in a recirculating mode with 100 ml oxygenated KH buffer.

NOTE: Krebs-Ringer bicarbonate buffer, which has twice the concentration of calcium and magnesium that KH buffer (see recipe) has, should be used if albumin or another protein is used as an oncotic agent in the perfusate. (The albumin binds some of the calcium and magnesium, such that their starting concentrations need to be higher.)

Materials

KH buffer (see recipe)
1000 U/ml heparin
D-Glucose, aliquots of 90.1 mg stored at room temperature
pH 7 buffer (for pH meter calibration)
Rat
50 mg/ml pentobarbital sodium

12 × 75–mm test tubes or 1-ml microcentrifuge tubes
Perfusion setup (Fig. 14.5.1), including:
- Two pumps capable of delivering 10 to 50 ml/min, preferably with minimal pulsatile flow
- 250-ml Erlenmeyer flask
- Water bath, 37°C
- Tank of 95% O_2/5% CO_2
- Glass humidifier and dispersion tube
- Tygon tubing: 0.12-in. (0.32-cm) inner diameter (i.d.) and 0.25-in. (0.64-cm) outer diameter (o.d.)
- In-line filter (Millipore XX43-047-00) containing a 1.2-µm filter (Millipore RAWP-047-00) and a prefilter (Millipore AP25-042-00)
- Gas exchange mechanism: 0.5-liter jar containing 7.7 m gas-permeable silastic tubing (Dow Corning 602-235) attached to y-shaped connector
- Perfusion dish: 10-cm plastic Petri dish with a 1-cm round hole cut in the center
- 100-ml, 3-neck perfusate reservoir (e.g., Kontes Glass 606020-0224), with a plastic funnel over the central neck of this reservoir
- pH meter and electrode
- Thermometer
- Small heater and blower

Operating tray
Surgical instruments, sterile, including:
- Hemostats, two
- Iridectomy scissors (i.e., fine, sharp-pointed scissors)

Forceps, two
Heavy scissors
Blunt-end scissors or scalpel
Suture, 3-0: one 30-cm length, folded in half, and four 15-cm lengths
Bile cannula: 16-cm length of PE-10 tubing, beveled at one end
Portal vein cannula: 14- or 16-G stainless steel, blunt-end needle with slight bevel forged at the end, connected to a three-way stopcock
Thoracic vena cava cannula: 2.5-cm length of PE-205 tubing, beveled at one end
Temperature monitor with small flexible temperature probe
Dewar flask, tall
Two 1-ml syringes attached to PE-90 tubing

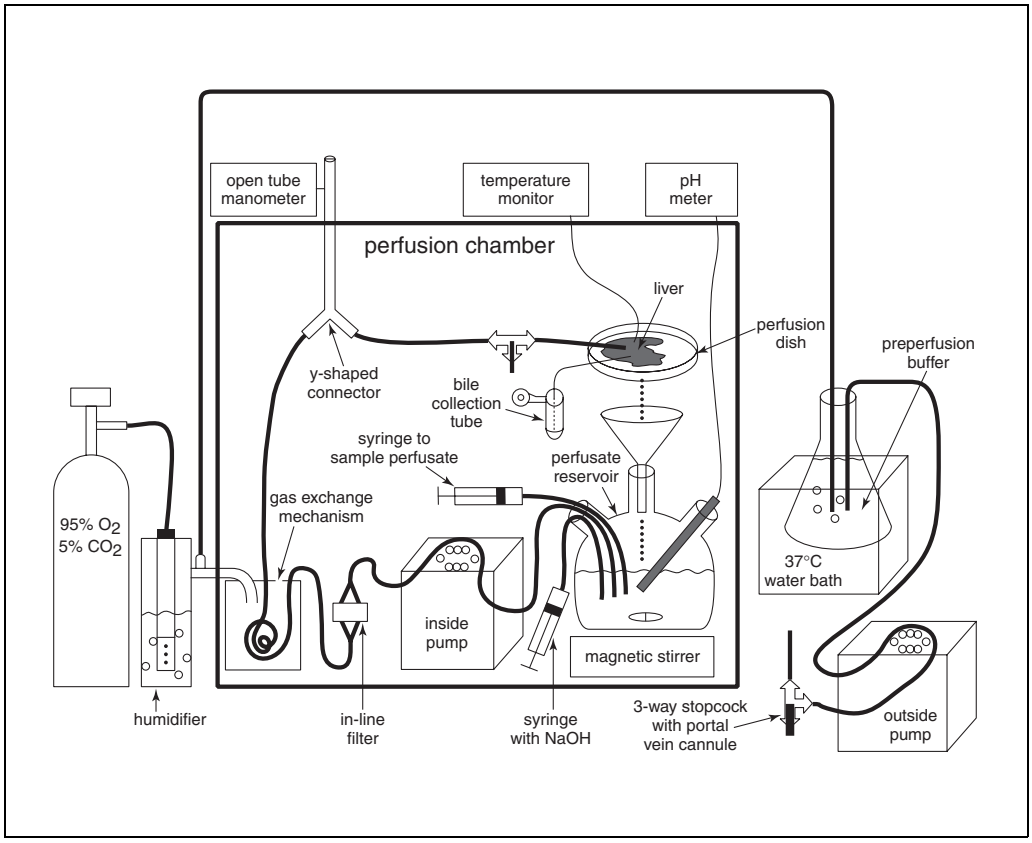

Figure 14.5.1 A perfusion chamber and preperfusion pump. The chamber contains a pump (inside pump) capable of delivering 10 to 50 ml/min, preferably with minimal pulsatile flow; an in-line filter containing a 1.2-μm filter and a prefilter; a gas exchange mechanism; a y-shaped connector; and a 100-ml, 3-neck perfusate reservoir on a magnetic stirrer. A bile collection tube is shown with the bile duct cannula, for collecting bile samples. The pump on the outside of the chamber (outside pump) and the preperfusion buffer are used in the initial perfusion during surgery. The tubing from this preperfusion pump is attached to a 3-way stopcock and a needle that will be inserted into the portal vein (i.e., the portal vein cannula). The stopcock and cannula are also shown within the perfusion chamber after they have been transferred to the inside pump for the perfusion. Humidified 95% O_2/5% CO_2 is passed into the jar of the gas exchange mechanism. As the perfusate circulates inside the gas-permeable tubing, oxygen enters the solution and carbon dioxide exits. The jar has a small hole on the top to allow excess gas to escape. The perfusion chamber also includes a small heater and blower (not shown) to maintain a constant temperature.

Prepare perfusion setup

1. Prelabel and weigh 12 × 75–mm test tubes or 1-ml microcentrifuge tubes to collect bile and perfusate samples and for liver tissue at the end of the experiment.
2. Assemble perfusion chamber and a preperfusion pump (outside pump) as illustrated in Figure 14.5.1.
3. For preperfusion buffer, place 250 ml KH buffer into a 250-ml Ehrlenmeyer flask and add 0.5 ml of 1000 U/ml heparin (~2 U/ml final). Suspend the flask in a 37°C water bath.
4. Connect a tank of 95% O_2/5% CO_2 to a dispersion tube placed within a glass humidifier that has been partially filled with water.
5. Run a length of Tygon tubing from the humidifier to the preperfusion buffer and bubble the buffer for ≥15 min. Turn on the preperfusion pump to begin to recirculate this solution at a rate of ~10 ml/min.
6. For perfusate, take 100 ml KH buffer and add a preweighed aliquot of D-glucose (90.1 mg).

Prepare chamber

7. Rinse all tubing (except for an in-line filter), gas exchange mechanism, perfusion dish, and a 100-ml, 3-neck perfusate reservoir by circulating ~80 ml preperfusion buffer through the system. Flush system completely and discard this solution.
8. Insert the in-line filter containing a 1.2-µm filter and a prefilter.

   The filter also serves as a trap for any air bubbles that may be aspirated from the perfusate reservoir.

9. Add perfusate to the perfusate reservoir. Turn on perfusion pump (inside pump) and invert the in-line filter so as to fill it with perfusate (by holding outlet upward). Set the initial flow to ~20 ml/min.

   This flow rate is increased gradually after the liver is added, to reach a setting of ~35 ml/min for a liver of 8 to 10 g (200- to 300-g rat). For optimal hepatic oxygenation, the perfusion flow rate should be ≥3.5 ml/min per gram liver when using hemoglobin-free perfusates.

10. Recirculate perfusate within the system, making sure that there are no leaks and no air bubbles. Pass humidified 95% O_2/5% CO_2 over the gas-exchange tubing.
11. Calibrate a pH electrode (using pH 7 buffer at 37°C) and insert into perfusate reservoir.

    pH adjustments are made during the experiment by delivering small aliquots of 0.15 M NaOH into the perfusate reservoir. A convenient way of delivering the NaOH is via a 3-ml plastic syringe fitted with a 23-G needle and about 50 cm of PE-50 tubing. The end of this tubing is inserted into the perfusate reservoir.

12. Close chamber door and stabilize heat to 37°C using a thermometer, a small heater, and a blower.

    The chamber should be equipped with a small heater and a blower to circulate air and maintain uniform temperature within the chamber and with a thermometer to monitor the temperature. A petri dish full of water is placed near the heater to provide moisture in the chamber.

13. Place prelabeled bile collection tubes (step 1) on ice.

Perform surgery

14. Weigh a rat and anesthetize with 60 mg/kg of 50 mg/ml pentobarbital sodium, intraperitoneally. Cover an operating tray with absorbent bench paper. Record the weight of the animal and position it on its back on top of the bench paper with its head facing away from the surgeon.

15. Using a scalpel or blunt-end scissors, make a midline incision in the abdomen that extends from the symphysis pubis to the suprasternal notch. Cut skin first and then the muscle layer. Hold the two flaps open to the side with hemostats.

    By staying in the midline, a lot of bleeding is avoided.

Cannulate bile duct

16. Pull out the duodenum and find and isolate the bile duct. Insert a folded 30-cm piece of suture underneath the bile duct, cut the suture in half, and use one piece of suture to ligate the distal end of the bile duct.

17. Use fine iridectomy scissors to make a nick in the bile duct and insert the beveled end of a bile cannula ~1 cm into the duct (Fig. 14.5.2). Align the other suture beneath the cannula. Tie down both sutures.

    It is helpful to put a mark near the beveled end of the cannula with an indelible marker, as this makes it easier to visualize the end of the tube within the bile duct.

    The second suture holds the cannula in place.

Prepare for perfusion

18. Place two 15-cm pieces of suture loosely around the portal vein, one above and one below the pancreatico-duodenal vein (Fig. 14.5.2). Put suture around portal vein only and avoid the hepatic artery.

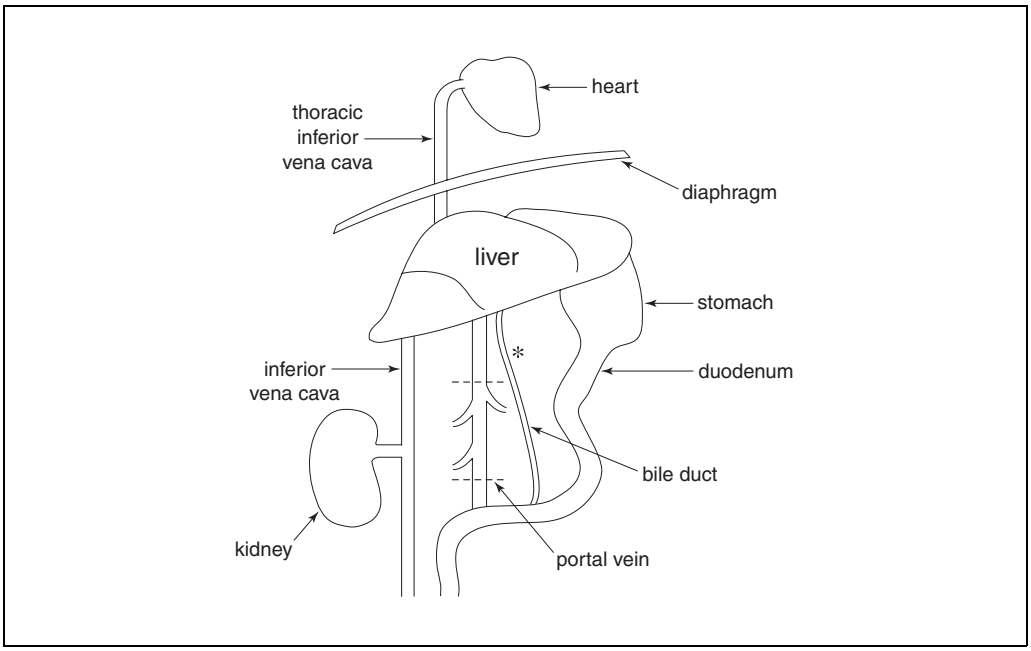

Figure 14.5.2 Anatomy of the rat abdominal cavity. The gastrointestinal tract has been retracted and moved to the right-hand side of the operating field, to expose the inferior vena cava and the right kidney of the rat. The approximate positions of the two portal vein sutures are indicated by dashed lines; the portal vein cannula is placed halfway between the sutures. The approximate position of the bile duct cannula is indicated by an asterisk; a suture is placed both above and below this site of insertion.

19. Retract the gastrointestinal tract and move it to the right-hand side of the operating field, to expose the inferior vena cava and the right kidney of the rat (Fig. 14.5.2). Place a loose 15-cm suture around the vena cava, above the animal's right kidney. Don't tie this suture down until just before portal vein cannulation.

20. Stop the inside pump and suspend the tubing from a piece of tape attached to the ceiling of the chamber. Set initial flow rate to ~20 to 25 ml/min. Make sure all of the tubing is filled with perfusate and that there are no air bubbles.

Cannulate portal vein

21. Attach a portal vein cannula to the outside pump (Fig. 14.5.2) and fill with preperfusion buffer. Place the cannula next to the rat and eliminate any air bubbles (particularly those that may be hiding in the 3-way stopcock).

    Because the pump is running, subsequent steps have to be performed in rapid succession, or the pump can be turned off temporarily.

    The portal vein can be cannulated with various types of needles. The tip of the needle must be completely smooth so as not to damage the portal vein once inserted. It is helpful to have some grooves engraved near the tip of the needle, as this will help hold the suture in place.

22. Tie the suture around the vena cava right above the animal's right kidney (Fig. 14.5.2). Ligate the distal suture (with respect to the liver) around the portal vein.

23. With fine forceps, hold the portal vein and cut a flap in the portal vein (at a 45° angle) using iridectomy scissors. Hold the flap with one hand and insert portal vein cannula with the other hand. Tie down the suture and immediately cut the vena cava below the animal's right kidney to allow blood to escape. Tie down the other suture around the portal vein cannula.

    Note that once blood flow to the liver is interrupted by ligation of the portal vein, there is a window of ~30 sec during which the cannula can be inserted before there is irreversible damage to the liver. Also, after the cannula is inserted, the inferior vena cava must be cut to avoid blood pressure buildup while liquid is pumped into the liver via the cannula.

Cannulate thoracic vena cava

24. Grab the xiphoid with hemostats and using heavy scissors cut through the ribs on both sides. Fold the resulting flap over the animal's head to expose the lungs and heart (Fig. 14.5.2). Use a hemostat to hold this flap in place.

25. Put a single loose 15-cm suture around the thoracic inferior vena cava near the diaphragm. Using iridectomy scissors, put a small hole in the vena cava next to the heart and insert a thoracic vena cava cannula. Secure the suture around the cannula.

Transfer liver to perfusion dish

26. Cut between the animal's right kidney and the suture in the vena cava, but don't cut the suture.

    Removing and transferring the liver is the most challenging part of the surgery.

27. Cut the diaphragm on the left side of the operating field (i.e., the animal's right side), all the way down to the esophagus and then on the right side, but don't cut the esophagus. Flip the largest lobe of the liver to the left to expose some connective tissue and the small lobes of the liver that need to be dissected out.

28. Cut under the bile duct and portal vein cannulas to free them from the underlying tissue. Then, while holding these two cannulas in one hand, gently lift the liver by the cannulas and cut any remaining connections between the liver and the rest of the carcass.

    The portal vein cannula is still attached to the outside pump.

29. Transfer the liver to the perfusion dish and connect the three-way stopcock to the perfusate in the chamber. As soon as the tubing is connected, turn the inside pump on and outside pump off, and immediately turn the stopcock to redirect perfusate. Disconnect the tubing coming from the preperfusion buffer.

30. Adjust the position of the liver lobes, making certain that the caval outflow cannula is centered in the perfusion dish opening and the bile duct cannula is resting over the edge of the dish, and downward to facilitate bile collection (Fig. 14.5.1).

31. Insert a small flexible probe of a temperature monitor between and underneath the large lobe of the liver, and cover the entire petri dish with a piece of clear plastic wrap.

    The plastic wrap maintains moisture over the surface of the liver.

Adjust perfusion setup

32. Make certain that bile is flowing by watching it drip into the bottom of the perfusion chamber. Gradually increase perfusion flow rate as the resistance decreases (look at the manometer; Fig. 14.5.1), to reach a perfusion flow rate of about 35 ml/min for a 10-g liver (~3.5 ml/min/g liver).

    The bile duct may be twisted in the transfer to the perfusion dish, which will prevent the flow of bile.

    The net perfusion pressure through the liver should be <6 cm water.

33. Shut off oxygen to preperfusion reservoir and check on the flow of oxygen into the jar containing the gas-exchange tubing by looking for bubbles in the gas humidifier (Fig. 14.5.1). Allow the liver to equilibrate for 10 min.

Collect bile

34. Fill a tall Dewar flask with ice, put a prechilled collection tube (step 13) into the ice, and position this close to the liver to facilitate bile collection. Using the bile duct cannula, collect bile in tube, changing the collection tube at 15-min intervals or more frequently if desired.

    Bile flow is normally 1 to 2 µl/min/g lower.

35. Take aliquots of perfusate (normally 0.5 ml) using a 1-ml syringe attached to PE90 tubing to access the perfusate reservoir through the sample port. Rinse the tubing and syringe by drawing fluid in and out of the syringe a few times before collecting the perfusate sample.

36. After all samples have been collected, confirm the perfusion flow rate by collecting the perfusate dripping from the bottom of the liver for 30 sec into a 50-ml graduated cylinder. Remove cannulas from the liver and weigh the liver. Measure perfusion pressure in the absence of the liver.

    Perfusion pressure should normally be 4 to 6 cm water.

SIMULTANEOUS ISOLATION OF RAT CANALICULAR AND BASOLATERAL LIVER PLASMA MEMBRANE VESICLES

This protocol is similar to the one devised by Meier et al. (1984; Meier and Boyer, 1990), with only minor modifications. The approach for isolating the canalicular and basolateral liver plasma membrane (cLPM and blLPM, respectively) vesicles is based on previous studies by Long et al. (1969) and Evans (1969) and utilizes two major centrifugation steps. In brief, a mixed liver plasma membrane subfraction is first separated out of a crude nuclear pellet by rate zonal flotation using a TZ-28 (Sorvall) zonal rotor. After tight homogenization, the vesiculated cLPMs are separated by high-speed centrifugation of the mixed liver plasma membranes through a three-step sucrose gradient. The membranes are collected, suspended in a buffered sucrose solution, and stored at −80°C.

Each membrane isolation requires six to eight fed male Sprague-Dawley rats (200 to 250 g) that have been kept for ≥4 days under constant environmental conditions before use. The animals are allowed food and water ad libitum and are killed between 7:00 and 8:00 a.m. The protocol can easily be scaled down to one rat liver (10 g).

NOTE: All steps are performed at 4°C with precooled solutions and equipment. The solutions (homogenization buffer and sucrose solutions) should be prepared 1 to 2 days in advance and stored at 4°C.

Materials

1 mM $NaHCO_3$, pH 7.4, ice cold
Male Sprague-Dawley rats, 200 to 250 g
50 mg/ml pentobarbital sodium, to anesthetize rats
Sucrose solutions: 8.1%, 31%, 34%, 36.5%, 38%, 44%, and 56% sucrose (see recipe), ice cold
Resuspension buffer: e.g., 250 mM sucrose/20 mM KCl/0.2 mM $CaCl_2$, buffered with 10 mM HEPES/TRIZMA, pH 7.5 (see recipe)

100-ml and 2-liter plastic beakers
250-ml and 1-liter glass beakers
7-, 40-, and 100-ml glass-glass Dounce homogenizers with loose-fitting type A and tight-fitting type B pestles
2-liter Erlenmeyer flasks
Guillotine
Scissors
Cheesecloth
250-ml plastic centrifuge tubes with caps
Superspeed centrifuge (e.g., Sorvall RC-5B), 4°C
Centrifuge rotors: Sorvall TZ-28-Zonal, GSA, TH-641, and T-865 (Sorvall Instruments), or equivalent, 4°C
Peristaltic pump
16 × 125–mm test tubes
10-ml plastic Pasteur pipets or transfer pipets
Ultracentrifuge (e.g., Sorvall OTD55B), 4°C
Spectrophotometer (700-nm wavelength)

Set up equipment

1. Place 100-ml plastic beakers (one for each animal) and a 250-ml glass beaker on ice. Fill beakers with ~50 ml of 1 mM $NaHCO_3$.
2. Place two 7-ml and a 40- and a 100-ml glass-glass Dounce homogenizers (with pestles), a 2-liter Erlenmeyer flask, a 2-liter plastic beaker, and a 1-liter glass beaker on ice.

Collect livers

3. Anesthetize six to eight male Sprague-Dawley rats using 60 mg/kg of 50 mg/ml sodium pentobarbital.

4. Using a guillotine, decapitate one rat and using scissors and forceps rapidly remove its liver. Quickly dissect away connective tissue with scissors, rinse liver in ice-cold 1 mM $NaHCO_3$ in the 250-ml glass beaker, and place in one of the 100-ml plastic beakers on ice (step 1). Immediately mince liver tissue with scissors.

5. Decapitate and remove and process livers from remaining animals, one at a time

6. Decant 1 mM $NaHCO_3$ from each of the 100-ml beakers and replace with 80 ml fresh, ice-cold 1 mM $NaHCO_3$ from the original stock bottle.

Homogenize livers

7. Homogenize each liver in 80 ml of 1 mM $NaHCO_3$ with loose-fitting pestle A, first by four strokes in precooled 100-ml Dounce homogenizer and then, in batches, by three strokes in precooled 40-ml Dounce homogenizer.

   One stroke is the equivalent of a complete up-and-down movement of the pestle.

8. Filter each homogenate through a funnel lined with four layers of cheesecloth into the 2-liter Erlenmeyer flask. Pool filtered homogenates in flask and bring total volume to 1500 ml with ice-cold 1 mM $NaHCO_3$. Remove a 1-ml aliquot for protein and enzyme determination and note final volume of homogenate (i.e., ~1500 ml).

   Alternatively, two layers of 60-grade cheesecloth can be used to filter the homogenates.

9. Pour homogenate into six 250-ml centrifuge bottles and spin in a superspeed centrifuge with a GSA rotor for 15 min at $1250 \times g_{ave}$ (3500 rpm for 15 min, including acceleration time).

10. Aspirate supernatant with water vacuum line, while holding bottle at an angle. Pour gelatinous pink pellets into a clean 100-ml Dounce homogenizer on ice. Adjust total volume to 70 ml with 1 mM $NaHCO_3$.

    The total volume of the crude nuclear pellet is ~60 to 70 ml. The final volume must not exceed 70 ml because of the capacity of the zonal rotor.

11. Homogenize with two strokes in the Dounce homogenizer with a loose-fitting pestle. Dilute crude nuclear pellet with 385 ml of 56% sucrose (i.e., 5.5 vol) and stir using the Dounce pestle in the prechilled 1-liter glass beaker.

Perform zonal density gradient centrifugation

12. Install a TZ-28 rotor in the superspeed centrifuge for dynamic loading at 3000 rpm. After reaching 3000 rpm, remove the brake and place centrifuge in the slow acceleration mode.

13. Load the following solutions using a peristaltic pump at a flow rate of ~80–90 ml/min in the order given:

    100 ml of 56% sucrose
    445 to 455 ml membrane suspension (step 11)
    400 ml of 44% sucrose
    200 ml of 36.5% sucrose
    175 to 185 ml of 8.1% sucrose (1330 ml total).

    Remove rotor-filling accessories and accelerate to 19,000 rpm for 120 min.

Collect and wash mixed membranes

14. After slow deceleration to a complete stop, unload the sample from the top of the rotor using the peristaltic pump at a flow rate of ~50 ml/min. Discard the first 750 ml and collect the rest into twenty-four 16 × 125–mm test tubes (17-ml fractions). Take a 1-ml aliquot of each fraction and measure absorbance at 700 nm (turbidity).

15. Combine ten fractions of the major turbidity peak (44%/36.5% interface) in a 1-liter graduated cylinder. Rinse tubes with 1 mM $NaHCO_3$ and add to cylinder to maximize yield.

16. Dilute pooled fractions to 1000 ml with ice-cold 1 mM $NaHCO_3$. Pour membrane suspension into four 250-ml centrifuge bottles and sediment at $6500 \times g_{ave}$ (8000 rpm) for 15 min in the GSA rotor.

17. Aspirate supernatant and rinse pellets with ice-cold 1 mM $NaHCO_3$ into a single bottle. Centrifuge 15 min at $3100 \times g_{ave}$ (5500 rpm).

18. Aspirate supernatant with water vacuum line. Using a 10-ml plastic Pasteur pipet or transfer pipet, add 10 ml of 8.1% sucrose to bottle and resuspend membranes. Transfer to 40-ml Dounce homogenizer on ice. Rinse bottle with additional 8.1% sucrose and transfer to homogenizer to give a total volume of 25 ml.

Isolate cLPMs and blLPMs

19. Homogenize mixed liver plasma membranes by 75 (three sets of 25) strokes in the 40-ml Dounce homogenizer with a tight-fitting type B pestle.

    The Dounce homogenizer is immersed in ice.

20. Sequentially pipet the following solutions into six clear TH-641 tubes:

    3.0 ml of 38% sucrose
    2.5 ml of 34% sucrose
    2.5 ml of 31% sucrose.

    Layer ~3.5 ml homogenized liver plasma membranes on top of the sucrose gradients.

21. Centrifuge tubes 3 hr in an ultracentrifuge with a TH-641 rotor at $195{,}000 \times g_{ave}$ (40,000 rpm), using relatively slow acceleration and deceleration rates to avoid disrupting the gradients.

    This centrifugation produces three distinct bands at the sucrose interfaces and a pellet at the bottom of the tube. The band on top of the 31% sucrose layer represents cLPMs, whereas the band at the 34%/38% interface corresponds to blLPMs.

Collect plasma membranes subfractions

22. Collect membrane bands on top of the 31% (cLPM) and 38% (blLPM) sucrose gradients with 10-ml plastic Pasteur pipets after carefully aspirating any overlying fluid. Divide each subfraction between two 26-ml centrifuge tubes and dilute with ice-cold 8.1% sucrose to fill the tubes.

23. Centrifuge 60 min at $105{,}000 \times g_{ave}$ (40,000 rpm) in a T-865 rotor. Decant supernatant, gently aspirate any remaining supernatant, and add resuspension buffer.

    Normally, each of the four tubes (i.e., 2 of the 31% and 2 of the 38%) will receive 0.5 to 1 ml resuspension buffer.

    The composition of the resuspension buffer is contingent on the ultimate use of the vesicles, but may consist simply of 250 mM sucrose with a pH 7.4 buffer—such as 250 mM sucrose buffered with 10 mM HEPES/TRIZMA pH 7.4 (see recipe).

24. Using 10-ml plastic Pasteur pipets, place these suspensions into precooled 7-ml Dounce homogenizers (one for 31% and one for 38% fractions). Using tight-fitting type B pestles, homogenize with fifteen strokes. Save small aliquots (three 20-µl) for protein and enzyme determination, and store the rest in 0.2 - 0.5-ml aliquots at –80°C for up to 6 months.

The normal yields from this procedure are 10 to 15 mg blLPM protein and 5 to 7 mg cLPM protein.

The membranes should be assessed for their degree of purification. Several marker enzymes have been used to test the relative purity and enrichment of blLPM and cLPM fractions (Meier et al., 1984; Meier and Boyer, 1990). For routine assessment of purification, the enzymes γ-glutamyltranspeptidase (canalicular; Rosalki and Tarlow, 1974) and Na^+,K^+-ATPase (basolateral; Scharschmidt et al., 1979) are probably the most useful.

REAGENTS AND SOLUTIONS

Use glass-distilled, Milli-Q-purified water or equivalent for the preparation of all buffers and in all protocol steps. For common stock solutions, see ***APPENDIX 2A;*** *for suppliers, see* ***SUPPLIERS APPENDIX.***

HEPES/TRIZMA stock, 500 mM

37.75 g HEPES
11.36 g TRIZMA
H_20 to 500 ml

Add this solution to a final concentration of 10 mM in resuspension solution or other solutions in which a buffer is needed, e.g., resuspension buffer or sucrose solution.

Krebs-Henseleit (KH) buffer

~1950 ml H_2O
13.80 g NaCl (118 mM final)
9.4 ml 1 M KCl (*APPENDIX 2A*; 4.7 mM final)
2.4 ml 1 M KH_2PO_4 (1.2 mM final)
4.20 g $NaHCO_3$ (25 mM final)
1.2 ml 1 M $MgSO_4 \cdot 7H_2O$ (*APPENDIX 2A*; 0.6 mM final)
2.5 ml 1 M $CaCl_2 \cdot 2H_2O$ (*APPENDIX 2A*; 1.25 mM final)
Add H_2O to 2 liters
Store up to 2 weeks at 4°C

The $MgSO_4 \cdot 7H_2O$ and $CaCl_2 \cdot 2H_2O$ should be added separately (last) to avoid precipitation.

The pH after gassing with 95% O_2/5% CO_2 for 15 to 20 min at 37°C should be ~7.5.

Krebs-Ringer bicarbonate buffer (with double the amount of $MgSO_4$ and $CaCl_2$) should be used if albumin or another protein is used as an oncotic agent in the perfusate. (The albumin binds some of the calcium and magnesium, such that their starting concentrations need to be higher.)

Sucrose solutions

Make up sucrose solutions according to recipes given in Table 14.5.1. Store solutions for up to 2 weeks at 4°C.

Even the highest sucrose solution should be clear. If yellowish discoloration is seen, filter through a 0.45-µm filter or change to a new sucrose batch.

The refractive index (n) should be checked before use with a refractometer (e.g., Bausch & Lomb). Do not use the sucrose solution if its refractive index deviates by more than ±0.0003 from the expected value.

Table 14.5.1 Sucrose solution recipes for isolation of liver plasma membrane vesicles

Percent weight (w/w)	Molarity (M)	g/liter solution (w/v)	Refractive index (*n*; 20°C)	Density (g/ml)
8.1	0.25	85.6	1.3458	1.0300
31	1.025	350.9	1.3829	1.1318
34	1.138	389.5	1.3883	1.1463
36.5	1.236	422.9	1.3930	1.1587
38	1.295	443.2	1.3958	1.1663
44	1.539	526.8	1.4076	1.1972
56	2.067	707.4	1.4329	1.2632

COMMENTARY

Background Information

The liver's complex microanatomy and reticuloendothelial system create a specialized epithelial barrier separating blood from bile (Boyer, 1986). Mammalian hepatocytes are arranged in plates or sheets that are only one cell thick and are surrounded by capillaries (sinusoids), thus maximizing surface area for exchange with plasma. The sinusoidal endothelium is highly fenestrated and has little if any basement membrane (Disse space). The sieve-like plates in the endothelial cells permit solutes up to the size of chylomicrons to pass from blood into the Disse space. As a result, xenobiotics that are soluble or that may be bound to particles of this size or smaller in blood plasma have direct access to the basolateral surface of hepatocytes.

Three distinct plasma membrane domains are present on hepatocytes: the sinusoidal, lateral, and canalicular membranes. The sinusoidal or basal surface is covered with numerous irregular microvilli that increase the surface membrane area thereby facilitating hepatic uptake. The lateral domain is a relatively smooth and straight extension of the sinusoidal membrane that projects between neighboring hepatocytes and lines the intercellular cleft. It contains gap junctions, desmosomes, and tight junctions, but no microvilli. In analogy with other epithelial cells, the sinusoidal and lateral domains together form the basolateral membrane. The apical or canalicular membrane differs histochemically and biochemically from the basolateral surface. Although the lumen of the canalicular space is only ~1 μm in diameter, the surface area is enlarged by an extensive network of microvilli, which often fill the lumen. The canalicular membrane constitutes ~13% of the plasma membrane surface.

Separation of blood spaces from the lumen of biliary spaces is accomplished largely by two belt-like junctional complexes that encircle each hepatocyte, enclosing the canaliculi and linking adjacent hepatocytes within the hepatic plate. The canalicular wall is therefore a specialized part of the hepatocellular plasma membrane. The tight junctions that separate bile from plasma were initially considered to be impermeable. It is now accepted, however, that the paracellular pathway is the major route for the movement of certain solutes and water between plasma and bile. Studies in perfused rat liver demonstrate that >75% of biliary Na^+, K^+, Cl^-, and water come directly from plasma via the paracellular pathway (Graf et al., 1984, 1987). Hepatocyte junctional complexes are of low electrical resistance and are somewhat cation selective, suggesting the presence of negative charges. Studies by Graf et al. (1987) in isolated rat hepatocyte couplets indicate that the cation selectivity of the paracellular pathway is relatively weak. Paracellular permeability appears to be regulated by hormones, Ca^{2+}, and other endogenous factors and is altered by some drugs and chemicals or during hepatic injury.

Differences in lipid and protein composition among the three plasma membrane domains generate the hepatocyte's functional polarity (Meier, 1988). The sinusoidal membrane is rich in receptors, enzymes, and transport proteins. Receptors for hormones and transmitters such as insulin, glucagon, vasopressin, and α-adrenergic agonists and for metabolites such as lipoproteins, asialoglycoproteins, transferrin, and IgA, are concentrated on this membrane domain. Hormone-sensitive adenylate cyclase and Na^+,K^+-ATPase enzyme activity are also localized to the sinusoidal membrane. Its high phagocytic and endocytic properties are re-

vealed by the presence of clathrin-coated and noncoated vesicles. Transport proteins are also abundant on the sinusoidal membrane. These proteins facilitate uptake of ions, nutrients, bile acids, and organic anions and cations, including certain drugs and xenobiotics from blood plasma. The sinusoidal membrane also has transport systems that facilitate efflux of H^+, Ca^{2+}, amino acids, and possibly other solutes from liver cells back into blood plasma.

The lateral membrane participates in cell-cell interactions but has not yet been shown to contain specific transport processes. Desmosomes and tight junctions within lateral membranes link adjacent hepatocytes and create the canalicular space, whereas its gap junctions are specialized for cell-cell communication. The canalicular membrane is also replete with membrane transport proteins. Transport systems for organic anions (MRP2), organic cations (MDR1), phospholipids (MDR2), and bile acids (BSEP), along with high specific activities of the enzymes γ-glutamyl transpeptidase, leucylnaphthylamidase, Mg^{2+}-ATPase, and alkaline phosphodiesterase are localized to the canalicular membrane.

These transporters are responsible for generating hepatic bile, which is an isoosmotic electrolyte solution containing mixed lipid micelles of bile acids, cholesterol, and phospholipids, along with porphyrins, proteins, peptides, amino acids, metals, and a variety of other endogenous and exogenous compounds (Boyer, 1986). Bile is secreted largely in response to the osmotic gradient between bile, liver tissue, and plasma, which is generated by active secretion of impermeant solutes into the canalicular spaces. Water, electrolytes, and other solutes move across the canalicular membrane as well as through the tight junctions to dissipate the osmotic gradient created by active secretion of bile acids (Sperber, 1959), glutathione (Ballatori and Truong, 1992), and possibly other solutes.

After its secretion, canalicular bile winds its way through the labyrinth of canaliculi towards the periphery of the hepatic lobule and drains into the hepatic ductules and ducts and, finally, into the common duct and gallbladder. At each of these sites, canalicular bile may be modified by both absorptive and secretory processes, and some of its components may be metabolized by membrane-bound ectoproteins (Ballatori et al., 1986, 1988; Ballatori and Truong, 1989), demonstrating that biliary epithelia are not inert conduits for bile but are actively involved in its postsecretory processing.

Overall, the complex microanatomy of bile secretion poses a special challenge in the design of experiments to investigate mechanisms of hepatobiliary transport. The intact animal and the isolated perfused liver model are the only systems that permit the simultaneous measurement of sinusoidal transport and biliary excretion; however, it is often difficult to obtain detailed kinetic data using these model systems. Other in vitro models are used more often, but all in vitro models share a major limitation, namely the inability to reproduce the ionic and ligand composition of blood and blood plasma, a critical factor in regulating xenobiotic clearance.

In the early 1980s, another useful model system was introduced: a technique for the separation of plasma membrane vesicles derived from the liver cell sinusoidal and canalicular membrane domains (Meier et al., 1984). This made it possible to examine transport at both poles of the cell separately, without interference from cell metabolic functions. With this system, the electrogenic features, energy dependence, and ion requirements could be determined with relative ease. The limitations of this system include cross-contamination with other intracellular or plasma membranes, orientation of the vesicles, functional integrity of the transport proteins or the vesicles themselves, and the relatively high degree of nonspecific binding that is often observed with hydrophobic compounds or with metals. Despite these limitations, the vesicle systems have provided invaluable information on the functional characteristics of these two hepatocellular membrane domains.

Critical Parameters and Troubleshooting

The most common complication of the in vivo bile collection method in anesthetized animals is obstruction of the bile duct or cannula. Occasionally, blood clots, biliary sludge, or air bubbles may partially or completely block bile flow. This is usually remedied by gently aspirating the end of the bile cannula with a transfer pipet or a syringe to dislodge the obstruction. If this procedure fails to dislodge the block, remove the cannula, verify that bile is dripping from the end of the bile duct, and insert a new cannula. Occasionally, the bile duct is twisted or bent during the surgery, and this may also obstruct bile flow. Visual inspection of duct anatomy and cannula orientation should reveal this complication, and the defect is usually

remedied by rotating or bending the duct or cannula in the appropriate direction.

Surgical isolation and in vitro perfusion of a rat liver require considerable manual dexterity and surgical skills and may require a significant number of practice trials to perfect the approach. For most investigators, the most difficult parts of the surgery are the cannulation of the portal vein (which should be completed within 30 sec of cutting the portal vein) and the resection of the liver from the body cavity. Considerable time should be invested in studying the gross anatomy of the rat, with a particular focus on the hepatic vascular system, and in practicing cannulating small vessels. The most common complications arise from trauma caused to the liver during surgery or transfer to the perfusion dish and from the incorrect positioning of the liver on the perfusion dish. If incorrectly positioned on the dish, some of the lobes of the liver may be twisted or bent, which would prevent adequate perfusion of those lobes. Likewise, the positioning of the portal vein, vena cava, and bile duct cannulas needs to be adjusted to mimic that in the in situ liver, thus maximizing flow through each cannula. Thorough knowledge of the gross anatomy of the liver will minimize these problems. Surgery is greatly facilitated by the use of sharp, high-quality instruments, and by a surgical lamp to brightly illuminate the operating field. Although the experiment may be performed by a single investigator, it is useful to have a surgical assistant, particularly during the training period.

The critical element of the membrane vesicle isolation protocol is temperature control, which is important for minimizing protein degradation and cross-contamination between basolateral and canalicular membranes. All solutions and equipment must be precooled on ice, and samples must not be allowed to sit for extended periods before processing. Another important element is the use of high-quality distilled or deionized water for the preparation of all solutions, and the use of high-grade sucrose for preparation of gradients and vesicle storage solutions. Sucrose solutions are prone to bacterial contamination and thus should be stored at 4°C and used within two weeks.

Anticipated Results

Bile flow rates in adult anesthetized rats are expected to be from 4 to 8 ml/hr/kg body weight or from 1.7 to 3.3 µl/min/g liver wet weight. These flow rates normally drop slowly with time of bile collection, owing largely to the interruption of the enterohepatic circulation and the consequent depletion of bile acids.

In the isolated perfused rat liver, bile flow rates are lower than in vivo (from 1 to 2 µl/min/g liver wet weight at the onset of perfusion) and also tend to decrease with time of perfusion. The lower flow rates in the isolated perfused liver as compared with the in vivo situation are explained largely by the absence of bile acids in the perfusate, as well as the gradual loss of bile acids and their precursors from liver tissue. Perfusion pressure in the isolated liver is normally from 4 to 6 cm water, and this is generally maintained throughout a perfusion period of <3 hr.

The recovery of membrane vesicle proteins ranges from 0.1 to 0.2 mg/g liver and 0.05 to 0.10 mg/g liver for basolateral and canalicular membranes, respectively, starting with a single liver homogenate. Given the capacity of the zonal rotor (i.e., starting with about 100 g liver wet weight), the yields of basolateral and canalicular membrane proteins range from 10 to 20 mg and 5 to 10 mg, respectively. In terms of marker enzyme activities, Na^+,K^+-ATPase is normally enriched 20- to 40-fold in basolateral membranes when compared with the starting liver homogenate and is only minimally enriched in canalicular membranes (2-fold). Conversely, γ-glutamyltranspeptidase is normally enriched 40- to 70-fold in canalicular membranes when compared with the starting liver homogenate and is enriched 10- to 20-fold in basolateral membranes. Thus, the basolateral membrane vesicles are normally contaminated with 10% to 20% canalicular membranes, and the canalicular membrane vesicles are normally contaminated with ~5% basolateral membranes.

Time Considerations

For the in vivo bile collections, the surgical procedure requires only ~5 to 10 min to complete, whereas for the perfused rat liver protocol, the surgical approach requires 20 to 30 min. Once the liver is on the perfusion dish, an additional 5 to 15 min is normally allowed for making adjustments to the liver's anatomical arrangement, perfusate flow rate, and temperature control, prior to initiating the experiment.

Isolation of canalicular and basolateral membranes requires ~11 hr (7:00 a.m. to 6:00 p.m.). This includes about 6.5 hr of centrifugation time.

CHAPTER 15
Gene Targeting

INTRODUCTION

The development of murine embryonic stem (ES) cells has brought about another revolution in the biological sciences. When considering the most important experiments of the last century, one must include those resulting in the discovery that clones derived from the inner cell mass of early embryos could be propagated in culture and that resultant cells could contribute to the germ line after reinjection into blastocysts (Evans and Kaufman, 1981; Bradley et al., 1984; Robertson et al., 1986). The marriage of pluripotent ES cells with an understanding of gene targeting through homologous recombination was the additional breakthrough that allowed application of this powerful approach to the murine system (Doetschman et al., 1988; Mansour et al., 1988).

As a result of these advances, a number of truly remarkable experimental avenues are now available to the general scientific population. In essence, ES cells and related gene targeting technologies allow us to alter any locus within the mouse genome, in essentially any way that is desired. The results of this new-found ability include the generation of better mouse models of human disease and the capacity to examine mutations within a whole-animal context. Moreover, the cell lines and organ culture models that can be derived from these experiments provide powerful systems for the analysis of gene-function relationships in simpler in vitro systems.

Like any new methodology, ES cells and gene targeting can be technically demanding. Because of this challenge, one can make the mistake of being intimidated and never attempting such experiments for oneself. In the early years of these techniques, avoidance of ES cell biology and gene targeting was understandable. ES cell lines were not readily available, generation of mouse embryonic fibroblasts required a large up-front commitment, serum lots had to be checked carefully for their capacity to maintain ES cell pluripotency, and the procurement of targeting vectors and related reagents was difficult. Add to this the fact that only a few experts knew what an ES cell colony looked like further sowed the seeds of intimidation. Today, avoidance of this technology is not as defensible. Pluripotent ES cell lines, the required feeder cells, ES-validated serum lots, and parent targeting vectors are available from a number of commercial vendors. In addition, most universities have core facilities that can easily handle the injection needs of the average investigator. With these technical obstacles out of the way, the only impediment left is the normal energy barrier that prevents us from beginning any new technique in the lab.

It is certain that ES cell technology will soon become a standard approach in the field of toxicology. At the very least, toxicologists will be able to benefit greatly from the use of mutant mice that have been generated by others. The utility of this technology to toxicology is less of a prediction than an observation. Already, null alleles at *Cyp* loci have proven that certain monooxygenases play a role in the toxicity of various chemicals (e.g., Lee et al., 1996; Zaher et al., 1998; Buters et al., 1999). Similarly, null alleles at loci encoding various cytokines are demonstrating a role for these factors in the mechanisms of certain toxicants (e.g., Ladenheim et al., 2000).

The protocols that follow should provide a solid start to those individuals ready to establish ES cell technology in their own laboratories. Although these protocols are fairly

Contributed by Christopher A. Bradfield
Current Protocols in Toxicology (2001) 15.0.1-15.0.2

detailed in nature, where appropriate, we have also tried to cite additional references and manuals in ES cell and mouse biology. In addition, a considerable discussion of ES cell biology can be found in *UNIT 1.3*. Here, we start with a section describing the general maintenance of ES cells, as well as the preparation of necessary feeder cells and related reagents (*UNIT 15.1)*. This is followed with a section describing protocols for the rapid genotyping of ES cells after a gene-targeting event (*UNIT 15.2*). The current version of this chapter also includes a description of how an investigator can make aggregation chimeras (*UNIT 15.3*). this protocol allows the study of chimeric mice and serves as a starting point for germ-line transmission. Additionally, we have begun to address how an investigator can examine Cre-expression methods in recombinant mice through the use of novel and widely available "reporter mice" (*UNIT 15.4*). In future supplements, we will address the construction of targeting vectors and the fundamentals of ES cell microinjection into blastocysts.

Christopher A. Bradfield

Embryonic Stem (ES) Cell Culture Basics

Embryonic stem (ES) cells are derived from the inner cell mass (ICM) of a 3.5-day mouse blastocyst. The ICM is that portion of the blastocyst that will form the embryo proper and at 3.5 days these cells are pluripotent with respect to developmental fate. These cells can be manipulated in culture and returned to a mouse embryo to generate an animal with a desired mutation. Perhaps the most important factor in a successful targeting project is the quality of the ES cells used. Improper culture conditions can result in ES cells that have begun to differentiate and therefore lost their pluripotency. ES cells are ordinarily maintained on a layer of mitomycin C–inactivated mouse fibroblasts, either primary mouse embryonic fibroblasts or a fibroblast cell line. The cytokine known as leukemia inhibitory factor (LIF) is added to ES cell culture medium as it has an important role in maintaining the ES cells in the undifferentiated state. Lastly, very stringent culture conditions must be employed when working with ES cells. These include feeding the cells every day and passaging every 2 to 3 days, all the while maintaining minimal time in culture.

This unit describes the techniques necessary to maintain ES cells in culture (Basic Protocol), prepare primary mouse fibroblasts (Support Protocol 1), introduce targeted modifications by homologous recombination (Support Protocol 2), select for this event (Support Protocol 3), and prepare ES cells for injection (Support Protocol 4).

NOTE: All solutions and equipment coming into contact with live cells must be sterile, and proper aseptic technique should be used accordingly. All reagents should be warmed to 37°C just before use and not left at 37°C any longer than necessary.

NOTE: Most laboratories prefer commercially supplied reagents, including PBS, for culture work because the quality of in-house-purified water is so variable.

NOTE: All culture incubations should be performed in a humidified 37°C, 5% CO_2 incubator unless otherwise specified.

ES CELL CULTURE

BASIC PROTOCOL

The key to successful culture of ES cells is to maintain the cells at the correct density. Cells split back too far will not regrow while cells allowed to become overly confluent may begin to differentiate. For more information on primary mouse embryonic fibroblasts (pMEFs), see Support Protocol 1.

Materials

0.1% (w/v) gelatin
Mitomycin C–inactivated primary mouse embryonic fibroblast (pMEF) cells in a 1.5-ml cryovial (see Support Protocol 1)
pMEF medium, 37°C (see recipe)
ES cells in a 1.5-ml cryovial (see Support Protocol 2)
ES cell medium, 37°C (see recipe)
Trypsin/EDTA: 0.05% (w/v) trypsin/53 mM Na_4 EDTA (Invitrogen)

10-cm tissue culture dish or 6- or 96-well tissue-culture plate
15-ml culture tube
Sterile medium boats (96-well plates)
Multichannel pipettor (96-well plates)

Contributed by Jennifer V. Schmidt
Current Protocols in Toxicology (2001) 15.1.1-15.1.15

Thaw pMEF feeder cells

1. Gelatinize a 10-cm tissue culture dish or 6- or 96-well plate by adding 0.1% (w/v) gelatin to cover the bottom of the dish or wells. Incubate undisturbed (5 to 30 min) while preparing pMEF feeder cells.
2. To prepare previously inactivated and frozen feeder cells—i.e., mitomycin C–inactivated primary mouse embryonic fibroblast (pMEF) cells—thaw quickly by gently shaking the 1.5-ml cryovial in a 37°C water bath until the medium is liquid. Rinse the outside of the vial with ethanol. Transfer cells to a 15-ml culture tube and add warm pMEF medium to 10 ml.

   Each frozen cryovial of mitomycin C–inactivated pMEF cells will make one 10-cm dish, 6-well, or 96-well plate of ES cell feeders.
3. Centrifuge cells 2 min at ~400 × *g*, room temperature. Aspirate medium.
4. Resuspend cell pellet in 10 ml pMEF medium to make either a 10-cm dish or 96-well plate, or 18 ml to make a 6-well plate.
5. Aspirate gelatin from the dish or plate prepared in step 1.

Plate pMEF feeder cells

6. Add the full volume resuspended pMEF cells to the gelatinized 10-cm dish, 3 ml to each well of the gelatinized 6-well plate, or transfer the cell suspension to a sterile medium boat and use a 12-channel multichannel pipettor to dispense 100 µl to each well of the gelatinized 96-well plate.
7. Incubate ≥6 hr.

   This incubation is done to allow mitomycin C–inactivated pMEF cells to attach before adding ES cells. A 12-hr incubation is preferred.

Thaw frozen ES cells

NOTE: ES cells should be started in the same size plate as they were frozen from. The authors typically freeze and thaw ES cells from individual wells of a 6-well plate, which is the method described here (steps 8 to 11). This procedure can be modified for different numbers of cells.

8. Thaw one 1.5-ml cryovial ES cells quickly by shaking gently in a 37°C water bath until the medium is liquid. Rinse the outside of the vial with ethanol. Transfer to a 15-ml culture tube and add 37°C ES cell medium to 10 ml.
9. Centrifuge 2 min at ~400 × *g*, room temperature. Aspirate the supernatant and resuspend cell pellet in 3 ml of 37°C ES cell medium.
10. Aspirate pMEF medium from one well of a new 6-well feeder-cell plate and add all of the resuspended ES cells gently to the well without detaching the feeder cells. Rock the plate back and forth by hand three or four times to distribute the cells.
11. Transfer to an incubator.
12. Change ES cell medium daily.

Split and expand ES cells

13. The day before splitting the ES cells, prepare the appropriate feeder-cell plates for the next passage (steps 1 to 7).

    ES cells should be split when ~80% confluent. Cells should never be split more than 1:5. The author's laboratory typically thaws a vial of ES cells to one well of a 6-well plate (see above), splits to the other 5 wells of the plate, and then splits to two 10-cm dishes, yielding enough cells for two electroporation reactions (see Support Protocol 2).

14. Feed ES cells with an appropriate volume ES cell medium 1 hr before trypsinization. Just prior to trypsinization, aspirate the pMEF medium from the new feeder-cell plates and replace with 37°C ES cell medium.
15. Rinse ES cells once by removing the medium, adding sufficient trypsin/EDTA to cover the bottom of the dish or individual wells, swirling briefly, and aspirating. Add 3 ml, 0.5 ml, or 35 µl trypsin/EDTA to the dish or each well of a 10-cm dish, 6-well, or 96-well plate, respectively.
16. Incubate 10 min. Check that cells have detached completely from the dish or plate. If cells have not detached incubate a minute or two longer.
17. Add an equivalent volume 37°C ES cell medium to neutralize the trypsin, and pipet cells several times through a serological pipet with a 200-µl pipet tip (i.e., yellow tip) on the end. Transfer cells to a 15-ml culture tube and add ES cell medium to 10 ml.

    pMEFs will also be passaged but because they are inactivated, they will not divide, and they will die off.
18. Centrifuge cells 2 min at ~400 × *g*.
19. Aspirate the supernatant and resuspend the cell pellet in an appropriate volume ES cell medium.
20. Pipet dropwise onto new feeder-cell dishes or plates.

PREPARATION OF PRIMARY MOUSE EMBRYONIC FIBROBLAST (pMEF) CELLS

SUPPORT PROTOCOL 1

Primary mouse embryonic fibroblasts (pMEFs) provide the ideal substrate for the culture of ES cells. These cells provide a support matrix for the ES cells and secrete factors that help keep the cells in an undifferentiated state. The feeder cells must be neomycin resistant so they are able to survive drug selection and are therefore obtained from mouse embryos transgenic for the *neo* gene. One embryo will yield ~20 plates of ES cell feeders.

Additional Materials *(also see Basic Protocol)*

Male transgenic mice homozygous for the *neo* gene (e.g., C57BL/6JTgN[pPGKneobpA]Ems, Jackson Laboratories)
Outbred nontransgenic female mice (preferably the same strain as the males)
PBS, fresh (*APPENDIX 2A*)
Freezing medium, 4°C (see recipe)
Mitomycin C medium (see recipe)

Dissecting equipment
Petri dish
Dissecting microscope
6-cm tissue culture dish
Razor or scalpel blades
10-ml serological pipets
10-ml syringe with 18-G needle
50-ml centrifuge tube
10-cm tissue culture dish
1.5-ml cryovials
Additional reagents and equipment for isolating postimplantation embryos (*UNIT 13.3*)

NOTE: All protocols using live animals must first be reviewed and approved by an Institutional Animal Care and Use Committee (IACUC) and must follow officially approved procedures for the care and use of laboratory animals.

Mate Neo transgenic mice

1. Set up mating pairs of male transgenic mice homozygous for the *neo* gene with strain-matched nontransgenic females. Check the females each morning for the presence of a copulation plug in the vagina.

   The copulation plug looks like a grain of rice and indicates that mating has occurred. The day of the plug is counted as embryonic day 0.5 (e0.5).

Isolate embryos

2. Working on a regular lab bench, sacrifice 1 to 2 pregnant females on day e13.5 to e14.5. Using dissecting equipment, remove the uterine horns from the mice (*UNIT 13.3*) and transfer into a petri dish containing PBS.

3. Move this dish to a clean area (e.g., a tissue culture room) and dissect the intact embryos into a petri dish containing fresh PBS. Release each embryo from its yolk sac and placenta, and transfer to a petri dish containing fresh PBS.

4. Cut the head off each embryo and using a dissecting microscope remove as much viscera as possible. Move each carcass into a petri dish containing fresh PBS.

5. Move the dish containing carcasses into a tissue culture hood.

   Work with 5 to 6 embryos at a time for the following volumes.

6. Put carcasses in a 6-cm tissue culture dish containing 5 ml fresh trypsin/EDTA. Mince very well with a razor or scalpel blade and incubate 5 min.

7. Add 5 ml of 37°C pMEF medium and pipet the embryo mixture up and down several times with a 10-ml serological pipet. Place an 18-G needle on a 10-ml syringe and pass the embryo mixture through the needle several times.

8. Transfer the embryo mixture to a 15-ml tissue culture tube and incubate undisturbed for 1 to 2 min to allow the largest debris to settle out.

9. Transfer the supernatant to a 50-ml centrifuge tube, add 40 ml pMEF medium, and centrifuge 2 min at ~400 × *g*, room temperature. Aspirate the supernatant and resuspend the cell pellet in 5 to 6 ml pMEF medium (i.e., 1 ml medium/initial embryo).

Plate pMEF cells

10. Treat all embryos as above and pool when finished to ensure uniformity in plating.

11. Prepare as many 10-cm tissue culture dishes as there were initial embryos, by adding 9 ml pMEF medium per dish.

12. Add 1 ml resuspended cells to each dish.

13. Transfer to an incubator, changing pMEF medium the following day and every 2 days after until cells have almost reached confluency (i.e., usually 3 to 5 days).

14. Aspirate all medium from each dish and replace with 3 ml trypsin/EDTA. Incubate 10 min. While plates are incubating, prepare four new 10-cm tissue culture dishes for each dish of pMEFs as described in step 11.

    There should be four new dishes for each starting embryo.

15. After incubation, check to see that cells have detached from the dish and add 3 ml pMEF medium to each. Pipet several times with a 10-ml serological pipet and transfer cells to a 50-ml centrifuge tube.

16. Add additional pMEF medium to 50 ml total and centrifuge 2 min at ~400 × *g*, room temperature

17. Aspirate the supernatant and resuspend the cell pellet in 4 ml pMEF medium (i.e., 1 ml per each new dish or 4 ml per each embryo).

18. Add 1 ml resuspended cells to each new dish.

19. Incubate to confluency, feeding cells with pMEF medium every 2 days.

When the pMEFs have again reached confluence, they can be frozen for later use or passaged again for mitomycin C inactivation.

Freeze cells for later use

20a. Trypsinize and centrifuge (see Basic Protocol, steps 15 to 17) but do not prepare new dishes. Aspirate the supernatant and resuspend the cell pellet in 4°C freezing medium at 1 ml per starting dish (i.e., 20 or 24 ml). Pool all cells for uniformity. Aliquot 1 ml cells into 1.5-ml cryovials and place in a −20°C freezer until frozen solid (i.e., 1 to 2 hr).

21a. Move cells to a −80°C freezer overnight. The following morning transfer cryovials to the vapor phase of a liquid nitrogen tank up to 1 year.

To continue with mitomycin C inactivation, perform steps 22 and 23.

Continue with mitomycin C inactivation

20b. Prepare four or five new plates as described in step 11.

21b. Split cells 1:4 or 1:5 and incubate to confluency (~4 to 5 days), feeding every 2 days.

Proceed to step 24.

Prepare mitomycin C–inactivated feeder cells

22. (*Optional*) If cells were frozen, thaw one or more cryovials pMEF cells quickly by gently shaking the cryovial(s) in a 37°C water bath until the medium is liquid. Transfer cells to a 15-ml tube and add 37°C pMEF medium to 10 ml. Centrifuge cells 2 min at ~400 × *g*, room temperature. While the centrifugation is proceeding, prepare five 10-cm tissue culture dishes by adding 9 ml warm pMEF medium.

23. (*Optional*) Aspirate supernatant and resuspend cell pellet in 5 ml pMEF medium per vial thawed. Add 1 ml cells to each 10-cm dish. Transfer to an incubator. Feed cells every 2 days with pMEF medium until confluent (~4 to 5 days).

24. Remove pMEF medium and replace with 6 ml mitomycin C medium per dish. Incubate 2 hr.

25. Wash cells three times gently with PBS. Trypsinize and centrifuge (see Basic Protocol, steps 15 to 17). Aspirate supernatant and resuspend cell pellets in 1 ml pMEF medium for each starting dish. Pool all cells when finished to ensure uniformity in plating.

26a. *For immediate use:* Prepare a new gelatinized dish (see Basic Protocol, step 1) for each starting dish. Transfer 1 ml to each new dish (i.e., split 1:1).

26b. *For later use:* Resuspend and freeze as described in steps 20a and 21a, omitting further trypsinization and centrifugation.

Feeder cells should be prepared at least 6, and preferably 12 hr before use, and may be used for up to 1 week after plating.

SUPPORT PROTOCOL 2

ELECTROPORATION OF ES CELLS

ES cell targeting is a laborious and time consuming endeavor. Use of a 96-well plate such as the one described in this protocol dramatically decreases the hands-on time required. One important concern during all ES cell work is to minimize the amount of time the cells spend in culture and thus the possibility they may begin to differentiate. For this reason, ES cells are never maintained as a continuously growing cell line. The author's laboratory freezes the cells in small batches, thawing and expanding them only to the extent necessary for electroporation, and freezing the targeted clones as soon as possible. One additional advantage of scaled-down protocols is that they allow the time in culture to be kept to a minimum.

Additional Materials *(also see Basic Protocol)*

Targeting plasmid
H_2O, sterile
ES cell cultures (see Basic Protocol)
G418 medium or G418/ganciclovir medium (see recipes)
Freezing medium (see recipe)

Electroporator (Bio-Rad) and appropriate cuvettes with a 4-mm gap
15-ml conical tube
96-well U- and flat-bottom plates
Microscope with 4× objective
200-µl micropipettor and tips, sterile
Styrofoam box

Additional reagents and equipment for plasmid preparation by cesium chloride equilibrium centrifugation, enzyme digestion, agarose gel electrophoresis, phenol/chloroform/isoamyl extraction, and ethanol precipitation (see Table A.3A.1 of *APPENDIX 3A*), preparing 10-cm feeder-cell dishes (see Support Protocol 1), and counting cells in a hemacytometer (*APPENDIX 3B*).

Prepare DNA for targeting

1. Prepare the targeting construct plasmid DNA by cesium chloride equilibrium centrifugation (*APPENDIX 3A*). Linearize 50 to 100 µg targeting construct with an appropriate enzyme and check a small amount of the DNA on an agarose gel (*APPENDIX 3A*) to make sure the linearization is complete.

   Instead of cesium chloride equilibrium centrifugation, the Qiagen method can be used for plasmid purification.

2. Extract DNA with phenol/chloroform, then chloroform/isoamyl alcohol and ethanol precipitate (*APPENDIX 3A*). Resuspend to a concentration of 1 µg/µl using sterile H_2O.

Electroporate ES cells

NOTE: ES cells should be electroporated when they reach 70% to 80% confluency. One 10-cm dish of ES cells at this density will yield ~2×10^7 cells (i.e., the number required for one electroporation); therefore, one targeting construct and a blank will require two 10-cm dishes of ES cells.

3. The day before electroporation, prepare three 10-cm feeder-cell dishes for each DNA electroporation (see Support Protocol 1).

   Only one feeder cell plate is necessary for the blank reaction.

4. Feed the ES cell cultures with ES cell medium 1 hr before electroporation. Just prior to electroporation, aspirate the pMEF medium from the feeder-cell dishes and replace with 9 ml of 37°C ES cell medium.

5. Trypsinize cells as described (see Basic Protocol, steps 15 to 19) and resuspend the cell pellet in 10 ml ES cell medium.

6. Add 20 µl ES cells to one chamber of a hemacytometer and count the center 25 squares (*APPENDIX 3B*). To obtain the total number of cells, multiply the number of cells in the center 25 squares by 10,000 then by the total volume of culture in milliliters.

7. Centrifuge 2 min at ~400 × *g*, room temperature. Adjust the cell concentration to 2 × 10^7 cells/800 µl with ES cell medium.

8. Mix 800 µl ES cells with 25 µg linearized DNA in a sterile microcentrifuge tube. Incubate 5 min at room temperature. Add mixture to an electroporation cuvette with a 0.4-mm gap and electroporate at settings of 250 V and 500 µF. Monitor the time constants, which should be between 7 and 10 msec.

   These settings are for a Bio-Rad electroporator and may need to be optimized for different machines.

9. Incubate the electroporated ES cells 5 min at room temperature. Use a Pasteur pipet to transfer all cells from the electroporation cuvette to a 15-ml conical tube. Adjust the cell volume to 3 ml with ES cell medium.

10. Add 1 ml reaction mixture to each of the three 10-cm feeder-cell plates. Transfer to an incubator.

    The blank reaction requires only one plate with ⅓ of the electroporated cells. This acts as a negative control and should show no colony growth in G418.

Select for drug resistance

NOTE: Drug selection should be begun 24 to 48 hr after electroporation. If selection is begun at 48 hr, cells should be fed with regular ES cell medium at 24 hr.

11. Replace ES cell medium with warm G418 or G418/ganciclovir medium. Change medium daily.

    The majority of the ES cells should begin to die after 1 to 2 days of drug selection and a large number of dead cells is normal for several days.

    DNA introduced into a cell can integrate homologously or heterologously; the frequency of homologous integration is quite low and selection is required to enrich for this event. Selection strategies incorporate a positive selectable marker such as neomycin into the targeting vector—incorporation of the neo gene renders a cell resistant to the drug geneticin, found in G418 medium. A second strategy known as negative selection is often employed to enrich for homologous recombinants. Incorporation of a negative selectable marker such as HSV-TK renders cells sensitive to the drug ganciclovir. By placing the HSV-TK gene in the targeting construct, outside of the region of homology, it will be incorporated in only those cells in which the DNA has integrated heterologously. The choice of positive alone or positive-negative selection is one of personal preference and cloning feasibility.

Pick colonies

NOTE: Colonies of ES cells should begin to be visible microscopically after 4 to 5 days of drug selection and are typically picked after 5 to 7 days of selection, when most of the background has cleared.

12. The day before picking colonies, prepare 96-well feeder-cell plates (see Basic Protocol, steps 1 to 7), for the number of clones to be picked.

    An initial analysis of 400 clones is a good number and can easily be managed by a single person.

13. When ready to pick, prepare the 96-well feeder-cell plate by replacing the pMEF medium with 100 µl of 37°C ES cell medium in each well. Prepare a 96-well U-bottom plate by adding 75 µl trypsin/EDTA to each well.

14. Move one plate ES cell colonies to a microscope with a 4× objective and use a 200-µl micropipettor set at 25 µl to pick and transfer individual colony to one of the wells of the 96-well U-bottom plate containing trypsin, using a fresh pipet tip for each clone. Repeat for all clones.

    The wells can be checked with the microscope to verify that the clone was transferred.

    ES cells are remarkably resistant to trypsin and can be left to disaggregate for up to 1 hr. Working quickly an entire 96-well plate can be picked at one time.

15. When finished picking colonies, add 75 µl ES cell medium to each well and pipet the clone up and down several times with a 200-µl micropipettor with an appropriate (i.e., yellow) tip.

16. Add disaggregated ES cells to the new feeder-cell plate, one clone per well. Transfer to an incubator.

Expand colonies

17. Feed picked clones daily with ES cell medium without drugs.

    Cells should begin to be visible in the wells after 3 to 4 days.

    Invariably all ES cell clones will not grow at the same rate. There will be some clones that are not yet confluent when the majority are ready to split. Regardless, the plate should be split when the majority of clones are ready, even if those with fewer cells may be lost.

18. The day before splitting, prepare one new 96-well feeder-cell plate (see Basic Protocol 1, steps 1 to 7), for each plate of colonies.

19. On the split day, add 0.1 % (w/v) gelatin to cover the bottom of two 96-well flat-bottom plates for each plate of clones. Let this sit while preparing to trypsinize. Replace the pMEF medium of each well of the new 96-well feeder-cell plates with 100 µl ES cell medium.

20. Rinse the ES clones with trypsin/EDTA, swirl, and aspirate. Replace with 75 µl trypsin/EDTA and incubate 10 min. While cells are trypsinizing, aspirate the gelatin in the flat-bottom 96-well plates replace with 100 µl ES cell medium in each well.

21. After incubation add 75 µl ES cell medium to each well and pipet the cells several times using a multichannel pipettor with 200-µl (i.e., yellow) tips. Transfer $\frac{1}{3}$ each clone suspension to each of the two gelatinized 96-well flat-bottom plates and the new feeder-cell plate. Transfer to an incubator.

22. Feed the ES cells on feeder cells daily with ES cell medium until confluent, then freeze plate for later retrieval.

    The cells on gelatin will be used to extract DNA (see UNIT 15.2, Basic Protocol 1). While in the author's laboratory cells are not normally fed after plating, they can be fed every 2 to 3 days if desired.

Freeze ES cell clones in 96-well plates

NOTE: Plates should be stored at −80°C for no more than a few weeks and should be placed in a position to avoid any freeze-thaw. This length of time is usually sufficient for analysis of the clone DNAs. If longer storage is necessary, the plates should be stored in the vapor phase of a liquid nitrogen tank.

23. Chill a small styrofoam box in a −80°C freezer.
24. Use a multichannel pipettor to aspirate the medium from each 96-well plate and replace with 50 µl freezing medium, 4°C.
25. Quickly wrap each plate in a double layer of Parafilm and place in the chilled box in a −80°C freezer.

Thaw and expand ES cells after genotyping

26. The day before thawing, prepare a 96-well plate of feeder cells (see Basic Protocol, steps 1 and 2). Just prior to thawing the ES clones replace the pMEF medium of each well with 100 µl of 37°C ES cell medium.

    ES cells should always be thawed to the same size plate as the one they were frozen from. For targeted cells being recovered after screening, this means thawing to a 96-well plate and sequentially expanding.

27. Remove the 96-well plate from the freezer and unwrap. Working quickly, locate the clone to be thawed and use a 200-µl micropipettor to add 200 µl of 37°C ES medium to the well; pipet up and down several times as the cells thaw. Transfer the cells to a 3-ml tube and repeat several times until all cells have been thawed and transferred. Add medium to 2 ml.

    The well can be examined under the microscope to ensure that all cells have been recovered.

28. Centrifuge the cells 2 min at ~400 × *g*, room temperature. Aspirate the supernatant, leaving ~100 µl medium in the tube. Use a 200-µl pipet tip to resuspend the cell pellet and transfer to one well of the feeder-cell plate. Repeat with all other clones to be thawed. Transfer to an incubator.
29. When cells are visible in the 96-well plate (4 to 6 days), prepare a new 24-well feeder-cell plate (see Basic Protocol, steps 1 to 7). Once cells reach 80% confluence, trypsinize as described previously (see Basic Protocol, steps 15 to 19) and plate cells from one well into one well of the 24-well plate.
30. When the cells again reach 80% confluence, expand further by plating into one well of a 6-well plate; then further again by splitting to the other 5 wells of the 6-well plate. When confluent again, freeze as 1 well/vial. Upon thawing, the clones should be genotyped (*UNIT 15.2*) to ensure the correct clone identity.

    This will give 5 vials of cells per clone for microinjection or subsequent protocols such as Cre excision. Upon thawing, the clones should be genotyped (UNIT 15.2) to ensure the correct clone identity.

TRANSFECTION OF CRE

SUPPORT PROTOCOL 3

The presence of the Neo transcription unit in a targeted locus can have unwanted effects on gene expression at the targeted locus, as well as at other nearby loci. Cre-lox technology allows the specific removal of the Neo selectable marker after gene targeting. During design of the gene targeting vector, the selectable marker is flanked by a direct repeat of 34-bp loxP sites. The Cre recombinase protein catalyzes recombination between the two loxP sites, resulting in excision of the intervening DNA segment and leaving behind a single loxP site. Cre excision is accomplished by the transient transfection of a circular Cre-expressing plasmid into the targeted ES cell clones. The circular Cre plasmid doesn't

integrate and is soon eliminated from the cells. The authors have found that the frequency of Cre-mediated excision can vary among similarly targeted ES cell clones; therefore, it is advisable to use 2 to 3 separate ES cell clones for Cre excision.

Additional Materials *(also see Basic Protocol)*

Circular Cre plasmid DNA
Targeted ES cells
H_2O, sterile
G418 medium (see recipe)

Electroporator and appropriate electroporation cuvettes with a 4-mm gap
Microscope with 4× objective lens
96-well flat-bottom plate

Additional reagents and equipment for plasmid preparation by cesium chloride equilibrium centrifugation (see Table A.3A.1 of *APPENDIX 3A*), counting cells in a hemocytometer (*APPENDIX 3B*), and Southern blotting (*UNIT 3.6* and *APPENDIX 3*).

Prepare Cre plasmid DNA

1. Prepare circular Cre plasmid DNA by cesium-chloride equilibrium centrifugation and resuspend the DNA in sterile water to a concentration of 1 µg/µl.

   Alternatively, instead of cesium chloride equilibrium centrifugation, the Qiagen method can be used for plasmid purification.

Thaw and expand ES cells

2. Thaw one vial of each targeted ES cell clone to be transfected to the appropriate sized plate and expand to at least 2×10^7 cells per clone (approximately one 10-cm plate at 80% confluence).

3. Prepare two 10-cm feeder-cell dishes (see Basic Protocol, steps 1 to 7) for each construct to be electroporated.

Transfect ES cells

4. Trypsinize cells as described (see Basic Protocol, steps 15 to 19), and resuspend the cell pellet in a total of 10 ml of 37°C ES cell medium. Add 20 µl cells to one chamber of a hemacytometer and count the center 25 squares (*APPENDIX 3B*). To obtain the total number of cells, multiply the number of cells by 10,000, then by the total number of milliliters. Centrifuge and adjust the cell concentration to 2×10^7 cells/800 µl with ES cell medium.

5. Mix 800 µl ES cells in a microcentrifuge tube with 25 µg Cre plasmid DNA. Transfer to an electroporation cuvette with a 4-mm gap and incubate 5 min at room temperature. Electroporate cells at settings of 250 V and 500 µF.

   These settings are for a Bio-Rad electroporator and may need to be optimized for different machines.

6. Resuspend each transfection reaction in 5 ml ES cell medium total. Plate the ES cells at concentrations of 1% and 0.1% (i.e., 50 and 5 µl, respectively) on the individual 10-cm feeder-cell plates prepared in step 3. Transfer to an incubator.

7. Feed plates daily for ~5 to 6 days with ES cell medium.

   Colonies should be visible at 3 to 4 days and picked after 5 to 6 days.

Pick colonies

8. The day before picking colonies, prepare sufficient 96-well feeder-cell plates (see Basic Protocol, steps 1 to 7) for the number of clones to be picked.

   An initial analysis of 200 clones per initial clone transfected is a good number.

   The number of Cre-transfected colonies that will need to be picked is largely dependent upon the transfection efficiency of the ES cells. The authors find that their efficiency of Cre-mediated recombination is between 3% and 5%; therefore, picking 100 to 200 colonies will usually give several recombinant clones.

9. Replace the pMEF medium of each well of a 96-well feeder-cell plate with 100 µl ES cell medium. Prepare a 96-well U-bottom plate by adding 75 µl trypsin/EDTA to each well.

10. Transfer one 10-cm dish of ES colonies to a microscope with a 4× objective lens and use a 200-µl micropipettor set at 25 µl to pick individual colonies.

11. Transfer each clone to one of the wells of the 96-well U-bottom plate containing trypsin/EDTA.

    The wells can be checked with the microscope to verify that the clone was transferred.

    ES cells are remarkably resistant to trypsin and can be left to disaggregate for up to 1 hr without harming the cells.

12. When finished picking colonies, add 75 µl ES cell medium to each well and pipet each clone up and down several times with a 200-µl micropipettor and appropriate tip.

13. Add disaggregated ES cells to the new feeder-cell plate at a density of one clone per well. Transfer to an incubator.

Expand and select for drug resistant colonies

14. Feed picked clones daily with ES cell medium.

    Cells should begin to be visible in the wells after 3 to 4 days.

15. Prepare two new 96-well feeder-cell plates for each plate of colonies.

    Once confluent, the transfected clones are split 1:3. One plate is used to determine sensitivity to G418, one for DNA extraction, and one plate is frozen for later retrieval.

16. On the day to split, add 0.1% (w/v) gelatin to cover the bottom of one 96-well flat-bottom plate for each plate of clones. Allow to incubate at room temperature while preparing to trypsinize.

17. Replace the pMEF medium in the wells of one of the new 96-well feeder-cell plates with 100 µl regular ES cell medium. Repeat the procedure with a second plate, except using G418 instead of ES cell medium.

18. Rinse the clone wells with 75 µl trypsin/EDTA and aspirate. Replace with 75 µl trypsin/EDTA and incubate 10 min.

19. During this incubation, aspirate the gelatin in the 96-well flat-bottom plate and add 100 µl ES cell medium to each well.

20. Add 75 µl ES cell medium to each well of the 96-well flat-bottom plates and pipet the cells several times using a multichannel pipettor with 200-µl tips. Transfer $\frac{1}{3}$ each clone suspension to the corresponding well of each of the new feeder cell and gelatin plates.

21. Transfer to an incubator. Feed cells daily with ES cell or G418 medium as appropriate.
22. Freeze the ES medium plates when most of the clones are ~80% confluent (see Support Protocol 2, steps 23 to 25)

    It will probably be a few days before G418 selection of the other plate is complete.
23. When there is a clear distinction between surviving and non-surviving clones on the plate under drug selection, score each clone for survival or death in G418. Those clones that died in G418 may have undergone Cre excision. Prepare DNA from only these clones and analyze by Southern blotting (*APPENDIX 3*) for evidence of Cre-mediated recombination.
24. Thaw those clones from the frozen plate (see Support Protocol 2) that have undergone appropriate Cre excision.

SUPPORT PROTOCOL 4

PREPARATION OF CELLS FOR MICROINJECTION

Cells for microinjection should be thawed ~5 days before the date of injection. In the author's laboratory, the protocol is to inject on a Thursday and Friday, thaw cells on Saturday, and split Tuesday for Thursday injection and Wednesday for Friday injection. This allows cells to be harvested for injection on day 2 after a split, at ~50% confluence. This protocol can be adapted to different injection schedules.

Materials

ES cell cultures (see Support Protocol 2)

1. Feed ~70% to 80% confluent ES cells 1 hr before trypsinization with ES cell medium.
2. Trypsinize and centrifuge cells as described (see Basic Protocol, steps 15 to 19). Resuspend in 10 ml ES cell medium.
3. To obtain the total number of cells, count the center 25 squares in a hemacytometer, multiply by 10,000, then by the total number of milliliters.
4. Centrifuge 2 min at ~400 × *g*, room temperature and adjust the cell concentration to 2×10^6 cells/ml with ES cell medium.
5. Plate the ES cells in a nongelatinized tissue culture plate. Incubate 15 min.

   The feeder cells will attach quickly to the plate and an enriched population of ES cells can be obtained.
6. Swirl the plate gently and pipet the enriched ES cells from the plate.

   The cells are now ready for injection into blastocysts.

REAGENTS AND SOLUTIONS

Use Milli-Q-purified water in all recipes and protocol steps. For common stock solutions, see ***APPENDIX 2A****; for suppliers, see* ***SUPPLIERS APPENDIX****.*

ES cell medium

To 500 ml high glucose DMEM, -glutamine, -pyruvate, add 75 ml heat-inactivated ES cell–qualified FBS, 5 ml of 100× L-glutamine (Invitrogen), 5 ml of 100× penicillin/streptomycin (Invitrogen), 5 ml of 2-mercaptoethanol solution (see recipe), and 50 µl LIF (Chemicon ESGrow). Store up to 2 months at 4°C. Replenish L-glutamine every 2 weeks.

NOTE: *Many companies now sell ES cell–qualified FBS; however, it is still desirable to test the serum on the ES cells used in the laboratory for its ability to inhibit differentiation of the cells.*

Freezing medium

Add additional heat-inactivated ES cell–qualified FBS to either pMEF or ES cell medium (see recipes) to a total of 20% (v/v) and DMSO to a total of 10% (v/v). Store up to 2 months at 4°C.

See note above concerning FBS.

Ganciclovir, 1000×

Make a 1 mM solution of ganciclovir in sterile water. Use a 10-ml syringe with a 0.2-µm filter to sterilize the drug and aliquot into 1-ml tubes. Store up to 1 year at 4°C.

G418/ganciclovir medium

Add 200 mg/ml geneticin (G418; see recipe) and 1 mM ganciclovir (see recipe) to ES cell medium (see recipe) at a 1:1000 dilution each. Store up to 2 months at 4°C.

G418 (geneticin), 1000×

Make a 200 mg/ml solution of active G418 (Invitrogen) in sterile water. Use a 10-ml syringe with a 0.2-µm filter to sterilize the drug and aliquot into 1-ml tubes. Store up to 1 year at 4°C.

The percentage of active drug varies with each lot and is indicated on the individual bottle.

G418 medium

Add 200 mg/ml G418 (see recipe) to ES cell medium (see recipe), at a 1:1000 dilution. Store up to 2 months at 4°C.

2-Mercaptoethanol solution

Add 7 µl of 2-mercaptoethanol to 10 ml complete DMEM (*APPENDIX 3B*). Store at 4°C and use within 2 weeks.

Mitomycin C medium

Dissolve a 2 mg vial mitomycin C (Sigma) in 2 ml PBS (*APPENDIX 2A*). Filter through a 0.2-µm syringe filter. Add the mitomycin C to pMEF medium at a 1:100 dilution. Store up to 2 weeks at 4°C or 2 months at −20°C.

pMEF medium

To 500 ml high-glucose DMEM, add 50 ml heat-inactivated FBS, 5 ml of 200 mM L-glutamine, and 5 ml of 100× penicillin/streptomycin (i.e., 10,000 U/ml penicillin and 10,000 µg/ml streptomycin). Store up to 2 months at 4°C, replenish L-glutamine every 2 weeks.

COMMENTARY

Background Information

Embryonic stem (ES) cells are derived from the inner cell mass of a mouse blastocyst at embryonic day 3.5 (e3.5). These cells are pluripotent with respect to developmental fate, an essential property for their use in gene targeting. ES cells were first isolated in 1981 and soon after shown to be capable of colonizing the germline when returned to a mouse embryo (Evans and Kaufman, 1981; Bradley et al., 1984). The ability to manipulate ES cells in culture has revolutionized the field of mouse molecular genetics and provided information on the function of many genes. Numerous groups have generated ES cell lines, with the most popular being the AB1, CCE, CJ7, D3, E14, J1, and R1 cell lines. Virtually all commonly used ES cell lines are obtained from strain 129 mice, since this strain has been shown to allow superior germline competence.

An important factor to consider when initiating a gene targeting project is the use of isogenic DNA—i.e., the DNA used to construct the gene targeting vector should be derived from a 129 mouse substrain identical or very closely related to the ES cells to be used, as recent work has shown the various 129 substrains to be genetically variable and highly

contaminated with other strain backgrounds (Simpson et al., 1997; Threadgill et al., 1997). Careful DNA-ES cell matching using a genealogy chart such as that shown in Simpson et al. (1997) will help ensure the use of properly isogenic DNA.

Proper culture of embryonic stem cells is perhaps the most critical step in any gene targeting procedure. The cells must be maintained under defined culture and cell density conditions to prevent their differentiation. Even slight differentiation can result in cells that will not contribute to the germline upon introduction into host embryos. Strict adherence to the protocols outlined here will help ensure the pluripotency of the ES cells and the success of the gene targeting project.

Critical Parameters and Troubleshooting

The most critical aspect of these protocols is to maintain the integrity of the ES cells. This includes the use of sterile technique to avoid contamination of the cells as well as following the procedures described to minimize ES cell differentiation. While strict cell culture protocols will help to maintain ES cells in the desired state, some cells may still begin to differentiate. An important skill is to learn to recognize early signs of differentiation and know how to handle them. Healthy and undifferentiated ES cells may display two characteristic morphologies depending on the particular ES cell line used. They may grow as broad and slightly raised colonies atop their feeder layers, or as more rounded up balls of cells. Either cell morphology should show highly refractile colony edges. Photos of undifferentiated ES cells can be found in the two protocol manuals listed at the end of this unit (Hogan et al., 1994; Robertson, 1997). In contrast to these pluripotent cells, cells that are beginning to differentiate will display one of two altered appearances. They may appear as tight balls of cells with darkening centers and edges that appear to be membrane-limited. Alternatively the cells may assume a flattened ring-like "donut" shape with nearly empty centers. These "donuts" will often show highly differentiated cell types at the periphery.

Differentiation will occasionally be seen during passage and expansion of ES cells. This often results from inadequate trypsinization during passage and/or the failure to obtain a single cell suspension following trypsinization. If the cells should begin to differentiate, they should be trypsinized immediately to prevent further differentiation. If the areas of differentiation are small, these cells can be removed prior to trypsinization by vacuum aspiration using a pipet with a 200-µl (i.e., yellow) tip. Passage of the remaining cells may then be able to halt any further differentiation. Most commonly, however, differentiation will be seen during drug selection when the cells are maintained without passage for many days. In the event this does occur, it is unlikely that all ES cell colonies will differentiate at the same time. The remaining undifferentiated colonies should be picked immediately and have a good chance of retaining germline competence.

Anticipated Results

This 96-well plate protocol for the handling and analysis of ES cell clones is a rapid way to manipulate large numbers of individual clones. This type of high-throughput system, however, invariably results in the loss of some clones at various steps of the protocol. Whole plates must be processed (e.g., trypsinized, frozen) when the majority of clones on the plate are ready; therefore, slower growing clones will be lost. The authors frequently lose ~10% of the original ES cell clones by the time the final plates are frozen. This reduces the numbers of clones screened only slightly and can be considered an acceptable loss. The authors have not seen any evidence to indicate that targeted clones may be slower growing and therefore selectively lost.

Time Considerations

Gene targeting is a time-consuming activity. Most often cloning of the targeting construct is the rate-limiting step in these experiments. Once the construct is prepared and ES cell work begins, the time for a single round of transfection, selection, and analysis is ~5 to 6 weeks. This time includes periods of drug selection requiring only daily medium changes, as well as periods of picking and passaging clones that will require several hands-on hours a day. Subsequent Cre-mediated excision and the time required for thawing and expansion of correctly targeted clones will result in a total time commitment of ~3 to 4 months.

Genotyping Embryonic Stem (ES) Cells

The techniques described in *UNIT 15.1* describe the process of using homologous recombination in embryonic stem (ES) cells to introduce a desired mutation into a gene. The frequency of homologous recombination is quite low, and selection protocols are used to enrich for this event. Even utilizing selection, however, only a fraction of the surviving cells will contain the correct recombination event. Therefore, a screening strategy is needed to identify those cells which are properly targeted. ES cell clones may be analyzed for gene targeting events using Southern blotting (see Basic Protocol) or PCR (see Alternate Protocol) to detect products unique to the recombined locus. A protocol for isolating DNA from ES cell clones is also described (see Support Protocol).

ANALYSIS OF ES CELL CLONES BY SOUTHERN BLOT HYBRIDIZATION

BASIC PROTOCOL

Genotyping by Southern blotting requires the addition or removal of a restriction enzyme site during generation of the targeting vector. A detection strategy for homologous recombinants must use a probe located outside the targeting vector so that it will analyze the locus for a polymorphism consistent with the correct targeting event rather than random integration of the vector.

Materials

Restriction enzyme cocktail (see recipe)
96-well plate containing ES cell clone genomic DNA (see Support Protocol)
10× loading dye (see recipe)
0.8% (w/v) agarose gel in TAE (see recipe)
0.25 M HCl (optional)
Denaturing solution (see recipe)
Renaturing solution (see recipe)
10× and 5× SSC (see recipe for 20×)
0.4 M NaOH
Hybridization solution (see recipe)
Radiolabeled and denatured probe
2×, 1×, and 0.1× and SSPE (see recipe for 20×)/0.1% SDS

Humidified chamber (e.g., plastic container lined with wet paper towels)
Camera
Ruler, fluorescent
UV transilluminator
Whatman paper
Hybond N+ nylon membrane (Amersham)
Blotting bridge
Blotting paper
Gel plate or other solid top
Weight (~500 g)
65°C hybridization oven and appropriate hybridization bottle
X-ray film

Run the Southern gel

1. Add 40 µl restriction enzyme cocktail (20 to 40 units per sample) directly to each well of the 96-well plate containing ES cell clone genomic DNA (Support Protocol) and resuspend by pipetting. Incubate in humidified chamber overnight in a 37°C incubator or warm room.

Contributed by Jennifer V. Schmidt
Current Protocols in Toxicology (2001) 15.2.1-15.2.10

The design of the vector and the restriction pattern of the locus dictate the choice of restriction enzyme. It is best to use a single enzyme because double digests of genomic DNA can be problematic under the best of circumstances.

2. Mix reaction mixture with 6 µl of 10× loading dye. Load onto a 0.8% agarose gel in TAE.

   The author usually uses 20 × 25–cm gels with two 36-well combs (Amersham-Pharmacia Biotech) that allow a total of 70 samples to be run per gel.

   For more information concerning pouring and running of agarose gels, see Table A.3A.1 of APPENDIX 3A.

3. Electrophorese as necessary for separation of the expected wild-type and targeted bands and photograph with a fluorescent ruler on a UV transilluminator.

4. (*Optional*) If any of the expected bands are >10 kb, "nick" the DNA by soaking the gel in 0.25 M HCl for 15 min to ensure efficient transfer to the membrane.

   If the band sizes are all <10 kb this step can be omitted.

   HCl depurinates the DNA and the apurinic sites are cleaved by incubation in denaturation solution (see Ramirez-Solis et al., 1992).

5. Incubate the gel in denaturing solution for 15 min. Incubate in renaturing solution 15 min. Rinse with water, then repeat the incubation in renaturing solution.

Transfer DNA to membrane

6. Cut two pieces of Whatman paper and one piece of Hybond N+ nylon membrane to the size of the gel. Place these in a dish of distilled water to wet. Cut a piece of Whatman paper to the same size as the blotting bridge, but slightly longer on the ends, to use for a wick.

   The protocol described here is for upward transfer at neutral pH; however, the DNA can be transferred using either upward or downward and either neutral or alkaline pH transfer (Fig. A.3E.1).

7. Fill a large dish with 400 to 500 ml 10× SSC. Wet the wick in 10× SSC, position the bridge in the SSC, and place the wick on top of the bridge so the ends of the wick are in the solution.

8. Position the gel face down (i.e., well openings down) in the center of the wick and use a gloved finger or a pipet to remove all air bubbles from under the gel.

9. Lay the membrane on top of the gel and the two Whatman papers on top of the membrane. Be careful not to trap any air bubbles between these layers; roll a pipet over the surface to remove any air.

10. Cover the gel sandwich (i.e., wick/gel/membrane) with a thick layer of blotting papers and a solid top such as a gel plate. Place a small (~500 g) weight on top of the gel plate. Transfer ≥8 hr (preferably overnight) at room temperature.

Hybridize membrane

11. When the transfer is complete, disassemble the apparatus, take the sandwich apart, and mark the positions of the wells on the back of the membrane with a pencil or marker.

12. Lay the membrane face up on a piece of Whatman paper saturated with 0.4 N NaOH for 30 min to fix the DNA to the membrane.

13. Neutralize the membrane by rinsing in 5× SSC.

14. Drain the membrane briefly and transfer to a hybridization bottle containing 20 ml hybridization solution. Prehybridize the membrane 6 hr to overnight in a 65°C hybridization oven.

15. Add radiolabeled and denatured probe to 20 ml fresh hybridization solution at a final concentration of 10^6 cpm/ml. Add this solution to the hybridization bottle and hybridize overnight in a 65°C hybridization oven.

    The choice of probe depends on the DNA sequence available surrounding the targeted region. The probe fragment must be located outside the region of homology and usually should be between 500 bp and 1 kb in size. The probe should be tested with wild-type mouse genomic DNA to ensure it contains no repetitive sequences and detects a band of the expected size. The method of probe labeling is a matter of personal choice; however, most investigators use random-primed labeling (APPENDIX 3).

16. Wash the membrane twice in 20 ml of 2× SSPE/0.1% SDS, then once each in 20 ml 1× SSPE/0.1% SDS and enough 0.1× SSPE/0.1% SDS to cover the membrane. Blot briefly on Whatman paper and wrap in plastic wrap.

    In the author's laboratory, the first three washes are usually performed in the hybridization bottle and the fourth (~200 ml) in a plastic container.

Analyze on X-ray film

17. In the dark, place the wrapped membrane in an X-ray cassette with an appropriate sized piece of X-ray film and an intensifying screen. Expose until bands are visible.

    Exposure times of 48 hr with one intensifying screen are usually sufficient.

18. Analyze film for the presence of the expected targeted band in a subset of clones.

    All clones will show at least one band on the Southern blot; this band is derived from the wild-type allele. The locus will be the same in the feeder cells as in the ES cells, and the contribution from the feeder cells will not be distinguishable from that of the wild-type ES cells. A targeted clone will show two bands, the wild-type band and the targeted band, because it has been targeted at only one of the two alleles (see Fig. 15.2.1).

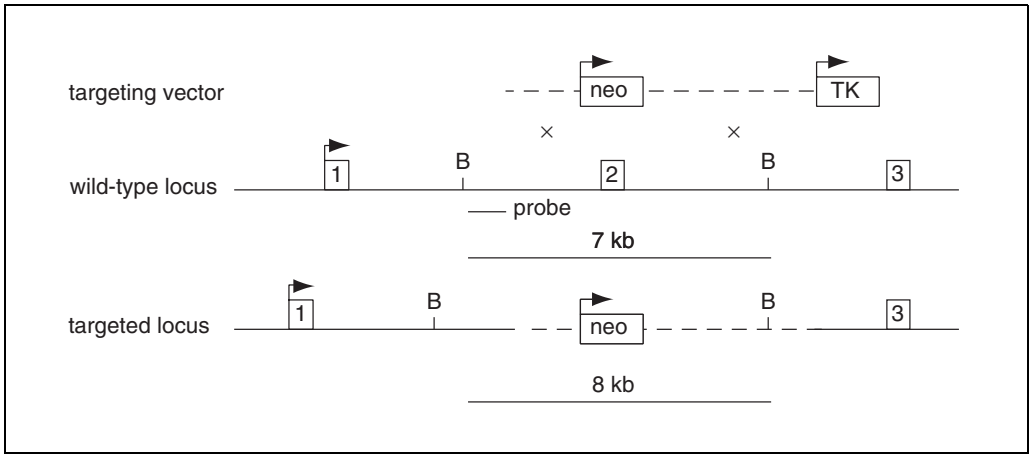

Figure 15.2.1 Southern blot detection of a homologous recombination event. The first three exons of a putative gene are shown; the targeting event replaces exon 2 with the neomycin-resistance gene. The two regions of homology (arms) of the targeting vector are depicted as dashed lines; the upstream is the shorter arm and the downstream the longer arm. The TK gene for negative selection is lost during homologous recombination. The particular gene contains a 7-kb *Bam*HI fragment in the wild-type allele that is detected by Southern blot with the indicated probe. Replacement of exon 2 with the neomycin gene results in an increase in the fragment to 8 kb in the targeted allele. Note that the probe fragment has no overlap with the targeting vector and will not detect heterologous integration events.

ALTERNATE PROTOCOL

ANALYSIS OF ES CELL CLONES BY PCR

While most people prefer to screen ES cell clones by Southern blot hybridization, a PCR assay can be designed to amplify a band specific to the correctly targeted locus. While a PCR strategy uses less DNA than Southern blotting it has a higher potential for missing positive clones. Choice of the correct primer pair is crucial for efficient PCR detection of targeted ES cell clones. The primer set must be chosen to amplify a unique product only in correctly targeted clones. This can be accomplished by using one primer located in sequences unique to the targeted locus, such as the *neo* gene, and another primer located in the locus outside of the targeted region. Detection of recombinants by PCR must be taken into account when designing the targeting construct. A construct designed for PCR analysis must be generated with one long arm and one short arm flanking the region of homology. The long arm should have enough homology for recombination, and the short arm should allow reliable PCR between the selectable marker and the DNA region outside the construct. The reproducible amplification of a PCR product limits the size of the short arm of the targeting construct to ~2 kb.

The inclusion of proper controls are essential to ensure the reliability of the PCR analysis. Use of a positive control ensures that the DNA is of sufficient quality to detect the targeted band if present and that all proper reagents were added to the PCR reaction. The ideal positive control will amplify a fragment of genomic DNA flanking the region to be targeted and will be approximately the same size. The control reaction should be run on all samples. A negative control should also be included, which is ordinarily a blank reaction to which H_2O is added in the place of DNA.

PCR conditions described here are those commonly used in the author's laboratory. Other conditions will work and may be substituted after appropriate verification. Annealing temperature will have to be optimized for each primer set (see *APPENDIX 3C*).

Materials

96-well plate containing ES cell clone genomic DNA (see Support Protocol)
TE buffer, pH 8.0 (*APPENDIX 3C*)
10× PCR buffer (supplied with the *Taq* DNA polymerase)
10 mM dNTPs (2.5 mM each dNTP)
Red juice (see recipe)
25 pmol/µl forward and reverse primers
5 U/µl *Taq* DNA polymerase (Perkin-Elmer)
0.8% (w/v) agarose or 7.5% (w/v) acrylamide gel (see recipes)

0.5-ml PCR tubes
Thermal cycler

1. Add 50 µl water or TE buffer, pH 8.0, to each well of a 96-well plate containing ES cell clone genomic DNA and resuspend the DNA by pipetting.
2. Make a sufficient volume of master mix for the number of samples plus one (i.e., to allow for pipetting loss) using the following recipe for one reaction as a guide. Keep master mix on ice while setting up the reaction to inhibit nonspecific priming (45 µl per reaction).

   5 µl 10× PCR buffer
   4 µl 10 mM dNTPs
   10 µl red juice
   1 µl each 25 pmol/µl forward and reverse primers
   0.25 µl 5 U/µl *Taq* DNA polymerase
   23.75 µl H_2O

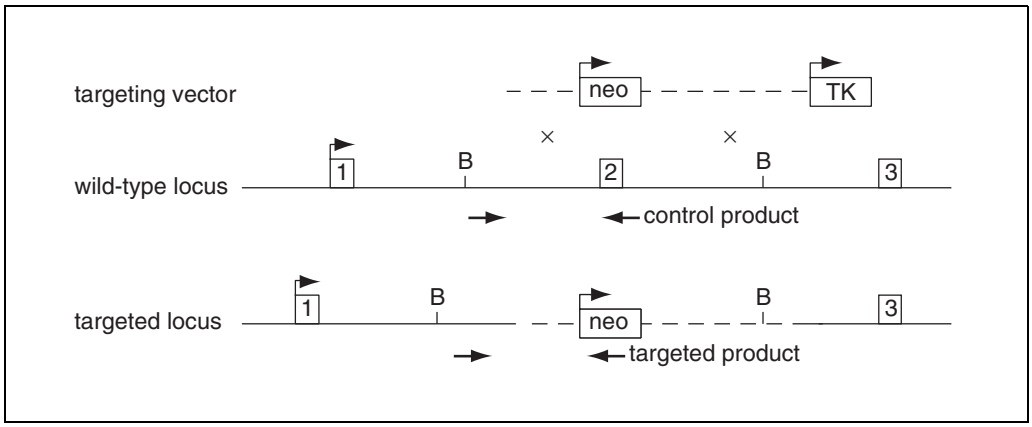

Figure 15.2.2 PCR detection of a homologous recombination event. The PCR strategy uses a primer within the selectable marker and amplification across one arm of the targeting vector to generate a unique product specific to the targeted allele. The control reaction detects a fragment found only in the wild-type allele, which should be present in all ES cell clones. Note that the length of the shorter arm of the targeting construct dictates the size of the PCR fragment that must be generated.

3. For each reaction, aliquot 45 µl master mix into 0.5-ml PCR tubes and add 5 µl ES cell genomic DNA. Keep on ice.
4. Program the thermal cycler with the appropriate conditions. Begin the cycle and when the block has reached 94°C transfer the PCR tubes directly from ice to the thermal cycler.

Initial step:	5 min	94°C	(denaturation)
35 cycles:	1 min	94°C	(denaturation)
	1 min	55°C	(annealing)
	1 min	72°C	(extension)
Final step:		4°C	(hold)

This program is a guide and may have to be optimized for individual PCR targets (APPENDIX 3C).

5. When cycling is complete, remove tubes and analyze 10 to 15 µl on a 0.8% agarose or 7.5% acrylamide gel for the presence of the targeting-specific band (see Fig. 15.2.2).

An agarose gel can be used for fragments ≥500 bp; however, for smaller fragments an acrylamide gel provides better resolution and sizing.

For more information concerning pouring and running of acrylamide and agarose gels, see Table A.3A.1 of APPENDIX 3A.

PREPARATION OF ES CLONE DNA

SUPPORT PROTOCOL

A variety of protocols have been published for the preparation of DNA in 96-well plates. The salting-out protocol described here generates DNA of sufficient quality for PCR or Southern blot analysis. As this protocol gives sufficient DNA for only one Southern blot analysis, the assay and probe should be tested ahead of time on ES cell genomic DNA.

Materials

Confluent cultures of ES cells in gelatinized 96-well feeder-cell plate (*UNIT 15.1*)
PBS (*APPENDIX 2A*)
Lysis buffer (see recipe)
75 mM NaCl in ethanol (see recipe)

70% ethanol

Multichannel pipettor
Humidified chamber (e.g., a plastic container lined with wet paper towels)
55° to 60°C incubator or hybridization oven
Tabletop centrifuge with microplate adapter

1. Using a multichannel pipettor aspirate medium from confluent ES cells on one gelatinized 96-well plate.

   If following the protocols in UNIT 15.1, there will be duplicate plates of ES cell clones for DNA extraction. Analyzing only one set of plates is recommended initially, as the duplicate plates may be held in the tissue culture incubator for another 2 to 3 days in case they are needed.

2. Working quickly, wash cells gently with PBS twice.
3. Add 50 µl lysis buffer to each well and incubate overnight in a humidified chamber (e.g., a plastic container lined with wet paper towels) in a 55° to 60°C oven.
4. Centrifuge 1 min at 2000 × *g*, room temperature, to collect condensation.
5. Add 100 µl of 75 mM NaCl in ethanol to each well and incubate 30 min at room temperature.

   DNA should be visible as strands of fibers at the edges of wells when viewed with a low-power microscope.

6. Centrifuge in a tabletop centrifuge with microplate adapter 5 min at 2000 × *g*, room temperature.
7. Invert the plate and blot gently on a paper towel to remove the ethanol solution.
8. Gently add 100 µl of 70% ethanol to each well. Centrifuge and invert the plate as described above. Repeat this rinse twice more. After the last wash air dry the plate for 15 min or until all remaining ethanol has evaporated.

   The DNA can remain dry for no longer than 30 min. Residual ethanol with impair loading onto the agarose gel. If necessary, open incubate plate at 37°C until all ethanol is gone.

   If genotyping by Southern blot hybridization, the DNA will be directly resuspended in the restriction enzyme cocktail by pipetting (see Basic Protocol). If genotyping by PCR, the DNA will be resuspended in water or TE buffer (see Alternate Protocol).

REAGENTS AND SOLUTIONS

*Use Milli-Q-purified water or equivalent in all recipes and protocol steps. For common stock solutions, see **APPENDIX 2A**; for suppliers, see **SUPPLIERS APPENDIX**.*

Acrylamide gel, 7.5% (w/v)

Add 6.25 ml of 30% acrylamide:bisacrylamide (i.e., 37.5:1) to 1.25 ml of 20× TBE (see recipe) and add 250 µl of 10% (w/v) ammonium persulfate. Bring to 25 ml with water and mix well. Prepare glass plates, spacers, and comb. Add 20 µl TEMED, mix well and pour gel between the glass plates quickly. Let gel polymerize for 30 min. Run in 1× TBE.

The gel can be wrapped in plastic wrap and stored overnight at 4°C if necessary.

CAUTION: *Acrylamide is toxic.*

Agarose gel, 0.8% (w/v)

Add 0.8 g agarose to 100 ml of 1× TAE or TBE (see recipes) in a beaker with a stir bar. Stir to suspend agarose. Microwave until all agarose particles are dissolved. Add 2 µl of 10 mg/ml ethidium bromide (*UNIT 2.2*). Transfer to a stir plate until cooled to ~55°C, then pour into casting tray. Allow gel to harden 30 min. Run in 1× TAE or TBE buffer.

CAUTION: *Ethidium bromide is a mutagen and must be handled carefully.*

For agarose gel analysis of PCR products the author's laboratory typically uses TBE buffer; however, for Southern blot analysis better band resolution is obtained with the use of TAE buffer.

The gel can be wrapped in plastic wrap and stored overnight if necessary.

Denaturing solution

Dissolve 88 g NaCl in 800 ml water. Add 50 ml of 10 M NaOH and bring volume to 1 liter. Store up to 1 year at room temperature.

Hybridization solution

62.6 ml 20× SSPE (see recipe)
12.5 ml 100× Denhardt's solution (*UNIT 2.7*)
12.5 ml 10% SDS (*APPENDIX 2A*)
162.5 ml H_2O
Heat to 65°C to dissolve ingredients
Filter through 0.2-µm filter
Add 500 µl 10 mg/ml salmon testis sperm DNA
Store up to 3 months at room temperature
Warm to 65°C before each use.

The salmon sperm DNA should be heated at 65°C before addition to the solution.

Loading dye, 10×

6.25 g Ficoll 400
60 mg bromphenol blue
60 mg xylene cyanol
H_2O to 25 ml
Incubate at 65°C with occasional shaking to dissolve ingredients
Store indefinitely at room temperature.

Lysis buffer

60 µl 1 M Tris·Cl, pH 7.5 (*APPENDIX 2A*)
120 µl 0.5 M EDTA (*APPENDIX 2A*)
12 µl 5 M NaCl (*APPENDIX 2A*)
300 µl 10% (w/v) Sarkosyl
600 µl 10 mg/ml proteinase K
4.9 ml H_2O
Prepare fresh.

This recipe makes 6 ml lysis buffer, sufficient for one 96-well plate.

NaCl in ethanol, 75 mM

For each 96-well plate add 150 µl of 5 M NaCl (*APPENDIX 2A*) to 10 ml ethanol, 4°C. The salt will precipitate out; therefore, mix before using. Prepare fresh.

Red juice

Dissolve 30 g sucrose in 50 ml water, 65°C. Add 20 mg cresol red and bring volume to 50 ml with water. Aliquot into 1.5-ml tubes and store up to 1 year at −20°C.

Renaturing solution

800 ml H_2O
88 g NaCl
79 g Tris base
2 ml 0.5 M EDTA, pH 8.0 (*APPENDIX 2A*)
Adjust pH to 7.2 with concentrated HCl
H_2O to 1 liter
Store up to 1 year at room temperature.

Restriction enzyme cocktail

400 µl 10× restriction enzyme buffer
40 µl 10 mg/ml BSA
4 µl 1 M spermidine
265 µl 20 U/µl restriction enzyme
3.3 ml H_2O
Prepare fresh.

This recipe makes 4 ml restriction enzyme cocktail, sufficient for one 96-well plate.

For less concentrated enzymes, use a larger volume of enzyme and adjust the water accordingly.

SSC, 20×

800 ml H_2O
175.3 g NaCl
88 g sodium citrate
Adjust pH to 7.0 with 1 M HCl
H_2O to 1 liter
Store up to 1 year at room temperature.

SSPE, 20×

800 ml H_2O
175.3 g NaCl
27.6 g NaH_2PO_4
40 ml 0.5 M EDTA (*APPENDIX 2A*)
Adjust pH to 7.4 with 10 M NaOH (*APPENDIX 2A*)
H_2O to 1 liter
Store up to 1 year at room temperature.

TAE, 50×

800 ml H_2O
242 g Tris base
57 ml glacial acetic acid
100 ml 0.5 M EDTA, pH 8.0 (*APPENDIX 2A*)
H_2O to 1 liter
Store up to 1 year at room temperature.

TBE, 20×

800 ml H_2O
216 g Tris base
110 g boric acid
80 ml 0.5 M EDTA, pH 8.0 (*APPENDIX 2A*)
H_2O to 1 liter
Autoclave or filter through Whatman no. 1 filter paper
Store up to 1 year at room temperature.

Autoclaving or filtering prevents precipitation of the buffer.

COMMENTARY

Background Information

The 96-well microplate DNA extraction protocol described in this unit is a continuation of the methodology presented in *UNIT 15.1*. This method has been used successfully by our laboratory and others to analyze ES cell clones (Ramirez-Solis et al., 1992). Numerous variations on this protocol have been described and may be substituted (e.g., Udy and Evans, 1994); however, it is recommended that any new protocol be tested on a small number of clones before beginning a large experiment.

Critical Parameters and Troubleshooting

Several common errors have been observed when performing this DNA extraction and analysis protocol for the first time. It is essential to centrifuge the 96-well plates after the precipitation and 70% ethanol washes or the DNA will be lost (see Support Protocol). It is also important to ensure that the DNA has completely dried before resuspending in restriction enzyme cocktail (see Basic Protocol). Residual ethanol will result in the DNA samples floating out of the wells of the agarose gel during loading. Should this happen, the remaining DNAs may often be salvaged by drying the open plates in a warm room for 30 min to evaporate the ethanol or by adding 2 to 3 times excess loading dye. If the DNAs are lost in preparation, the duplicate ES cell plate may be prepared and analyzed.

Errors during analysis of the ES cell clones are those inherent in any Southern blotting or PCR assay. Most commonly seen during Southern blot hybridization is incomplete digestion of the ES cell genomic DNA. This will manifest as high background and partial digestion bands on the Southern films and can be avoided by a pilot experiment before beginning targeting. Extraction and Southern blotting of wild-type ES cell DNA using the desired protocol and restriction enzyme will help determine the digestion conditions required for full cutting. Additionally, Ramirez-Solis et al. (1992) have tested numerous restriction enzymes for their digestion efficiency on ES cell genomic DNA extracted by the method presented here.

The most important concern in a PCR strategy is the possibility of false negative results. Because the absence of a targeted allele–specific band is interpreted as a nonrecombinant clone, the failure of this reaction for any technical reason has the potential for missing positive clones. Unfortunately there is no good way to avoid the possibility of this happening, and many laboratories, the author's included, feel the danger is high enough that all screening is done by Southern blotting. Should a PCR detection strategy be necessary or desirable, however, the possibility of false negatives can best be avoided by running the control reaction on all clones at the same time that the targeting-specific reaction is run. While this cannot completely ensure that false negatives will not occur, it will control for many variables such as DNA quality, proper reagent aliquotting, enzyme activity, and thermal cycler performance.

Anticipated Results

Gene targeting frequencies can vary greatly; in the author's laboratory frequencies ranging from 1 in every 2 to 1 in every 800 drug-selected colonies have been observed. These frequencies are dependent upon many factors, including the use of isogenic DNA (Te Reile et al., 1992), the length of homology contained within the targeting construct (Deng and Capecchi, 1992), and the accessibility of a particular locus to recombination. Initial analysis of 400 selected ES cell colonies is recommended for the protocols outlined in *UNIT 15.1*. At average targeting frequencies this is usually sufficient to obtain targeted clones. If analysis of 400 clones reveals no targeting, several diagnostic steps should be taken. First, the targeting construct should be carefully reanalyzed to assure that it is correctly constructed. One common cloning mistake is the inversion of one arm of the construct. Additionally, the diagnostic digest should be verified as accurate, perhaps by additional mapping of the locus. If the targeting construct and diagnostic digest appear correct, it is usually worthwhile to screen another 400 to 600 clones. If no positive clones are obtained after 1000 clones are screened, it may be helpful to design a slightly different targeting construct. The addition of more sequence to the flanking arms can often increase targeting frequency. If the size of the targeting vector cannot be further increased, it may be useful to flip the long and short arms of the construct, thereby including different DNA sequences even if the total amount of homology is unchanged.

Time Considerations

Extraction and analysis of the ES cell clone DNAs will take ~1 week, depending on the

autoradiographic exposure time needed. It is advantageous to prepare and analyze the ES clone DNAs as quickly as possible. The frozen ES cell clones are stable at −80°C for only a short time and should be retrieved within 2 to 3 weeks for most efficient thawing.

Aggregation Chimeras (ES Cell–Embryo)

Embryo stem (ES) cells are used for introducing genetic changes into mice when the genetic change occurs at a low frequency, such as in gene targeting experiments. The genetic change is introduced into a population of ES cells, which are then screened for the correct genetic modification. Once ES cell clones with the desired change are identified, they are used to generate chimeric mice that contain a mixture of ES and wild-type cells. The chimeric mice are then bred to wild-type mice. If the germ cells (i.e., sperm or oocytes) of the chimera are derived from the ES cells, then the offspring of the chimeric mouse will be heterzygous for the transgene, and the line is said to have "gone germline."

Chimeric mice can be made either by injecting the ES cells into blastocyst-stage embryos (Stewart, 1993) or by aggregating the ES cells to 8-cell stage embryos (Wood et al., 1993). In each case, the embryo hosts are collected from superovulated female "donor" mice, and the chimeric embryos are transferred back into pseudopregnant recipient females to develop to term; however, the aggregation method requires less technical training and expensive equipment than blastocyst injection.

The following protocols are based on techniques developed in Dr. A. Nagy's laboratory (Wood et al., 1993). They describe how to flush 8-cell stage embryos from female donor mice, remove the zona pellucida to prepare the embryos for aggregation, and then aggregate them (see Basic Protocol) in a specially prepared plate (see Support Protocol 2). After overnight incubation, the ES cell/embryo aggregates are transferred into a recipient female. A protocol describing some of the mouse husbandry required during the course of the experiment is also provided (see Support Protocol 1).

NOTE: All protocols using live animals must first be reviewed and approved by an Institutional Animal Care and Use Committee (IACUC) and must follow governmental procedures for the care and use of laboratory animals.

PREPARING ES CELL–EMBRYO AGGREGATION CHIMERAS

BASIC PROTOCOL

Outbred albino (e.g., CD-1) females are superovulated (see Support Protocol 1) and mated. Two days later—i.e., 2.5 days post coitus (dpc)—these donor females are sacrificed and embryos (4 to 16 cell stage) are flushed from the oviduct and the upper part of the uterus. Individual embryos are placed into an incubator in KSOM medium until all the embryos are collected. The embryos are then treated for a brief time with acid Tyrode's solution to dissolve the zona pellucida (via the low pH), which must be removed from the embryos to allow the ES cells to adhere. ES cells and embryos are transferred to the individual depressions of an aggregation plate (see Support Protocol 2). The following morning, the majority of aggregates should have formed blastocysts. A maximum of 8 to 10 embryos are then transferred into each uterine horn of a 2.5-dpc 6-week-old CD-1 pseudopregnant recipient. In the event of a recipient shortage, it is possible to culture the aggregates (preferably morulae) for one more day and transfer them into 2.5-dpc pseudopregnant females, or to use 3.5-dpc pseudopregnant females.

ES cells are thawed onto a feeder plate three days before the aggregation and split 1 day before the aggregation as sparse single cells onto gelatinized plates. The split onto gelatinized plates should include 1:10, 1:20, and 1:30 dilutions. When the embryos have been placed in the aggregation plate, or alternatively before the embryos are treated with acid Tyrode's solution, ES cells are briefly trypsinized, which is stopped by adding

Contributed by Corrinne G. Lobe and Caiying Guo
Current Protocols in Toxicology (2001) 15.3.1-15.3.12

medium to the plate. The clumps of cells are then picked from the plate and transferred to depressions in the aggregation plate.

Before removing zona pellucida, the embryos can be stored in KSOM under oil in the incubator while the ES cells are prepared and added to the aggregation plate. It is easier to place the ES cell clumps in the aggregation wells first, followed by the embryos.

Materials

M2 medium (see recipe)
KSOM medium (see recipe)
2.5-dpc superovulated donor mice (e.g., CD-1; see Support Protocol 1)
Acid Tyrode's solution (Sigma)
ES cells (*UNIT 15.1*), trypsinized
Light mineral oil, embryo tested
2.5- or 3.5-dpc pseudopregnant recipient mice (see Support Protocol 1)
1.25% (w/v) avertin (see recipe)
70% (v/v) ethanol in a squeeze bottle

1- and 5-ml syringes with 26-G needles
100 × 15–mm petri dish, sterile
Surgical instruments: 2 straight or curved forceps with serrated tips, small straight or curved scissors, no. 5 forceps (Dumont), forceps with 1 × 2 teeth (i.e., "rat's tooth"), sharp forceps, serrefine clamps (e.g., Fine Scientific Tools), and suture clips and applier (Fine Scientific Tools)
1-ml syringe with flushing needle (see recipe)
Dissecting microscope
Finger pipet (see recipe)
Prepared aggregation plate with depressions (see Support Protocol 2)
Embryo-transfer pipet (see recipe) and appropriate mouth piece
28-G needle
Lamp

NOTE: All solutions and equipment coming into contact with living cells must be sterile and aseptic techniques should be used accordingly.

NOTE: All culture incubations should be performed in a humidified 37° C, 5% CO_2 incubator unless otherwise specified.

Prepare for oviduct removal

1. Draw a small amount of M2 medium into a 5-ml syringe attached to a 26-G needle.
2. Draw a small amount of KSOM medium into a 1-ml syringe attached to a 26-G needle.
3. Place a large drop of M2 medium from the syringe onto one side of a sterile 100 × 15–mm petri dish. Retain the remaining medium in the syringe.

Remove oviducts

4. Sacrifice all or half of the 2.5-dpc superovulated donor mice, depending on how many there are, by cervical dislocation. Using straight or curved forceps with serrated tips, and small straight or curved scissors, make a horizontal incision along the abdomen through the skin, then through the body wall. Push aside the intestines and locate the uterine horn on one side.

   Typically, 5 to 10 mice should be done at one time.

5. Pull up the uterus with the forceps and tease away the connective tissue with closed scissors. Grasp the uterus just under the oviduct with forceps and cut it first between the oviduct and the ovary, and then ~1 cm under the oviduct so as to include a bit of the uterus.

6. Place the oviduct into the large drop of M2 medium (step 3). Repeat steps 5 and 6 for each oviduct (two per animal) of each mouse, placing all oviducts in the large drop of M2 medium.

7. Use the syringe loaded with M2 medium to place several small drops (i.e., one per oviduct) in the other half of the petri dish. Place each of the oviducts into an individual drop of M2 medium.

Flush embryos from oviducts

8. Load M2 medium into the 1-ml syringe with the flushing needle by pulling the liquid up into the barrel of the syringe without the needle on, putting on the needle, flicking up the air bubbles, and pushing them out.

   Do not pull liquid up the flushing needle, only push it out.

9. Put the plate containing the oviducts (step 6) under a dissecting microscope.

10. Select an oviduct. Find the oviduct opening (infundibulum) using the flushing needle and no. 5 forceps to handle the tissue. Locate the end, grab it loosely with the no. 5 forceps in the left hand (assuming a right-handed experimenter), and carefully place the needle into the opening.

    Make sure the flushing needle and the oviduct opening are oriented in the same direction before trying to slip in the needle.

11. Once the needle is in the opening, secure it firmly by gripping more tightly with the forceps. Push some of the M2 medium from the needle into the oviduct.

    If the needle is inserted properly, the oviduct will expand as the M2 is pushed out and the embryos and debris are flushed out. Typically, 0.1 ml M2 is used to flush each oviduct.

12. After flushing, place the oviduct onto the edge of the plate with forceps. Repeat steps 9 to 12 for each oviduct.

Remove zona pellucida

13. Collect the embryos using a finger pipet and wash them through several drops of M2 medium to remove any debris.

    Transfer embryos using the finger pipet for steps 13 to 24. Some experimenters find it easier to handle the embryos using a mouthpiece and tubing connected to an embryo transfer pipet with a wide bore rather than a finger pipet.

14. In a fresh 100 × 15–mm petri dish, place a drop of M2 medium to the left and right side of the dish. Place 2 drops of acid Tyrode's solution in a vertical row in the center of the dish.

15. Transfer the embryos to the drop of M2 on the left. Empty all the M2 medium from the finger pipet, then take up some acid Tyrode's solution from the container. Return to the drop of M2 containing the embryos and displace the acid Tyrode's over the embryos. Pipet up as many embryos as can be easily pipetted up and down (usually ~50 to 60 embryos).

    In this way the embryos are taken up with a minimum amount of M2.

16. Transfer the embryos into the upper drop of acid Tyrode's solution, and then transfer them immediately to the lower drop. While observing under the dissecting microscope, continue to pipet the embryos up and down until the zona pellucida dissolves (~2 min).

    Transferring quickly between the upper and lower drops avoids dilution of the acid Tyrode's solution by M2 medium.

    The zona pellucida appears as an outline surrounding the embryo. When it dissolves, the outline will be invisible and the borders of the embryo cells will be sharper.

    Watch carefully. If the embryos incubate too long in acid Tyrode's solution, they will begin to fall apart.

17. Transfer the embryos into the drop of M2 medium on the right as soon as the dissolution is complete. Repeat steps 16 and 17 with the remaining embryos.

Aggregate embryos and ES cells

18. Place microdrops of KSOM medium onto an aggregation plate, both in and outside of the depressions. Cover the drops with light embryo-tested mineral oil.

19. Wash the embryos at least twice in KSOM drops.

20. Transfer embryos into the aggregation plate by placing them one by one inside each depression.

    It is easiest to pick up ~30 to 60 embryos at a time and put six into each microdrop with depressions, then put an embryo into each depression.

    Alternatively, add all ES cells to the wells, then use acid Tyrode's solution to treat the embryos and add them to the wells with ES cells.

21. Choose clumps of loosely connected, trypsinized ES cells and transfer them into drops of KSOM medium in a petri dish using a finger pipet. From these drops select appropriately sized clumps (8 to 20 cells) and transfer them into the microdrops on the aggregation plate without depressions.

22. Transfer clumps of ES cells into the microdrops containing depressions, using at least six clumps of ES cells per microdrop. Finally, place an ES cell clump into each depression.

23. Assemble all aggregates in this manner, check the plate, and culture overnight.

Prepare for transfer of embryos to recipient females

24. Under the dissecting microscope, use an embryo-transfer pipet to transfer the embryos from the aggregation plate to a drop of M2. Group the embryos according to number per uterus to be implanted.

25. Anesthetize a recipient 2.5- or 3.5-dpc pseudopregnant recipient mouse with 0.2 ml/10 g of 1.25% avertin.

26. Draw a small quantity of M2 medium from the side of the drop with embryos into the embryo-transfer pipet, followed by an air bubble, then more M2 medium. Repeat until there are approximately four air bubbles to allow good control of the pipet.

27. Take up approximately ten embryos. Lay the loaded pipet on the bench, with the pipet on right and the mouthpiece on the left of the microscope (for right-handers).

    For steps 27 to 37 use a fine embryo transfer pipet and mouthpiece to manipulate embryos.

Isolate uterus for transfer

28. Put the anesthetized mouse on the lid of a petri dish. Blow on the hair of its back to part it and apply 70% ethanol from a squeeze bottle to wet the hair down.

29. Make a 1-cm incision through the skin along the dorsal midline, placing the top of the incision at the hump where the ribs end.

30. Use a pair of forceps with 1×2 teeth (i.e., "rat's tooth") to hold the skin and pull the opening to the right side, while using sharp forceps to clear the connective fascia until the fat pad and ovary can be seen.

31. Make an incision through the body wall over the fat pad.

32. Use dull forceps with serrated tips to reach into the incision and grab the fat pad. Pull it out to place the ovary and uterus over the back. Clamp the fat pad close to the ovary with serrefine clamps. Lay the clamp over the back, so the uterus is stretched out over the top of the back. Move the mouse (still on the petri dish lid) to the microscope, positioning it so the clamp holding the uterus is away from the experimenter.

Transfer embryos to uterus

33. Place the mouthpiece connected to the embryo transfer pipet in the mouth. Hold the serrated forceps in one hand and a 28-G needle in the other hand.

34. While holding the fat pad at the clamp with forceps, put the needle into the uterus to make a hole in the top, narrow part of the uterus (i.e., one of the uterine horns), avoiding blood vessels.

35. Leaving the needle in, carefully put down the forceps, and pick up the embryo-transfer pipet. Pull out the needle and put the transfer pipet in the same hole, being careful to insert the transfer pipet into the lumen of the uterus.

    The 28-G needle, still in hand, can be used to pull the uterus taut by pressing against the clamp or to turn the uterus, as required.

36. Once the embryo-transfer pipet is placed well into the uterus, pull it out a little so the tip isn't against the uterine wall, and start blowing out the embryos. Continue to pull the pipet out a little as all the embryos are blown into the uterus, up to the first air bubble. Pull out the transfer pipet and clean any blood off by wiping it on the fat pad.

37. Release the clamp and use the serrated forceps to carefully put the ovary and uterus back into the body cavity, making sure to place it below the body wall. Avoid touching the ovary and uterus.

Repeat transfer with the other uterine horn

38. Pull the outside edge of the body wall over the inside edge. Rotate the plate so the mouse's head is now toward the experimenter.

39. Pull up ten more embryos into the transfer pipet.

40. Repeat the transfer into the other uterine horn.

Close incision and allow animals to recover

41. Pull the edges of the skin together over the midline with the edges up, away from the animal. While holding the edges up together, place one to two woundclips over the incision using an appropriate clip applier.

42. Place the mouse on its stomach in a fresh cage. Wrap a tissue around it and shine a lamp a safe distance away to keep the mouse warm until it recovers. After each operation, lay each successive mouse along the previous one, also for warmth.

SUPPORT PROTOCOL 1

MOUSE HUSBANDRY

Four populations of mice are required for the aggregation experiments: a stock of 4-week-old donor females (e.g., outbred CD1), which should be ordered weekly; stud males, which can be maintained as a stock and should be used only once to twice per week (i.e., cage cards should be marked with the date of each successful and unsuccessful mating, with males presenting <50% plug rate being replaced); vasectomized males, which can be ordered or prepared in house; and a stock of 6-week-old recipient females, which can be maintained and checked for estrus before being mated to vasectomized males. Vasectomized males should be removed from females for 2 weeks after surgery before using to plug recipient females. For weekly experiments, a reasonable mouse transgenic colony would consist of 20 donor females, 80 recipient females, 20 stud males, and 15 vasectomized males. Each stud and each vasectomized male can be mated with 1 to 2 donor and recipient females, respectively, at a time.

To superovulate the females that will serve as embryo donors, inject mice 2 days before mating with 0.1 cc of 20× pregnant mare serum i.p. (PMS; ~5 IU final; see recipe) and 46 hr later with 0.1 cc of 20× human chorionic gonadotropin (hCG; 5 U final; see recipe). After hCG injection place donor females with stud males and check for copulation plugs the next morning. Each plugged female will yield ~ 15 to 30 embryos; therefore, ~ 10 to 15 females are required per ES cell line to be aggregated.

SUPPORT PROTOCOL 2

MAKING AGGREGATION PLATES

A plate with depressions to hold the embryos and ES cells in contact (Wood et al., 1993) is used for aggregation, with one such plate required for every 60 embryos. Usually 3 to 4 are made for each experiment.

Additional Materials *(also see Basic Protocol)*

35 × 10–mm tissue culture dishes, sterile
Aggregation (i.e., darning) needle (BLS)

1. Place four rows of KSOM microdrops (~3 mm in diameter) into a 35 ×10–mm tissue culture dish using a 1-ml syringe and 26-G needle (3 drops in the first and fourth row, 4 to 5 drops in the second and third rows). Cover with light embryo-tested mineral oil.
2. Sterilize the aggregation (i.e., darning) needle by washing in 70% ethanol.
3. Make six depressions in the plastic of the dish, arranged in a circle, in each microdrop of the second and third rows, by pressing the aggregation needle into the plastic and making a slight circular movement. Do not twist the needle.

   This movement creates a tiny depression with a clear smooth wall. It should be deep enough to hold the embryo.

4. Place the plate in a tissue culture incubator until use.

REAGENTS AND SOLUTIONS

Use Milli-Q-purified water or equivalent for the preparation of all reagents and in all protocol steps. For common stock solutions, see ***APPENDIX 2A****; for suppliers, see* ***SUPPLIERS APPENDIX****.*

Avertin, 1.25% (w/v)

Dissolve 2.5 g of 2,2,2-tribromoethyl alcohol in 5.0 ml 2-methyl-2-butanol (*tert*-amyl alcohol). Add to 200 ml distilled water or physiological saline. Place on a magnetic stirrer until solution is in phase. Store protected from light (e.g., in a covered or brown bottle) up to 1 year at 4°C. Before use, perform a decomposition test by adding 1 drop of Congo Red to 5 ml of 1.25% avertin.

If purple color develops at pH < 5, it indicates decomposition to dibromoacetic aldehyde and hydrobromic acid and the solution should be discarded.

Dosage is 0.2 ml/10 g body weight (250 mg/kg).

Embryo-transfer pipet

Starting with one Pasteur pipet, heat the narrow end in a flame until soft. Remove from the flame and pull it out until it is the right thickness (i.e., a long and not-too-thin needle, ~1 mm in diameter). Break it at either end to get a thin glass tube ~2 in. long. Fire polish one end. Check under a dissecting microscope for a smooth bevel.

Pull out another pipet at the lower part of the neck of the pipet. Break the glass off close to the barrel. Put the thin needle into the broken off barrel. Warm a block of paraffin wax over a flame to form a drop, and let the drop fall on the joint where the needle meets the barrel. Hold the joint with the drop of wax on it close enough to the flame to heat up the glass and allow the molten wax to travel up the joint by capillary action (Fig. 15.3.1).

This pipet gives a shorter transfer pipet that is easier to hold than the long conventional drawn-out pipet. See Wood et al. (1993) for more information.

Finger pipet

Prepare a finger pipet for manipulating the embryos by flaming a 9-in. glass Pasteur pipet at a point 1 to 2 inches from the narrow end until it becomes soft. Remove the pipet from the flame and pull to obtain a long, narrow shaft of 1 to 2 in. that changes diameter gradually. Break the glass in the middle of the narrow shaft by pulling straight out while pinching slightly to generate a tip with an even end. Fire polish the end by briefly passing it through the flame. Check the tip of the resultant transfer pipet for correct size and smoothness under the dissecting microscope (See Fig. 15.3.2).

Flushing needle

Cut off the tip of a ½-in. 30-G needle and round the end using a sharpening stone. Attach to a 1-ml syringe. After each day's use, rinse the needle several times with ethanol by loading the syringe with the needle off, attaching the needle, and then pushing fluid through.

HEPES/phenol red, 10×

5.958% (w/v) HEPES
0.001% (w/v) phenol red

Add half of the final volume of water and adjust the pH to 7.4 with 1 M NaOH. Add water to volume. Store in 10-ml aliquots up to 3 months at –20°C.

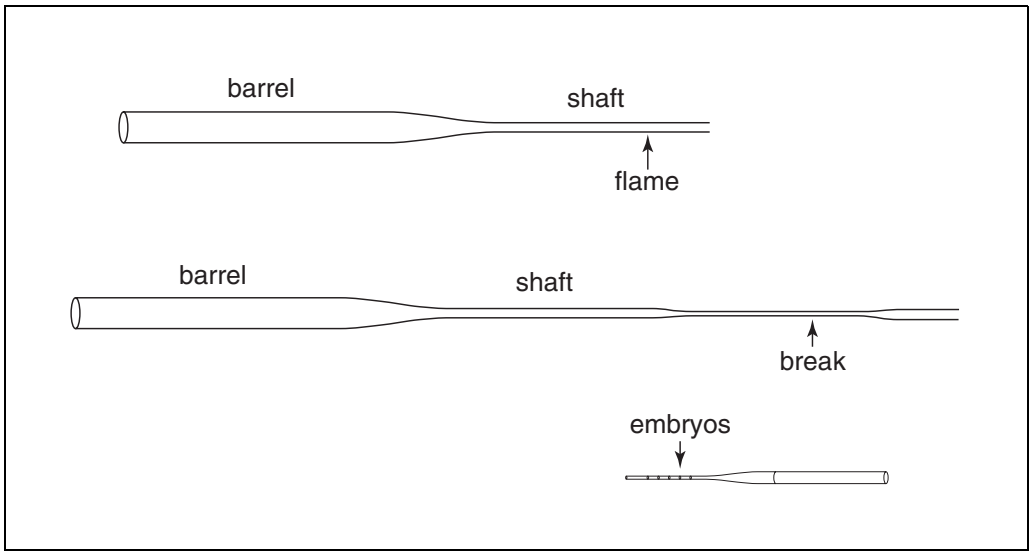

Figure 15.3.1 Schematic of a finger pipet.

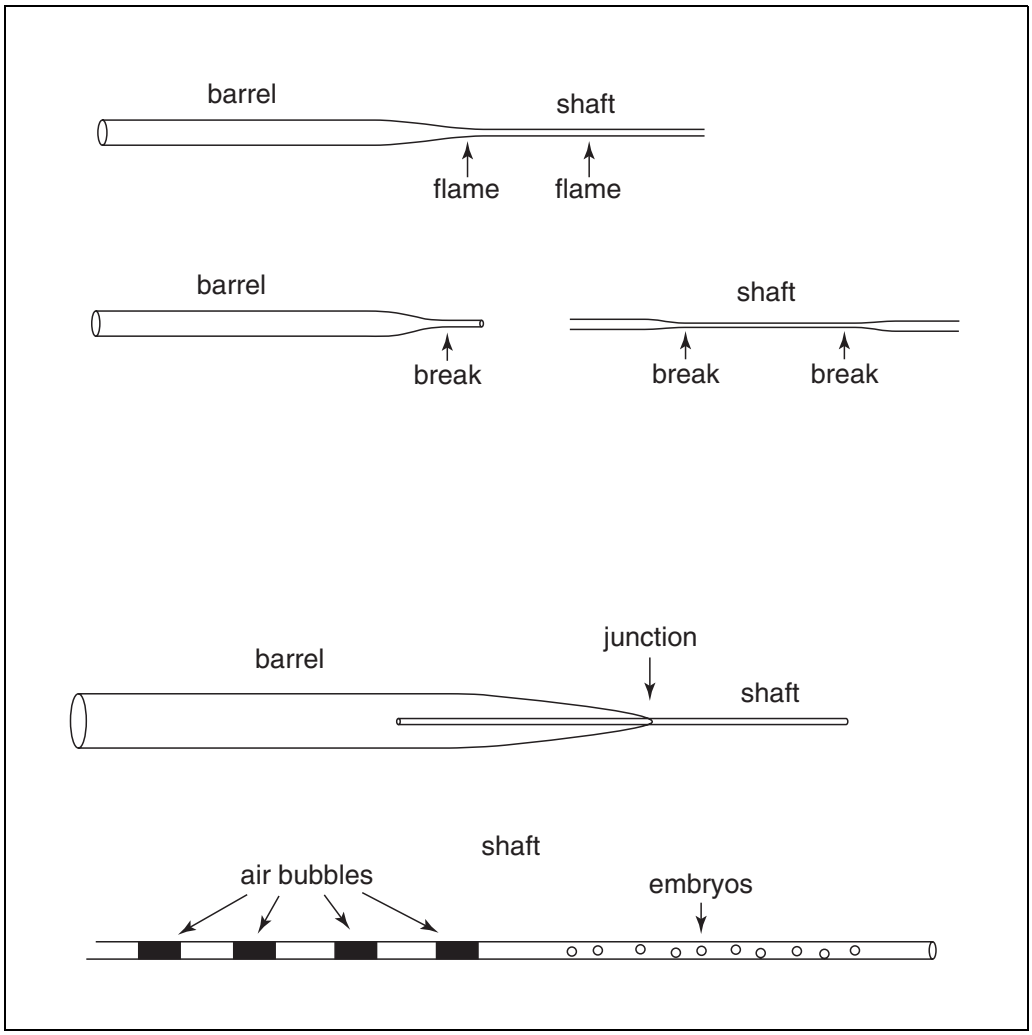

Figure 15.3.2 Schematic of an embryo-transfer pipet.

Human chorionic gonadotropin (hCG), 20×

Reconstitute 10,000 IU hCG (Wyeth-Ayerst) with the 10 ml of solution provided with hormone (1000 IU/ml). Store in 75-µl aliquots up to 3 months at −20°C. Reconstitute with 1.5 ml phosphate buffered saline (PBS; *APPENDIX 2A*) before using.

KSOM medium

10 ml 10× KSOM salts/antibiotics (see recipe)
10 ml 2.101% (w/v) $NaHCO_3$/0.001% (w/v) phenol red
1.0 ml 0.022% (w/v) sodium pyruvate
1.0 ml 0.252% (w/v) $CaCl_2 \cdot 2\ H_2O$
0.01 ml 0.372 M disodium EDTA
0.5 ml 200 mM glutamine (Life Technologies)
90 ml H_2O
400 mg BSA

Rinse all pipets and tubes thoroughly into the final flask. Add 400 mg BSA, allow to dissolve, and gently stir the medium with a magnetic stirrer, avoiding excessive frothing. Bubble 5% CO_2 through the solution in air to adjust to pH 7.4, or place in a humidified 37°C, 5% CO_2 incubator for several hours (e.g., overnight) with a loose cap. Filter sterilize through a 0.2-µm filter and aliquot into polypropylene tubes. Store in polypropylene tubes up to 2 weeks at 4°C.

The concentrated stock solutions can be stored at −80°C for 6 months, or −20°C for a shorter time (e.g., 3 months).

KSOM salts/antibiotics, 10×

5.534% (w/v) NaCl
0.186% (w/v) KCl
0.0476% (w/v) KH_2PO_4
0.0493% (w/v) $MgSO_4 \cdot 7\ H_2O$
1.87 g 60% sodium lactate syrup (rinse the boat well and add wash to the flask)
0.036% (w/v) D-glucose
0.060% (w/v) penicillin G
0.050% (w/v) streptomycin
Store in 10-ml aliquots up to 3 months at −20°C.

M2 medium

10 ml 10× M2 salts/antibiotics (see recipe)
1.6 ml 2.101% (w/v) $NaHCO_3$/0.001% (w/v) phenol red
1.0 ml 0.036% (w/v) sodium pyruvate
1.0 ml 0.252% (w/v) $CaCl_2 \cdot 2\ H_2O$
8.4 ml 10× HEPES/phenol red (see recipe)
78.0 ml H_20

Rinse all pipets and tubes thoroughly into final flask. Add 400 mg BSA, allow to dissolve, and gently stir the medium with a magnetic stirrer, avoiding excessive frothing. If necessary, readjust to between pH 7.2 to 7.4 with 1 M NaOH before making up to volume. Filter sterilize through a 0.2-µm filter and aliquot into polypropylene tubes. Test the medium and culture conditions by collecting 1-cell-stage embryos (0.5 dpc) and culturing them through the blastocyst stage. Store in polypropylene tubes up to 2 weeks at 4°C.

The concentrated stock solutions can be stored at −80°C for 6 months, or −20°C for shorter time (e.g., 3 months).

M2 salts/antibiotics, 10×

5.534% (w/v) NaCl
0.356% (w/v) KCl
0.162% (w/v) KH_2PO_4
0.293% (w/v) $MgSO_4 \cdot 7\ H_2O$
4.349 g 60% sodium lactate syrup (rinse the boat well and add wash to the flask)
1.000% (w/v) D-glucose
0.060% (w/v) penicillin G
0.050% (w/v) streptomycin
Store in 10-ml aliquots up to 3 months at −20°C.

Pregnant mare serum (PMS), 20×

Store 1000 IU/ml PMS (Wyeth-Ayerst) in 75-µl aliquots up to 3 months at −20°C. Reconstitute with 1.5 ml PBS (*APPENDIX 2A*) before using.

COMMENTARY

Background Information

Transgenic mice can be produced by injecting the transgene into the pronucleus of a one-cell stage embryo or by introducing the transgene into ES cells and then producing chimeric mice between the ES cells and a host embryo. The latter, ES cell–mediated transgenesis, is the preferred approach when a rare event such as homologous recombination is required because it is more practical to screen a large number of ES cell clones in culture than it is to screen a large number of transgenic mice. Examples of applications for ES cell-mediated transgenesis are gene targeting (Thomas and Capecchi, 1987; Doetschman et al., 1988), gene trap strategies (Friedrich and Soriano, 1991; Skarnes et al., 1992), and to prescreen transgenes for expression or copy number (Lobe et al., 1999). The disadvantage of ES cell–mediated transgenesis is the additional 3 months required to breed the chimeras and obtain transgenic offspring. As well, not all ES lines will provide germline chimeras.

If ES cell-mediated transgenesis is used, a second choice is whether to introduce the ES cells into host embryos by injection (Stewart, 1993) or by aggregation (Wood et al., 1993). The technique of ES cell–embryo aggregation has the advantage that the technique is less technical, is easier and faster to learn, and does not require expensive microinjection equipment. One potential disadvantage is that not all ES cell lines work equally well in aggregation experiments. Thus, some preliminary confirmation that a particular cell line contributes to the germ line by this approach may be useful.

Commonly used ES cell lines are derived from a male blastocyst and are therefore XY (Bradley, 1990; Doetschman et al., 1985; Nagy et al., 1993; Robertson, 1991). Germline chimeras are typically, but not exclusively, males. This has the advantage that male chimeras will provide more offspring over their lifetime than females.

For ES lines derived from a pigmented mouse strain, albino embryo donors are used, so that the degree of chimerism can be seen by coat color. For example, R1 ES cells are derived from 129 agouti mice and are commonly used with albino CD-1 female donors.

Critical Parameters

The success rate of obtaining germline chimeras is critically dependent on the potential of the ES cell line being aggregated. As discussed in other sections of this chapter, care must be taken to maintain high quality undifferentiated ES cells (see *UNIT 15.1*). The passage number should be kept to a minimum, ideally 10 to 15 passages in total. It is safest to maintain the ES cells on feeder layers of embryo fibroblasts and include LIF in the medium. It is always best for an investigator to have at least three different ES cell clones for each transgene or to gene knockout because different clones will have different abilities to contribute to the germline.

The water used to prepare M2 and KSOM medium should be of the highest possible purity. Water that has been purified by a combination of reverse osmosis and Milli-Q filtration contains minimal contaminants. The conductivity should be at least 18 MΩ. Prolonged storage of water is not advised. Clean glass bottles reserved for media use and that have been thoroughly rinsed or plastic tissue culture flasks are used to collect water and prepare stocks and media.

Table 15.3.1 Troubleshooting Guide for Preparation of Aggregation Chimeras

Problem	Possible cause	Solution
Low plug rate	Males too young or too old	Use 8-week to 9-month old males. Males with <50% plug rate should be replaced.
	Males mated too often	Males should only be mated 1 to 2 times per week
	High traffic in mouse room	Limit access to mouse room
Poor embryo yield	Superovulation ineffective	Titrate PMS or try a new batch of hormone
	Oviduct flushing is faulty	Be sure oviduct swells when flushed
ES cells not incorporated into embryo	Sides of well are rough and sticky	The aggregation well should have smooth walls. Use a small circular motion with the aggregation needle
Embryos not developing into blastocyst	Medium conditions not optimized	Test the medium by incubating flushed embryos without ES cells overnight. Virtually all should develop to blastocysts overnight.
Recipient females not pregnant	Embryo transfer is poor	Insert the transfer pipet well into the uterus. Avoid touching the uterus or ovary with the forceps.
No chimeras	ES cell clumps too big or ES line compromised, so chimeras are dying in utero	Pick smaller ES cell clumps for aggregation. Try a different ES cell clone.
Only weak chimeras	ES cell line is compromised	Use a different ES cell clone.
	ES cell clumps too small (seldom a problem; it is more common to use clumps that are too large)	Pick larger ES clumps for aggregation.
Chimeras die after birth, or survive but are sterile	ES cell line compromised	Use a different ES cell clone.

Table 15.3.2 Time Course of a Typical Experiment

Timepoint	Procedure
Day 1	Inject donors with PMS (e.g., at 2 p.m. for a 7 a.m. to 7 p.m. light cycle)
Day 3	Inject donors with hCG (e.g. at 12 noon for a 7 a.m. to 7 p.m. light cycle) and pair with stud males. Thaw ES cells to be aggregated onto feeder plate.
Day 4	Check plugs of donors. Check recipient females for estrus and pair with vasectomized males.
Day 5	Check plugs of recipients. Split ES cells to be aggregated onto gelatin plate.
Day 6	Flush embryos from donor females. Aggregate embryos with ES cells.
Day 7	Transfer ES cell–embryo aggregates into psuedopregnant recipient females
Day 22	Split pregnant recipient females into individual cages
Day 24	Pups are born

All chemicals should be of the highest grade possible. Some embryo-tested chemicals are available. Chemicals used to prepare media should be reserved only for this purpose.

Troubleshooting

Table 15.3.1 presents some common problems and their solutions.

Anticipated Results

To obtain a sufficient number of male germline chimeras, at least 120 aggregations should be done per ES cell line. This should provide ~10 male chimeras with >50% coat color chimerism, from which three germline transmitters should be obtained.

Time Considerations

Table 15.3.2 presents a time course for an average experiment.

Reporter Genes to Detect Cre Excision in Mice

The development of mouse embryonic stem (ES) cells has provided the opportunity to introduce many types of genetic alterations into the mouse (*UNIT 1.3*). Recently the Cre/*loxP* system has been combined with ES cell technology to accomplish virtually any type of genetic alteration that occurs in human disease. In addition, the Cre/*loxP* system allows conditional genome alterations that are spatially and temporally restricted (Sauer, 1998).

The Cre recombinase of the P1 bacteriophage catalyzes recombination between two 34-bp consensus sequences (*loxP* sites; Sternberg and Hamilton, 1981). The *loxP* sites are palindromic except for an 8-bp asymmetric core sequence that provides each *loxP* site with an orientation (Hoess et al., 1986). If two *loxP* sites lie in the same orientation in the same DNA strand, introduction of Cre enzyme will result in recombination between the *loxP* sites and excision of the intervening DNA sequence.

The Cre/*loxP* system has become a powerful tool to make conditional alterations to the mouse genome. Typically two lines of mice are required: the first is a transgenic mouse line with *loxP* sites strategically placed in the genome using standard transgenic technologies; the second is a Cre transgenic mouse line. The transgenic mice carrying *loxP* sites are crossed to the Cre transgenic line to effect recombination in the double-transgenic offspring. Recombination can be directed to a specific tissue or stage of the animal's life, depending on the gene promoter driving Cre expression.

To fulfill the potential of this new approach, a collection of Cre transgenic mice must be developed that express Cre recombinase with a variety of tissue and temporal specificities. The establishment of these lines is an ongoing effort in many laboratories. To achieve spatial restriction, the Cre recombinase coding sequence in these transgenic mice is under the regulation of a variety of tissue-specific promoters or has been "knocked in" to a gene (see Internet Resources). Several approaches to provide inducible Cre activity in transgenic mice by administration of exogenous compounds are also now emerging, opening the possibility of restricting site-specific recombination to later stages in the animal (Furth et al., 1994; Feil et al., 1996; Kellendonk et al., 1996; Rivera et al., 1996). A major impediment to the development of these mice has been the lack of an assay for Cre excision in the transgenic mice.

To address this problem, several Cre reporter mouse lines have been developed that provide a read-out of Cre activity (Tsien et al., 1996; Akagi et al., 1997; Lobe et al., 1999; Mao et al., 1999; Soriano, 1999; Kawamoto et al., 2000; Novak et al., 2000). In some of these reporter lines, Cre excision leads to activation of a *lacZ* reporter gene. In other double-reporter lines, Cre excision causes a switch from one reporter gene to another, including chloramphenicol acetyltransferase (CAT) to *lacZ*, CAT to enhanced green fluorescent protein (EGFP), *lacZ* to human alkaline phosphatase (hPLAP), also known as the Z/AP line, or *lacZ* to EGFP, also known as the Z/EG line. Thus, when a Cre reporter mouse is crossed to a Cre transgenic mouse, the double-transgenic offspring display a change in reporter gene expression that reflects the tissue and temporal specificity of the Cre transgene.

The protocols that follow describe detection of the *lacZ*, hPLAP, and EGFP reporter genes in whole-mount embryos or tissues (Basic Protocol 1) and in tissue sections (Basic Protocol 2). Samples can be analyzed sequentially for *lacZ* and hPLAP or EGFP and *lacZ*. Support Protocols 1 and 2 provide methods for genotyping mice.

Current Protocols in Toxicology (2001) 15.4.1-15.4.11

ANALYZING WHOLE-MOUNT EMBRYOS OR TISSUES FOR REPORTER GENE EXPRESSION

Embryos or tissues can be stained as whole mounts (i.e., without sectioning onto slides). EGFP visualization is done directly. For *lacZ* staining, samples are first fixed and then stained. Staining for hPLAP also requires tissue fixation first, as well as a heat inactivation step to eliminate endogenous alkaline phosphatase activity.

This protocol describes the detection of multiple markers. EGFP should be assayed first because the fluorescence intensity decreases over time. Likewise, hPLAP should be assayed last because the heat inactivation will eliminate *lacZ* and EGFP activity.

Materials

Dissected Cre reporter double-transgenic mouse embryos or tissues (see Support Protocols 1 and 2 for genotyping)
PBS (*APPENDIX 2A*), ice cold
100 mM sodium phosphate buffer, pH 7.3 (see recipe), optional
lacZ fixative (see recipe), ice cold
2% (w/v) paraformaldehyde/0.2% (v/v) glutaraldehyde in PBS, for large (≥E9.5) embryos only, ice cold
lacZ wash buffer (see recipe), ice cold
lacZ staining solution (see recipe)
AP wash buffer (see recipe)
AP staining solution (see recipe)
0.1% (v/v) Tween 20/2 mM $MgCl_2$ in PBS

Petri dishes
24-well and 6-well tissue culture plates
Dissecting microscope with light source and filter set for GFP visualization (Leica or BLS-Ltd.)
15- or 50-ml snap-cap tubes (e.g., Falcon), for en masse hPLAP staining
70° to 75°C water bath

CAUTION: Paraformaldehyde and glutaraldehyde are hazardous chemicals; follow appropriate precautions for handling, storage, and disposal.

NOTE: Signals will be best if initial tissue fixation and washing is done in ice-cold solutions on ice and with gentle shaking.

Visualize EGFP

1. Place a dissected Cre reporter double-transgenic mouse embryo or tissue in a petri dish containing ice-cold PBS.
2. View whole embryo or tissue under the blue-wavelength light and yellow filter of a dissecting microscope with light source and filter set for GFP visualization.

   The EGFP signal persists for 24 hr in PBS at 4°C.

Fix sample

3. Place individual embryos in 24-well plate (for small embryos) or 6-well plate (for large embryos). Rinse embryo or tissue in 100 mM sodium phosphate buffer or PBS.

4a. *For small embryos (<E9.5):* Fix 30 min in an excess of *lacZ* fixative on ice, with gentle shaking.

4b. *For large embryos:* Fix 30 min in an excess of 2% paraformaldehyde/0.2% glutaraldehyde in PBS on ice with shaking, then bisect and fix for an additional 30 to 60 min on ice in *lacZ* fixative.

4c. *For large tissues:* Fix 4 hr in an excess of *lacZ* fixative on ice with shaking, bisecting the tissue after the first hour to allow penetrance of the fixative solution.

Stain for lacZ

5. Wash embryo or tissue three times, 15 to 30 min each, in *lacZ* wash buffer.
6. Stain in *lacZ* staining solution at 37°C or room temperature for 30 min to overnight, with shaking and protection from light.

   Stain will appear blue.

7. Wash three times, 10 min each, in PBS. If not doing the hPLAP stain, store samples in *lacZ* wash buffer at 4°C for up to one month.

Stain for hPLAP

8. Fill a 6-well tissue culture plate (for individual staining) or a 15- or 50-ml snap-cap tube (for en masse staining) with PBS and place in a 70°C water bath to preheat.

   If samples are not first stained for lacZ, they should be dissected and fixed as described in steps 1 to 4, then washed as described in step 7 before staining for hPLAP. For better penetration of the hPLAP substrates, 0.02% Nonidet P-40 and 0.01% sodium deoxycholate can be included in the fixative solution.

   The plate or tube should be placed in the hot water bath in advance to ensure that it is up to temperature and should be left in the water bath for the entire 30-min incubation.

9. Rinse sample in PBS.
10. Incubate sample 30 min in PBS at 70° to 75°C to inactivate endogenous AP.
11. Rinse sample in PBS at room temperature.
12. Wash sample 10 min in AP wash buffer.
13. Stain with AP staining solution at room temperature for 5 to 10 min or at 4°C for 0.5 to 36 hr.

    Stain will appear dark purple. If staining reaction is continued too long, a brown background stain appears.

14. Wash three times for 10 min each, in 0.1% Tween 20/2 mM $MgCl_2$ in PBS.

ANALYZING TISSUE SECTIONS FOR REPORTER GENE EXPRESSION

BASIC PROTOCOL 2

To visualize Cre activity through reporter expression at the cell level, tissues or embryos are cryosectioned, and the slides are stained for expression of the relevant reporters. For EGFP reporters, slides should simply be coverslipped after fixation. For the Z/AP double-reporter mice, slides can be stained for *lacZ* first and then for AP.

Materials

Dissected Cre reporter double-transgenic mouse embryos or tissues (see Support Protocols 1 and 2 for genotyping)
PBS (*APPENDIX 2A*), ice cold
Tissue-Tek OCT
15% and 30% (w/v) sucrose in PBS, 4°C
0.2% glutaraldehyde (v/v) in PBS, 4°C

lacZ wash buffer (see recipe), 4°C
lacZ staining solution (see recipe)
AP wash buffer (see recipe)
AP staining solution (see recipe)
0.1% (v/v) Tween 20/2 mM $MgCl_2$ in PBS
Nuclear fast red stain: 5% (w/v) aluminum sulfate/0.1% (w/v) fast red (optional)
70% and 90% (v/v) ethanol in PBS
100% ethanol
1:1 (v/v) ethanol/xylene
Xylene
Mounting solution (e.g., Cytoseal; Fisher)

Petri dishes
Coverslips
Compound microscope with light source and filter set for GFP visualization (Leica or BLS-Ltd.)
Plastic molds for cryofreezing
Box for storing embedded samples, optional
Cryostat, −20°C
Poly-lysine coated slides (e.g., Fisher)
Slide box
Staining jars
70° to 75°C water bath
Light-protected container, such as a plastic food container wrapped in foil

Additional reagents and equipment for fixing samples (see Basic Protocol 1)

CAUTION: Glutaraldehyde and xylene are hazardous chemicals; follow appropriate precautions for handling, storage, and disposal.

NOTE: Signals will be best if initial tissue fixation and washing is done in ice-cold solutions on ice and with gentle shaking.

Prepare sample

1. Place a Cre reporter double-transgenic mouse embryo or tissue in a petri dish containing ice-cold PBS.

For lacZ and hPLAP staining:

2. Fix sample as described for whole mounts (see Basic Protocol 1, step 4). For EGFP visualization, fix in 4% w/v PFA in PBS. Do not use glutaraldehyde.

   Petri dishes or 6-well plates work well for containers.

3. Wash sample three times, 20 min each, in PBS.

For EGFP visualization:

4a. Rinse sample once for 2 to 5 min through Tissue-Tek OCT.

   a. Freeze sample in Tissue-Tek OCT as described in steps 6 to 8.
   b. Section sample and apply sections to slides as described in steps 9 to 10.
   c. Mount slides with coverslips and view under a compound microscope equipped with a light source and filter set for GFP visualization.

4b. Cryoprotect sample in 15% sucrose in PBS for 1 hr at 4°C followed by 30% sucrose in PBS overnight at 4°C.

5b. Place sample in Tissue-Tek OCT at 4°C for several hours (≥1 hr).

Embed and section sample

6. Fill a plastic mold (which has been labeled) with Tissue-Tek OCT. Place the sample in the center of the mold and orient it.

7. Place the mold on dry ice and hold it level, being careful to maintain the orientation of the sample. Keep the mold on dry ice until the OCT is completely frozen.

   It is best to have some dry ice in a plastic tray.

8. *Optional:* Wrap sample in plastic wrap, place in a labeled box, and store up to 1 month at −80°C.

9. Equilibrate embedded sample in the chamber of a −20°C cryostat. Cryosection block at 7 µm and place the sections onto poly-lysine coated slides.

10. Dry slides for 1 to 4 hr at room temperature.

11. Store slides at −20°C in a slide box with a little desiccant. Tape the box shut.

Fix sections

12. Allow box of slides to equilibrate to room temperature before opening the box.

13. Preheat a large staining jar with PBS in a 70°C water bath.

    This step is unnecessary if only lacZ staining is to be carried out.

14. Place slides to be stained in another staining jar.

    Unused slides can be placed back into −20°C with desiccant and stored up to 1 week.

15. Fill staining jar with cold 0.2% glutaraldehyde in PBS and fix slides 10 min.

    If only hPLAP staining is to be carried out, the slides should be washed three times, 5 min each, in PBS following fixation and then stained as described in steps 19 to 25.

Stain for lacZ

16. Remove fixative and wash slides three times, 5 min each, in *lacZ* wash buffer.

17. Stain 4 to 6 hr in *lacZ* staining solution at 37°C, protected from light.

18. When the staining is complete, rinse slides three times, 5 min each, in PBS.

    Staining is complete when blue color appears. Slides can be briefly viewed under a dissecting microscope without covering. Do not allow slides to dry.

    If only lacZ staining is to be carried out, the slides should be dehydrated and mounted at this point as described in steps 28 to 29.

Stain for hPLAP

19. Transfer slides to staining jar containing preheated PBS and incubate 30 min at 70° to 75°C to inactivate endogenous alkaline phosphatase.

    The temperature of the PBS should be checked with a thermometer. A common mistake is to not have the PBS at 70°C so that the endogenous alkaline phosphatases are not inactivated.

20. Cool slides at room temperature for 1 to 2 min.

21. Rinse slides with PBS and then wash 10 min in AP wash buffer.
22. Shake excess liquid from slides and place slides flat in a light-protected container.
23. Overlay slides with 0.5 to 1 ml AP staining solution/slide. Cover the container and, if necessary, cover with foil to protect from light.
24. Stain slides 10 to 30 min at room temperature.
25. When the stain is complete, wash the slides three times, 10 min each, in 0.1% Tween 20/2 mM $MgCl_2$ in PBS.

    Staining is complete when dark purple color appears. Color reaction can be monitored as described in step 18.

Counterstain (optional)

26. Incubate slides 5 min in PBS.
27. Incubate slides 30 sec to 5 min in nuclear fast red stain until sections are faintly pink.

    The length of incubation depends on the freshness of the nuclear fast red stain.

Dehydrate and mount slides

28. Dehydrate slides through an ethanol series as follows:

    5 min in PBS
    5 min in 70% ethanol in PBS
    5 min in 90% ethanol in PBS
    5 min in 100% ethanol
    5 min in 1:1 ethanol/xylene
    5 min in xylene
    5 min in xylene.

29. Mount with coverslips using a mounting solution. View with a compound microscope.

    lacZ expression will appear as blue-stained cells, and hPLAP expression will appear as dark purple. The AP stain localizers move to the cell periphery.

SUPPORT PROTOCOL 1

GENOTYPING Cre REPORTER MICE AND Cre TRANSGENIC MICE BY PCR

To establish the genotype of mice, genomic DNA is prepared from ear punch or tail biopsy samples, digested with a restriction enzyme, and used in Southern blot analysis (Southern, 1975). Alternatively, for Cre genotyping the DNA can be used in a PCR reaction as described below (also see *APPENDIX 3C*). In the case of mice that express a reporter such as *lacZ*, the ear punch can be used in a *lacZ* staining reaction to identify pups carrying the transgene (see Support Protocol 2). General information about transgenic mice is described in *UNIT 1.3*.

Materials

Yolk sac, tail biopsy, or ear punch from potential transgenic mouse
PBS (*APPENDIX 2A*)
1× proteinase K buffer (see recipe)
Mineral oil
dNTP cocktail: 2 mM each dATP, dCTP, dGTP, dTTP
Taq DNA polymerase
10× PCR buffer (*APPENDIX 3C*)
10 μM PCR primer for Cre recombinase:
5′-ATG TCC AAT TTA CTG ACC CC-3′
5′-CGC CGC ATA ACC AGT GAA AC-3′

50°C incubator
PCR tubes
Thermal cycler

Additional reagents and equipment for agarose gel electrophoresis (*APPENDIX 3A*)

1. Dissect yolk sac, tail biopsy, or ear punch and rinse thoroughly in PBS.

   As a positive control, a sample from the transgene-positive parent can be used. A transgene negative control should be included, which can simply be siblings in the litter.

2. Place yolk sac, tail biopsy, or ear punch in a microcentrifuge tube with 100 µl of proteinase K buffer containing 1 mg/ml proteinase K.
3. Incubate overnight in a 50°C incubator.
4. Place 10 µl proteinase K–treated material into a PCR tube with 35 µl water and overlay with two drops of mineral oil.

   Too much tissue can inhibit the PCR.

5. Incubate tube 10 min at 94°C in a thermal cycler to denature the proteinase K.
6. Bring the thermal cycler to the annealing temperature (step 7) and add:

   10 µl dNTP cocktail
   10 µl 10× PCR buffer
   2.5 µl each 10 µM PCR primer
   0.5 µl, 2.5 U/µl *Taq* DNA polymerase.

   The final concentration of dNTPs should be 200 µM. Bring the final volume to 100 µl with water.

7. Carry out PCR using the following amplification cycles:

Initial step:	4 min	94°C	(denaturation)
30 to 40 cycles:	45 sec	94°C	(denaturation)
	45 sec	58°C	(annealing)
	1 min	72°C	(extension; 1 minute per kb)
Final step:	10 min	72°C	(extension).

8. Analyze products by gel electrophoresis (*APPENDIX 3A*) on a 1.0% agarose gel.

   The amplified Cre fragment is 356 bp.

GENOTYPING Cre REPORTER MICE AND Cre TRANSGENIC MICE BY *lacZ* EXPRESSION

SUPPORT PROTOCOL 2

If mice express *lacZ*, they can be rapidly and easily genotyped by using an ear biopsy, collected when enumerating the pups, for *lacZ* stain.

Materials

Ear punch from potential transgenic mouse
PBS (*APPENDIX 2A*)
0.2% (v/v) glutaraldehyde in PBS
lacZ staining solution (see recipe)

96-well plate
37°C incubator, optional
Dissecting microscope

CAUTION: Glutaraldehyde is a hazardous chemical; follow appropriate precautions for handling, storage, and disposal.

1. Place an ear punch, 2 to 3 mm in diameter, from a potential transgenic mouse in PBS in a 96-well plate.
2. Aspirate off PBS and fix sample 5 to 15 min in 0.2% glutaraldehyde in PBS.
3. Wash three times, 5 min each, in PBS.
4. Add 50 to 100 µl *lacZ* staining solution and stain 5 min in a 37°C incubator (or at room temperature for a longer time) protected from light.

   Staining is usually visible after 5 min if fresh stain is used.

5. Examine ear punch for *lacZ* staining using a dissecting microscope.

REAGENTS AND SOLUTIONS

Use Milli-Q-purified water or equivalent for the preparation of all reagents and in all protocol steps. For common stock solutions, see ***APPENDIX 2A****; for suppliers, see* ***SUPPLIERS APPENDIX****.*

Alkaline phosphatase (AP) staining solution

2 ml 1 M Tris·Cl, pH 9.5 (*APPENDIX 2A*)
0.4 ml 5 M NaCl
1 ml 1 M $MgCl_2$
200 µl 1% (w/v) sodium deoxycholate (0.01% final)
200 µl 2% (w/v) Nonidet P-40 (NP-40; stored at 4°C; 0.02% final)
70 µl 100 mg/ml nitroblue tetrazolium (NBT; 337 µg/ml final)
70 µl 50 mg/ml 5-bromo-4-chloro-3-indolyl phosphate (BCIP; 175 µg/ml final)
16 ml water
Do not store; prepare shortly before use.

Alkaline phosphatase (AP) wash buffer

10 ml 1 M Tris·Cl, pH 9.5 (*APPENDIX 2A*)
2 ml 5 M NaCl
1 ml 1 M $MgCl_2$
87 ml water
Store indefinitely at room temperature.

lacZ fixative

43.8 ml 100 mM sodium phosphate buffer, pH 7.3 (see recipe) or PBS (*APPENDIX 2A*)
5.0 ml 1 M $MgCl_2$
0.2 ml 50% (v/v) glutaraldehyde
1.0 ml 250 mM EGTA, pH 7.3
Store up to 1 week at 4°C

For whole-mount hPLAP staining, a mixture of 0.2% (v/v) glutaraldehyde in PBS, 0.02% (w/v) NP-40, and 0.01% (w/v) sodium deoxycholate may be used in place of this fix solution to improve penetration of stain.

lacZ staining solution

70.5 ml *lacZ* wash buffer (see recipe)
3.0 ml 25 mg/ml 5-bromo-4-chloro-3-indolyl-β-D-galactoside (Xgal; dissolved in dimethyl sulfoxide)
750 µl 500 mM potassium ferrocyanide
750 µl 500 mM potassium ferricyanide

This stain can be stored for 1 to 2 weeks at room temperature, but optimal staining occurs with freshly prepared stain solution.

lacZ wash buffer

489 ml 100 mM sodium phosphate buffer, pH 7.3 (see recipe)
1.0 ml 1 M $MgCl_2$
5.0 ml 1% (w/v) sodium deoxycholate (stored at 4°C)
5.0 ml 2% (w/v) NP-40 (stored at 4°C)
Store up to 3 months at 4°C

Proteinase K buffer, 1×

10 mM Tris·Cl, pH 7.5 (*APPENDIX 2A*)
10 mM EDTA
10 mM NaCl
0.5% (w/v) Sarkosyl
For enzyme solution: 1 mg/ml proteinase K (add just before use)

Sodium phosphate buffer (pH 7.3), 100 mM

11.5 ml 1 M NaH_2PO_4
38.5 ml 1 M Na_2HPO_4
450 ml water
Store indefinitely at room temperature.

This mixture should be pH 7.3. Do not adjust with acid/base.

COMMENTARY

Background Information

The use of Cre recombinase has become a powerful tool in manipulating the mouse genome. Some applications are to activate expression of transgenes, perform conditional or tissue-specific gene knockouts, or remove the phosphoglycerate kinase promoter (PGK)-neo sequence used in gene targeting (reviewed in Lobe and Nagy, 1998). A large number of Cre transgenic mouse lines have been and continue to be developed. In order to test the tissue and temporal specificity of these transgenic lines, the Cre mice can be crossed to a reporter mouse line, and the double-transgenic offspring analyzed for reporter gene expression.

The *lacZ* reporter gene, which encodes the β-galactosidase enzyme, has been used in transgenic mice for many years. Its expression is assumed to be innocuous; however, high levels of *lacZ* expression seem to be poorly tolerated by some tissues and may lead to stunted growth (Lobe et al., 1999). More recently, the human placental alkaline phosphatase (hPLAP) gene has been used as a reporter gene in transgenic mice. The hPLAP reporter may be better tolerated than *lacZ* because it is of mammalian rather than bacterial origin, and alkaline phosphatases are commonly expressed in cells. hPLAP activity can be differentiated from endogenous alkaline phosphatase activity because of its resistance to heat inactivation. Both the *lacZ*-encoded β-galactosidase and the hPLAP enzyme are visualized by incubation with substrates that are converted to insoluble colored products.

GFP is a powerful new reporter that can be visualized in live tissue. However, fixation in glutaraldehyde causes autofluorescence and therefore high background, and must be avoided. However it is compatible with sorting of fluorescence-labeled cells (Novak et al., 2000), and thus it has great potential for expression analyses in hematopoietic lineages.

Critical Parameters

Cre activity may be assayed in embryos or in adult tissues. If embryos at E9 or earlier are being analyzed, the whole-mount staining procedure (see Basic Protocol 1) is generally used. The whole-mount procedure can also be used to get a general picture of Cre activity in small pieces of dissected adult tissues. For older embryos and to determine expression at the cell level, the protocol for tissue sections (see Basic Protocol 2) is followed.

During the staining step, the color development can be monitored by eye or under a dissecting microscope, however do not leave samples exposed to light more than 1 to 2 min or let slides dry out. For *lacZ* stain, look for a dark blue color and for AP stain look for dark purple. If a brown color starts to develop in the AP staining, stop the reaction because this is background not a hPLAP signal.

To test tissue specificity of Cre expression, the mouse breeding should be between a male

Table 15.4.1 Troubleshooting Guide for Cre Reporter Detection Methods

Problem	Cause/Solution
Poor *lacZ* signal	Cells fixed too long, particularly with paraformaldehyde.
High background hAP signal	Endogenous hAP activity was not completely inactivated.
	PBS should be preheated to 70°C and tissues incubated ≥30 min in PBS at 70°C.
	Stain allowed to proceed too long, allowing the background to become high.
GFP signal washes out of cells	If cells are treated with alcohol to fix or to dehydrate, the GFP leaches out of the cells.
	Some media for coverslip mounting leeches out the GFP.
	Minimal processing for the GFP reporter should be used.

Cre transgenic mouse and a female Cre reporter mouse. If, instead, the Cre-expressing mouse is the female, maternal expression of the Cre transgene can produce sporadic, nonspecific Cre excision in the embryos.

For timed matings, check females in the mornings for a vaginal plug and sacrifice the female and dissect the embryos at the required stage. For tissues, sacrifice the animal and dissect tissues into cold PBS. Signals will be best if initial tissue fixation and washing is done in ice-cold solutions on ice and with gentle shaking. Note that paraformaldehyde fixation will decrease *lacZ* activity, therefore it should be kept to a minimum and used at 4°C.

Troubleshooting

See Table 15.4.1 for potential problems related to reporter-gene staining and their solutions.

Anticipated Results

With Cre reporter mice, blue *lacZ* reporter gene activity typically shows up rapidly, and purple hPLAP staining occurs even more quickly. In double-reporter mice such as Z/AP, blue *lacZ*-positive tissues are negative for Cre excision and purple hPLAP-positive tissues have Cre activity. In most single-reporter mice, *lacZ* staining indicates Cre activity. However, negative tissues should be evaluated for their potential to express the reporter gene before assuming they lack Cre activity, because some Cre reporter mice have restricted expression of the reporter gene. This can be checked by crossing the Cre reporter mice to a Cre line that gives Cre excision in all tissues.

Many tissue-specific Cre lines have been found to have ectopic Cre activity. This is more significant in a Cre/*loxP* system than in an inducible promoter system because if Cre is expressed in a population of cells, a genomic alteration is made between the target *loxP* sites, and all descendants of those cells will also have the genomic alteration.

Different Cre reporters can have different sensitivities to Cre excision (Hebert and McConnell, 2000). This variability likely is due to different chromatin structure and probably reflects an equal variance in other *loxP* target sites used in experiments.

Time Considerations

Processing the tissues for whole-mount staining can be done in 1 day. After the initial fixation and washing steps, which take 1 to 2 hr, the *lacZ* stain usually goes for 2 to 4 hr. Subsequent preparation and staining for hPLAP takes an additional 2 hr, and slides can be dehydrated and coverslips mounted in another hour.

For tissue sections, samples are fixed and washed the first day and left in sucrose overnight. The second day they are equilibrated in OCT and can be frozen that day or the next (third) day. It normally takes ≥1 day (day three to day four) to section samples. Staining the slides requires one more day, making the process ~4 to 6 days.

Genotyping by PCR requires 1 hr on the first day, and ~30 min on the second day to start the PCR reaction. Gel analysis requires an additional 2 to 3 hr on the second or third day. Genotyping by *lacZ* expression requires 2 to 3 hr.

CHAPTER 16
Male Reproductive Toxicology

INTRODUCTION

Over the past 20 to 25 years, male reproductive toxicology, like other specialties in toxicology, has evolved significantly. This maturation is evidenced by a broad acceptance and codification of what were previously research methods in detection and quantification, and by a generalized understanding of the relationships among the various endpoints. For example, the use of Bouin's as the fixative of choice for testes was a novel concept just 15 years ago, and is now recommended in the testing guidelines of multiple agencies. We recognize that sperm measures relate pretty directly to fertility, that Sertoli cell numbers underlie sperm count, and that Sertoli cell numbers can be manipulated during development with lasting effects into adulthood. Despite this progressive codification, there is still evolution of protocols, and refining of methods is a continual process.

The research forefront of many parts of male reproductive toxicology involves the elucidation of relationships among different interacting cell types, subcellular signaling systems that mediate these interactions, and the mechanisms by which toxicants perturb intracellular physiology. Progress in our understanding of mechanisms in reproductive toxicology is tightly linked with progress in reproductive biology and physiology. And these are truly exciting times, as our knowledge of reproductive biology and physiology is expanding at an exponential rate. Technical advances in the identification and quantification of expressed genes and their protein products are rapidly expanding both the sophistication of our insights and the inherent complexity of the processes we study.

In our initial organizational discussions, we—the editors of this chapter—started with the idea that we needed to provide non-expert readers with the tools to address apparently simple questions, such as "How do I determine the target cell of this novel male reproductive toxicant?" or "Why is my male transgenic mouse infertile?" Of course, given the complexity of male reproduction, these apparently simple questions can be difficult, and sometimes impossible, to answer. Nonetheless, the initial chapters in this unit are designed to present the conceptual framework and most up-to-date tools available to investigate targets of toxicants and mechanisms of male reproductive failure.

The units presented in this chapter were chosen to represent the continuing evolution of our field. Rochelle Tyl has done a superb job in capturing both the more standard methods of assessing fertility in toxicant-treated or gene-knockout animals (*UNIT 16.1*), and additionally provides a unit (*UNIT 16.2*) on measuring the more subtle endpoints of the development of the reproductive system, endpoints which have been shown to be sensitive to prenatal hormonal exposures. Dr. Tyls' references to the ways to integrate the various endpoints will be complemented by a group of units that provide details in quantifying spermatogenesis. Dianne Creasy provides two units on histopathology in the male reproductive system: how to prepare the tissues for analysis (*UNIT 16.3*), and how to evaluate them once you've got the sections (*UNIT 16.4*). This represents the very latest thinking in the most appropriate use of "staging", a concept that often strikes fear into the hearts of pathologists. Dr. Creasy explains why this fear is needless, what is really meant by the term "staging", and when stages of spermatogenesis should be counted versus when you simply need to examine the sections with a basic understanding of spermatogenesis. Rather than leaving you there, she then refers to sources that can provide this basic

Contributed by K. Boekelheide and R. Chapin
Current Protocols in Toxicology (2004) 16.0.1-16.0.2

understanding. Drs. Fail and Anderson (*UNIT 16.5*) provide a detailed explanation of alternative approaches that use in-dwelling catheters for repeated blood sampling in the rat. This valuable technique minimizes animal stress and handling while maximizing the quality of the hormonal data. In a new unit Dr. Wang (*UNIT 16.6*) succinctly describes a detailed procedure for determining epididymal sperm counts and sperm density in rodents. This is complemented by the method of Seung et al. who describe the quantitation of testicular homogenization resistant spermatid heads as a way of quantifying the latter parts of spermatogenesis (*UNIT 16.7*). Collectively these units provide good tools for describing spermatogenesis both qualitatively and quantitatively, and both approaches should be used whenever possible. In a new unit (*UNIT 16.8*), Drs. Ostby and Gray provide definitive information on how to evaluate a novel toxicant suspected of endocrine disrupting activity, a current "hot topic" in reproductive developmental toxicology.

Future units are envisioned which focus on advanced research techniques in reproductive toxicology, using methods for studying various cellular and subcellular processes in vivo and in vitro. Examples of such approaches include gene transfection, viral infection, and germ cell transplantation, all techniques which require sophisticated manipulations and offer the advantage of selective targeting. In addition, future units will focus on classes of toxicants with special properties. We hope you enjoy these units and derive as much benefit from reading and using them as we have.

In Vivo Models for Male Reproductive Toxicology

MALE REPRODUCTION

Male reproduction encompasses the production of viable sperm, their delivery into the female reproductive tract, fertilization of the female oocytes, and production of normal offspring. Successful male fertility requires an adequate sperm count, adequate sperm motility, the appropriate functioning of accessory sex organs (to produce and concentrate semen and to activate and capacitate sperm), and appropriate sexual behavior (i.e., mounting, intromission, ejaculation). The production of viable sperm (spermatogenesis) in the testes is under genetic control (a male-determining gene on the Y chromosome) and neuroendocrine regulation initiated in the brain by the hypothalamic-pituitary-gonadal (HPG) axis. There is also intratesticular endocrine, autocrine, and paracrine regulation. Once the sperm are produced and delivered to the epididymis, they are stored in the cauda epididymis and moved into the vas deferens. Epididymal maturation must occur; this includes acquisition of motility and the ability to penetrate and fertilize the oocytes, and acrosomal cap activation. Semen is produced from accessory sex organs—seminal vesicles, coagulating glands, the prostate, bulbourethral (Cowper's) glands, and preputial glands. The sperm in semen are moved through the blood-engorged erect penis and ejaculated into the female's vagina-cervix-uterus. Indirect influences also play a role, such as nutritional status, liver metabolism of xenobiotics and endogenous hormones, and vascularization. The testis is relatively anoxic, with low blood flow and low oxygen tension; insult can alter the permeability of the testicular vasculature and consequently affect blood flow (Miller, 1998).

Regulation of the neuroendocrine system begins with specialized cells in the hypothalamus in the brain that release gonadotropin-releasing hormone (GnRH) in a pulsatile pattern. GnRH travels via the hypothalamic-pituitary portal system directly to the anterior lobe of the pituitary. In a receptor-mediated process, GnRH stimulates cells of the anterior lobe of the pituitary to secrete the gonadotrophins, luteinizing hormone (LH), and follicle-stimulating hormone (FSH). LH and FSH travel via the systemic blood supply to the testes. LH binds to receptors on the interstitial cells of Leydig to stimulate steroidogenesis (i.e., synthesis of testosterone) in these cells. FSH binds to receptors on the intratubular Sertoli cells, which act as nurse cells for the developing germ cells and are necessary for spermatogenesis.

Inhibin, produced by the Sertoli cells, and testosterone (T) from the Leydig cells both exert negative feedback on the pituitary production of FSH and LH. T also exerts negative feedback on the hypothalamic production of GnRH (Russell et al., 1990; Miller, 1998). Sertoli cells have receptors for both FSH and T for additional coordination between the Sertoli and Leydig cell populations (Russell et al., 1990).

Male reproductive toxicants have been classified in a number of ways, based on direct or indirect action. Mattison (as described by Miller, 1998) proposed that direct-acting toxicants interacted with cellular components, based on inherent chemical reactivity or via specific receptor binding, whereas indirect-acting toxicants acted via disruption of endocrine homeostatis or by metabolic activation to a direct toxicant. Working (also described by Miller, 1998) used the direct-acting versus indirect-acting classification but proposed that a direct toxicant affects the testis without endocrine mediation, whereas an indirect toxicant acts at a non-germ-cell site (e.g., hypothalamic-pituitary axis or the Leydig cell; see discussion in Miller, 1998).

Miller (1998) also used the direct- versus indirect-acting classification but defined direct-acting toxicants as those that produced their primary effects on testicular cells, the duct system (e.g., the epididymis), or on mature spermatozoa. This definition would include effects on non-germ-cell testicular cell types such as the Leydig or Sertoli cells. Because the testis is subject to hormonal control and regulatory feedback loops, the action of direct toxicants on testicular cell types would result in secondary disruption of endocrine homeostasis. Indirect toxicants are defined as having a primary action on hypothalamic-pituitary neuroendocrine controls or on extragonadal systems. This last classification, which is based on the processes altered, does not consider whether the parent compound or a metabolite is eliciting the toxicity (Miller, 1998).

Other indirect effects that could affect male reproduction include anosmia (the absence or loss of the sense of smell), so that the male is

Contributed by Rochelle W. Tyl

Current Protocols in Toxicology (2002) 16.1.1-16.1.15

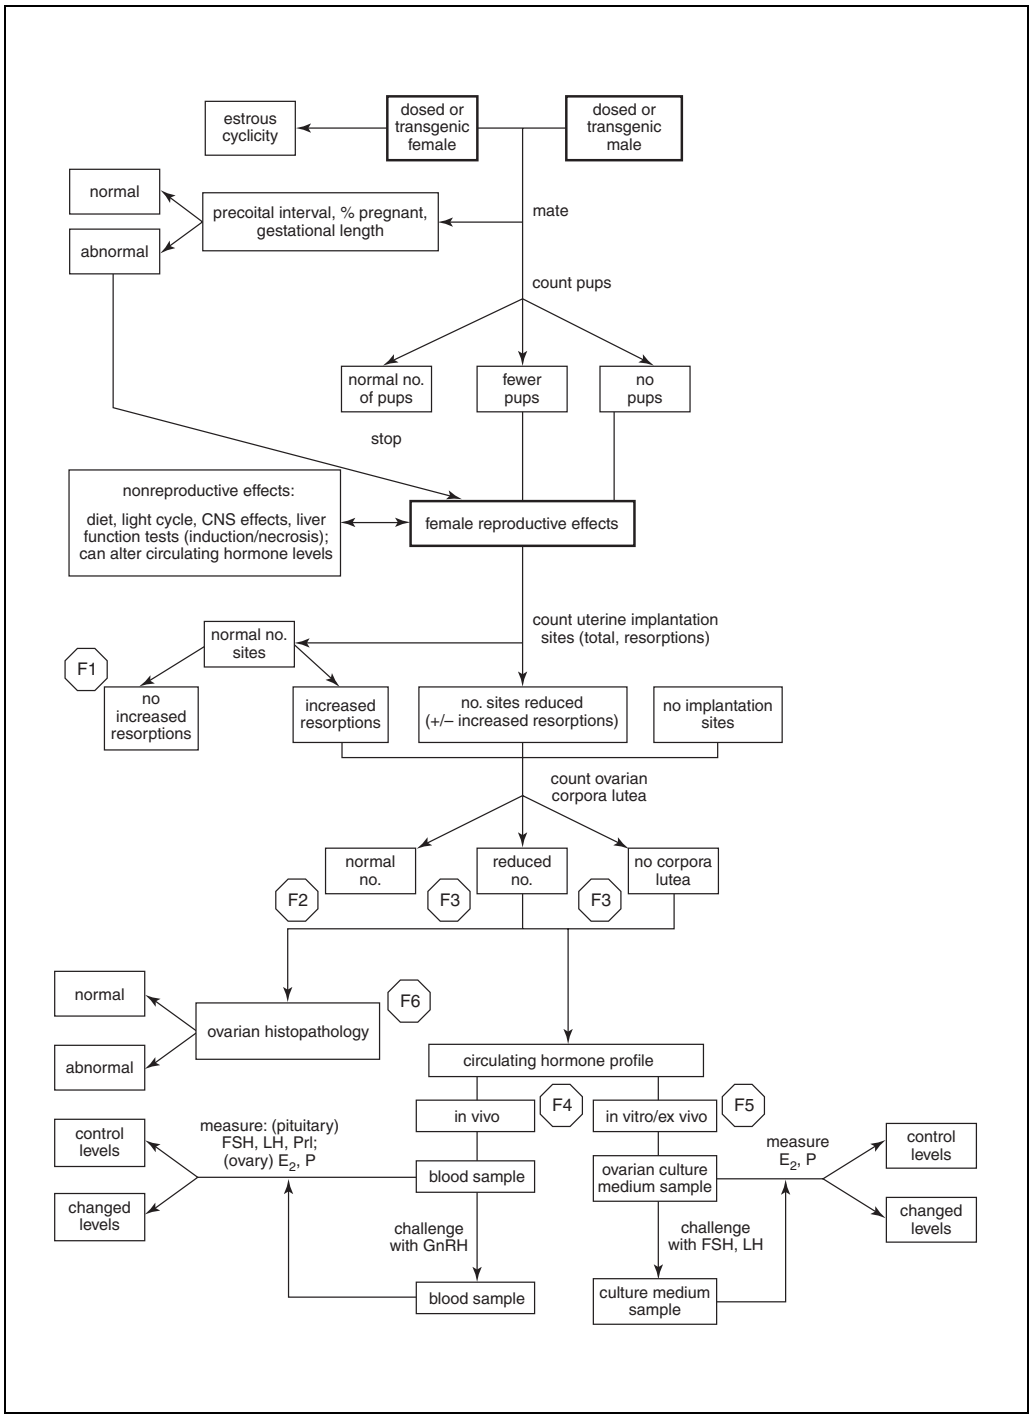
unable to detect pheromonal signals from receptive females. They also include peripheral neuropathy, so that the male cannot mount the female due to his hindlimb weakness or achieve appropriate intromission, ejaculation, and/or stimulation of the cervix. Inhibition of brain aromatase enzyme, which locally converts T to estrogen in the male rat brain, can also result in altered male reproduction. Local estrogen masculinizes the male rat brain, for example, the sexually dimorphic nucleus of the preoptic area (SDN-POA), and sexually dimorphic behaviors (e.g., play, mating, aggression) early in perinatal development. Either an absence of or reduction in brain-localized estrogen in the male rat will affect mating behavior, resulting in impaired reproductive performance. Alterations in neonatal thyroid hormone levels can also result in changes in testis size and sperm production. Goitrogen administration increases these parameters, presumably through a delay in differentiation of Sertoli cells, so that they continue to divide and, in the mature testis, can support more sperm per cell, resulting in larger testes and increased sperm production in the mouse (Joyce et al., 1993) and in rats and humans (Chowdury et al., 1984).

Steroidogenesis—the production of T and dihydrotestosterone (DHT) from cholesterol by a series of P450 enzymes in the Leydig cells of the testis—is necessary for both spermatogenesis and for development of secondary sex characteristics. In utero, T (produced locally by the interstitial cells of Leydig, which are regulated by LH) is responsible for the differentiation of the Wolffian ducts into the epididymides, vasa deferentia, seminal vesicles, and the growth of the levator ani-muscle and bulbocavernosus gland (the LABC complex). DHT (produced locally in the testis by the conversion of T using the enzyme 5-α-reductase) is responsible for the differentiation of the genital tubercle into the external genitalia and the urogenital sinus into the prostate and Cowper's glands, and for the regression of nipple anlagen in male fetuses. The Sertoli cells are also necessary for spermatogenesis. Inhibin (also called the Müllerian inhibiting substance) is produced locally by the fetal Sertoli cells and is regulated by FSH. It causes the Müllerian ducts (which are initially present in both sexes in utero and which form oviducts and the uterus in female fetuses) to regress, thereby suppressing female reproductive development. At puberty, there is another surge of FSH and LH and, therefore, T, which initiates preputial separation (PPS) in the rodent, development of tertiary sex characteristics, and spermatogene-

Figure 16.1.1 *(at right)* Detection of male reproductive toxicity when both sexes are exposed or transgenic. F1 through F6 indicate female reproductive effects and experimental strategies, as follows. F1: If there are fewer or no pups, and implantation sites are normal (with or without increased resorptions), the site of action is in utero development and/or altered corpus luteum function (so that postimplantation survival is compromised). F2: If there are fewer or no pups, implantation sites are reduced or absent, and corpora lutea counts are normal, then site of action is fertilization or implantation and/or maintenance of implantation. F3: If there are fewer or no pups, implantation sites are reduced or absent, and corpora lutea counts are reduced or absent, then site of action is ovarian (histopathology) or the hypothalamus-pituitary (gonadal) axis. F4: For exposed (or transgenic) females in vivo, measure plasma or serum for baseline follicle stimulating hormone (FSH), luteinizing hormone (LH), and prolactin (Prl) of pituitary origin, and 17β-estradiol (E_2) and progesterone (P) of ovarian origin. Challenge female in vivo with gonadotropin-releasing hormone (GnRH) of hypothalamic origin and sample plasma or serum for above hormones. If baseline and challenge levels are normal, the hypothalamic-pituitary-gonadal (HPG) axis is normal. If baseline and/or challenge levels are abnormal and the pituitary levels are abnormal, the pituitary is affected. The ovaries would be affected as well. If the pituitary levels are normal and ovarian hormones are abnormal, then the ovaries are affected. F5: For a specific evaluation, the in vitro assay involves control (untreated) minced ovaries exposed to test material in culture for E_2 and P release. Challenge would involve adding FSH or LH to culture medium and assaying for E_2 and P. If there is a response in baseline or challenge levels, the ovaries are affected. This assay does not evaluate hypothalamic or pituitary effects (Lasky et al., 1994). The ex vivo assay involves culturing ovaries from treated females and determining baseline and challenge ovarian hormone levels, as above. F6: Histopathologic evaluation of ovaries should include step sections with determination of profile of primordial, small antral, large antral, and mature Graafian follicles. If there is an effect, one can determine when in the cycle the effect may reside and in which cells derived from the follicle (e.g., granulosa or thecal) the insult occurred (Heindel et al., 1989). The double-headed arrow between female reproductive and nonreproductive effects indicates that each effect can, in turn, affect the other.

sis. Testis descent through the inguinal ring and into the scrotal sacs prior to puberty appears to be controlled by both T and DHT.

Male reproductive impairment can result from: (1) exposure to a xenobiotic during the perinatal (prenatal and early postnatal), peripubertal, or adult period of life; (2) a spontaneous mutation in regulatory and/or structural genes (or ligand receptors) involved in the development, structure, and/or function of the reproductive system; (3) construction of a transgenic animal (carrying an inserted gene or genes from another species) in order to evaluate the role of a particular gene or genes in the reproductive process, or in order to evaluate the role of the transgene in an entirely different process, organ, or developmental phase, with inadvertent effects on reproduction; or (4) construction of a so-called knockout animal, in which a particular gene (or genes) is deleted or otherwise prevented from producing its gene product. The deleted or blocked genes may be intentionally



relevant to the reproductive process or may be directed to an entirely different system or function, with inadvertent effects on reproductive development and/or function.

This unit describes scenarios in which indications of possible male reproductive toxicity may be identified and the sequence to follow to determine the extent and nature of the toxicity. Useful in vivo models, methods, and endpoints are presented, as well as suggestions on how to interpret the results. *UNIT 16.2* presents guidelines for rodent mating.

Figure 16.1.1 is a flow chart illustrating how to detect male reproductive toxicity when both males and females are exposed to a xenobiotic (or are transgenic), with the focus on female assessment (the male assessment is presented in Fig. 16.1.2). Figure 16.1.2 is a similar flow chart showing how to detect male reproductive toxicity when the male is exposed or transgenic (regardless of the status of the female). Both flow charts begin with mating the male(s) of concern and assessing reproductive outcome. As the chart progresses, the type of potential adverse outcome is identified, with follow-up procedures to identify the site of the insult by in vivo, in vitro, or ex vivo evaluations, including options based on whether or not the male of concern can be necropsied. The specific endpoints are discussed in the figure legends.

IN VIVO MODELS

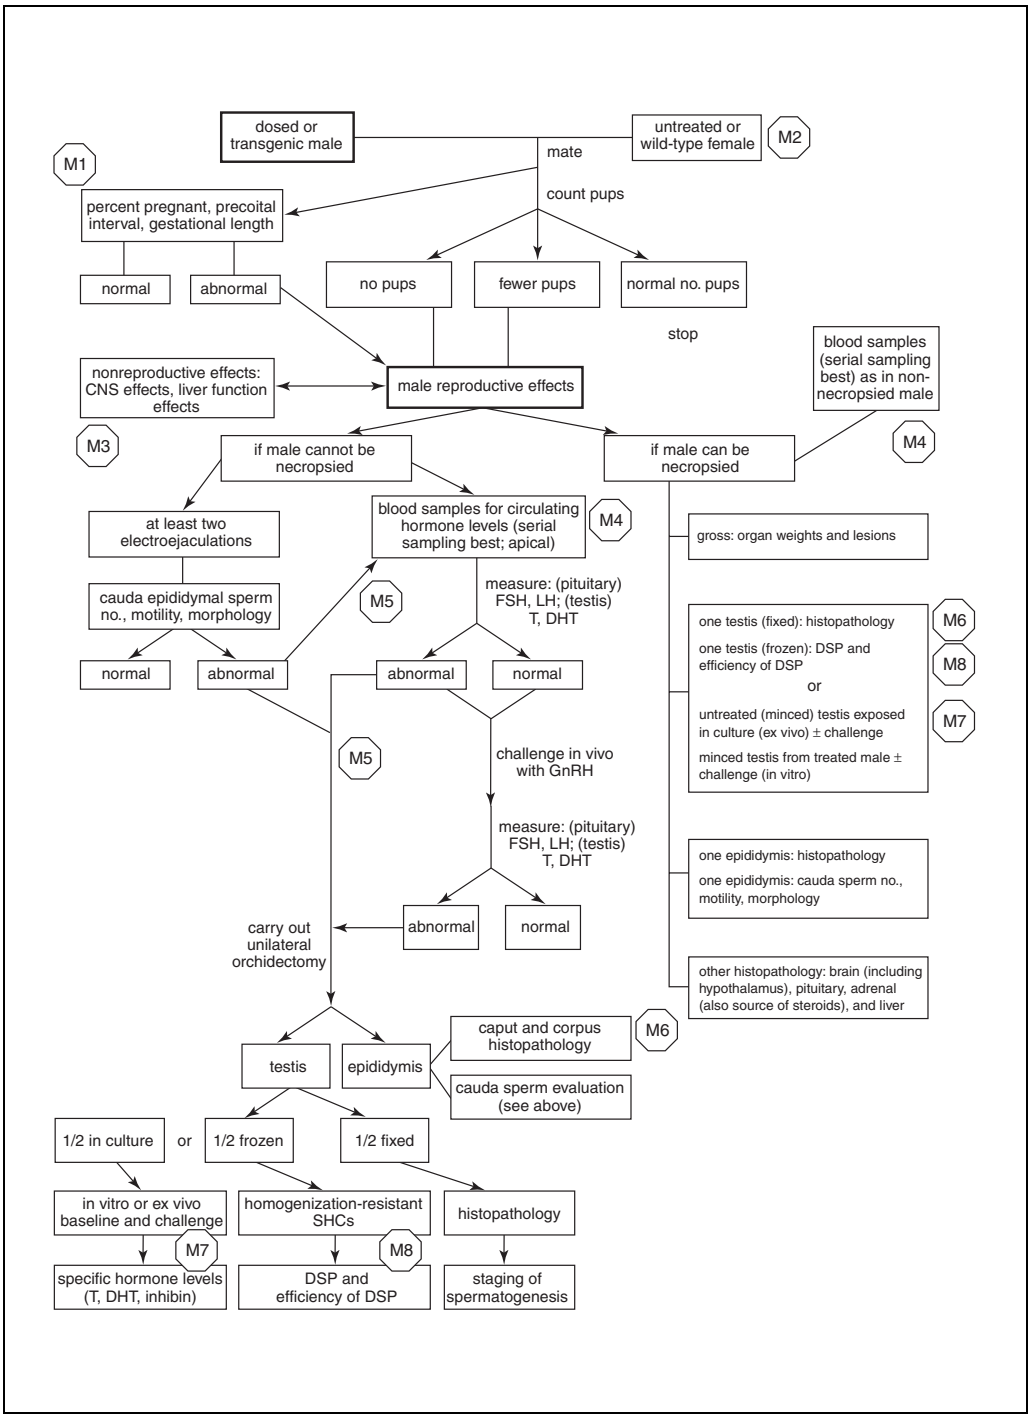
There are two general research or testing scenarios in which results may indicate or suggest possible direct or indirect male reproductive toxicity (Stoker et al., 2000 for males; Goldman et al., 2000 for females). In the first scenario, the study design is not oriented to reproductive evaluations. This would include acute studies, multiple-dose studies (such as 5 days, 14 days, or 28 days), subchronic studies (90 days), and/or chronic or carcinogenicity studies (e.g., 2-year studies in rats, 18-month studies in mice, 1-year studies in dogs). However, information collected may provide clues such as the following.

If exposure is during pre- or postnatal development, such as in the Food and Drug Administration (FDA) carcinogenicity study design where indirect exposure begins during gesta-

Figure 16.1.2 *(at right)* Detection of male reproductive toxicity when only the male is exposed or transgenic. M1 through M8 indicate male reproductive effects and experimental strategies, as follows. M1: Effects on pregnancy rate and precoital interval may be due to male reproductive dysfunction. M2: Although the assumption for an untreated (wild-type) female is that she is reproductively normal, she may not be. Evaluation of uterine implantation sites (total and resorptions) and ovarian corpora lutea (Fig. 16.1.1) may indicate that she is the cause of the reduced fertility or infertility, not the male. M3: Central nervous system (CNS) effects may be detected by use of a functional observational battery (FOB), which assesses home cage observations (e.g., convulsions, gait, tremors, abnormal motor movements), handling observations (e.g., muscle tone, ease of handling, signs of stress), open-field observations (e.g., posture, tremors, gait, convulsions, abnormal motor movements, rearing), and sensory and neuromuscular observations (e.g., approach, startle, tail pinch response, pupil size and response [Moser et al., 1991], forelimb and hindlimb grip strength, hindlimb foot splay [Meyer et al., 1979]). Effects on these parameters could interfere with mounting, intromission, and ejaculation. The double-headed arrow indicates that each effect can, in turn, affect the other. M4: Because release of male-specific hormones is pulsatile, serial blood samples will detect the normal (or abnormal) cyclical pattern. Serial samples can be obtained from multiple withdrawals from the lateral tail vein or from a cannulated animal. M5: Measure plasma or serum for follicle stimulating hormone (FSH) and luteinizing hormone (LH), originating in the pituitary in both sexes; testosterone (T) and dihydrotestosterone (DHT) from the testis; and gonadotropin-releasing hormone (GnRH), originating from the hypothalamus in both sexes. Challenge male in vivo with GnRH of hypothalamic origin and sample plasma or serum for above hormones (Fail et al. 1994). Results are interpreted as described (Fig. 16.1.1.1; F4). M6: Histopathologic evaluation of testis (and epididymis) should be performed after Bouin's or formalin fixation, embedding in glycol methacrylate (GMA) plastic or paraffin, sectioning at 2 to 4 μm, and staining with periodic acid Schiff's stain/hematoxylin (PAS-H). It should include integrity of cell types in seminiferous tubules (Sertoli, spermatogenic cells) and in the interstitium between the tubules (Leydig cells); spermatogenic staging may be necessary (Russell et al., 1990). M7: Ex vivo and in vitro evaluation of minced testes in culture performed like ex vivo and in vitro ovarian culture with challenge by FSH or LH (Payne and Sha, 1993; Fig. 16.1.1). Testicular hormonal output in culture is T, DHT, and inhibin. M8: Determination of homogenization-resistant spermatid head counts (SHCs) and calculation of daily sperm production (DSP) and efficiency of DSP (e.g., Sharpe et al., 1996).

tion and lactation and then direct exposure continues following weaning for 18 to 24 months, then anogenital distance (AGD) is a significant measure on postnatal day (P) 0 (at birth) and also on P21 (at weaning) and/or in adults; endocrine-mediated changes in AGD persist to adulthood. In the author's laboratory, based on six studies from 1996 to 2001, AGD on P0 is 0.73 to 0.96 mm in females and 1.97 to 2.25 mm in males for control CD (Sprague-Dawley; SD) rats.

The retention of areolae and/or nipples in preweanling (P11 to P13) males can be determined. In the author's laboratory, areolae are present in 0% to 3.5% of control CD (SD) male rats on P12 (out of over 500 control male pups examined to date). Dr. L. Earl Gray, Jr. of the U.S. Environmental Protection Agency (EPA) reports a 0% to 5% incidence in control prepubertal Long-Evans rats (L.E. Gray, Jr., unpub. observ.). The presence of retained nipples in males is usually detected on P11 to P13 before



the hair grows in (but endocrine-mediated retained nipples persist through adulthood and can be detected on the shaved ventrum). In the author's laboratory, no retained nipples have been observed in control CD (SD) male rats on P11 to P13, based on over 500 control males examined (and over 3000 males examined in total).

Testis descent (into the scrotal sacs from the abdominal cavity through the inguinal canal and ring) is usually complete by P15 to P20 in male rats.

Acquisition of puberty, balanopreputial separation (or PPS) in male rodents, is defined as the age when the foreskin can be fully retracted from the penis. In the author's laboratory, the grand mean age at PPS for control CD (SD) rats is 41.9 days (based on fifteen studies from 1996 to 2001, with study means of 40.9 to 43.6 days).

Acquisition of puberty is defined as vaginal patency (VP) in female rodents. In the author's laboratory, the grand mean age at VP for CD (SD) rats is 31.1 days (based on fifteen studies from 1996 to 2001, with study means of 29.9 to 32.5 days).

Gross alterations in external genitalia (e.g., hypospadias, epispadias, and either unilateral or bilateral ectopic, small, or missing undescended testes) can also occur. Detection of these alterations is best done after puberty.

Postpubertal adult exposure to a xenobiotic obviously cannot interfere with normal reproductive system development perinatally or peripubertally. However, such exposure can result in toxicity to already formed organs. This toxicity may be expressed as reduced organ weights or evidence of impaired or lost function from histopathologic examination of target organs. The same consequences may occur in a transgenic male in which the apoptotic cascade is turned on inappropriately, with consequent cell death and damage to already formed organs. Damage to the adult testis from insult may be transient, with full or partial recovery, if the interstitial cells of Leydig (which produce T) are not completely lost, and if the intratubular Sertoli cells and spermatogonial cells (which divide mitotically to produce one daughter cell that goes through spermatogenesis and one daughter cell that remains a spermatogonial cell) are not completely lost.

The following endpoints are useful for monitoring effects of exposure to xenobiotics: (1) reproductive organ weights (absolute and relative to terminal body weight); (2) gross examination of reproductive organs; (3) histopathologic evaluations of reproductive organs; (4) andrologic assessments of epididymis and testis; and (5) circulating hormonal profiles for FSH, LH, prolactin (Prl), T, and DHT.

At necropsy, the following measures are suggested: (1) gross alterations in reproductive and associated organs; (2) organ weights for testes, epididymides, seminal vesicles, coagulating glands, prostate (whole and/or ventral and dorsolateral lobes), preputial glands, Cowper's glands, LABC complex, and glans penis (preferably absolute and relative weights, the better to correct for changes in body weights); and (3) histopathology of the above organs plus pituitary (especially anterior lobe), brain (especially hypothalamus and SDN-POA), adrenal gland (especially cortex), and liver (for possible effects on reproductive development, structure, and function).

In the second scenario, mating is part of the study design. This could include multigeneration studies (EPA, 1996, 1997, 1998a), the National Toxicology Program (NTP) reproductive assessment by continuous breeding (RACB; Reel et al., 1985; Chapin et al., 1997), the NTP 35-day assay (Kaiser et al., 1996, 1997, 1998; L.B. Kaiser, G.W. Wolfe, L. Lanning, R.E. Chapin, G. Klinefelter, and E.S. Hunt, unpub. observ.; and see Internet Resources), FDA Segment I and III studies (FDA, 1982, 1993, 2000), Organization for Economic and Cooperative Development 421 (OECD, 1995) and 422 (OECD, 1996) studies, and dominant lethal studies (Green et al., 1976, 1985; Ehling et al., 1978; EPA, 1998b). This scenario would also include transgenic males being bred to generate a colony of such animals. However, rodents are robust reproducers with excess sperm capacity and will reproduce normally when significant portions (up to ~80%) of the testes are damaged. Therefore, selection of in vivo parameters to be evaluated from animals in either scenario is critical to determine if there is potential reproductive toxicity. Obviously, histopathology and other postnecropsy assessments are definitive, but they require the demise of the study animals.

Assume in the breeding component of a rat study (the second scenario discussed above) that there is evidence of reduced fertility and/or fecundity (the former term relating to whether or not the female becomes pregnant, and the latter term relating to litter size and/or number of litters if there is continued or multiple periods of cohabitation, such as the NTP RACB protocol). If both sexes are exposed (Fig. 16.1.1), the effect from exposure could be in

either or both sexes. If only one sex is exposed (Fig. 16.1.2), the effect(s) from exposure must reside in the exposed sex.

If the female is expendable and was not exposed, we can assume (or evaluate) that she was cycling normally, had ovulated the appropriate number of eggs, and was appropriately receptive to the male. Female rats will continue to cycle in the absence of a male. Female mice will become anestrus in the absence of a male but can be induced to begin cycling if a male is maintained nearby or if the female is housed with dirty cage litter from a male. (Estrous cyclicity is obviously induced by a pheromone in the urine; Whitten, 1956.) Rabbit females do not ovulate until after copulation.

To assess reproductive toxicity, one must determine: (1) whether the male adequately stimulated the female and achieved intromission; (2) whether the male had motile, normal, capacitated sperm that reached the upper oviducts; (3) whether the sperm fertilized the ovulated eggs; (4) whether the zygote was able to implant in the uterine lining; and (5) whether the conceptus was able to develop normally to term (again, assume or confirm that the exposed female has a normal hormonal milieu and hospitable uterus). Male rats with very low epididymal sperm motility and progressive motility (defined as the percentage of motile sperm that move a predetermined linear distance over a predetermined time) and a high incidence of abnormal sperm can typically sire normal litters (Tyl et al., 1999, 2002; Table 16.2.3).

If the female was exposed, the same questions are relevant, in addition to the following questions: (1) was she cycling normally? (2) were her hormone levels normal? and (3) what was the incidence of preimplantation and/or postimplantation loss? These parameters should be normal in an unexposed female; historical control data are very important.

Evaluations of the female are listed below. They may be appropriate for both unexposed and exposed females.

1. Estrous cyclicity, its presence, duration, and normalcy, which requires examination for ≥14 days (21 days is best), should be analyzed.

2. Blood samples taken from the lateral tail vein should be analyzed for 17β-estradiol (E_2), progesterone (P), Prl, FSH, LH, and GnRH levels to assess the hormonal environment.

3. At necropsy the stage of estrus should be determined, as this information may be very useful to correlate with the appearance of the uterus.

4. If the necropsy occurs within 4 days of parturition (delivery of the litter), ovarian corpora lutea should be counted as a measure of the number of eggs ovulated in the cycle of interest. The corpora lutea involute after delivery. By P21 (when rat and mouse litters are usually weaned), the corpora lutea have fully involuted and regressed to corpora albicans, which are essentially indistinguishable from corpora albicans from previous estrous cycles.

5. Uterine nidation scars and sites of conceptual implantation and placental attachment can be counted at least out to 41 days postparturition and probably longer (R.W. Tyl, unpub. observ.). These scars are visible in the fresh tissue dissection if the conceptuses went to term.

6. If one or more conceptuses died in utero, then depending on the timing of demise, resorption sites (early, middle, or late) and dead fetuses should be visible in fresh uterine tissue. If the demise was early in gestation, the resorption site(s) may not be visible without staining. The fresh uterus (intact for rodents, longitudinally dissected for rabbits), when added to 10% ammonium or sodium sulfide, will exhibit blue-black deposits of elemental sulfur at the implantation and early resorption sites (within 10 to 15 min at room temperature for rodents; after overnight exposure at room temperature for rabbits). These can readily be counted and will remain visible for at least a week (Salewski, 1964). Incubation in the sulfide renders the tissue unsuitable for any subsequent biochemical or histological assessment. The formalin-fixed (buffered neutral 10% formalin) uterus, exposed to potassium ferricyanide (R.W. Tyl, unpub. observ. since 1988), will exhibit deposits of elemental iron at the implantation and early resorption sites. After staining and counting of the sites, the tissue preparation can be cleared (i.e., the stain washed out) with water rinses, and the tissue replaced in fixative. This staining procedure does not interfere with subsequent histologic assessments. Some laboratories compress the fresh uterine horns between glass or Plexiglas plates to discern early resorptions and total implantation sites. Dey (1989) reported in an abstract that he could intravenously inject maternal mice on gestational day (gd) 5 with a dye and visualize very early uterine implantation sites (the mouse conceptuses implant on gd 4 to 5; obviously, this method terminates the mouse as well as the pregnancy). These techniques can also be used when there is an apparent one-horn pregnancy or an apparent nonpregnant uterus.

The female maternal endpoints are as follows:

1. The number (or percent) of sperm-positive or copulation plug–positive females (based on the number paired).
2. The number (or percent) of pregnant females, based on the number paired and the number of sperm- or plug-positive females.
3. The number of ovarian corpora lutea per dam.
4. The number of total uterine implantations per dam.
5. The percent preimplantation loss (IL_{pre}) per litter:

$$IL_{pre} = (CL - I)/CL \times 100$$

where CL is the number of corpora lutea and *I* is the number of total implantations.

6. The number (or percent) of early (by staining or placenta only), middle (in the author's laboratory, placenta plus some fetal tissue), and late (in the author's laboratory, placenta plus fetus with limb buds) resorptions per litter.
7. The number (or percent) of dead fetuses (in the author's laboratory, above a certain fetal body weight with discernible digits) per litter.
8. The number (or percent) nonlive (resorptions plus dead fetuses) per litter.
9. The percent postimplantation loss (IL_{post}) per litter:

$$IL_{post} = (I - L)/I \times 100$$

where L is the number of live pups at term.

10. The percent prenatal loss (PL), which is the equivalent of IL_{pre} plus IL_{post}, or:

$$PL = (CL - L)/CL \times 100$$

11. The number of ovarian primordial follicles per female (which requires ovarian serial or step sections).
12. Organ weights: ovaries, uterus, pituitary, other (e.g., liver, adrenals, kidneys, spleen, brain).

INTERPRETATION OF RESULTS

In unexposed (or wild-type) females, the number of corpora lutea should be normal because ovulation is under the female rat's control. If preimplantation loss and/or postimplantation loss is increased or litter size is reduced (with or without increased prenatal loss), the male's sperm count, motility, and/or morphology may be affected (in such a way that fertility is impaired), and/or the sperm may bear induced mutation(s) that are incompatible with preimplantation or postimplantation survival (i.e., dominant lethal). Other direct or indirect toxicity to the male reproductive behavior, structures, and/or functions, including sperm, cannot be ruled out from this evaluation (see Male Endpoints).

In exposed (or transgenic) females, the number of ovarian corpora lutea may be affected if the test material affected the HPG axis, and the appropriate products from this neuroendocrine gland complex were not released, such as gonadotrophic releasing hormones (GnRH from the hypothalamus); FSH and LH from the anterior lobe of the pituitary; and E2, P, and Prl from the ovaries. Alternatively, there may be direct effects on the ovary.

If the number of corpora lutea is normal but fewer conceptuses implanted, preimplantation loss would be increased. This would also result in fewer total and live pups per litter. If preimplantation loss is increased, there may be something wrong with the eggs per se (if exposure to the test material occurred for this female while she was in utero and producing all the primary oocytes she will ever have or if the test material is toxic to the oocytes). Damage to the zygote (e.g., mutagenicity, clastogenicity or breakage in chromosomes) or to the male's sperm (that fertilized the egg) may also result in increased preimplantation loss.

Effects on the uterus or its hormonal controls, especially those that prepare the uterine lining for implantation, could also result in increased preimplantation loss. Partial litter losses (a reduced number of normal pups or fetuses in the absence of increased resorptions and/or dead fetuses) may be due to fewer eggs ovulated (and thus a reduced number of corpora lutea) and not intrauterine demise. If the study design precludes examining the dams for corpora lutea at parturition (i.e., a multigenerational reproductive toxicity study where the dams must maintain their litters until weaning on P21), and examination can only be done on P21, then the corpora lutea will have involuted into corpora albicans. These corpora albicans are indistinguishable from corpora albicans of previous estrous cycles, and one cannot ascertain whether there were any effects on the number of eggs ovulated and, therefore, on preimplantation loss.

If the corpora lutea count is normal and preimplantation loss is normal, but postimplantation loss is increased, then the interpretation depends on whether there was a full litter loss

or partial litter loss. Most researchers in this area interpret full litter losses as due to the compromised status of the dam (e.g., Narotsky et al., 1993; Bielmeier et al., 2001), such as hormonal imbalances (so that the uterine lining is not adequately maintained by the corpora lutea early in the pregnancy and/or by the placentas later) or an inhospitable uterus. The latter may result from an inappropriate release of oxytocin from the posterior pituitary or alterations in oxytocin receptors in the uterus, which would result in inappropriate contractions and would expel the conceptus. Incompetent cervix, in humans at least, also leads to premature delivery. Whereas the dogma is that rats do not abort, this author has observed multigestational abortions in rats twice in her 40 years in the laboratory. If there are normal corpora lutea and normal preimplantation loss but increased postimplantation loss, this could also lead to fewer live pups or fetuses (i.e., partial litter loss). This last observation could be due to an induction of malformations in the offspring or genetic alterations (mutagenesis, clastogenesis, altered genetic regulation) in the gametes or offspring that are incompatible with postimplantation prenatal survival. This is the outcome observed in a dominant lethal assay with a positive test material: increased postimplantation and possibly preimplantation loss.

The dominant lethal assay, as currently performed, is designed to evaluate germinal cell damage in male rodents (rats or mice), including effects on prenatal viability of offspring after exposure to a test agent (by the appropriate route of administration after one exposure or multiple or continuous exposures) by mating the exposed males to unexposed females. The males may be specifically obtained and exposed for this assay, or they may be part of a long-term study such as a 90-day or 2-year bioassay, or a multigeneration study. This dominant lethal breeding procedure may be done on a one male:one female or one male:two females (concurrently) basis until vaginal sperm are found or a predetermined period of time has elapsed, whichever comes first. Alternatively, the breeding may be done by pairing the male to one or more females consecutively for a number of weeks (usually the female or females are changed weekly). The females may be monitored for a period of time prior to breeding to ensure estrous cyclicity so that receptive females are provided to the males. Successfully bred females are sacrificed in midpregnancy (usually gd 13 to 15 in either rats or mice), and the following reproductive parameters are examined for each female: the number of ovarian corpora lutea (a measure of the number of eggs ovulated), the number of total uterine implantation sites (a measure of the number of fertilized eggs or zygotes implanted), and the number of live and nonlive conceptuses (a measure of postimplantation survival and loss). The extent of pre- and postimplantation loss can then be assessed.

The rationale for the assay is as follows: a dominant lethal mutation in a germ cell is one that does not cause dysfunction of the gamete (so that fertilization can occur) but that is lethal to the fertilized egg (prior to implantation) or developing embryo or fetus (after implantation). Dominant lethal mutations are generally accepted to be the result of chromosomal aberrations—structural breaks, rearrangements (clastogenic effects), and/or numerical changes (aneuploidy)—but gene mutations and toxic effects cannot be excluded. If a dominant lethal mutation is induced by treatment in the male and the male is mated to an unexposed female, the presence of the genetic lesion will be manifested as an increase in prenatal deaths. If the male is exposed acutely (for 1 to 5 days) and then mated consecutively to unexposed females for 8 to 10 weeks (rats) or 5 to 8 weeks (mice), and an effect is observed, then the stage of the spermatogenic cycle that was affected can be identified by determining what stage the sperm were in when the lesion was induced. For example, if the effect is observed in the first week of breeding, the target stage is epididymal sperm; if the effect is observed after the fifth week of breeding (in mice), then the target stage (the stage the sperm were in when the animal was last exposed) is spermatogonial cells.

The data reported may include the following:

1. The number of pregnant females per number of females mated (expressed as a ratio and/or percentage).
2. The number of fertile males per number of males mated (expressed as a ratio and/or percentage).
3. The number of ovarian corpora lutea per pregnant female.
4. Mean number of total uterine implantations (live plus dead or resorbed) per pregnant female.
5. Mean number of live implantations per pregnant female.
6. Mean number of dead implantations (early and late, includes resorptions and dead fetuses if applicable).

7. Dead implantations per total implantations (expressed as mean and total per group).

8. Percent preimplantation loss, calculated as described (see In Vivo Models) using totals per group.

9. Percent postimplantation loss, calculated as described (see In Vivo Models) using totals per group.

10. Frequency of dominant lethal factors, F_L, calculated as a percentage:

$$F_L = (I_T / I_C) \times 100$$

where I_T is the number of live implantations per female of the test group and I_C is the number of live implantations per female of the control group (Green et al., 1976, 1985; Ehling et al., 1978; EPA, 1998b).

Increased postimplantation loss may be due to a localized uterine problem, so that the losses are clustered at the ovarian and cervical ends of the uterine horns. This distribution of effects may be due to blood flow differences to specific conceptuses by uterine location, as spontaneous resorptions in rats and mice also occur preferentially at the ovarian and cervical ends of the horns.

Counting the follicles at the various stages of oogenesis in serial or step sections of the maternal ovaries will provide information on whether there is a full complement of primordial, primary, small preantral, large preantral, and antral (mature, Graafian) follicles in the ovary. One might see fewer primordial follicles if exposure occurred during the dam's own in utero development or if there was specific ovarian toxicity. Conversely, increased numbers of primordial follicles (and fewer later stage follicles) may be seen if the appropriate hormonal triggers are not functioning to cause normal cyclical waves of initiation of follicular development and atresia during her postpuberty estrous cycles.

MALE ENDPOINTS

A number of measures can be made on the living male animal, including: (1) an external examination of the urogenital region; (2) the number (or percent) of successful copulations (i.e., sperm-positive females); (3) the number (or percent) of successful breeders (the number of pregnant females, based on the number paired and the number of sperm- or plug-positive females); and (4) litter size (total, live, dead, and resorbed).

Sometimes the male is not expendable and is exposed. The male may be required for subsequent matings (e.g., he is an expensive, important, transgenic knockout animal; he carries an important mutation; it is important that his genotype continue). In this case, breeding data can be collected. Ejaculated sperm samples can also be obtained from these precious males by using an artificial vagina and a tubally-ligated teaser female in rabbits or electroejaculation (in rats it can be used only for a limited number of times, but it is very useful for repeated sperm sampling in rabbits, dogs, and other species). One could also surgically remove one testis and epididymis for the andrological assessments listed below during necropsy. The male will still be reproductively functional and fertile (if he was initially). One or more blood samples (e.g., from the lateral tail vein) could be taken for determination of circulating levels of GnRH, FSH, LH, T, DHT, and other hormones.

At necropsy, the following additional information is available.

Organ Weights and Histopathology

The sizes and weights of items one through eight, below, are T-dependent.

1. Testis (or testes).
2. Epididymis (or epididymides).
3. Seminal vesicles and their contents with coagulating glands and their contents (or separately).
4. Prostate (intact or separated into ventral and dorsolateral lobes).
5. Preputial glands.
6. Cowper's glands.
7. LABC complex
8. Glans penis.
9. Other organs, such as liver, kidneys, adrenals, spleen, brain.

Epididymal Andrology

1. Epididymal sperm (usually from the cauda epididymis) data: number (per cauda and per gram cauda); motility (the percentage of sperm that move relative to the total number of sperm present in the field), which is typically 85% to 95%; and progressive motility, which is typically 65% to 75% (Seed et al., 1996; ESHRE, 1998; Tyl et al., 2002).

2. Epididymal sperm morphology, which is currently almost always analyzed manually (Seed et al., 1996). Hamilton Thorne Biosciences, however, has developed a software module for sperm morphology in the rat using the angle of the arc between the tip of the acrosomal cap on the head to the mid-piece; thus historical control data on incidences of

abnormal sperm from manual examination, which ranges from ~1.5% to 3.5% in CD (SD) rats in the author's laboratory, will change if (or when) the automated module is used because the parameters evaluated are different.

3. Epididymal transit time (see below).

4. Blood sample(s) for GnRH, FSH, LH, circulating T, and other hormones.

Testicular Andrology

For these analyses, one testis is frozen and one is processed for histopathology (as discussed in the following section).

1. Intratesticular T levels.

2. Homogenization-resistant spermatid head counts (SHCs; see discussion of SHC below).

3. Daily sperm production per testis (DSP; see below).

4. Efficiency of DSP per gram testis (see below).

Current governmental test guidelines (EPA, 1996, 1997, 1998a) for assessment of reproductive toxicity in animal models require, among other parameters, the measurement of epididymal sperm numbers and testicular homogenization-resistant SHCs on parental males at necropsy. These parameters provide information on the integrity of the spermatogenesis process and, along with weights and histopathology of the testis, epididymis, and accessory sex organs (e.g., preputial glands, seminal vesicles, coagulating glands, prostate glands), provide a sensitive and relatively comprehensive assessment of the structural and functional state of the male reproductive system. Calculation of DSP (i.e., a measure of testicular output) and of efficiency of DSP (i.e., a measure of testicular output per gram of testis) can provide additional information to increase the sensitivity of reproductive assessment in laboratory models such as rats (Robb et al., 1978) and mice (Joyce et al., 1993), for extrapolation to human risk assessment, as well as to other mammals and non-mammalian populations (i.e., wildlife) potentially at risk from exposures to environmental contaminants.

Daily sperm production (DSP)

At necropsy, one testis from each male is weighed and frozen; the testis is subsequently thawed and homogenized. Certain specific stages (and steps) of spermatids formed during the process of spermatogenesis (from spermatogonia cells to spermatozoa) survive the homogenization step, and their nuclei are counted to provide the number of testicular homogenization-resistant spermatid heads (i.e., a SHC). The number of testicular homogenization-resistant spermatid heads in the testis is then divided by the duration (in days) during the spermatogenic cycle that the developing spermatids are in the homogenization-resistant stages, to obtain the DSP in millions of sperm produced per day.

For mice, the homogenization-resistant stages are II to VIII, steps 14 to 16, and the duration is 4.84 days (Joyce et al., 1993; vom Saal et al., 1998). For rats, the homogenization-resistant stages are VI to VIII, steps 18 and 19, and the duration is 4.61 days (Leblond and Clermont, 1952; Robb et al., 1978; Sharpe et al., 1996).

A sample calculation for a rat with a homogenization-resistant stage duration of 4.61 and a SHC per testis of 221.93×10^6 is as follows:

$$\text{DSP} = \frac{\text{SHC per testis}}{\text{homogenization-resistant duration}}$$

Therefore,

$$\text{DSP} = \frac{221.93 \times 10^6}{4.61 \text{ days}}$$

$$= 48.141 \times 10^6 \text{ sperm/testis/day}$$

Efficiency of DSP

Calculation of the efficiency of DSP requires the weight of the testis in grams as well as the calculation of the DSP. The DSP per testis is divided by the weight of the testis in grams to obtain the efficiency of DSP as millions of sperm per day per gram testis.

A sample calculation for a rat with a testis weight of 1.9293 g and a SHC per testis of 221.93×10^6 (i.e., the same DSP as calculated above) is as follows:

Efficiency of DSP = DSP/testis weight

Therefore,

$$\text{Efficiency of DSP} = \frac{48.141 \times 10^6 \text{ sperm/testis/day}}{1.9293 \text{ g}}$$

$$= 24.953 \times 10^6 \text{ sperm/g testis}$$

These calculations are made per animal and averaged within groups to obtain a mean ± SD or SE for each group. The means can then be statistically analyzed to evaluate whether there is a significant difference between groups. (Alternatively, these calculations can be made from group means for a relatively crude com-

parison.) Scientific judgment and the weight of the evidence (i.e., other information such as mating, fecundity, and fertility evaluations; histopathology of testes and other reproductive organs; and epididymal sperm number, motility, and morphology) will then be used to determine whether there is an effect of the test material on male reproductive function.

DSP may also be used to calculate epididymal transit time, the time it takes sperm to travel from the caput (head), through the corpus (body), and into the cauda (tail) of the epididymis. Sperm are modified during their transit through epididymis, becoming prepared for motility once ejaculated and mixed with accessory sex organ fluids and the fluids from the female reproductive tract; sperm sampled from the cauda epididymis are also motile. The typical epididymal transit time in rats is 1 to 2 weeks (Miller, 1998), but it can be accelerated (i.e., reduced) in response to estrogenic compounds or slowed (i.e., increased) in response to agents affecting smooth muscle motility in the absence (or presence) of any effects on DSP. The determination is as follows:

1. The testicular homogenization-resistant SHC is measured, and the DSP is calculated (see above).
2. The total number of epididymal sperm (from caput, corpus, and cauda) is determined. If cauda transit time is the parameter of interest, only the total number of cauda sperm is used.
3. The ratio of total epididymal sperm to testicular DSP will determine the number of days of sperm production in the testis that is required to result in the total epididymal sperm content and, therefore, the number of days it will take for the sperm to move through the epididymis (i.e., epididymal transit time). As an example, in the rat, DSP is typically 50×10^6 sperm/day, and the total number of epididymal sperm is typically (650×10^6 sperm). Therefore, transit time would be equal to (650×10^6 sperm)/(50×10^6 sperm/day) or 13.0 days.

Histopathology

The spermatogenic index, a semiquantitative estimate of the sperm-producing ability of the testes, is based on the types and percentage of germ cells in each stage present in the seminiferous epithelium. Testicular sections (preferably from fixed and glycol methacrylate-embedded tissue) are rated on a standardized scale (0 to 6), based upon the histologic appearance of the spermatogenic cells in the seminiferous tubules throughout one or more cross-sections of the rodent testis. Evaluation of the seminiferous tubules to assign the rating includes an assessment of the types of cells present (and the general impression that they are present in normal ratios) and quantitation of the number of late spermatids (steps 12 to 16 for mice and 15 to 19 for rats) present in the seminiferous tubules.

The numerical index and the criteria for rating are as follows: 0, no cells or only Sertoli cells present; 1, Sertoli and spermatogonia present; 2, spermatogonia and spermatocytes present; 3, spermatogonia, spermatocytes, and round early (i.e., steps 1 to 9 for mice and rats) spermatids present in normal numbers with fewer than 5 late spermatids per tubule; 4, spermatogonia, spermatocytes, and early spermatids with 5 to 25 late spermatids present per tubule; 5, all cell types present and 50 to 75 late spermatids present per tubule; or 6, all cell types present and more than 100 late spermatids present per tubule.

Several underlying assumptions are implicit when evaluating the testis using the spermatogenic index:

1. All stages of the seminiferous epithelium are affected in a similar manner by the parameter being studied.
2. Late spermatid counts are made in stage VII and VIII tubules where they are presented near the lumen.
3. Some stages of spermatogenesis normally have fewer cell types present, and ratios of cell types will vary.
4. Even normal testes may have some atrophied tubules.
5. At least 200 tubules are observed.
6. If the first assumption is violated (based on microscopic examination of testicular sections), a composite spermatogenic index must be estimated for each animal.

The spermatogenic index was first developed and used by Dr. Patricia A. Fail (née Noden) in the early 1980s (Whitsett et al., 1984, in deer mice; Fail et al., 1989, 1991, in Swiss mice; it has also been used in rats, P.A. Fail, unpub. observ.).

If spermatogenesis is evaluated in newly sexually mature males, the entire epididymis should be used for epididymal sperm parameters. Prior to P70 in rats (and P50 in mice), the cauda epididymis will contain little or no sperm from the first wave of spermatogenesis, which has just occurred in the testis, because the spermatozoa have not yet completed the transit from the testis through the epididymis to the cauda and have not yet accumulated in the cauda. Evaluation of sperm from the caput and

corpus of the epididymis (or the entire epididymis) is recommended in these young males. Also, if the male has been used for breeding, at least 4 to 7 days should transpire after cohabitation prior to necropsy and andrological assessment. If the assessment is performed too soon after copulation, the epididymal counts will be lower in males that were sexually active (and will skew the data).

Guidelines for Mating Rodents

Proper animal husbandry is essential for studies of male reproductive toxicology (*UNIT 16.1*), as it is for female toxicology and reproductive toxicology in general. This unit contains protocols for establishing estrous cyclicity (see Basic Protocol 1); mating (see Basic Protocol 2); and gestation, lactation, and postlactation (see Basic Protocol 3) in rats and mice. For the uninitiated, the following are recommendations gleaned from over 40 years of experience.

NOTE: All protocols using live animals must first be reviewed and approved by an Institutional Animal Care and Use Committee (IACUC) and must conform to governmental regulations regarding the care and use of animals.

DETERMINATION OF ESTROUS CYCLICITY IN RODENTS

BASIC PROTOCOL 1

It is necessary to establish that the female rat or mouse is cycling to accurately set up matings and to verify that the female is reproductively capable. The procedure is the same for both rat and mouse. This protocol is based on Haas (1981) as modified by Ms. T.-Y. Chang, HT-ASCP, histotechnologist in the author's research center.

Materials

Female rat or mouse
Saline: 0.9% (w/v) NaCl, sterile (*APPENDIX 2A*)
Spray-Cyte fixative (Clay Adam)
50%, 70%, 80%, 95%, and 100% (v/v) ethanol
1% (w/v) toluidine blue/1% (w/v) sodium borate
Xylene
Permount (Fisher)

Fire-polished eye dropper
Glass microscope slide prelabeled with a six-cell grid using a permanent marker (e.g., Securline Marker II/Superfrost; Precision Dynamics)
Coverslips

CAUTION: Xylene is toxic and should be used in a fume hood.

Collect cervical cells

1. At the same time each day (usually in the morning), for ≥14 consecutive days (a 21-day period is better), evaluate a female rat or mouse for the stage of sloughed cervical cells by gently inserting a fire-polished eyedropper containing 0.05 to 0.1 ml sterile saline into the vaginal tract.

   The eyedropper is fire-polished to ensure that the tip is absolutely smooth.

2. Instill (express) the saline into the tract and then draw it back up into the eyedropper.

3. Express the fluid in the eyedropper onto a prelabeled glass microscope slide and air dry. Use one slide per female per 6-day sampling period.

   The slide should be premarked with a numbered six-box grid using a permanent marker. Do not use a nonpermanent marker (e.g., Sharpie), as it will wash off during staining.

4. When the last vaginal smear for that female is placed on the slide, air dry for ≥1 day.

5. Spray the slide with Spray-Cyte fixative and air dry 1 additional day.

Contributed by Rochelle W. Tyl
Current Protocols in Toxicology (2002) 16.2.1-16.2.11

Stain and mount cells

6. Rehydrate the slide through an ethanol series consisting of 30-sec steps in 95%, 95%, 95%, 80%, 70%, and 50% ethanol.

   These instructions are for a Linistain GLX Stainer (Thermo Shandon). The staining can also be carried out manually.

7. Put the slide through running water twice, for 30 sec each.
8. Stain the slide with 1% toluidine blue/1% sodium borate for two 30-sec periods.
9. Rehydrate the slide with five 30-sec washes with running water.
10. Dry the slide for two 30-sec periods.

    If the staining procedure is done manually, drying (here and in step 12) is unnecessary.

11. Dehydrate the slide through an ethanol series consisting of 30-sec steps in 95%, 100%, and 100% ethanol.
12. Thoroughly dry slide with eight 30-sec drying periods.
13. Place slide in xylene (to clear the cells) until it is coverslipped.

    Slides should be coverslipped as soon as the batch of slides is processed; they should not sit in xylene.

14. Mount the slide with a coverslip using Permount.

Analyze cyclicity

15. Examine each slide under a microscope for the presence and duration of the stages of the cycle:

    a. Estrus: nucleated, cornified cells along with mostly nonnucleated squamous epithelial cells; duration ~12 hr in rodents.
    b. Metestrus: equal number of leukocytes and large, folded epithelial cells with translucent nuclei; duration ~21 hr.
    c. Diestrus: predominantly leukocytes and cell debris; duration ~57 hr.
    d. Proestrus: largely nucleated and some cornified epithelial cells; duration ~12 hr.

    The leukocyte cytoplasmic granules will stain red to purple, and the nuclei will stain blue.

    Some specialists do not identify metestrus at all, so only three stages are tracked.

16. Once the stages have been determined and recorded, examine the data to determine if the female is cycling. Consider the following questions:

    a. If she is not cycling, is she exhibiting persistent estrus or diestrus (most common)?
    b. If she is cycling, is it a normal cycle?
    c. If it is an abnormal cycle, which is defined as prolongation of specific stage or stages beyond normal as set by the laboratory, is estrus, metestrus, diestrus, or proestrus prolonged?

    Laboratory conventions should be set up and followed for such situations as mixed stages, the absence of any cells, or the inability to determine the stage.

17. Calculate the duration of the cycle using a stage that is easy to detect (e.g., estrus) and/or that is observed to periodically repeat.

    For example, the cycle length may be calculated from the sum of the duration of all cycles, beginning with the day after the sentinel stage to the first day of the next sentinel stage,

divided by the number of cycles, for each female. Although estrus is the most easily recognized, it is of very brief duration and may have occurred between the once-daily smears. It is safe to assume that it did occur if proestrus and metestrus are observed sequentially, or another sentinel stage can be selected to determine cycle length.

Charles River Laboratories will provide CD (Sprague-Dawley; SD) female rats with guaranteed 4- or 5-day cycles, but because shipment will most likely shift the cycle 1 day, it is strongly recommended to confirm cyclicity.

RODENT MATING

BASIC PROTOCOL 2

For studies of male or female reproductive toxicology, it is necessary to include mating of the male or female. The procedure is slightly different for rat and mouse.

Materials

Male and female mice or rats
Saline: 0.9% (w/v) NaCl, sterile (*APPENDIX 2A*), for rats only

Cages, for mating (with either a solid bottom and contact bedding or a wire bottom)
Plastic cages, for mated females (with a solid bottom and contact bedding)
Fire-polished eyedropper, for rats only
Glass microscope slides, for rats only
Microscope (with 10× and 40× eyepieces), for rats only

For mating mice:

1a. Pair one male mouse with two female mice, or preferably one male with one female. Place the female in the male's cage in the afternoon after he has been in that cage for at least a few hours.

If the male is paired with two females and inseminates both females on the same night, the second female may not be pregnant. Because a male mates numerous times with a receptive female, the successive ejaculations may exhaust the sperm reserves readily available for ejaculation, and one female may receive fewer sperm (or no sperm) relative to the other female and appear less fertile or nonpregnant.

The male should not be put in the female's cage. The animals should also not be placed in a clean cage at the same time. Placing the female in the male's cage allows him to mark his territory by appropriately placed urine deposits prior to the female's arrival.

The wire mesh bottom must be fine enough to allow the male to maintain his balance while mounting.

Female mice become acyclic (anestrus) without close proximity to a male (actually a pheromone in his urine). If necessary, estrous cyclicity can be reinstated in females by housing them near males or in cages with soiled bedding from the male cage (i.e., priming; Whitten, 1956).

Female mice exhibit 4- to 5-day estrous cycles, so one can determine the stage of the cycle for each female and only place females in proestrus or estrus with males, which should provide a high mating index. Alternatively, females can be paired with males (1:1) without checking the stage of the estrous cycle. From the latter random pairing, 20% to 25% of the females should be inseminated (based on the percentage of females in proestrus or estrus out of a 4- or 5-day cycle at any time).

2a. Check for insemination, as indicated by the presence of a copulation plug in the vaginal tract of the female, on the following morning.

Female rodents usually exhibit the luteinizing hormone (LH) surge prior to ovulation between 1300 and 1600 hr on the afternoon of proestrus and ovulate between 0100 and 0300 hr on the following morning.

continued

To precisely identify the time of insemination, a 2-hr pairing can be set up in late afternoon, but the insemination rate (mating index) will be low.

The copulation plug is produced during ejaculation by the male, from protein secretions in the seminal fluid from the coagulating gland; the proteins form a yellow-white, waxy coagulum (presumably to retain the seminal fluid, including the sperm, in the female's reproductive tract). The plug can usually be detected by external examination (with the female also exhibiting swollen external genitalia), but a more definitive determination (especially if the plug is not visible upon inspection) is to place the female on the top of the cage, press down gently on her lower back, lift up her hind end by her tail, and place a blunt probe in her vaginal tract (making sure to avoid hitting the pelvic girdle). The presence of the copulation plug will prevent penetration of the probe. The copulation plug will ultimately drop, shrink, and fall out (although this takes a number of hours), so females

Table 16.2.3 Historical Control Data on Selected Reproductive Parameters From Multigeneration Studies in CD (SD) Rats[a], continued

Parameter	F0	F1	F2	F3[b]
Acquisition of puberty:

[a]Data are either from eight studies (F0, F1, F2) or one study (F3). Data are presented as group means with 25 to 30 animals of each sex per group. Data are presented as control group means. Abbreviations: AGD, anogenital distance; DSP, daily sperm production; F0, parental generation (also termed P0); F1, first filial generation (offspring); F2, second filial generation; F3, third filial generation; NA, not appropriate (i.e., cannot be done given the study design); PPS, preputial separation; SHC, spermatid head count; VP, vaginal patency.

[b]F3 offspring were not mated.

[c]Defined as (number of sperm- or plug-positive females/number of paired males) × 100.

[d]Defined as (number of pregnant females/number of mated males) × 100.

[e]As defined or discussed in *UNIT 16.1*.

[f]One control male exhibited low sperm motility and a high incidence of abnormal sperm; he sired a live litter.

[g]Defined as (number of sperm- or plug-positive females/number of paired females) × 100.

[h]Defined as (number of pregnant females/number of mated females) × 100.

[i]Defined as (number of females with live litters/number of pregnant females) × 100.

[j]Data were collected from only one study.

[k]Both ovaries per female (≥10/group) are embedded in paraffin, sectioned (10 ovarian sections taken ≥100 µm apart from the inner third of each ovary), stained, and then 20 section/female are examined for the number of primordial follicles.

[l]Measured at P0.

without plugs can be evaluated for sperm in the vaginal tract (see step 2b). If the mice are housed in wire bottom cages, the copulation plug (usually multiple plugs) can be identified on the paper below the cage.

3a. On the day of insemination, house the female singly in a plastic cage with a solid bottom and contact bedding.

The usual convention is to designate the date of copulation detection as gestational day (gd) 0, although some laboratories designate it as gd 0.5 or gd 1.

Alternatively, females with the same gd 0 date (and in the same dose group) can be housed together, up to four to five females per cage. Close to term, and especially if the dam will be allowed to litter, each female should be singly housed and provided with one or more cotton squares (e.g., Nestlets; Ancare) so she can build a nest.

Table 16.2.1 provides historical control data on reproductive parameters in CD-1 (Swiss) mice; these are a sturdy outbred strain with good fertility and fecundity. Based on five recent studies, the mean estrous cycle length is 4.3 days. The mating index, fertility or pregnancy index, and gestational index were all high.

For mating rats:

1b. Place a single female rat into a male rat's cage.

Rat females do not become acyclic in the absence of a male, so priming (Whitten, 1956) is unnecessary in rats.

Female rats are also 4- to 5-day cyclers; this should be taken into consideration when setting up mating pairs.

2b. Detect insemination in the female by the presence of sperm in the vaginal tract. On the morning after pairing (or each morning thereafter if the pair has previously been sperm negative), remove the female from the cage, restrain her, and gently insert a

fire-polished eyedropper containing 0.05 to 0.1 ml sterile saline into the vaginal tract. Instill (express) the saline into the tract and withdraw fluid from the tract.

Insemination can also be detected by dropped copulation plug(s) if the mating pair is housed in wire bottom cages. In the rat female, the copulation plug dries, shrinks, and falls out of the vaginal tract quickly, so it is rarely present in the vaginal tract. Therefore, vaginal smears for presence of sperm are the only reliable method to detect insemination if the mating pair is housed in solid-bottom cages and if there is no plug in the vaginal tract. For pairs housed in wire bottom cages, the plug drops through the bottom of the wire grid to the paper-covered shelf below. It is also suggested to confirm insemination in mating pairs housed in wire bottom cages with or without dropped plugs.

3b. Place the fluid on a glass microscope slide and examine it immediately under low and then high power on a microscope equipped with 10× and 40× eyepieces to detect sperm.

Sperm in the vaginal tract are usually accompanied by swollen, blood-engorged, external labia.

There may be one or more clumps of sperm (the earlier in the morning this is done, the better), or there may be only a few sperm in the entire smear.

4b. House the inseminated female singly in a plastic cage with a solid bottom and contact bedding.

The day insemination is confirmed is designated as gd 0.

Alternatively, one to three females with the same gd 0 date (and in the same dose group) can be housed together, but if they will litter, they must be singly housed by gd 18.

No Nestlets are needed, but the cage should have a solid bottom with contact bedding so the female can make a nest.

Tables 16.2.2 and 16.2.3 provide historical control data on reproductive parameters in CD (SD) rats from segment I, II, and III studies (Table 16.2.2) and from multigeneration reproductive toxicity studies (Table 16.2.3). The CD (SD) rat is a robust outbred strain with excellent fertility and fecundity. As with the CD-1 mouse, the CD (SD) rat mating, fertility, pregnancy, and gestational indices are all very high (slightly lower in multigenerational studies).

BASIC PROTOCOL 3

GESTATION AND LACTATION IN RATS AND MICE

For studies that include the analysis of reproductive outcomes, pregnant animals are allowed to complete gestation and may raise the pups to maturity. Mated females are housed appropriately, with a single animal per cage as they reach term. The author strongly suggests that dams with litters not be housed on metal floored caging (e.g., metal plates placed on cages with wire grid flooring), even with bedding, because dams will mound bedding around the pups to create a nest. The pups will therefore be lying directly on the metal floor (which acts as a heat sink) and become hypothermic. Pup mortality will increase, as will maternal infanticide and ingestion of offspring. Obviously, smaller, weaker pups will be at greater risk for morbidity or mortality. This may confound any treatment- or gene-related perinatal losses.

Neonatal and/or postnatal observations usually taken on litters include the following:

Parturition

Mice usually deliver on gd 19 ± 1, and rats usually deliver on gd 22 ± 1 (if date of copulation is designated gd 0). Unless there is a problem, the delivery usually takes a few hours. In the author's laboratory, pregnant females are examined at least twice daily,

starting 2 days before expected parturition. When the extra-pup membranes and placentas are eaten by the dam and the pups are licked clean and in a nesting pile, the litter is usually complete. Occasionally, it will appear that the litter is complete and an additional pup(s) will be present later (even the next day if the littering was completed late in the previous day). In the author's laboratory, if the litter is, in fact, complete on the following day, that day is designated postnatal day (P) 0. On the day of birth, pups are counted, sexed (by external qualitative examination of anogenital distance, unless anogenital distance is to be measured), weighed individually, and examined externally. By the following day (P1), a milk band (the visualization through the skin of the thin-walled stomach filled with milk) is present on the left-to-midline ventral abdominal area, if the dam has milk and the pup is nursing. The absence of a milk band should be noted, as well as pups cool to the touch, bluish in pallor (in which case it is likely that the ductus arteriosus, which is open between the pulmonary arch and aortic arch in utero to allow oxygenated blood from the dam to go from the heart to the systemic circulation, has not closed on schedule once the pup begins to breathe), or not in the nesting pile as evidence of impaired maternal care and/or problems with the pup(s). Typically, the greatest mortality is between P0 to P4. Count the litter daily to track any pup losses (the dam may fully or partially cannibalize dead or moribund pups, so there may be no dead pups in the cage but there may be missing pups). Pups can be identified at birth by tattooing the paws in a code within litters, but it takes a very light touch to subcutaneously inject enough dye on the dorsal surface of the foot to provide the tattoo, yet not so much that the paw swells (in which case the pup may be injured and/or the dam will chew off the paw).

Anogenital Distance

Anogenital distance (AGD) is the method to externally sex newborn rodents. It will also detect endocrine-mediated effects—the distance is under dihydroxytestosterone (DHT) control—although it is confounded by pup body weight. This measurement is from the cephalad (anterior) lip of the anus to the posterior base of the genital papilla (in the author's laboratory) for newborns, or to the base of the penis (for males) or to the caudal (posterior) lip of the open vagina (for females). The measurement on newborns can be done with an ocular reticle calibrated to a microscope stage micrometer (precision to 0.2 to 0.1 mm) or with a vernier or dial calipers (precision to 0.1 mm). For older animals, the vernier or dial calipers is strongly recommended. Newborn animals can be measured alive, but measurement of older animals (e.g., at wean or adulthood) is usually done at necropsy after terminal anesthesia. The intratechnician and intertechnician consistency of the extension of the animal on its back for measurement is critical because inconsistency will affect the distance measured. At weaning in CD (SD) rats, AGD is ~15 to 18 mm in males and 8 to 11 mm in females.

Standardization of Litters

Litters are usually standardized to eight or ten (with as equal a sex ratio as possible) on P4 by random selection procedures. The standardized litter removes the confounder of litter size (larger litters have lighter pups) and sex ratio (males are heavier than females). Pups can be individually identified within litters by tattooing the paw(s) (see discussion of parturition). The later this is done, the easier it is for the technician and the less stressful it is for the pups.

Nipple or Areolae Retention

In utero, both offspring sexes have nipple anlagen on the ventrum. In the presence of testosterone (T) or DHT in male fetuses, the anlagen regress. In the presence of an antiandrogen, the nipples and/or areolae in males are retained. In the author's laboratory,

preweanling male rats are examined on P11 to P13, when there is enough hair growth to detect areolae (roughly round areas of no hair), but not so much hair to obscure the nipples. Examination of older animals will require shaving the ventrum. Depending on the identity, potency, and dose of the antiandrogen (or in the presence of any one of a number of mutations in receptors such as androgen-insensitivity syndrome, or in enzymes such as 5-α-reductase), the male nipple count may approach or equal that of the normal female rats (usually 8 to 10).

Testis Descent

Testis descent, which occurs in the latter portion of lactation (typically P16 to P18 for rats), may be assessed in males. In the author's laboratory, males are placed in a transparent plastic cage and examined from below to detect the testes in the scrotal sacs. If the animal is held, he may retract the testis(es) into the abdominal cavity.

Weaning

CD (SD) rats are usually weaned on P21, as are CD-1 mice; Fischer 344 rats are usually weaned on P28. Weaning is accomplished by removing the dam (who is euthanized and necropsied, or mated again, depending on the researcher's intent) and counting, sexing, and individually weighing the pups. The pups are then selected for necropsy (if appropriate), for continuation to puberty or adulthood (to produce the next generation), or euthanized. Any nonselected pups are discarded (if appropriate). Selected rat pups should be individually and uniquely identified at weaning by eartag (e.g., Monel tag; National Band and Tag). Alternatively, rats may be tattooed with a unique number on the tail. For mice, in the author's laboratory, weanling mice to be eartagged may have the hole in the ear made a day or two before (because the ears are small and fragile) and the tag inserted into the prepared hole at weaning. Postweanling rats (and mice) may be housed individually or by sex by litter. If they are housed individually, the staff should check that they can reach the water and food sources. The pups can be placed against the sipper tube of the water bottle or the nipple of the automatic watering system to make sure they can find it and use it. If male rodents are housed together, especially mice, there is a dominance hierarchy established; the dominant male may barber the subservient males (i.e., remove the hair until the skin looks shaved). The dominant male may also exhibit heavier testes and sex accessory glands as an adult than the subservient males in the same cage.

Acquisition of Puberty

See *UNIT 16.1* for discussion. Vaginal patency (VP) in females and preputial separation (PPS) in males are the indicators of acquisition of puberty in rats. (VP and PPS are not so tightly correlated with onset of puberty in mice.) Starting on P25 in CD (SD) rats, on P35 in F344 rats, and on P20 in CD-1 mice (or earlier if a strong estrogen is involved or suspected), and continuing once daily until acquisition of VP, each offspring female is examined as follows. The pup's head and shoulders are restrained (with one hand), and the tail is raised with the other hand, exposing the urogenital area. The vaginal orifice is below the anal opening. Prior to VP, the membrane over the vagina thins and appears puckered; at VP, the opening appears as a pinhole. It may be necessary to gently spread the area with the fingers to see the vagina more clearly. Alternatively, the female may be held by the tail and allowed to grasp a wire cage lid. The tail is then lifted, as above, to expose the urogenital area. Starting on P35 in CD (SD) rats, on P40 in F344 rats, and on P25 in CD-1 mice, and continuing once daily until acquisition of PPS, each offspring male is examined as follows. The pup is restrained by one hand while the other hand gently attempts to retract the prepuce. PPS is acquired when the prepuce can be fully retracted to expose the glans penis, and the foreskin can be cuffed around the base of the

penis. The date, age in days, and body weight at acquisition are recorded for both sexes at acquisition. In females, age at first estrus or onset of estrous cyclicity is another commonly monitored parameter. This is done by commencing vaginal lavage, as described in Basic Protocol 1, as soon as the vagina is patent, and examining the slides for the first indication of estrus.

Other Endpoints

Other endpoints are also to be evaluated (e.g., body weights, developmental landmarks, neurotoxicity endpoints), the identity and timing of which would depend on the study design, objectives of the study, and/or the hypothesis being tested.

Histopathology of the Male Reproductive System I: Techniques

Effective evaluation of the male reproductive system relies on adequate sampling of the various parts of the reproductive tract as well as appropriate fixation, orientation, processing, embedding, and staining of the tissues. This unit describes protocols for these various aspects of tissue preparation.

The presence or absence, as well as the anatomical arrangement, of various components of the reproductive tract varies with species. These differences must be appreciated to ensure appropriate sampling. Basic Protocol 1 and Support Protocol 1 describe the identification and dissection procedures for the reproductive organs from the rodent, dog, and primate, which are the animals most frequently used in toxicological research. Basic Protocol 1 describes the routine immersion fixation of these tissues followed by processing and embedding in paraffin wax. For a variety of reasons, the testis presents a problem for good fixation. Conventional immersion fixation in formalin generally results in poor preservation of the seminiferous tubules, and the use of an alternative fixative, such as Bouin's, is recommended in most regulatory guidelines. Although Bouin's provides good morphology suitable for detecting subtle disturbances in spermatogenesis, it suffers from a number of increasingly important safety and disposal problems and also results in significant shrinkage of the tubules. This protocol recommends the use of a novel, alcohol-based fixative (modified Davidson's fixative), which provides comparable cellular and nuclear preservation to that achieved with Bouin's but with less tubular shrinkage and none of its safety and disposal hazards.

Once the tissues are fixed, sampling of specific structures and tissue orientation are very important to ensure that critical regions of the reproductive tract are presented for examination. Support Protocol 1 provides guidance on how to trim and sample tissues from rodents, dogs, and primates.

Basic Protocol 2 describes the methodology used to obtain excellent preservation of the rodent testis by whole-body perfusion via the heart. The testes of large animals can also be fixed by perfusion, but to reduce the volume of fixative required this is best carried out by introducing the fixative into the testicular artery. Support Protocols 2 and 3 describe the processing procedures required for embedding in epoxy and glycol methacrylate resin, respectively. Perfusion fixation followed by embedding in resin is essential for proper evaluation of the testis by electron microscopy. The use of epoxy resin is necessary to maintain stability of the section under the electron beam; however, epoxy-embedded tissue can only be stained with toluidine blue for light microscopic examination. Glycol methacrylate resin is a water-soluble resin that can be used to prepare semithin (2 μm) sections that can be stained with conventional histologic stains for high-resolution light microscopy. A compromise between the convenience of immersion fixation followed by paraffin embedding and the labor-intensive perfusion fixation followed by resin embedding can be achieved by immersion fixation followed by embedding in glycol methacrylate resin.

CAUTION: Many of the chemicals used in these protocols are hazardous, including formalin, glutaraldehyde, propylene oxide, epoxy and glycol methacrylate resins, sodium cacodylate, and osmium tetroxide. Refer to material safety data sheets for appropriate handling, storage, and disposal.

NOTE: All protocols using live animals must first be reviewed and approved by an Institutional Animal Care and Use Committee (IACUC) and must conform to governmental regulations regarding the care and use of laboratory animals.

BASIC PROTOCOL 1

DISSECTION, IMMERSION FIXATION, AND PARAFFIN EMBEDDING OF MALE REPRODUCTIVE-TRACT TISSUES

This procedure is suitable for routine screening of tissues for toxicological changes. It involves dissection of the major reproductive tissues, measurement of organ weights, and immersion fixation of the testes using a special fixative (the remaining tissues can be fixed in the same fixative or in neutral buffered formalin). This is followed by careful trimming of the tissues to include specific structures and conventional processing through an ascending series of alcohols and clearing agents, followed by embedding in paraffin wax. Sections are then cut and stained with periodic acid Schiff's stain/hematoxylin (PAS-H; for testes and epididymides) and hematoxylin and eosin (for remaining tissues).

Materials

Male rodent, dog, or primate
Modified Davidson's fixative (see recipe)
10% neutral buffered formalin (~4% [w/v] formaldehyde; Sigma or standard recipe, see Bancroft et al., 1990)
Surgical instruments for dissection

Additional reagents and equipment for euthanization; dissecting the testes, epididymides, and accessory sex glands (see Support Protocol 1); dehydration, clearing, and infiltration with paraffin wax (Bancroft et al., 1990); and paraffin sectioning and staining (Bancroft et al., 1990)

1. Euthanize a male rodent, dog, or primate by an approved method.

   Some examples of euthanization methods include carbon dioxide (for rodents) and sodium pentobarbital (e.g., Sleepaway).

2. Depending on the species under investigation (Table 16.3.1), use surgical instruments to dissect out the testes, epididymides, and accessory sex glands (i.e., seminal vesicles with coagulating glands and prostate; see Support Protocol 1).

   Standard dissection guides, such as Feldman and Seeley (1988) and Evans (2000), contain detailed dissection procedures.

   It is important to minimize squeezing of the testes during handling to prevent artifactual sloughing of the germ cells from the seminiferous epithelium. When trimming the epididymis from the testes, take care not to cut the testicular capsule, which will cause extrusion of the seminiferous tubules through the cut and consequent disruption of tissue architecture.

3. Weigh each organ and record the weight to the nearest 1 mg (for rodents) or 100 mg (for dogs or primates).

   For paired organs, individual weights provide valuable information to support unilateral microscopic findings. Individual organ weights are also required where one testis and one epididymis are used for quantifying sperm parameters (Table 16.3.2).

   When weighing seminal vesicles and the prostate, it is important that the fluid be included in the weight because its volume reflects the functional activity of the glands. For some regulatory guidelines, the combined weight of seminal vesicles and prostate is recommended (Table 16.3.2). If separate weights are desired, dissect out the prostate and seminal vesicles as a unit, being careful to retain all fluids, and then separate the seminal vesicles and coagulating glands from the prostate over a weigh boat, so that any fluid leakage from the seminal vesicles is caught and included for weighing.

Table 16.3.1 Presence of Accessory Sex Glands in Common Laboratory Species

Species	Ampulla ductus deferens	Bulbourethral (Cowper's) glands	Coagulating glands	Preputial gland	Prostate	Seminal vesicles
Dog	+	–	–	–	+	–
Mouse	+	+	+	+	+	+
Primate	+	+	–	–	+[a]	+
Rabbit	+	+	–	+	+	+[b]
Rat	+	+	+	+	+	+

[a]No anterior lobe present.

[b]Present as rudimentary glandula vesicularis.

Table 16.3.2 Recommendations from Recently Revised Regulatory Guidelines for Reproductive Studies Relating to Sampling and Fixation of Male Reproductive Tissues

Guideline[a]	Tissues to be weighed	Tissues to be preserved	Tissues to be examined
OECD 416: Two-generation reproduction toxicity study (OECD, 2001)	Testes	One testis[b,c]	Testis
	Epididymides (total and cauda)	One epididymis[b]	Epididymis
	Seminal vesicles with coagulating glands and their fluids and prostate (as one unit)	Seminal vesicles	Seminal vesicles
		Coagulating glands	Coagulating glands

	Epididymides (total and cauda)	Right epididymis[b]	Epididymis
	Seminal vesicles with coagulating glands and their fluids	Seminal vesicles	Seminal vesicles
		Coagulating glands	Coagulating glands
	Prostate	Prostate	Prostate
ICH S5A and S5B: Detection of toxicity to reproduction for medicinal products (ICH, 1994, 1996[d])	None	Testes[c] and epididymides	Testes and epididymides if indicated by altered fertility indices

[a]Abbreviations: ICH, International Conference on Harmonization of Technical Requirements of Registration of Pharmaceuticals for Human Use; OECD, Organization for Economic Cooperation and Development; OPPTS, Office of Prevention, Pesticides, and Toxic Substances.

[b]Remaining testis or epididymis is retained for assessment of sperm parameters (*UNITS 16.1 & 16.2*).

[c]Preserved in Bouin's or comparable fixative.

[d]An addendum on male fertility studies.

4. Place the testes into modified Davidson's fixative for ≥48 hr at room temperature and then transfer to 10% neutral buffered formalin for storage. Place the remaining tissues into 10% neutral buffered formalin for ≥48 hr at room temperature until required for processing.

   Speed of penetration of the fixative can be improved by pricking or nicking the capsule before immersion and also by slicing the testis following several hours in fixative (see Critical Parameters and Troubleshooting, discussion of choice of fixative).

   The tissues can be stored in 10% neutral buffered formalin for up to 10 years at room temperature.

   For convenience, the epididymides and secondary sex organs can also be fixed in Davidson's fixative, but the cytological and staining characteristics are slightly inferior to those of formalins.

5. Trim the tissues according to Support Protocol 1 and process through standard histology procedures for dehydration, clearing, and infiltration with paraffin wax. Embed in paraffin wax (Table 16.3.3).

   Standard histological processing methodology can be found in Bancroft et al. (1990).

   Alternatively, for high resolution light microscopy, the tissues can be embedded in glycol methacrylate resin following immersion fixation (see Support Protocol 3).

6. Prepare sections at 5 to 6 μm.

   Standard paraffin sectioning is described in Bancroft et al. (1990).

7. Stain testes and epididymides with PAS-H stain and the remaining tissues with hematoxylin and eosin.

   Standard histological staining methodology can be found in Bancroft et al. (1990).

   PAS-H staining in the testis will stain the glycoprotein component of the spermatid acrosomic granule or acrosome cap. These are very small structures, which can be difficult to visualize if the stain is not optimal. It is important that the periodic acid and the Schiff reagent are relatively fresh solutions. In dog testes, the acrosome does not stain with PAS and cannot be adequately distinguished in paraffin-embedded sections (see Anticipated Results).

Table 16.3.3 Schedule for Processing Fixed Tissues From Rodent, Dog, or Primate into Paraffin Wax

Solution[a]	Temperature (°C)	Time (hr)	
		Rodent	Dog/primate
Neutral buffered formalin	37	0.5	0.5
70% ethanol	37	1.0	1.0
80% ethanol	37	1.5	2.0
90% ethanol	37	1.0	1.5
100% ethanol	37	1.0	1.0
100% ethanol	37	1.5	1.5
100% ethanol	37	2.0	2.0
Xylene	37	0.5	0.5

PERFUSION FIXATION OF THE MALE RODENT REPRODUCTIVE TRACT BY CARDIAC PERFUSION AND RESIN EMBEDDING OF TISSUES

This method is used when high-resolution light microscopy or electron microscopy is required. The methodology is time consuming and labor intensive and is more suited to investigative studies than to large-scale screening studies. The procedure involves anesthetizing the animal, cannulating the thoracic aorta through the heart, and flushing out the systemic vasculature with Ringer's solution followed by systemic perfusion with a buffered paraformaldehyde and glutaraldehyde fixative. The method described is a whole-body perfusion using a peristaltic pump to maintain a constant pressure during perfusion. Following fixation, the tissue may be embedded in glycol methacrylate or epoxy resin for light microscopy. Electron microscopy requires the use of epoxy resin. Whole-body perfusion is not suitable for large animals such as primates and dogs because of the large volume of fixative required. An alternative technique introduces the fixative into the testicular artery (Frederick and Doorn, 1973; Russell et al., 1990).

Materials

Krebs Ringer's solution (see recipe)
Karnovsky's fixative (see recipe)
Male rodent
65 mg/ml sodium pentobarbital solution (e.g., Sleepaway; Fort Dodge Animal Health) or equivalent for anesthesia
0.1 M sodium cacodylate buffer (see recipe)
Osmium tetroxide/potassium ferrocyanide fixative (see recipe)

Perfusion setup (Fig. 16.3.1), including:
- Two 1-liter stoppered bottles, each connected to a length of silastic tubing (~3.0 mm internal diameter) and each vented to air
- Silastic tubing, ~3.0 mm internal diameter (e.g., Masterflex L/S 16 pump tubing; Cole-Parmer Instrument)
- Three-way stopcock
- Variable-speed peristaltic pump (e.g., Masterflex; Cole-Parmer Instrument)
- Manometer
- Dosing needle: stainless steel intubation needle with bulbous end, 16 to 18G (depending on size of animal), attached to a cut-off 1-ml tuberculin syringe
- Dissection board suspended in a tray
- Vacuum pump connected to 1-liter bottle trap

Rubber bands
Dissecting tools, including:
- Scalpel
- Hemostats
- Forceps

5-cm (2-in) Dieffenbach serrefine (bulldog) clamp
Single-edged blades

Additional reagents and equipment for dehydrating, infiltrating, and embedding in epoxy resin (see Support Protocol 2); sectioning and staining for electron microscopy *or* dehydrating, infiltrating, and embedding in glycol methacrylate (see Support Protocol 3); sectioning and staining for high-resolution light microscopy

Set up perfusion apparatus

1. Set up a perfusion apparatus as shown in Figure 16.3.1.

The perfusion needs to be carried out under a ventilation hood or on a ventilated table.

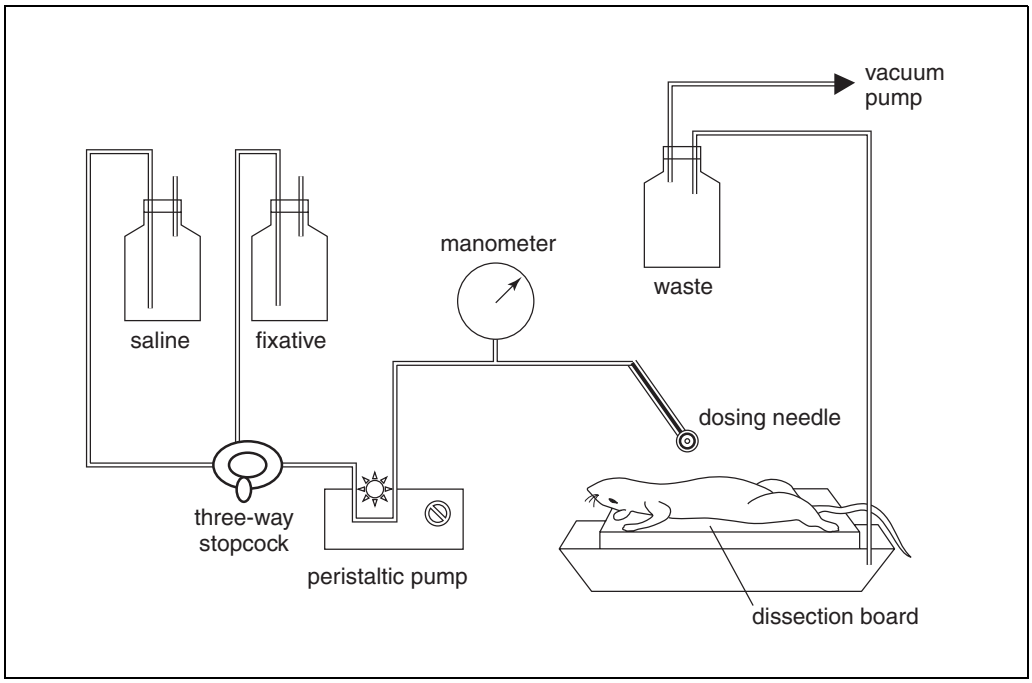

Figure 16.3.1 Apparatus for perfusion fixation of rodents. Two bottles, one containing Krebs Ringer's saline and the other containing fixative are connected via a three-way stopcock to tubing terminating in a blunt-ended gavage dosing needle. Perfusion pressure is generated using a peristaltic pump and monitored using an in-line manometer.

2. Fill one 1-liter bottle with Krebs Ringer's solution and a second one with Karnovsky's fixative. Connect these with silastic tubing and a three-way stopcock to a variable-speed peristaltic pump. Connect a manometer in-line and attach a dosing needle to the end of the tubing.
3. Open the stopcock and flush the tubing with Krebs Ringer's solution. Ensure that the tubing of the perfusion apparatus is filled with fluid and free of air bubbles.
4. Using the manometer, calibrate the speed of the peristaltic pump to a flow rate of 110 to 130 µl/min. This should be equivalent to a perfusion pressure of 100 to 120 mm Hg. During the perfusion the pressures should not be allowed to rise above 150 mm Hg.
5. Set up a dissection board suspended in a tray and a vacuum pump connected to a 1-liter bottle trap to drain used fluids.

Perfuse animal

6. Anesthetize a male rodent with 0.8 to 1.0 µl/Hg of 65 mg/ml sodium pentobarbital solution.

   It is important to achieve a level of anesthesia that results in maintenance of shallow breathing and adequate cardiac output and yet produces a sufficient level of surgical anesthesia.

   Speed is critical to the success of the technique. Once the animal is adequately anesthetized, dissection and introduction of the Krebs Ringer's solution must be accomplished as efficiently and quickly as possible.

7. Secure the animal on its back to the dissection board using rubber bands around its paws.

   The dissection board should be located over a draining vessel to catch the perfusion fluids.

8. Make a midline incision with a scalpel to open the abdomen and then cut through the rib cage in a V shape from the xiphoid process to the axilla. Avoid cutting any major blood vessels in the axilla or along the sternum.

9. Clamp the xiphoid process with a pair of hemostats and displace the flap of thoracic tissue cranially.

10. Cut through the pericardium and reflect it back from the heart and aorta.

11. Turn on perfusion pump and begin flow of Krebs Ringer's solution through the perfusion apparatus at 110 to 120 ml/min.

12. Grasping the ventricular apex with a pair of forceps, rapidly make an incision in the right ventricle to allow fluid efflux. Then make a small incision in the left ventricle and insert the dosing needle through the ventricle and into the aorta so that it is just visible through the vessel wall. Clamp it in place using a Dieffenbach serrefine clamp on the proximal portion of the aortic arch.

    Krebs Ringer's solution should be flowing through the apparatus when the dosing needle is inserted. The needle must not be pushed too far into the aorta, otherwise it will press against the aortic arch and block the flow. Once the perfusion is underway, the angle that the needle enters the heart and aorta needs to be maintained at a slight elevation so that the outflow of the fluid is not obstructed. This can be accomplished using clamps or supports.

13. Perfuse the animal at a flow rate of 110 to 120 ml/min until the blood has cleared from the testes (~1 to 2 min).

    The blood will gradually be replaced by the Krebs Ringer's solution.

14. During the perfusion, expose the testes by cutting through the scrotum. Leave the testes in situ and watch for the coiled, capsular testicular artery to clear of blood and for the testicular tissue to become uniformly pale.

Fix tissue

15. Once the testes have become pale and the effusate from the right ventricle is clear (~1 to 2 min), turn the stopcock to change over to fixative. Infuse the fixative for ≥30 min for electron microscopy and ≥20 min for light microscopy only. After the first 2 to 3 min, slow the rate of perfusion to ~10 ml/min.

    Duration of perfusion is more important than the volume of fluid perfused. The initial pressure and flow rate is important to introduce fixative rapidly while minimizing pressure artifacts. Once the vasculature and basic architecture have been stabilized, the perfusion pressure can be reduced to conserve fixative. A volume of ~300 ml is appropriate for a 300-g animal.

    As described, the technique will provide excellent fixation for ultrastructural studies with minimal fixation and handling artifacts. If the tissue is only intended for high-resolution light microscopy, then the perfusion time with fixative can be reduced. With this shorter time, the tissue may be subject to some minor handling artifacts.

16. Between perfusions, flush the perfusion line thoroughly with Krebs Ringer's solution to remove all traces of fixative.

Remove, trim, and process tissue

For electron microscopy:

17a. Remove the testes or tissue of interest and dice into cubes of ≤1 mm using a sharp single-edged blade. Place these into fresh fixative for ~1.5 hr at 4°C.

18a. Wash in three changes of 0.1 M sodium cacodylate buffer at 4°C, with one wash being overnight and other washes ≥15 min.

19a. Postfix 1 hr in osmium tetroxide/potassium ferrocyanide fixative at room temperature.

20a. Dehydrate, infiltrate, and embed tissues in epoxy resin as described (see Support Protocol 2).

21a. Section embedded tissue at 1 to 2 µm, float sections onto a hot water bath at ~60°C, and pick up onto grease-free glass microscope slides.

22a. Stain sections and examine with a light microscope.

A solution of 1% (w/v) toluidine blue at 60°C can be used for staining. Bancroft et al. (1990) describes resin sectioning and staining techniques.

23a. Section on an ultramicrotome (silver or gold interface colors), float sections onto water at room temperature, and pick up onto electron microscopy grids.

24a. Stain sections with uranyl acetate and lead citrate and examine under an electron microscope.

Preparation of tissues for examination by electron microscopy requires specialized techniques and equipment. Detailed instructions can be found in Hayat (1989).

For high-resolution light microscopy:

17b. Remove the testes or tissue of interest and trim with a single-edged blade to provide samples ~1 cm × 1 cm × 1 mm thick.

18b. Dehydrate, infiltrate, and embed samples in glycol methacrylate as described (see Support Protocol 3).

19b. Section at ~2 µm using a purpose-designed motorized, retracting microtome and a tungsten-carbide or large-area glass (Ralph) knife.

Examples of appropriate microtomes include the Reichert-Jung Supercut and LKB Historange.

When the resin blocks are trimmed to reach the tissue, the use of 70% (v/v) ethanol on the surface of the block will soften the resin and allow thicker sections to be taken without shattering the resin.

20b. Float the sections on a water bath at room temperature until the resin has expanded maximally (~1 to 2 min).

21b. Pick up sections on a grease-free glass slide and dry on a hot plate or in an oven at 60°C for ≥30 min before staining.

Flattening and picking up the section is aided if the water bath is previously wiped with 70% (v/v) ethanol to reduce surface tension.

22b. Stain with periodic acid Schiff's (PAS) stain with a light counterstain of hematoxylin (i.e., PAS-H) or with hematoxylin and eosin.

Staining times will depend on the solutions used. Bancroft et al. (1990) describe standard histological staining methodology.

PAS-H on the testis will stain the glycoprotein component of the spermatid acrosomic granule or acrosome cap. These are very small structures, which can be difficult to visualize if the stain is not optimal. It is important that the periodic acid and the Schiff reagent are relatively fresh solutions.

REMOVAL, TRIMMING, AND ORIENTATION OF MALE TESTES, EPIDIDYMIDES, AND ACCESSORY SEX GLANDS

This protocol describes the dissection of testes, epididymides, and accessory sex glands for male rodents, dogs, and primates that have been euthanized as described in Basic Protocol 1. Specific directions for fixing and sectioning the samples are described in Basic Protocol 1.

Rodent

For a male rodent, remove the testes and epididymides as a unit. Separate the epididymides from the testes and trim to remove the surrounding adipose tissue. Weigh the testes and epididymides separately. After fixation, take a 5-mm transverse section through the testis slightly cranial to the midline to include a small portion of the rete testis (which is subcapsular and originates at the point where the epididymis is attached and is where all the capsular blood vessels converge at the cranial pole). Alternatively, take a longitudinal section through the plane of the rete testis. (For a discussion of the advantages and disadvantages of the plane of section, see Critical Parameters and Troubleshooting, discussion of sampling and orientation of tissues). Take a longitudinal section through the epididymis to include the caput (head), corpus (body), and cauda (tail). To achieve this, trim a thin slice of tissue from the caput and the cauda so that the length of the epididymis can be embedded flat.

Remove the seminal vesicles, coagulating glands, prostate, and bladder as a unit (Fig. 16.3.2A). For detailed dissection guidance, see Feldman and Seeley (1988). Carefully remove the bladder and weigh and fix the seminal vesicles, coagulating glands, and prostate as a unit. If individual weights of seminal vesicles and prostate are required, carefully separate the glands, minimizing egress of fluid. Do this over a weigh boat to catch any fluid. After fixation, separate the seminal vesicles (with the coagulating glands) from the prostate. Take a transverse section through each seminal vesicle and its coagu-

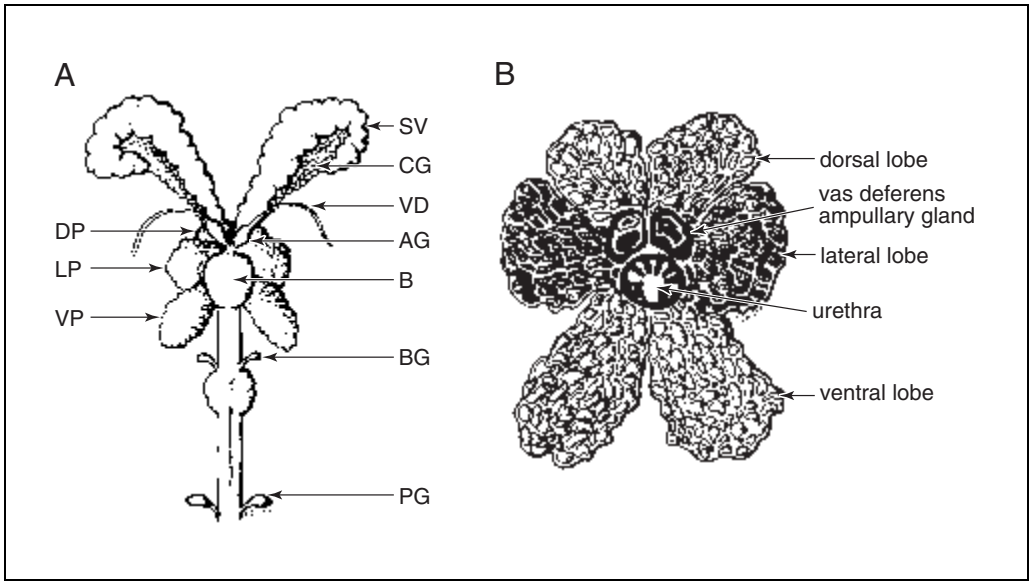

Figure 16.3.2 Accessory male reproductive organs in the rat. (**A**) Anatomic layout. (**B**) Histologic appearance of a longitudinal section of the prostate. In addition to the dorsal, lateral, and ventral lobes, sections through the urethra as well as the vas deferens (VD), with varying amounts of associated ampullary gland (AG), may be included. B, bladder; BG, bulbourethral gland; CG, coagulating gland; DP, dorsal prostrate; LP, lateral prostate; PG, preputial gland; SV, seminal vesicles; Ventral prostate. Figure drawn by Ann Hoffenberg.

lating gland. Take a midtransverse section through the prostate to include dorsal, lateral, and ventral lobes (Fig. 16.3.2B; Suwa et al., 2001).

Dog

For a male dog, remove each testis and epididymis as a unit. Carefully separate the epididymis from the testis and trim away any adipose tissue. Weigh the testes and epididymides separately. After fixation, take a 5-mm transverse slice through the midline of the testis. Depending on the size of the testis, it may be necessary to trim this further to fit into a standard histology processing cassette. If so, ensure that the rete testis (which is enclosed in the mediastinum and runs as a longitudinal central core through the middle of the testis) is included. Bisect the epididymis transversely through the corpus so that half remains with the caput and half with the cauda. Trim off a thin, longitudinal slice of tissue from the caput and the cauda to allow the tissue to be embedded flat. This will provide a longitudinal section through the caput, corpus, and cauda.

Remove the prostate and bladder as a unit (Fig. 16.3.3A). For detailed dissection guidance, see Evans (2000). Carefully remove the bladder. Weigh and fix the prostate. Take a transverse section through the prostate and the central urethra (Fig. 16.3.3B).

Primate

For a male primate, remove each testis and epididymis as a unit. Carefully separate the epididymis from the testis and trim away any adipose tissue. Weigh the testes and epididymides separately. After fixation, take a 5-mm transverse slice through the midline of the testis. Depending on the size of the testis, it may be necessary to trim this further to fit into a standard histology processing cassette. In primates, the rete testis lies in a subcapsular location along the epididymal edge. Ensure that this portion of the testis is sampled. Bisect the epididymis transversely through the corpus so that half remains with the caput and half with the cauda. Trim off a thin, longitudinal slice of tissue from the caput and the cauda to allow the tissue to be embedded flat. This will provide a longitudinal section through the caput, corpus, and cauda.

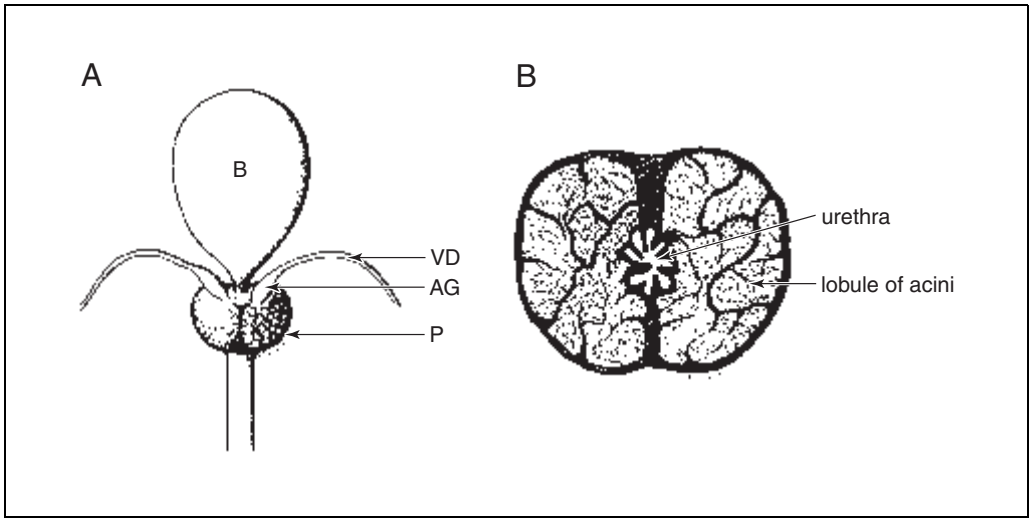

Figure 16.3.3 Accessory male reproductive organs in the dog. (**A**) Anatomic layout. (**B**) Transverse section through the prostate with lobules of acini separated by connective tissue trabeculae surrounding the central urethra. AG, ampullary gland; B, bladder; P, prostate; VD, vas deferens. Figure drawn by Ann Hoffenberg.

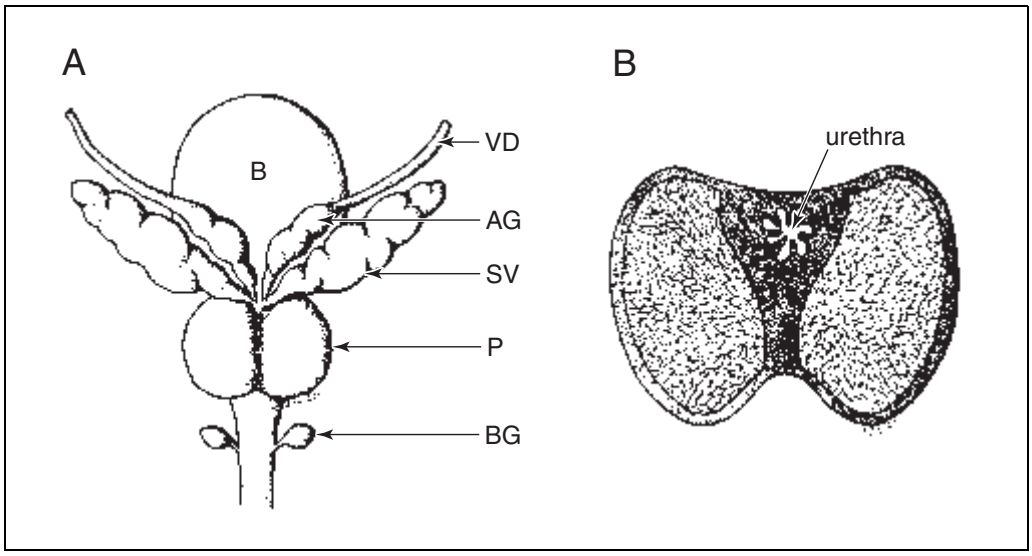

Figure 16.3.4 Accessory male reproductive organs in the primate. (**A**) Anatomic layout. (**B**) Transverse section through cynomologous monkey prostate, in which glandular acini are absent from the anterior aspect. AG, ampullary gland; B, bladder; BG, bulbourethral gland; P, prostate; SV, seminal vesicles; VD, vas deferens. Figure drawn by Ann Hoffenberg.

Remove the seminal vesicles, prostate, and bladder as a unit (Fig. 16.3.4A). Carefully remove the bladder. Weigh and fix the seminal vesicles and prostate as a unit. If individual weights of seminal vesicles and prostate are required, carefully separate the glands, minimizing egress of fluid. Do this over a weigh boat to catch any fluid. After fixation, separate the seminal vesicles from the prostate. Take a transverse section through each seminal vesicle and take a transverse section through the prostate and the prostatic urethra (Fig. 16.3.4B).

PROCESSING AND EMBEDDING OF TISSUES IN EPOXY RESIN

SUPPORT PROTOCOL 2

Epoxy resin embedding is used for fixed tissues to be examined by electron microscopy.

Materials

Fixed tissue sample postfixed in 1% osmium tetroxide/1.25% potassium ferrocyanide (see Basic Protocol 2)
30%, 50%, 70%, 85%, 95%, and 100% (v/v) ethanol
Propylene oxide (e.g., Electron Microscopy Sciences)
1:1 propylene oxide/epoxy resin
Epoxy resin (e.g., Araldite 502 or 506 lufts; Electron Microscopy Sciences)
Mold suitable for electron microscopy blocks (e.g., Electron Microscopy Sciences)

NOTE: During processing, all steps should be carried out with agitation.

1. Dehydrate a fixed tissue sample postfixed in 1% osmium tetroxide/1.25% potassium ferrocyanide using an alcohol series consisting of 15-min steps in 30%, 50%, 70%, 85%, 95%, and 100% ethanol.
2. Transfer sample to propylene oxide and incubate 5 min without agitation.
3. Incubate 1 hr in 1:1 propylene oxide/epoxy resin at room temperature.

   Incubation times here and in step 4 will vary. Refer to manufacturer's instructions for specific resin for details.
4. Incubate in epoxy resin, two changes, 1.5 hr each at room temperature.
5. Orient sample in a mold and embed in fresh resin. Polymerize ≥48 hr at 60°C.

SUPPORT PROTOCOL 3

PROCESSING AND EMBEDDING OF TISSUES IN GLYCOL METHACRYLATE

Fixed tissues are postfixed (optional) and embedded in glycol methacrylate for high-resolution light microscopy.

Materials

Fixed tissue sample, 3 to 5 mm thick (see Basic Protocol 2)
0.1 M sodium cacodylate buffer (Electron Microscopy Sciences or see recipe), optional
Osmium tetroxide/potassium ferrocyanide fixative (see recipe), optional
50%, 70%, 80%, 95%, and 100% (v/v) ethanol
JB4 glycol methacrylate embedding kit (e.g., Polysciences), including:
  Solution A (acrylic monomer)
  Catalyst (organic peroxide)
  Solution B (accelerator)
Ice bath
Glycol methocrylate embedding molds, available as block-mold system that allows polymerization directly onto a metal or plastic microtome chuck (Polysciences)

1. *Optional:* Wash the fixed tissue sample overnight in 0.1 M sodium cacodylate buffer and postfix 1 hr in 1% osmium tetroxide/1.25% potassium ferrocyanide at room temperature. Wash again in two changes, 15 min each, 0.1 M sodium cacodylate buffer.

   This step will provide improved fixation quality, but is optional.

2. Dehydrate tissue using an alcohol series consisting of 30-min steps in 50%, 70%, 80%, 95%, and 100% ethanol.

   NOTE*: Sample should be agitated slowly during all dehydration and infiltration steps.*

3. Prepare the glycol methacrylate infiltration solution according to the kit instructions by adding 100 ml solution A/1 g catalyst. Stir at room temperature to dissolve and store at 4°C for use in steps 4 to 7.

   Polymerization of the resin is an exothermic reaction, and the heat generated can cause artifacts in the tissue. A smaller proportion of catalyst can be used (0.7 g/100 ml solution A) to slow polymerization time and reduce heat artifacts. This is particularly important when larger blocks (e.g., 1.5 cm^2) are produced.

4. Infiltrate tissue sample with a 1:1 mixture of 100% ethanol/infiltration solution for 2 hr at 4°C.

5. Infiltrate overnight in full-strength infiltration solution at 4°C.

6. Infiltrate 2 hr in a second change of infiltration solution at 4°C.

7. Prepare the embedding solution by adding 1 ml solution B to 15 ml infiltration solution. Use immediately and keep solution in an ice bath while embedding.

8. Orient sample in a glycol methacrylate embedding mold and fill mold with embedding solution. Polymerize overnight at 4°C.

   Polymerization needs to be carried out in the absence of oxygen and in a dry atmosphere. The design of the molds largely excludes contact with air, but as an additional safety measure polymerization may be carried out in a vacuum desiccator or in a nitrogen-filled desiccator.

The use of glycol methacrylate resin as an embedding medium is technically demanding and potentially subject to numerous problems, including difficulties obtaining satisfactory polymerization (leading to sectioning difficulties) as well as morphological artifacts and difficulties with staining (Hess and Moore, 1993). It is advisable to experiment with the technique prior to its use in a study.

REAGENTS AND SOLUTIONS

Use Milli-Q-purified water or equivalent in all recipes and protocol steps. For common stock solutions, see ***APPENDIX 2A****; for suppliers, see* ***SUPPLIERS APPENDIX****.*

Karnovsky's fixative

10 ml 10% (w/v) paraformaldehyde (see recipe; 1% final)
35 ml 0.2 M sodium cacodylate (0.07 M final)
12 ml 25% (w/v) glutaraldehyde (e.g., Electron Microscopy Sciences; 3% final)
43 ml deionized H_2O
Adjust to pH 7.4 with 0.1 N hydrochloric acid
Store up to 1 week at 4°C.

Krebs Ringer's solution

Dissolve 6.6 g sodium chloride, 0.15 g potassium chloride, and 0.15 g calcium chloride in 1 liter deionized water. Adjust to pH 7.6 with 5% (w/v) sodium bicarbonate. Store up to 1 month at 4°C. Immediately before use add 5 g procaine hydrochloride and 1 ml heparin (10,000 IU).

Modified Davidson's fixative

140 ml ethanol
62.5 ml glacial acetic acid
375 ml 37% (w/v) formaldehyde
422.5 ml distilled H_2O
Store up to 3 months at room temperature.

Osmium tetroxide/potassium ferrocyanide fixative

Prepare a 2% (w/v) aqueous solution of osmium tetroxide and a 2.5% (w/v) aqueous solution of potassium ferrocyanide. Mix equal volumes together immediately before use (1% osmium tetroxide and 1.25% potassium ferrocyanide, final concentrations).

Paraformaldehyde, 10%

Dissolve 2 g paraformaldehyde in 20 ml deionized water. Stir 20 min at 60°C. Add a few drops of 1 M sodium hydroxide to clear the solution. Cool and filter through Whatman no. 5 filter paper. Store up to 1 month at 4°C.

Sodium cacodylate buffer, 0.1 M

Dissolve 10.7 g sodium cacodylate in 500 ml deionized water. Store up to 1 month at room temperature.

This buffer is also commercially available from Electron Microscopy Sciences.

COMMENTARY

Background Information

The procedures used for reproductive-tract histology will largely depend on the objectives of the study. For example, a regulatory screening study to detect toxicity will generally weigh and sample the tissues according to the appropriate regulatory guidelines (Table 16.3.2) and use routine immersion fixation followed by paraffin embedding. An investigative study to characterize toxicity may concentrate on target tissues of interest and use perfusion fixation followed by resin embedding. The latter procedure will provide enhanced resolution for light microscopy and, if epoxy resin is used, allow for ultrastructural examination with the electron microscope.

Critical Parameters and Troubleshooting

Sampling and orientation of tissues

Testes. There are a number of factors to consider when deciding how to trim the various tissues of the reproductive tract. In the case of the testes, a longitudinal or transverse section can be taken. The advantage of a longitudinal section is that it provides more tissue to examine and provides frequent longitudinal sections through seminiferous tubules, many of which will include consecutive stages of the spermatogenic cycle. The advantage of a transverse section is that it provides consistent cross-sections through all the seminiferous tubules. This makes staging of the tubule easier and allows quantitation of cell numbers and tubular measurements, if required. Most technicians sample the testis by taking a midline sample. However, the testis has asymmetric structures that may be missed by a midline section. For example, in the rodent, the rete testis (the network of canals into which the seminiferous tubules empty) is located at the cranial pole of the testis and spreads down directly beneath the capsule towards the midline. The rete can provide important information regarding fluid dynamics of the seminiferous tubule fluid. In cases of obstruction of the excurrent duct system or disturbances in fluid reabsorption, it will show dilation. It can also be the site of proliferative lesions and rete testis tumors. Both ends of the seminiferous tubules empty into the rete and this often appears to be a preferential site for germ cell degeneration and depletion for both spontaneous and chemically induced lesions. It is therefore an important site to sample, and routine sectioning should include at least part of the rete complex. In the dog the rete forms a central core that extends from the cranial surface to approximately two-thirds of the way towards the caudal tip and will be adequately sectioned with a midline transverse section. In the primate it is located in a peripheral position along the medial aspect for approximately half the medial border. Again it will be adequately sampled with a midline transverse section but a longitudinal sample needs to be specifically orientated to include it.

Efferent ducts. The efferent ducts link the rete testis with the ductus epididymis, which is a single, highly coiled duct, the convolutions of which form the caput, corpus, and cauda epididymis. The number and course of the efferent ducts vary with species. They are long and tortuous in rodents, extending up into the epididymal fat pad surrounding the caput epididymis; they are normally trimmed off and discarded when the epididymis is trimmed for weighing. In the dog and primate they are very short because the epididymis is more closely applied to the testis in these species; they are rarely sampled in routine studies but can be an important site for lesions. The efferent ducts in the dog are a frequent site for sperm granulomas because of the presence of numerous blind-ending tubules. Similarly in the rat, this may be the location of sperm granulomas that give rise to tubular dilation in the testes and absence or decreased sperm in the epididymis. More importantly, they have been shown to be a target site for a number of chemicals (Hess, 1998). Although it may not be practical to sample them in routine studies, their potential as a target site for toxicity or as a cause of secondary changes in the testes and epididymides should be appreciated.

Epididymides. The cellular composition and the function of the epididymis vary with region, and it is important that the different regions are sampled and examined. Routine sampling of the epididymis often only includes the cauda epididymis, but this precludes important information. There are a number of chemicals that have been shown to produce site-specific lesions to the epididymal epithelium, some in the caput, others in the cauda. An additional reason for sampling the entire epididymis is that the density of sperm and the presence of germ cells within the lumen of various segments of the epididymis reflect time-dependent events in the testis. For example, in the rodent, dog and primate sperm and cells present in the cauda epididymis were released from the testis ~2 weeks prior to their arrival there. The sperm in the caput epididymis reflect the release of sperm only days previously. Depending on the duration of the study, differential effects on the contents of the caput and cauda can provide important information on the timing of a toxic effect.

Prostate. The prostate of rodents is a heterogeneous gland with anatomically distinct ventral, dorsal, and lateral lobes (Fig. 16.3.2B). The histologic structure and the response to toxicants vary between lobes such that it is important to routinely sample as much as possible. A midtransverse section through the prostatic complex allows an adequate sample of all three lobes and often also includes the ampullary gland of the ductus deferens as it enters the prostatic urethra (Lee and Holland, 1987; Suwa et al., 2001). In the dog and the primate, the

glandular tissue is arranged circumferentially around the urethra, although in the primate it is only present on the posterior surface of the urogenital canal. In these species, a transverse section provides an appropriate sample for examination (Figs. 16.3.3B and 16.3.4B).

Seminal vesicles and coagulating gland. In rodents, a coagulating gland lies on the anterior aspect of each seminal vesicle. Both can be sampled by a cross-section. Similarly, a cross-section of the seminal vesicles in the primate provides adequate sampling. These organs are absent in the dog.

Choice of fixative

All of the recently revised regulatory guidelines for reproductive toxicity studies specifically recommend fixing the testes in Bouin's or a comparable fixative (Table 16.3.2). Implicit in this recommendation is that the use of formalin is avoided due to the excessive shrinkage of Sertoli cell and germ cell nuclei and cytoplasm, which occurs when formalin-fixed testes are embedded in paraffin. Although acceptable results can be obtained with formalin (Harleman and Nolte, 1997), Bouin's provides more reliable and consistent results. Testes fixed in Bouin's show greatly improved preservation of the nuclear and cytoplasmic features of Sertoli cells and germ cells, with very little shrinkage of the cells away from one another. However, due to its picric acid component, Bouin's has a number of drawbacks. It is potentially explosive, mutagenic, and possibly carcinogenic, presenting significant safety and disposal problems to laboratory personnel when used on a large scale. It also results in significant shrinkage of the tubules away from the interstitial tissue, especially in the center of the testis. Testes fixed with modified Davidson's fixative (see Basic Protocol 1) show comparable cellular and nuclear resolution with very little shrinkage of the germ cells and Sertoli cells. In addition, the tubules show significantly less shrinkage from the interstitial tissue than is seen with Bouin's. Interestingly, the problems with formalin fixation are associated with subsequent processing into paraffin wax, because formalin fixation of rodent testes followed by embedding in glycol methacrylate results in better preservation of structure than with Bouin's (Chapin et al., 1984). However, this does not hold true for all species and should be experimented with prior to use. For a detailed review of methods and the results that can be obtained using various combinations of fixatives, fixation methods, and embedding procedures for rodent testes, see Chapin et al. (1984), Russell et al. (1990), and Hess and Moore (1993).

Many of the difficulties associated with preserving the testes are due to the requirement to fix the tissue whole. This is necessary so that the architecture of the tubules and interstitial tissue is maintained and to prevent artifactual sloughing of germ cells. If the capsule is cut or removed, the tubules erupt and flow out of the holes. However, improved penetration of fixative can be achieved by pricking the capsule of rodent testes or making nicks in the capsule of dog or primate testes before immersing in fixative. (Large-animal testes have more fibrovascular stroma and are less likely to erupt than rodent testes.) If the pricks and cuts are made superficially and at a location distant from the area to be sampled, this will not disturb the architecture. Fixation quality can also be significantly improved if the testis is sliced after it has been partially fixed by immersion. Allow ≥4 to 5 hr (or overnight) before cutting the testis and then cut it in half or make 5-mm slices. Return to fixative to allow a total fixation time of 48 hr. Tissues should not be left in Bouin's or Davidson's for very much longer than 48 hr, otherwise they will harden and become difficult to section.

The Karnovsky's fixative recommended in Basic Protocol 2 and the subsequent postfixation in osmium tetroxide and potassium ferrocyanide are designed to give optimal fixation and staining of testicular structure for ultrastructural examination while minimizing osmotic artifacts. The high water content of testicular tissue and the distance of the seminiferous epithelium from the interstitial vasculature make fixation difficult and artifacts frequent. One of the most common artifacts seen is basal vacuolation of the seminiferous tubules. This is caused by the use of hyperosmotic fixative, which causes shrinkage of the cells in the basal compartment (below the level of the Sertoli cell tight junctions). Hyperosmotic fixatives will also cause artifactual condensation of Sertoli cell cytoplasm at the ultrastructural level. For ultrastructural studies it is therefore important to use approximately isotonic solutions and fixatives. The use of the osmium/ferrocyanide mixture as a postfixative is particularly good for membrane preservation, but it also has the advantage of improving the staining characteristics and resolution of Leydig cell structure at the ultrastructural level (Russell and Burguet, 1977). The choice of buffer for glutaraldehyde-based fixatives is a matter of personal prefer-

ence. Cacodylate buffer has been recommended in this protocol, but due to its toxicity and associated disposal problems, a phosphate buffer may be preferred as a substitute (Hess and Moore, 1993).

Perfusion

There are various techniques for perfusion fixation of tissues. The choice is largely a matter of personal preference and resource limitations. The procedure described in Basic Protocol 2 uses a peristaltic pump to perfuse the whole animal. This maintains a constant flow of fixative for a given speed of the pump, despite the increasing vascular resistance. A gravity-fed system can also be used, as described by Sprando (1990). This has the advantage of not requiring a peristaltic pump but has the disadvantage of requiring the fixative and saline bottles to be located some distance above the animal. With gravity-based perfusion, the flow rate also decreases as the vascular resistance increases.

Rather than perfuse the whole animal as described in this protocol, it is also possible to limit perfusion only to the abdominal tissues. Hess and Moore (1993) describe a method of cannulating the abdominal aorta via the left ventricle, which bypasses perfusion of the cranial and thoracic tissues. This conserves fixative, but the cannulation is slightly more technically demanding.

A critical step in the perfusion technique is the successful clearance of blood from the entire vascular bed. If vessels constrict or intravascular thrombi form, then the fixative will not be uniformly distributed. Clearance of the testicular vasculature appears to be particularly problematic. To overcome this problem, heparin and/or vasodilators have been employed. In this protocol the incorporation of both heparin and procaine in the flushing solution (Hess and Moore, 1993) has been recommended on the basis of a very good success rate combined with simplicity. However, Sprando (1990) suggests that the preinjection of animals with 130 to 150 IU heparin/kg body weight by intraperitoneal injection 15 min prior to perfusion improves the success rate without the need for additives to the perfusion fluids.

Anticipated Results

Using Basic Protocol 1, the quality of the paraffin sections of testes stained with periodic acid Schiff's stain/hematoxylin (PAS-H) will be suitable for detailed qualitative evaluation of spermatogenesis. Resolution and staining of the spermatid acrosome in rodent testes will be adequate to identify individual stages of the spermatogenic cycle. In dog and primate testes, the acrosome does not stain with PAS and cannot be adequately distinguished in paraffin-embedded sections. Therefore staging has to rely on the characteristics of the spermatocyte and round spermatid population in conjunction with the shape and position of the elongating spermatid population. Cytoplasmic and nuclear detail of the germ cells, Sertoli cells, and Leydig cells will be suitable for detecting early degenerative changes. Although quantitative procedures, such as cell counting and measuring tubular diameters is possible, it is better carried out on resin-embedded tissue where section thickness is more consistent and nuclear chromatin resolution is improved.

Longitudinal sections through the epididymis will provide information on the cellular morphology of the entire length of the coiled epididymal duct and of the relative sperm and cell content of the ductular lumen. In the dog and primate, the longitudinal section of the epididymis may also include some of the efferent ducts. The transverse section through the rodent prostate should provide comparative morphology of the dorsolateral lobes and ventral lobes of the tissue and may also include cross-sections of the vas deferens and of the associated ampullary gland of the vas. The secretory products of the various lobes and of the ampullary gland have different affinities for eosin. The differential staining pattern can be used to identify various regions (Lee and Holland, 1987; Yuan et al., 1987). In the dog and the primate, the prostatic acini should appear more or less homogeneous with no regional variation.

Using Basic Protocol 2, perfusion fixation should provide tissue with a minimum of artifacts. All interstitial capillaries should be open and empty of erythrocytes. There should be no shrinkage of tubules away from the interstitial tissue and no shrinkage of germ cells away from Sertoli cells. Vacuoles between adjacent Sertoli cells should be minimal or nonexistent and there should be no sloughing of germ cells into the tubular lumen. When viewed by electron microscopy, the morphology of the smooth endoplasmic reticulum and mitochondria in the basal Sertoli cell cytoplasm are good indicators of fixation quality. Toluidine blue–stained resin sections can be used to distinguish the spermatid acrosome in all species including the dog, although the thinness of the section results in many acrosomes being incompletely sectioned

or out of the plane of section. Glycol methacrylate–embedded, immersion-fixed tissue generally results in less tubular and cellular shrinkage than paraffin-embedded tissue and shows improved resolution of nuclear and cytoplasmic features. It too suffers from reduced numbers of complete acrosomes in the plane of section.

Time Considerations

Immersion fixation and embedding tissue in paraffin wax is the most economical methodology in terms of time and cost. Because all the procedures are more or less standard routine for a histology laboratory, the processing, embedding, and staining is largely automated. Overall time depends on the number of tissues sampled and weighed from each animal and the number of animals processed. For a routine study size (e.g., two to five treatment groups, each with five to ten animals), allowing 48 hr fixation time plus ~1 day processing and embedding into paraffin and 1 day sectioning and staining, sections could be ready for evaluation within a week.

Processing for glycol methacrylate can also be automated using routine, paraffin-embedding processors up to the point of resin infiltration. Processing for epoxy resin can be automated through to the point of embedding, but this requires a purpose-designed machine to handle the small tissue size and the viscuous resin mixtures. The alternative is to carry out the procedure in individual bottles, carefully draining and filling each with new solution. Embedding in resin requires special molds and special polymerization conditions and can take up to 48 hr for adequate polymerization. Sectioning of resin blocks requires the use of a special, automated microtome that uses prepared glass or tungsten carbide knives and is a technically demanding procedure requiring at least 1 to 2 days training and several days practice to become proficient. With glycol methacrylate, consistent polymerization of the resin and control of the relative hydration of the resin during sectioning can also add to the difficulty and the time taken to produce acceptable sections. Overall, the size of the tissue block and the proficiency and experience of the technician will determine the time taken to prepare adequate resin sections, but, as a guide, it probably takes at least twice to three times longer to prepare a 2- to 3-µm resin section than it does to prepare a paraffin section.

The duration of the perfusion means that this is also a time- and labor-intensive technique. If large numbers of animals are to be fixed by this method, multiple perfusion stations are required, and animals must be staggered through the various procedures. With three perfusion stations and two people carrying out the perfusions, it is feasible to complete 20 animals in a normal working day. (Sprando, 1990).

Histopathology of the Male Reproductive System II: Interpretation

Toxicants can affect the male reproductive system at a broad range of target sites including the testis, epididymis, secondary sex organs, and the neuroendocrine/CNS regulatory system. No single endpoint can adequately reflect changes at such a diversity of sites, but it has been repeatedly demonstrated that histopathologic evaluation represents the most sensitive and reliable indicator of toxicologic disturbance in the tract as a whole (Linder et al., 1992; Ulbrich and Palmer, 1995). This is only true if the appropriate tissues have been taken and have been fixed and sampled in such a way that subtle or localized changes are adequately preserved and presented to the pathologist for examination. These preparative procedures are dealt with in *UNIT 16.3*. Even if material has been appropriately fixed and sampled, it is incumbent on the pathologist to have an adequate understanding of the organization and dynamics of spermatogenesis in the species under investigation. Without this, lesions will be missed or the significance of findings will be misinterpreted. Although it is beyond the scope of this unit to provide this knowledge, an attempt is made to illustrate why and when such knowledge is essential.

Once identified, interpretation of the significance of the findings to overall reproductive function and their implications for functional or morphological changes in the rest of the reproductive tract relies on a basic knowledge of reproductive physiology. Some examples of common chemically induced findings in the reproductive tract, their possible etiology, and their likely functional significance are provided. The pattern of morphological change as well as the specificity and severity of the findings are significantly influenced by the duration of dosing, such that the approach to examination is different in a short-term versus a long-term study. This unit includes a section providing practical guidance on how to evaluate testicular and epididymal sections for evidence of a chemically induced effect, including what to look for and how hard to look for it. This involves using knowledge of staging to identify when cells are missing or when cells are inappropriately present.

Terminology of findings and how to grade severity is a unique problem in the testis; whether to grade on the basis of number of germ cells affected, number of tubules affected, or both; whether to use broad terminology such as tubular atrophy and tubular degeneration, or to use specific terminology that differentiates between effects on specific types of germ cells and their stage localization. The decision is strongly influenced by the type of study and the specificity of the present findings.

As with the toxicological evaluation of any tissue, the species, age, and history of spontaneous pathology need to be taken into account. These factors are particularly important with respect to the testis because, in some species, such as dog, the relatively high incidence of spontaneous degenerative lesions, confounded by the small group size of animals used can provide difficult data for interpretation. In addition, the use of immature or borderline mature animals, which is the case for some regulatory studies, can mask or be mistaken for toxicologically induced lesions. It is important that these limitations are realized. Most of the discussion in this unit relates to the rat because this is the most commonly used species in toxicological research. It is also the species for which most information is available. Other species are specifically mentioned where appropriate.

ESSENTIAL KNOWLEDGE FOR EVALUATION AND INTERPRETATION OF TESTICULAR PATHOLOGY

Spermatogenesis and the Spermatogenic Cycle

The process and regulation of spermatogenesis is essentially similar in all mammalian species. Stem cell spermatogonia proliferate by mitosis and produce a population of differentiating or committed spermatogonia. These in turn divide and produce spermatocytes, which undergo DNA replication and divide by meiosis to produce haploid spermatids. A complex series of morphological transformations of the simple round spermatid finally produces a differentiated sperm, which is released into the tubule lumen and transported on into the epididymis. In the rat, the whole process takes ~56 days with spermatogonial divisions taking ~2 weeks, spermatocyte meiosis lasting >3 weeks, and spermatid development also requiring ~3 weeks. The arrangement of the different

Current Protocols in Toxicology (2002) 16.4.1-16.4.14

populations of germ cells within the seminiferous tubule is also similar between species, with Sertoli cells providing a supporting structural framework for discrete layers of the different germ cell types. Spermatogonia are always at the base of the tubule and progressively more mature germ cells are found in layers moving toward the lumen. In all species, 3 or 4 generations of germ cells are developing within a tubule at any given time. The development of each of these generations occurs in synchrony with each other, giving rise to specific and predictable cellular associations (Fig. 16.4.1). The complete sequence of cellular associations is referred to as the cycle of spermatogenesis while the individual cell associations form the stages of the cycle. Each stage is therefore defined by its germ cell complement and consequently, identifying the stage defines what cells should be in that tubule (and what cells are missing). In order for a pathologist to detect subtle changes in germ cell loss or, in the case of spermatid retention, the inappropriate presence of a population of germ cells, a thorough understanding of the cellular makeup of the spermatogenic cycle is essential.

Species-Specific Variations in the Organization of Spermatogenesis

Although the fundamentals of the spermatogenic cycle are similar between species, there are certain details that vary. These can have a significant impact on histopathologic evaluation.

Number of stages

The number of stages and their cellular makeup varies between species and depends on the morphological criteria used by the classification system. It is important that the pathologist is familiar with the germ cell development and the stage map of the species under investigation. A highly recommended text that explains in detail how to stage tubules in a number of common species and provides stage maps for each species is provided by Russell et al. (1990).

Duration

The duration of spermatogenesis (the time taken for a spermatogonium to develop into sperm) and the duration of the spermatogenic cycle (the time taken to complete a cycle of cell associations) varies between species. This information is important so that the pathologist can predict how long it should take for any particular cell to reach a later cell type (e.g., if a toxicant affects leptotene spermatocytes, how long will it take before the animal becomes infertile?). Alternatively, if a particular cell type is missing at some defined period after dosing, knowing the dynamics of the spermatogenic cycle will allow extrapolation as to what stage of development that cell was in when dosing began. Software programs have also been developed to calculate this type of information (Hess and Chen, 1992).

Cell associations

The organization of cell associations along the length of the tubule is linear for most mammalian species, including most species of monkey used in toxicological studies. This means that a tubular cross section normally contains only one cell association and that the adjoining length of tubule (which is often the adjacent tubule in a cross section of testis) will generally contain the consecutive stage. This is not the case in humans where cell associations are arranged in a helical pattern resulting in a mosaic of cell associations in a single cross section. In dogs, although only one stage is present in a cross section, adjoining lengths of tubule do not necessarily contain consecutive stages.

Disturbances in Spermatogenesis

Almost regardless of the cellular target of toxicity within the reproductive system, the most common morphological consequence of injury is a disturbance in spermatogenesis. This is because spermatogenesis is dependent on, or sensitive to, functional perturbations in most other parts of the reproductive tract. Spermatogenic disruption may reflect a direct effect on the seminiferous epithelium, affecting either the Sertoli cell or any one of the germ cell populations, or it may occur as a secondary response to altered hormone levels, altered vascular supply or altered fluid balance, either within the testis or within the epididymis. It is therefore extremely important that disturbances in spermatogenesis are detected. The pattern of disturbance can be very specific and diagnostic of the mechanism of toxicity, but generally, this is only seen during the early development of the lesion. With longer periods of dosing, the development of maturation depletion (whereby death of a specific precursor germ cell causes the progressive loss of its descendant generations), reduces the specificity of the pattern of spermatogenic disturbance as the tubules become depleted of more and more germ cells.

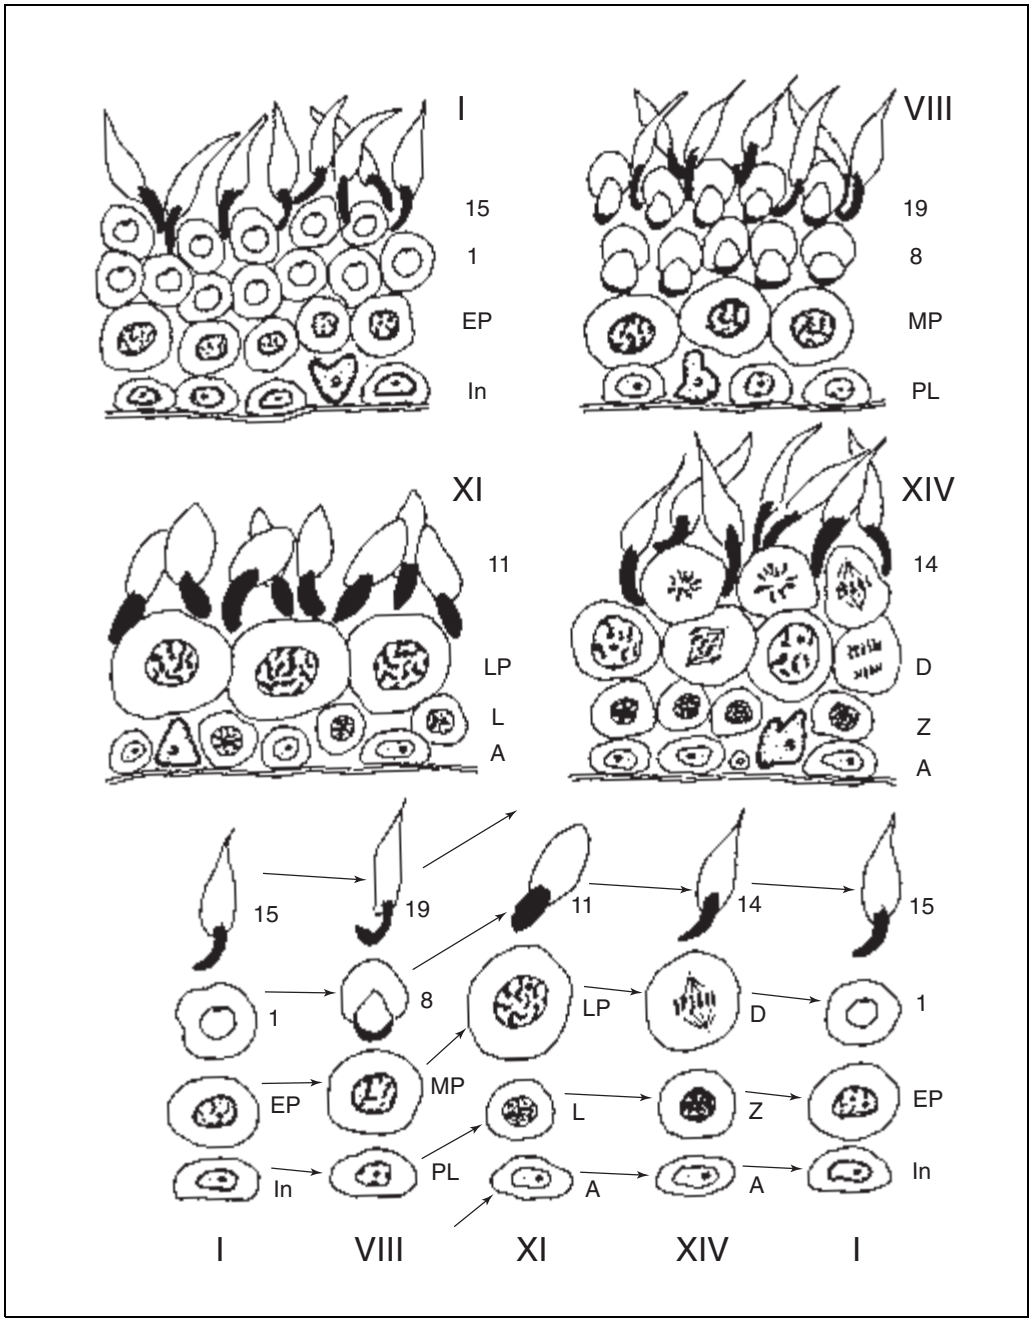

Figure 16.4.1 Stages of the spermatogenic cycle of the rat. Cell associations for 4 of the 14 stages of the spermatogenic cycle of the rat (stages I, VIII, XI, XIV). *Spermatogonia*: A, type A; In, intermediate; *Spermatocytes*: PL, preleptotene; L, leptotene; Z, zygotene; EP, early pachytene; MP, mid pachytene; LP, late pachytene; D, dividing. *Spermatids:* 1, 8, 11, 14, 15, and 19 indicates steps 1 to 19 of spermatid development. The tubular cross sections (stages I, VIII, XI, and XIV) show the arrangement of cells within the seminiferous epithelium. The columns of cells at the base of the figure show the maturation of the cells during one spermatogenic cycle. Each generation of cells develops sequentially. During stage VIII, the mature step 19 spermatids are shed into the lumen (arrows) while a new generation develops from stem cell spermatogonia. As spermatocytes undergo meiotic division (D) in stage XIV, they produce step 1 spermatids and the cell association returns to stage I to begin another cycle. Table 16.4.1 Specific EPA and OECD Recommendations for Histopathological Examination of the Testes and Epididymides in Studies to Detect Effects on Reproduction and Fertility

Testis	Epididymis
Detailed histopathological examination of testes should be conducted in order to identify treatment-related effects such as:	Examination of the intact epididymis should include the caput, corpus, and cauda. The epididymis should be evaluated for:
Retained spermatids	Leukocyte infiltration
Missing germ cell layers or types	Sperm granulomas
Multinucleate giant cells	Change in prevalence of cell types
Sloughing of spermatogenic cells into the lumen	Absence of clear cells in the cauda epithelium
	Aberrent cell types in the lumen
	Phagocytosis of sperm

Regulatory Guidelines and the Role of "Staging" in Histopathologic Examination of the Testis

Recently revised regulatory guidelines have placed increased emphasis on the importance of histopathology for detecting toxicological effects in the male reproductive system. Recommendations have been made, not only for fixation and staining procedures but also for the microscopic examination of tissues, providing examples of findings that should be recorded (Table 16.4.1). During the drafting of these guidelines, there was much discussion relating to the subject of "staging" of testes, and although there is no mention of staging in the final issued guidelines, the issue has become surrounded by confusion. The ability to recognize stages of the spermatogenic cycle is important in order for the pathologist to recognize when cells are missing or are inappropriately present. Due to the lack of understanding of this concept, there has been a move to expect the pathologist to produce a quantitative assessment of stages—e.g., a frequency distribution of tubules for individual stages of the spermatogenic cycle. While this may be useful information in an investigative study to determine whether the dynamics of the spermatogenic cycle have been disturbed (Hess, 1990), it is inappropriate to carry out in a regulatory study, which is designed as a screening study to detect effects on spermatogenesis. Knowledge of staging should be used in a qualitative way to evaluate the normality of the cellular makeup of the seminiferous tubules. In other words, the testis should be examined with an understanding of the normal progression of the stages of the spermatogenic cycle. This approach is explained below. For a more detailed discussion of this issue see Creasy (1997) and Chapin and Conner (1999).

COMMON TOXICOLOGICALLY INDUCED FINDINGS AND THEIR POSSIBLE SIGNIFICANCE

As with any tissue, the cellular response to injury is limited and at times, nonspecific. However, certain aspects of the early pathogenesis of toxicologically induced lesions in the testis and accessory tissues can provide important information on the mechanism of injury. Additional information can be found in Nolte et al. (1995), Creasy (2001), and Creasy and Foster (2001).

Testes

Germ cell degeneration/multinucleate aggregates

Whether spontaneous or induced, death of germ cells appears to occur predominantly through apoptosis, a process that is closely regulated by the Sertoli cell (Lee et al., 1997, 1999). This is particularly true for spermatogonia, which may be seen apoptosing in occasional stage XII tubules. However, many of the dying cells do not have the classic morphological appearance of apoptotic cells. Dying spermatocytes generally develop cytoplasmic eosinophilia and nuclear pyknosis while round spermatids show chromatin margination. If cell death progresses rapidly, then the apoptotic cell is rapidly phagocytized by the surrounding Sertoli cell cytoplasm and all evidence of cell death is rapidly removed. Cell death and phagocytosis of the remains can be complete within 24 hr, so if the process is not examined during this time span, the only evidence of cell death will be an absence of the cell (cell depletion). If the degenerative process is slow, then adjacent germ cells belonging to the same cohort, may form a multinucleate syncitium (symplast, multinucleate giant cells) probably due to the

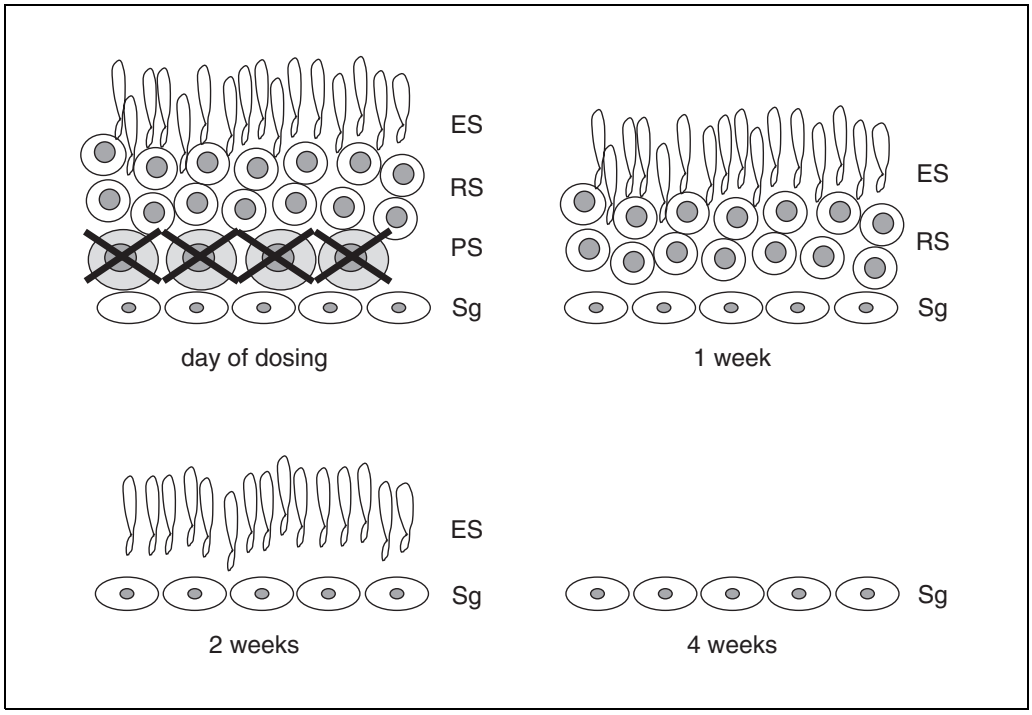

Figure 16.4.2 Development of maturation depletion following daily dosing with a spermatocyte toxicant. Time-dependent progression of maturation depletion following cell-specific damage to pachytene spermatocytes (PS). If the tubule is examined on the day of dosing, spermatocyte degeneration and necrosis will be seen (top left). Phagocytosis of the necrotic cells by Sertoli cells results in their rapid disappearance and because dosing continues, newly formed pachytene spermatocytes will also be killed. Examination of the same stage tubule after 1 week of dosing (top right) will reveal an absence of pachytene spermatocytes. After 2 weeks of dosing (one spermatogenic cycle duration) pachytene spermatocytes will still be missing but round spermatids will also be absent because their precursor cells were destroyed in the previous cycle (bottom left). Similarly, after 4 weeks of dosing (bottom right), pachytene spermatocytes, round spermatids, and elongated spermatids will be absent, leaving only spermatogonia. This progressive loss of subsequent germ cells following injury to a previous cell type is termed maturation depletion. ES, elongated spermatids; RS, round spermatids; PS, pachytene spermatocytes; Sg, spermatogonia. (Reproduced from Creasy, 1997, with permission.)

breakdown of the cytoskeletal fibers supporting the interconnecting cytoplasmic bridges. Multinucleate aggregates are less readily phagocytized by Sertoli cells and are present for longer periods and therefore more frequently seen. They are most often composed of round spermatids, but can also be formed by fusion of neighboring spermatocytes or elongating spermatids.

Germ cell depletion

This is the most common sequel to spermatogenic disturbance and is generally a consequence of germ cell death rather than exfoliation. It may be seen as a generalized or partial depletion of the germ cells or it may only affect a specific cell type (e.g., spermatogonia). Sometimes a specific cell type within specific stages may be affected (e.g., pachytene spermatocytes in stages XII and XIII). Once the cell has been phagocytized, the only way of recognizing the lesion is by the abnormal cellular association of individual stages of the spermatogenic cycle and the progressive development of maturation depletion with time (Fig. 16.4.2). The appearance of the testis, in terms of what cells are missing, will depend largely on how severe the initial effect was and how long after dosing the testis is examined.

Instead of a specific cell type being killed, a focal cohort of cells within a tubule may be affected and result in a focal "blow out" of the epithelium. This may be due to an effect on a few adjacent spermatogonia, which then fail to produce their cohort of spermatocytes and spermatids, or on one or two Sertoli cells, which are then unable to support spermatogenesis.

Partial or generalized germ cell depletion may affect only a small number of tubular profiles or a large proportion of the tubules. When only a few scattered tubules are affected, it is not possible to determine whether they

represent multiple convolutions of the same tubule or focal segments of multiple affected tubules. Prolonged dosing with a number of testicular toxicants may cause generalized germ cell depletion, affecting a large proportion of the tubules. It generally represents an advanced or end-stage lesion, and in order to elucidate the primary target cell, a time course study needs to be carried out.

It is not possible to say whether spermatogenic depletion is or is not reversible without carrying out an appropriate study. If spermatogonia are still present, then the lesion is potentially reversible but if the Sertoli cells are functionally compromised, spermatogenesis may not be supportable. The chronic effects of 2,5-hexanedione on the rat testis exemplify this. Although spermatogonia remain and are seen to divide, spermatogenesis does not recover. This is thought to be due to the inhibition of a critical Sertoli cell factor (Blanchard et al., 1998). Conversely, spermatogonia may be significantly depleted, but if the Sertoli cells are functionally intact and sufficient time is allowed for stem cell renewal and repopulation (and this may require several spermatogenic periods), substantial recovery may be seen (Meistrich, 1986).

Germ cell exfoliation

Loss of adhesion between Sertoli cell and germ cell, or shearing of Sertoli cell cytoplasm (as seen with cytoskeletal disrupting agents) will result in exfoliation of germ cells into the lumen of the seminiferous tubule and subsequent transport of the cells to the rete testis and the epididymis. The exfoliated cells may appear morphologically normal but are rapidly removed from the testis. Once the cells have been removed, cell depletion is the only recognizable finding. Lumenal germ cells may also be present as a result of handling trauma at necropsy. Care must be taken to distinguish between real and artifactual exfoliation (Foley, 2001). Abnormal residual bodies shed into the lumen can sometimes be mistaken for exfoliated germ cells. These generally occur as a result of disturbances in spermiation (see below).

Tubular vacuolation

Vacuolation within or between Sertoli cells is a common early sign of Sertoli cell damage. The vacuoles may be solitary and situated amongst the germ cells at varying depths throughout the epithelium. It is generally not possible by light microscopy to determine whether they are intra- or extra-cellular. In other cases, intracellular microvacuolation or swelling may be seen affecting the basal area of the Sertoli cell cytoplasm and causing germ cell displacement and disorganization. Such findings are suggestive of disturbances within the Sertoli cell and may represent alterations in the smooth endoplasmic reticulum or in fluid homeostasis. Vacuolation may also be seen in end-stage lesions, associated with extensive germ cell loss. In this situation, it should not be regarded as a primary effect on the Sertoli cell.

Occasional solitary vacuoles are sometimes seen in tubules from normal testes but these are generally few in number. Vacuoles in the basal compartment of the tubule, surrounding spermatogonia are generally fixation-induced artifacts due to osmotic shrinkage.

Tubular contraction

Reduction in the overall diameter of the seminiferous tubule will occur as a result of germ cell depletion and/or as a result of reduced secretion of seminiferous tubule fluid. Seminiferous tubule fluid is secreted by the Sertoli cell and maintains the lumenal size, which varies with the stage of spermatogenesis. This is an androgen-dependent function of the Sertoli cell and will be affected by altered testosterone secretion. Another major regulatory factor for fluid secretion is the presence of elongating and elongated spermatids. Therefore, if these cells are depleted, fluid production and consequently lumenal size are decreased. Germ cell loss and decreased fluid will have a significant effect on testis weight.

Tubular dilatation

Dilatation of the tubular lumen will occur as a result of increased lumenal fluid volume. This can occur through increased secretion by the Sertoli cell or decreased expulsion of fluid from the tubule, which is thought to be a function of the contractile peritubular cells. Also decreased resorption of fluid by the epithelial cells of the rete and efferent ducts or obstruction of the outflow (e.g., a sperm granuloma) can cause increased tubular fluid. The increased fluid volume will generally be reflected by an increased weight of the testis unless there is an accompanying significant cell loss. The pathological consequences of the finding depend on the severity and duration of the effect. Prolonged increased pressure on the seminiferous epithelium will generally result in pressure atrophy of varying degrees and may also lead to inspissated sperm and granulomatous inflammation.

Spermatid retention

This is a subtle but relatively common finding that may be caused by a number of chemicals as well as by hormonal disturbance. It is characterized by the retention of step 19 spermatids (which should be released during stage VIII) through stages VIII to XII. The position of the retained spermatids varies with different chemicals. In some cases, e.g., boric acid (Chapin and Ku, 1994), the retained spermatids remain in a predominantly lumenal position through stages VIII to XI and are then pulled down into the basal cytoplasm of stage XII tubules where they are phagocytized. With other chemicals the step 19 spermatids are rapidly pulled down into the basal cytoplasm and phagocytized during stages VIII to XI, leaving very few in a lumenal position. The formation and behavior of the residual bodies is often also disturbed with residual bodies of abnormal shape and size being seen in the tubular or epididymal lumen. Descent and phagocytosis of residual bodies normally occurs during stages IX to XI but in cases of spermatid retention this may be delayed into stage XII. The pathological significance of spermatid retention can be varied. It is often associated with abnormal sperm parameters (number, motility, or morphology) and it may be associated with alterations in fertility parameters. If homogenization resistant spermatids are measured, the retained spermatids should be reflected by an increase in this parameter. However, identification by histopathology is a much more sensitive endpoint since it can detect very small numbers of phagocytized spermatids.

Tubular necrosis

While germ-cell necrosis proceeds by apoptosis, tubular necrosis is characterized by coagulative (oncotic) necrosis of Sertoli and germ cells. Sertoli cells are normally highly resistant to cell death even though they may be very sensitive to functional perturbations. Consequently, they are often the only cell left lining severely damaged tubules (Sertoli cell–only tubules). Ischemia is one of the few situations where they are killed. The effects of this can be seen with cadmium toxicity, which damages the testicular capillary endothelium. It can also be seen following administration of vasoactive compounds such as serotonin. Necrosis and loss of the Sertoli cells from tubules is the major characteristic of the lesion, and this is associated with gross disorganization and necrosis of the germ cells as well as stasis of sperm in the tubular lumen. Due to the loss of the Sertoli cell blood-tubule barrier, the changes are also accompanied by an inflammatory infiltrate, which is an otherwise rare accompaniment to toxic injury. Tubular necrosis is a serious irreversible lesion because Sertoli cells are unable to proliferate and the affected tubules are likely to involute and be replaced by scar tissue.

Dilated rete

Both ends of the seminiferous tubules empty into the rete. Most of the tubule fluid is reabsorbed in the epithelium of the rete and efferent ducts. If there is an obstruction in the efferent ducts or in the epididymis, the fluid back-pressure will cause the rete to dilate and if the obstruction is severe, the back pressure will progressively dilate the seminiferous tubules. The tubules in the area of the rete also appear to be a preferential location for some testicular toxicants, but this should not be confused with the transitional tubuli rectii that join the seminiferous tubules to the rete and can be mistaken for depleted tubules.

Leydig cell atrophy/hypertrophy/ hyperplasia/adenoma

Testosterone secretion is the major function of the Leydig cell and the abundance of smooth endoplasmic reticulum in the cell reflects this activity. Increased stimulation by luteinizing hormone results in functional hypertrophy and hyperplasia. With prolonged gonadotropin stimulation in the rat, Leydig cell hyperplasia will usually progress to adenoma formation. Many classes of compounds with diverse chemical structures have been shown to produce this effect in the rat but the significance to man is considered limited (Clegg et al., 1997). Decreased secretion of testosterone, whether through inhibition of biosynthesis or decreased gonadotropin stimulation, will lead to atrophic changes in the Leydig cell.

Recognition of atrophy, hypertrophy, and hyperplasia on a qualitative basis is not easy unless the changes are marked. Contraction of tubules due to cell loss will result in an apparent increase in the volume of the interstitial space. This may or may not be contributed to by a real increase in size and number of Leydig cells, but quantitative analysis may be necessary to separate real from apparent effects.

Epididymis

Lumenal germ cells/debris

Cells and residual bodies exfoliated from the testis will be transported into the epididymis.

This can serve as useful confirmatory evidence for changes seen in the testis. It can also alert the pathologist to changes that may have been overlooked in the testis. Occasional exfoliated germ cells are sometimes seen in normal animals, and in immature and peripubertal animals this number is significantly increased. Abnormal residual bodies may also be detected in the epididymis as a consequence of disturbed spermiation in the testis. The presence or absence of germ cells in the luminal contents can also aid the pathologist in evaluating whether apparently exfoliated germ cells in the lumina of seminiferous tubules are real effects or artifacts of trimming; such artifacts will not be present in epididymal lumena.

Epithelial vacuolation

Microvacuolation of the epididymal epithelium can be seen as a specific chemically induced finding. Macrovacuolation and cribriform change (infolding of the epithelium within itself) is often seen accompanying contraction of the atrophic aspermic epididymis. This may represent a normal mechanism of surface area reduction but has also been reported as a toxicologic change (Foley, 2001). Epithelial vacuoles are also sometimes seen as a normal finding in some species at the junction of the corpus and cauda. Since fluid absorption and secretion are both major functions of the epididymal epithelium, vacuolation is a likely sequel to disturbance of either function.

Epithelial inflammation and sperm granuloma

The antigenically foreign sperm in the epididymal lumen and in the seminiferous tubule are in an immunologically protected environment. The protection is afforded by the lumenal tight junctions between epithelial cells in the excurrent ducts and by the basal occlusive junctions between Sertoli cells in the testis. If these barriers are damaged, then an inflammatory response against the sperm develops and generally progresses to form a sperm granuloma. This is a chronic, progressive lesion and in the coiled epididymal duct has the added complication of causing obstruction to the passage of sperm. Furthermore, the oxidative free radicals produced by inflammatory cells in contact with sperm can lead to genotoxic damage, which may have implications for male-mediated congenital defects and post-implantation losses (Chellman et al., 1986). The efferent ducts, which join the caput epididymis with the rete testis, are a particular site for damage. Certain chemicals, e.g., carbamates, cause sperm stasis and inflammation of these ducts resulting in partial or complete obstruction to sperm transit and secondary dilatation of seminiferous tubules. The mechanism may be through increased fluid absorption resulting in sperm stasis and inflammation (Hess, 1998). The efferent ducts are also a frequent site for the occurrence of spontaneous sperm granulomas. In species such as the dog, they often form blind ending tubules that contain inspissated sperm, which can develop inflammation and progress to sperm granulomas.

Ductular dilatation/interstitial edema

This can occur as a result of fluid imbalance mediated through the vasculature or inhibited fluid reabsorption by the epithelial cells. Inflammatory infiltrate and sperm granulomas are a frequent consequence.

Prostate/Seminal Vesicles

Acinar atrophy

Secretory activity by the prostate and seminal vesicles is a sensitive, androgen-dependent function. Decreased circulating testosterone levels, or interference with androgen receptors in these two tissues will result in reduced secretion leading to atrophic changes. These may be detected by organ weight changes as well as by microscopic changes

PRACTICAL APPROACH FOR EXAMINATION OF THE TESTIS AND EPIDIDYMIS FOR TOXICOLOGICAL EFFECTS

The approach used is influenced by the duration of the study. Cell- and stage-specific disturbances in spermatogenesis are usually only seen in short duration studies of <28 days. As discussed above, the kinetics of spermatogenesis combined with the process of maturation depletion, result in a progressive, germ cell loss, which becomes more generalized and affects more stages of spermatogenic cycle the longer dosing continues. Table 16.4.2 provides a rapid reference guide to common changes and their possible etiologic significance.

1. Review the testis and epididymis weights. Absolute weights are generally more useful than relative values because testis, like brain weight, is less influenced by body weight than most other tissues. A decrease in testis weight generally reflects germ cell loss and decreased tubule fluid production, while a decreased epididymal weight is likely to reflect

decreased sperm and fluid content. An increased weight in either tissue generally reflects increased fluid content, which is either interstitial or tubule fluid. Increased interstitial fluid will be seen as edema and suggests a vascular-mediated lesion while increased tubule fluid will be reflected by dilated tubular or ductal lumen size. There are various possible reasons for this (see Common Toxicologically Induced Findings and Their Possible Significance).

2. If testicular homogenization-resistant spermatids (HRS) and/or epididymal sperm have been counted, review these data. A decrease in HRS indicates a reduced number of elongated spermatids. This could be due to a direct effect on these cells or due to maturation depletion following effects on an earlier cell type (the answer should be apparent by histopathology). HRS data are particularly useful for confirming or alerting the pathologist to slight reductions in sperm production which may not be immediately obvious by qualitative histopathology. A reduction in HRS should be reflected by a decrease in epididymal sperm count, but only if sufficient time has elapsed between release of the reduced numbers of sperm from the testis and their arrival in the cauda epididymis or vas (~2 weeks). If caudal sperm are decreased in the absence of any effect on HRS, a direct effect on epididymal sperm or on sperm transit time is likely. An increase in HRS numbers suggests retention of elongated spermatids in the testis and should be confirmable by pathology.

3. Examine the testis at low power. Look for obvious depletion or disorganization of germ cells within the epithelium or exfoliation of germ cells into the lumen. Look for occasional atrophic tubules (shrunken tubules lined only by Sertoli cells) and determine whether the number is increased over control levels. Look for an increase in the number of vacuoles within the tubular epithelium. Look for tubular dilatation or tubular contraction.

4. At higher power, randomly scan tubules and check that the appropriate cell layers are present in their approximately normal numbers—i.e., that stages I to VIII contain a layer of spermatogonia, a layer of pachytene spermatocytes, and several layers of round spermatids interspersed with elongated spermatids. Stages IX to XIV should contain a layer of prepachytene spermatocytes, several layers of late pachytene or dividing (stage XIV) spermatocytes, and several layers of elongating spermatids. This does not require individual identification of stages, just a familiarization with the cellular make up of the two halves of the spermatogenic cycle. It will allow for the identification of when a cell population is missing. This is particularly important in studies of ≤28-days duration, where maturation depletion may not have progressed to produce an obvious lesion. If, for example, in a 28-day study in the rat, spermatogonia are killed, the most obvious finding in the terminal kill animals will be a loss of prepachytene spermatocytes in stages IX to XIV. Otherwise the testes may appear superficially normal. Check Leydig cells for relative number and evidence of hypertrophy, atrophy, or vacuolation. However, bear in mind that the morphological appearance of the Leydig cell is not a very sensitive indicator of function.

5. Identify a few tubules between stages IX to XI (there will be relatively few) and examine these at high power for evidence of sperm retention. There should be only one population of elongating spermatids at the lumen. Also examine a few stage XII tubules for evidence of sperm head phagocytosis in the basal Sertoli cell cytoplasm. These may occasionally be seen in normal stage XII tubules but rarely exceed more than ~2 to 3 per tubule cross section. Check a few stage VII tubules to ensure approximately normal numbers of step 19 (mature) sperm at the lumen and a normal appearing layer of residual bodies at the lumen. Also check stage VII tubules for any evidence of degenerate pachytene spermatocytes and round spermatids. Decreased testosterone levels will lead to an increased rate of degeneration in these cells in stages VII. The number of cells affected at any one time can be small (2 to 3 cells per tubule cross-section) but this stage-specific lesion is characteristic for and the most sensitive marker of decreased testosterone levels in the testis. Effects will become progressively more obvious with time, due to maturation depletion and direct effects on the elongating spermatids.

6. Examine the epididymis at low power for evidence of reduced sperm content, sperm granulomas, interstitial inflammation, or edema.

7. At higher power, examine ductal contents for evidence of testicular germ cells or residual bodies (increased above control levels). Examine epididymal epithelium for presence of vacuoles, inflammation, or altered cellular characteristics or complement compared with controls. If any alterations in sperm or cellular content of the epididymis is seen, go

Table 16.4.2 Rapid Reference Guide to Evaluation and Interpretation of Weight Changes and Histopathologic Findings in the Reproductive Tract

Finding/observation	What to look for	Possible causes
Increased testis weight	Seminiferous tubular lumen dilatation	Increased seminiferous tubule fluid that may be due to obstruction of outflow, decreased emptying of tubules, decreased resorption of fluid by rete/epididymis, increased production by Sertoli cell
	Increased interstitial fluid (interstitial edema)	Altered hemodynamics, injury to vascular endothelium, reduced lymphatic drainage
Decreased testis weight	Germ cell depletion	Disruption of spermatogenesis through effects on germ cells, Sertoli cells, hormonal disturbance, or blood supply
	Seminiferous tubule lumen contraction	Decreased production of seminiferous tubule fluid that may result from loss of elongating spermatids and/or decreased testosterone production
Increased epididymal weight	Increased interstitial fluid	Altered hemodynamics, injury to vascular endothelium, reduced lymphatic drainage
	Increased ductular fluid	Decreased resorption of fluid by rete, efferent ducts, and caput epithelium
	Sperm granulomas	May be spontaneous but may be induced by any agent causing inflammation or damage to the epididymal epithelial lining
Decreased epididymal weight	Reduced sperm content and contraction of ductular lumen size	Disruption of spermatogenesis resulting in reduced sperm production or release from the testis
Decreased weight of seminal vesicles and/or prostate	Atrophic changes in the secretory epithelium and decreased secretory product	Reduced levels of circulating testosterone, inhibition of 5-α reductase, or disruption of androgen receptor binding
Germ cell loss	Is a specific cell type(s) affected? Does the germ cell loss fit into a pattern of maturation depletion or is it nonspecific? Is it focal or diffuse, is it partial or generalized?	The pattern of the germ cell loss will provide valuable clues as to the likely mechanism of injury, but this will also be very much influenced by the duration of the study (see main text for detail). The pathogenesis of germ cell loss is best investigated in a short time-course study.
Loss of elongate and elongating spermatids	Degeneration of step 7 spermatids and pachytene spermatocytes in stage VII tubules	Disruption of testosterone secretion, which may be caused by direct effects on the Leydig cells or endocrine mediated effects. Alternatively, direct effects on elongating spermatids
Degeneration/apoptosis of germ cells	Is a specific cell type affected? Are the dying cells restricted to a specific tubular stage? Are the affected cells forming multinucleate aggregates?	The cause may be direct toxicity to the affected germ cell but it may also be mediated through a stage-specific disturbance to the Sertoli cell. Apoptotic cells are rapidly removed. Multinucleate aggregates suggest a slow, nonspecific degenerative process

continued

Table 16.4.2 Rapid Reference Guide to Evaluation and Interpretation of Weight Changes and Histopathologic Findings in the Reproductive Tract, continued

Finding/observation	What to look for	Possible causes
Germ cell exfoliation	Presence of exfoliated germ cells in the rete and epididymal lumens	Disruption of Sertoli/germ cell junctions leading to loss of adhesion; disruption of Sertoli cell cytoskeletal fibers leading to sloughing of apical Sertoli cell cytoplasm and attached germ cells
Macro/micro tubular vacuolation (in the absence of severe germ cell injury/loss)	Is this located in the basal Sertoli cell cytoplasm or scattered as large vacuoles throughout tubule? Look for accompanying or additional focal germ cell loss (suggesting focal Sertoli cell damage).	Disturbance of Sertoli cell function leading to vacuolation of organelles or disturbance of fluid balance. Do not confuse with osmotic-induced fixation artifact.
Necrosis and disorganization of tubular contents (including Sertoli cells)	Evidence of acute inflammatory infiltrate around affected tubules	Disturbance in hemodynamics or damage to the vascular endothelium leading to ischemic necrosis
Spermatid retention	Alteration in epididymal sperm parameters (morphology, motility, and count) and possible increase in HRS	Disturbance in testosterone secretion, in Sertoli cell function, or in spermatid development leading to failure in spermiation
Dilated seminiferous tubule lumens	Blockage of efferent ducts or epididymal duct; evidence of pressure-induced germ cell loss	Increased seminiferous tubule fluid that may be due to obstruction of outflow, decreased emptying of tubules, decreased resorption of fluid by rete/epididymis, increased production of fluid by Sertoli cell

back to the testis and examine carefully, since this probably reflects spermatogenic disturbance.

NOMENCLATURE AND SEVERITY GRADING OF SPERMATOGENIC DISTURBANCE (GERM CELL DEPLETION/GERM CELL DEGENERATION)

The nomenclature used to describe depletion and degeneration in the seminiferous epithelium will depend on the specificity of the findings seen, and this is most often related to the duration of the study. In a 1- or 2-year chronic study, any disturbance in spermatogenesis is likely to show as generalized germ cell depletion from some or all of the seminiferous tubules. Due to the duration of dosing and the effects of maturation depletion, there is unlikely to be any specificity in the germ cells lost or in the stages of tubules affected. The lesion seen is an end-stage lesion and therefore nonspecific terminology and simple severity grading based on proportion of tubules affected can be used (Table 16.4.3). Regulatory studies of ≤28 days duration or investigational time-course studies are much more likely to demonstrate specific patterns of germ cell loss and degeneration that may be restricted to specific stages of the spermatogenic cycle. The terminology used will depend on the specificity of such findings. Examples of general and specific findings are provided in Table 16.4.4.

The employment of a severity grading system will also depend on the nature of the findings. A general grading system based on the proportion of tubules affected by a given finding can be used for most nonspecific findings (Table 16.4.2). Grading becomes difficult for cell-specific and stage-specific findings. For example, if 50% of the pachytene spermatocytes in 100% of stage VII tubules are degenerate, how should this be graded? Although 100% of stage VII tubules are affected, this only constitutes ~20% of the total number of tubules in the testis cross section, and then only a proportion of the spermatocytes within the tubule are affected. Such situations have to be dealt with on a case-by-case basis and the terminology for each finding has to be made sufficiently detailed to impart the necessary information.

Table 16.4.3 Semiquantitative Grading System to Record the Severity of Germ Cell Degeneration or Depletion in Seminiferous Tubules

Severity grade	Approximate proportion of tubules affected
1 (minimal)	<5% of tubules affected
2 (slight)	5% to 25% tubules affected
3 (moderate)	25% to 50% tubules affected
4 (marked)	50% to 75% tubules affected
5 (severe)	>75% tubules affected

Table 16.4.4 Examples of NonSpecific and Specific Terminology to Categorize Germ Cell Loss and Degeneration in Seminiferous Tubules[a]

Nonspecific	Specific
Tubules with generalized germ cell depletion	Depletion/degeneration spermatogonia
Tubules with partial germ cell depletion	Depletion/degeneration prepachytene spermatocytes
Tubules with focal germ cell depletion	Depletion/degeneration pachytene spermatocytes
Occasional Sertoli cell–only (atrophic) tubules	Depletion/degeneration round spermatids
Germ cell degeneration/multinucleate aggregates	Depletion/degeneration elongating spermatids
	Depletion/degeneration elongated spermatids

[a]The choice of whether to use nonspecific or specific terminology depends on the cell specificity of the changes seen. In longer duration studies, germ cell loss is often patchy and nonspecific but shorter duration studies are more likely to show a cell-specific pattern of germ cell loss. If necessary, the cell-specific changes can be further specified in terms of the individual spermatogenic stage or range of stages affected. Each of the findings can then be graded using the approximate percentage of tubules affected (see Table 16.4.3).

ARTIFACTS, SPONTANEOUS PATHOLOGY, AND IMMATURITY

Preparative and Fixation Artifacts

As with any tissue, fixation and processing artifacts as well as spontaneous pathology need to be distinguished from toxicologic changes. Bouins fixation results in appreciable tubular shrinkage, which is more marked in the center than at the periphery of the testis. The enlarged interstitial area surrounding these shrunken tubules can be mistaken for edema. Formalin fixation, particularly in large animal testes can result in sufficiently severe cellular shrinkage that the cells appear pyknotic and the epithelium appears extensively vacuolated. Pressure from forceps during necropsy, or cutting into the testis before it is adequately fixed can result in displacement of germ cells into the tubular lumen that can be mistaken for exfoliation. For a review of some of the more common artifacts see Foley (2001).

Immaturity

In the testis, an additional factor that needs to be considered is the age and maturity of the animal. In the peripubertal animal, spermatogenesis is incomplete and inefficient. This is characterized by reduced numbers of elongating and elongated spermatids and a significantly increased population of degenerating germ cells of all types (spermatogonia, spermatocytes, and spermatids). Significant numbers of exfoliated germ cells and cell debris in the epididymal ducts and an absence or reduction of sperm usually accompany this. This appearance can be indistinguishable from chemically induced effects on spermatogenesis. In regulatory toxicity studies, this has proved a particular problem with respect to dogs since the regulatory guidelines recommend starting studies with dogs of an immature age (5 to 7 months). In studies of 13 weeks duration, the dogs are then on the borderline of maturity. Small group sizes and significant variations in the age that dogs attain full sexual maturity (8 to 12 months) can lead to difficulties in separating the appearance of varying levels of immaturity from chemically induced changes.

Primates used in toxicity testing are frequently immature and the variation between

age and maturity of individuals within a study can be marked. As a general guide, Cynomologous monkeys <4 years of age are likely to show varying levels of immaturity. An additional problem with primates is the effect of hierarchical status on testosterone levels and testicular development and regression.

In most routine regulatory studies using rodents, the guidelines recommend using animals of an age that are sexually mature by the termination of the study. In addition, there is much less variation in the age at which rodents attain sexual maturity. However, if a study design calls for the use of prepubertal animals, the increased rate of germ cell degeneration and the relative disorganization of the epithelium in this age of animal should be appreciated.

Spontaneous Pathology

Dog testes present a particular problem in terms of the level of spontaneous degenerative lesions and the prevalence of incomplete spermatogenesis in many tubules. Rehm (2001) has reported and quantified the incidence of various degenerative lesions in the testes of pure bred beagle dogs at various ages. Dogs 8 to 11 months of age showed a 27% incidence of testes with hypospermatogenesis (tubules with partial depletion of germ cells), a 100% incidence of testes with degenerating germ cells, and a 45% incidence of testes with segmental atrophy/hypoplasia. Since these changes are often indistinguishable from the nonspecific spermatogenic changes induced by chemical toxicants and because regulatory studies generally employ small group sizes, interpretation of slight increases in incidence can be a significant problem.

Rodent testes generally demonstrate a far lower incidence of spontaneous lesions. Unilateral or bilateral generalized tubular atrophy (Sertoli cell–only tubules) are not uncommon findings and occasional animals with partial or focal depletion of germ cells are also seen. However, in comparison with large animals, the use of larger group sizes generally allows ready distinction between spontaneous and treatment-related effects.

KEY REFERENCES

Chapin and Conner, 1999. See above.

This chapter provides an overview on how to approach and carry out histopathological evaluation of the testis including the use of staging. It also reviews the inter-relationship of morphologic changes in the testis with functional outcome and discusses the utility of sperm parameters.

Creasy, 1997. See above.

This key reference provides more in-depth consideration of the proper use of an understanding of spermatogenesis in the histopathologic interpretation of testis lesions, and will help the pathologist understand the proper application of staging in the regulatory framework.

Creasy and Foster, 2001. See above.

This chapter provides a general overview of the structure, function and physiology of the male reproductive system as well as responses of the system to toxicologic disturbance.

Knobil, E., Neill, J., Greenwald, G., Markert, C., and Pfaff, D. 1994. The Physiology of Reproduction, 2nd Ed. Raven Press, New York.

This is an invaluable and comprehensive reference text dealing with all aspects of reproductive physiology.

Russell et al., 1990. See above.

This is an essential reference text for beginners as well as those experienced in testicular histopathology. It provides detailed instruction on how to identify stages of the spermatogenic cycle in the rat, mouse, and dog. It also provides a wealth of information on testicular biology, histopathological and toxicological evaluation, fixation, ultrastructure and much more.

Monitoring Endocrine Function in Males: Using Intra-Atrial Cannulas to Monitor Plasma Hormonal Dynamics in Toxicology Experiments

The regulation of male reproductive function involves complicated, dynamic hormonal controls that include systemic (endocrine), local (paracrine), and intracellular (autocrine) components. As a result, concentrations of peripheral blood hormones are characterized by a great deal of inherent variation. Changes occur from point to point, minute to minute, hour to hour, and/or day to day. Given this situation, a single blood sample, for example at necropsy, is a poor representation of the dynamic health of any given hormone control system. A chronically cannulated animal provides a much better representation of endocrine homeostasis in animals being treated with potential toxicants. In a standard in vivo toxicology protocol, such as a multigeneration test or even a 30-day protocol, indirect evidence can suggest that an endocrine disruption has occurred (Tyl, 2002). Evidence of an endocrinopathy in endocrine organs (e.g., testes) or target organs of the hormones (e.g., prostate) includes increased or decreased organ size or altered histology. Significant differences in one or more organ parameters would suggest the presence of an endocrine anomaly and would provide additional information regarding the nature of that endocrinopathy. Finally, major changes in hormone secretion could be detected in a single sample of blood or urine.

Whereas some information can be obtained from a single blood sample or a cross-sectional experimental design (with different animals examined at each time point after treatment), longitudinal experimental designs optimize the data. With the cannulated rat model, one can assess (1) the point-to-point changes in a specific hormone (the pattern of release), (2) the relative changes in two or more hormones, and (3) the response (both acute and short term) to a hormonal or nonhormonal stimulus.

Other advantages of a cannula include (1) the elimination of multiple phlebotomies, (2) the ability to obtain longitudinal information (multiple samples) from a single animal, (3) a decrease in interanimal variability, and (4) a requirement for fewer animals (as compared with cross-sectional experiments). Cannulas can be used in combination with a tethering system to eliminate handling stressors and/or an automatic or manual infusion device for static treatment or rehydration.

When a toxicant affects the male reproductive organs, an endocrine disruption is very likely the cause. The cannulated rodent model can be used in one or more of these protocols to more clearly define endocrinopathies. This unit describes the authors' methods for surgical preparation for intra-atrial cannulation using a permanent tether apparatus (Basic Protocol 1) or a vascular access port (Basic Protocol 2) and blood sampling and collection (Support Protocol). The authors also present representative data obtained from two experimental designs that utilized these techniques.

NOTE: All protocols using live animals must first be reviewed and approved by an Institutional Animal Care and Use Committee (IACUC) and must conform to governmental regulations regarding the care and use of animals.

NOTE: Sterile technique should be used during all surgical procedures. Surgical instruments should be sterilized between animals. The surgeon should wear sterile gloves and use a sterile drape for each animal whenever possible.

BASIC PROTOCOL 1

INTRA-ATRIAL CANNULATION OF A MALE RAT WITH A PERMANENT TETHER APPARATUS

This method utilizes a permanently affixed tether system, sutured directly to the dorsal musculature between the scapulae. The rat has freedom of movement within its cage, and blood samples can be collected from outside the cage without disturbing the animal (Fig. 16.5.1). The animal cannot, however, be removed from its cage without the accompanying tether system. Maintenance of patency is more time consuming than with other techniques. This technique works best for studies of a shorter duration (7 to 10 days).

Materials

Silicone adhesive
Heparinized saline with gentamicin: 0.9% (w/v) NaCl (*APPENDIX 2A*)/20 IU/ml heparin/0.05 mg/ml gentamicin sulfate, sterile
Male rat
Anesthetic
Iodide scrub
70% (v/v) ethanol
Veterinary ophthalmic ointment (e.g., Paralube, Pharmaderm)
Microrenathane polyurethane tubing, 0.06-cm (0.025-in.) i.d., 0.1-cm (0.04-in.) o.d. and 0.1-cm (0.04-in.) i.d., 2-cm (0.8-in.) o.d. (Braintree Scientific)
Polysulfone anchor button with attached stainless steel spring tether (Instech Laboratories)
Swivel (Instech Laboratories)
Swivel-to-tether clamp (Instech Laboratories)
Ethylene oxide gas sterilizer
No. 22 scalpel blades, sterile
1-cc plastic tuberculin syringe with 23-G blunt-end needle, heparinized (i.e., coated with 1000 IU/ml liquid sodium heparin solution and allowed to dry)
Electric clipper
Toenail clipper or scissors
Hemostats and/or forceps, sterile
4-0 silk suture, sterile
20-G needles, sterile
Wound clips
Heating pad or heat lamp

Prepare cannula and tether system

1. Cut a 50.4-cm length of 0.06-cm i.d., 0.1-cm o.d. Microrenathane polyurethane tubing and a 3- to 4-mm piece of 0.1-cm i.d., 2-cm o.d. tubing to use as a collar.
2. Slide the short piece of tubing (collar) over the cannula tubing and place it ~5.0 cm from the end of the cannula.
3. Use a silicone adhesive to glue the collar in place at each end, forming a dumbbell-shaped anchor for sutures (Fig. 16.5.1A).

   The length of the cannula from the proximal end of the collar to the cannula tip will need to be modified at the time of surgery. This length is based on the weight of the rat (Table 16.5.1).

4. Thread the distal end of the cannula through a polysulfone anchor button and up through the attached spring tether. Attach the end of the tether to a swivel via a swivel-to-tether clamp.

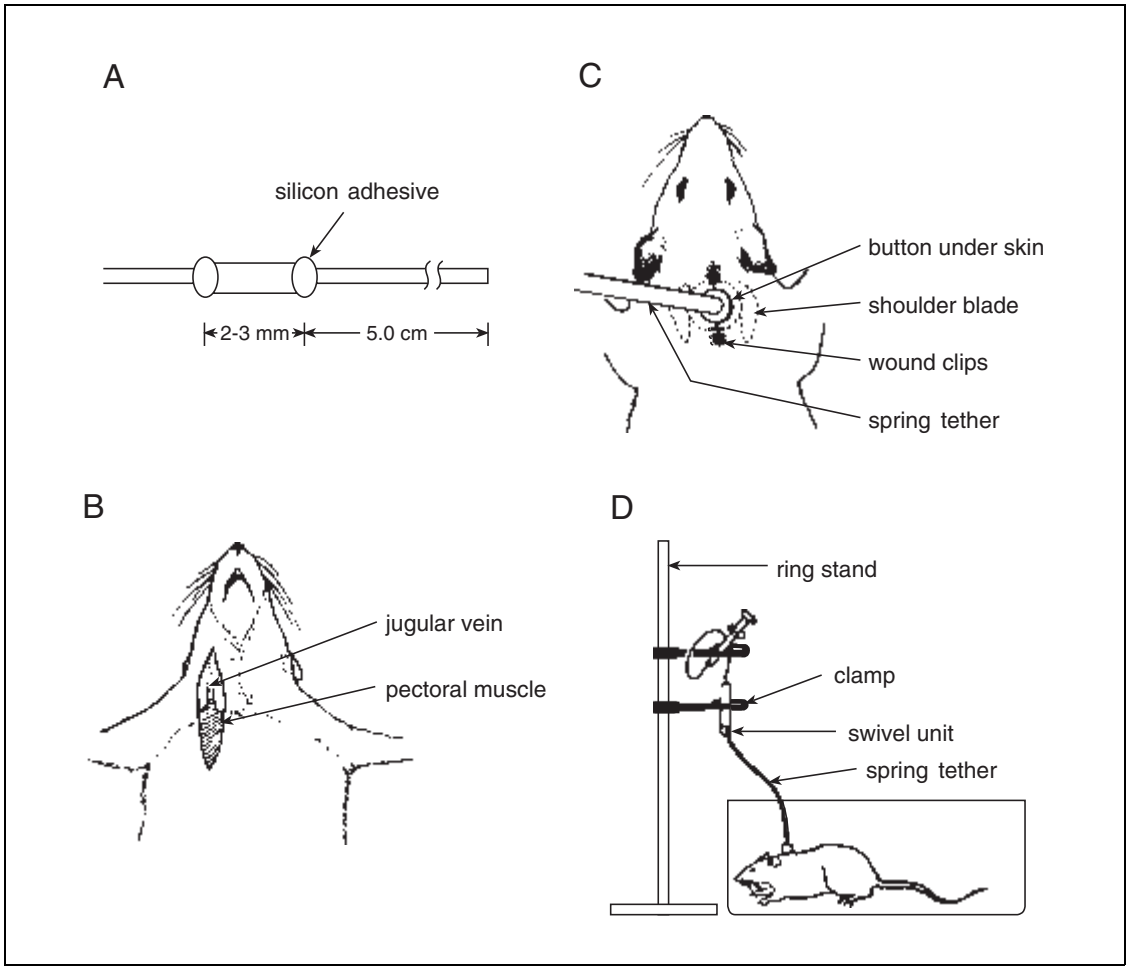

Figure 16.5.1 Cannulation procedure and permanently attached tether setup (see Basic Protocol 1). (**A**) The cannula with the attachment collar. (**B**) Surgical preparation of jugular vein. (**C**) Connection of permanent spring tether. (**D**) Relationship of animal to tether apparatus.

Table 16.5.1 Cannulation Surgery Information

Body weight range (g)	Cannula length (cm)[a]
210-245	2.5
246-60	2.6
261-320	2.8
321-350	3.2
351-375	3.4
376-400	3.6
401-450	3.8
451-475	4.0
476-525	4.2
525-550	4.3
>550	4.5

[a]The volume of the polyurethane cannula varies with its length and is ~0.15 ml; the volume of the Mini-Port is ~0.25 ml.

5. Sterilize the complete tether setup in an ethylene oxide gas sterilizer.

   Alternatively, complete sterile tether systems with custom-designed cannulas can be purchased (Strategic Applications) instead of being made in the lab.

Prepare for surgery

6. Place the sterilized tether system on a sterile surface. Use a sterile no. 22 scalpel blade to cut the cannula to the appropriate length based on the weight of the animal into which it will be inserted (Table 16.5.1). Cut the tip of the cannula at a 90° angle.

   A well-lit benchtop covered with an autoclaved drape is an appropriate sterile surface.

   The cannulation procedure can probably be carried out using smaller rats or even mice.

7. Fill a heparinized 1-cc plastic tuberculin syringe with a 23-G blunt-end needle with sterile heparinized saline with gentamicin and attach it to the distal end of the cannula. Fill the cannula with this flush solution, clearing all air from the cannula, and leave the syringe attached.

   The heparinized saline with gentamicin is used as the flush solution during surgery. It may be used with a computerized infusion pump for continuous infusion for maintenance of patency and hydration.

8. Clamp the cannula to a ring stand at the swivel for ease in handling during surgery.

9. Anesthetize a male rat using an appropriate anesthetic.

   Suggested choices are ketamine/xylazine/acepromazine (10:1:0.1 [w/w/w], 80 to 100 mg/kg intraperitoneally) or an inhalation anesthetic such as isoflurane. Injectable anesthesia can be supplemented with a methoxyflurane nose cone as needed.

10. Use an electric clipper to shave the fur from the ventral neck area and the dorsal surface over the scapulae. Clean both areas using an iodide scrub and 70% ethanol. Place a veterinary opthalmic ointment in each eye to protect them from drying during surgery.

11. Use a toenail clipper or a pair of scissors to trim the claws on all feet to reduce the chance of wound irritation by scratching.

12. Place the anesthetized rat and the prepared cannula and tether system on the surgical table.

Perform surgery

13. Use a sterile no. 22 scalpel blade to make an ~1-cm incision in the skin between the scapulae (midsagittal plane). Make a ventral incision (~2 cm) from below the point of the right lower jaw to just above the right clavicle (Fig. 16.5.1B).

14. Using sterile hemostats or forceps, bluntly tunnel subcutaneously from the ventral incision to the dorsal incision. Using the forceps, grasp the collar of the cannula and pull the cannula through the tunnel to the ventral incision.

15. Isolate the right jugular vein by bluntly dissecting away surrounding tissue. Elevate the vessel by placing forceps underneath it or by using a piece of sterile 4-0 silk suture held in one hand.

16. Using a sterile 20-G needle, make a hole in the jugular vein ~5 mm above the point where the vein widens to pass under the pectoral musculature (Fig. 16.5.1B).

    Pressure from the elevating forceps or suture should keep the vessel from bleeding.

17. Insert the cannula tip and advance it until the collar reaches the hole in the vein. Confirm correct placement of the cannula tip in the right atrium by drawing back on the syringe attached to the distal end of the cannula until blood appears in the proximal end. Flush blood back out of the cannula (into the animal) after confirming patency.

18. Pass one loop of 4-0 silk suture under the collar and vein and tie off between the ends of the collar to secure the cannula in place in the vein. Place a second suture under the vein and through surrounding muscle and fat and tie off between the collar ends to ensure that the cannula and vein are anchored to the surrounding tissue.

19. Close the ventral incision with wound clips.

20. Place the anchor button at the end of the spring tether under the skin and secure it by suturing it through at least two of the anchor holes to the underlying musculature. Close the incision over the anchor button with wound clips and/or suture (Fig. 16.5.1C).

21. Return the rat to its cage. Pass the tether and swivel through the wire cage top and secure the swivel to an appropriate anchor.

    A ring stand (Fig. 16.5.1D) or specially designed cages and/or cage racks can be used. Basic cage racks can be modified to accommodate ten cages with swivels clamped to permanent rack braces.

22. Disconnect the distal end of the cannula from the needle and syringe and connect it to the bottom of the swivel, leaving enough tubing to avoid tangling. Attach a second piece of 0.06-cm i.d., 0.1-cm o.d. tubing to the top of the swivel.

    This tubing may be connected to a blunt-end needle and syringe containing heparinized saline or may be connected to an infusion pump containing the same saline solution. Continuous infusion increases the length of time the cannula is patent for sampling and provides the needed postsurgical fluids (≤400 μl/hr may be infused). If the needle and syringe are used, ~0.3 to 0.5 ml solution should be flushed through the cannula at least three times per day.

23. Monitor animals following surgery for evidence of hemorrhage or other adverse clinical signs. If possible, use a heating pad under the cage or a heat lamp to keep the animal warm while it recovers from anesthesia. Provide a minimal 24-hr recovery period after surgery before proceeding with blood sampling experiments (see Support Protocol).

    In general, rats may be maintained with this tethering system for ≤10 days.

INTRA-ATRIAL CANNULATION OF A MALE RAT WITH A VASCULAR ACCESS PORT

BASIC PROTOCOL 2

This method utilizes the SIMS Deltec Preclinical Mini-Port. This is a totally implantable vascular access device that allows for repeated access for intravenous or intra-arterial injection or infusion (Fig. 16.5.2). The animal is not permanently attached to a tether and thus can move freely around the cage and can easily be removed from the cage. With proper cannula placement and postsurgical maintenance, the portal should remain patent (for infusion and blood sampling) for several months. The following surgical method that the authors use has been summarized from the *Preclinical Mini-Port Instructions for Use* pamphlet, which comes with the box of portals (see Key Reference).

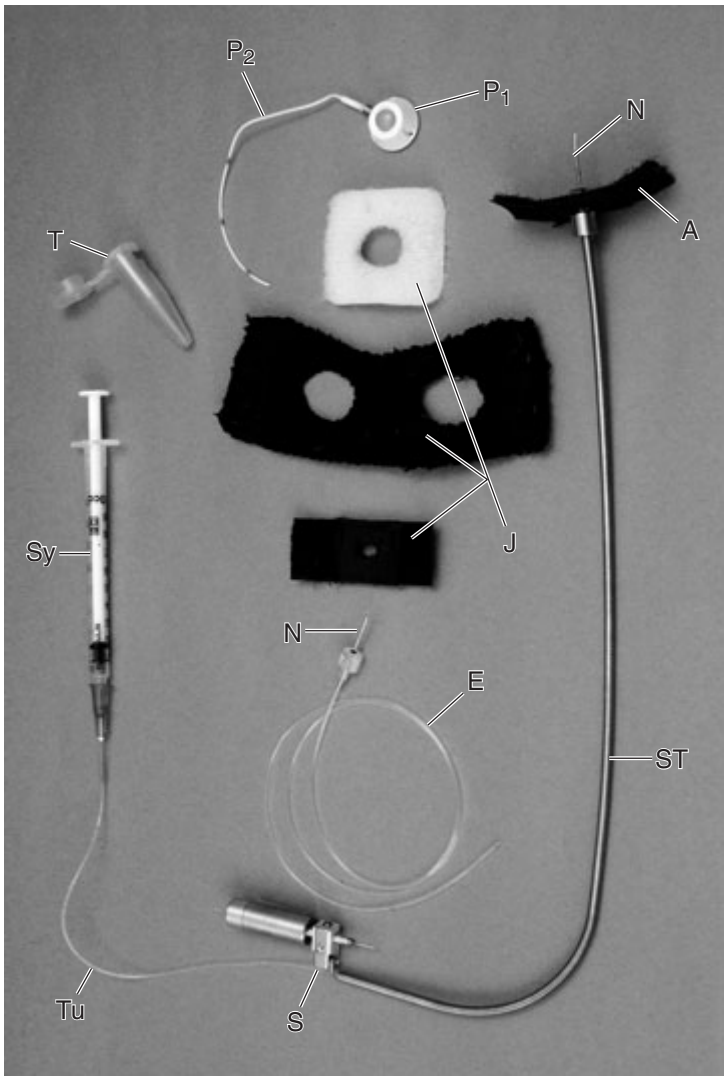

Figure 16.5.2 Mini-Port, tether apparatus, and jacket (see Basic Protocol 2). Shown are the vascular access port (P_1) with attached cannula (P_2); the jacket components (J); the external tubing (E) and noncoring needle (N); the assembled attachable tether (ST) with noncoring needle (N), jacket attachment (A), and spring (S) swivel, tubing (Tu), and sampling syringe (Sy); and polyethylene snap-cap blood sampling tube (T). Figure, without labels, used with permission from SIMS Deltec.

Materials

22-G noncoring Port-a-Cath needles (SIMS Deltec) attached to 5-ml syringes filled with sterile 0.9% (w/v) NaCl (saline; *APPENDIX 2A*)

Flush solution for ports: 0.9% (w/v) NaCl (*APPENDIX 2A*)/100 IU/ml heparin/0.05 mg/ml gentamicin sulfate, sterile

Surgical drape, sterile

Ruler with millimeter markings, sterile

Preclinical Mini-Port (SIMS Deltec)

Heating pad or heat lamp

Additional reagents and equipment for rat surgery (see Basic Protocol 1)

Prepare Mini-Port and catheter

1. Prepare a work area with good lighting, a sterile surgical drape, a sterilized ruler, and sterile no. 22 scalpel blades.
2. While wearing sterile gloves, place a sterile Preclinical Mini-Port on the sterile work area. Using a sterile 5-ml syringe and 22-G noncoring Port-a-Cath needle, flush the portal and catheter with sterile saline to remove all air from the reservoir. Hold the portal with the catheter attachment upward, and tap the portal gently while injecting the solution to remove air from the portal chamber.
3. Move the suture beads back toward the portal. To accomplish this, wet the catheter with sterile saline and then gently stretch a small section of the catheter at the bead site and begin moving the bead.
4. Cut off ~32 to 34 cm of excess tubing. Make the cut at a 90° angle to the catheter. Make sure the suture beads are still on the catheter tubing attached to the portal.

   The catheter has black marking at 2-cm increments to assist in measurement of the length to be removed.

5. Move the suture beads to the desired position.

   The distance from the tip of the catheter to the first suture bead will depend on the weight of the animal (Table 16.5.1). The second suture bead should be positioned ~3 to 5 mm from the first bead.

Perform surgery

6. Anesthetize a male rat and prepare the surgical sites as described (see Basic Protocol 1, steps 9 to 12).
7. Make a 3- to 4-cm dorsal incision just to the side of where the portal will be placed. Use blunt dissection to prepare a subcutaneous pocket that is just large enough to hold the portal. By trial insertion, check that the portal is the right size and that the portal does not lie directly under the incision.

   The portal should sit in the scapulae area.

8. Make a ventral incision (~2 cm) from below the point of the right lower jaw to just above the right clavicle. Make a small subcutaneous tunnel from the ventral incision to the portal pocket site. Grasp the catheter at the suture beads and gently pull it through the tunnel.

   Never use forceps with teeth to grasp the catheter. If the beads move as they are pulled through the subcutaneous tunnel, remeasure and reposition the beads before proceeding with jugular cannulation.

9. Isolate the right jugular vein by bluntly dissecting away surrounding tissue. Elevate the vessel by placing forceps underneath it or by using a piece of sterile 4-0 silk suture held in one hand.
10. Using a sterile 20-G needle, make a hole in the jugular vein ~5 mm above the point where the vein widens to pass under the pectoral musculature (Fig. 16.5.1B).

    Pressure from the elevating forceps or suture should keep the vessel from bleeding.

11. Insert the catheter into the vessel. Position the first suture bead inside the vessel if possible. Pass one loop of sterile 4-0 silk suture under the catheter and vein and tie off between the suture beads to secure the catheter in place in the vein. Place a second suture under the vein and through surrounding muscle and fat and tie off between the suture beads to ensure that the catheter and vein are anchored to the surrounding tissue. Place a tension loop (growth) at the site of insertion.

    The tension loop will provide extra catheter length to accommodate the growth of the animal.

12. Check for patency by flushing a small amount of saline through the portal and catheter using a 5-ml syringe and noncoring needle. Draw back on the syringe until blood is visible in the catheter. Flush the blood back into the animal with 0.4 to 0.6 ml sterile saline.

13. Lock the system by flushing through 0.3 ml flush solution for ports. Continue to inject the flushing solution while at the same time withdrawing the needle. Stabilize the portal using the thumb and finger.

    Injecting the flush solution while withdrawing the needle avoids the reflux of blood into the catheter.

14. Suture the portal to the underlying musculature using the portal suture holes. Close the incision with wound clips or suture, making sure the incision is not directly over the portal. Close the ventral incision with wound clips.

15. Return the animal to its home cage. If possible, use a heating pad under the cage or a heat lamp to keep the animal warm while it recovers from anesthesia. Observe the animal for any adverse clinical signs including wound hematoma, swelling, or any post-operative bleeding.

Perform postoperative maintenance

16. On the day after surgery, shave excess hair over the portal. Clean the area with an iodide scrub and 70% ethanol.

    Aseptic technique should be used when accessing the port whenever possible.

17. Palpate the area to locate the portal and stabilize it. Puncture the skin directly over and perpendicular to the plane of the septum using a 22-G noncoring Port-a-Cath needle attached to a 5-ml syringe filled with sterile saline.

18. Flush in ~0.2 ml saline, and then draw back on the plunger to confirm blood flow.

19. Flush blood out of the portal and catheter with 0.4 to 0.6 ml sterile saline.

20. Lock the system by flushing with 0.3 ml flush solution for ports. Continue injecting the flush solution while withdrawing the needle to avoid the reflux of blood into the catheter.

21. Repeat steps 16 to 20 on every other day following the surgery for the first week. Continue to flush the system twice a week for the next 4 weeks and weekly thereafter. Always flush the portal system well after injection or infusion or blood collection.

    As long as patency is maintained, this system can be used for ≤60 days.

SUPPORT PROTOCOL

COLLECTING AND PROCESSING BLOOD SAMPLES FROM A CANNULATED MALE RAT

Blood may be collected via the exteriorized cannula from outside the animal's cage with either of the cannulation techniques described above. When using the Preclinical Mini-Port, each rat must be fitted with a special jacket with attached tether, tubing, and specialized noncoring needle. The tether is then attached outside the cage to a swivel as in Basic Protocol 1. Blood samples are then collected in the same manner for either cannulation technique.

It is also possible to collect blood without using the jacket by removing the animal from the cage and accessing the port directly with a noncoring needle and syringe. The jacket system, however, avoids the effects of handling stress on parameters of interest.

Materials

Male rat with an intra-atrial cannulation with either a permanent tether apparatus (see Basic Protocol 1) or a vascular access port (see Basic Protocol 2)

Heparinized saline: 0.9% (w/v) NaCl (*APPENDIX 2A*)/20 IU/ml heparin, sterile

Rat jacket, steel spring tether, swivel, and polyurethane tubing with 1-cc syringe attached at distal end (complete setup may be purchased through Strategic Applications or jackets may be custom made; Fig. 16.5.2), for use with vascular access port only

Hand-held tubing clamp

1-cc syringes with 23-G (with 22-G i.d.) blunt-end needles, heparinized (i.e., coated with 1000 IU/ml liquid sodium heparin solution and allowed to dry)

1.5-ml heparinized blood collection tube

Prepare precollection setup

For vascular access port:

1a. Place a male rat with an intra-atrial cannulation with a vascular access port into a rat jacket.

The rat should be acclimated to the jacket for several days prior to blood collection. On the day of collection, acclimation of ≥30 min is suggested prior to blood sample collection.

2a. Before attaching the tethering system (which consists of a steel spring tether, swivel, and polyurethane tubing with a 1-cc syringe containing heparinized saline attached at the distal end) to the rat, fill the cannula with heparinized saline.

On the proximal end is the specialty noncoring needle attached to the tubing and the tether.

3a. Restrain the rat, insert the noncoring needle into the port, and secure the tethering system to the jacket.

4a. Return the rat to its cage. Attach the swivel to an appropriate anchor outside the cage (see Basic Protocol 1, step 21).

For permanent tether apparatus:

1b. Using a male rat with an intra-atrial cannulation with a permanent tether apparatus, proceed with blood collection as described in step 5.

Collect blood sample

5. Clamp the distal end of the cannula with a hand-held tubing clamp and disconnect the cannula from the swivel.

6. Attach a 1-cc syringe with a 23-G blunt-end needle to the end of the cannula, unclamp, and withdraw ~0.05 ml blood and heparinized saline into the syringe.

This is the presample consisting of the heparinized saline that was in the cannula and a small amount of blood. The presample syringe does not need to be heparinized, as this sample is discarded.

7. Clamp the cannula again and disconnect the presample syringe. Discard the presample and set needle and syringe aside for later use.

The presample needle and syringe can be used again for withdrawing heparinized saline from the cannulas of other animals.

8. Attach a second heparinized (clean) 1-cc syringe, unclamp the cannula, and withdraw the desired amount of blood. Place the blood in a labeled 1.5-ml heparinized blood collection tube.

Other appropriately sized containers can be used to hold blood sample.

9. Microcentrifuge the sample 2 min at 1200 × *g*. Using an appropriate pipet, remove the plasma, place in an appropriately labeled container, and freeze.

   Each blood sample should be immediately processed for plasma collection. Plasma storage conditions will depend on the requirements of the protocol.

Reinfuse red blood cells

10. Resuspend the remaining RBCs in a volume of heparinized saline (or other acceptable plasma substitute) equal to approximately one half of the total blood sample volume collected.

    These processing steps are generally done by personnel outside of the animal blood collection room.

    Because of the large blood volume collected for each blood sample, RBC reinfusion is necessary (blood sample size is usually 0.5 to 1.0 ml per sample as plasma is often analyzed for multiple hormones). If blood samples are being collected from some other indication (e.g., pharmacokinetics), then very small amounts of blood are collected at each time point (100 to 200 µl), and reinfusion is not done (no more than 15% of total blood volume should be removed in an 8-hr period). A different cannulation technique can be used. This approach, however, will not be discussed here.

11. Gently vortex (or invert) tube and draw the resuspended cells into a 1-cc syringe and attach a blunt-end needle, making sure there is no air in the syringe and needle.

12. Immediately after collecting a blood sample, attach the blood-filled syringe to the cannula, unclamp, and slowly reinfuse the resuspended sample.

    The resuspended RBCs from the previously collected blood sample should be reinfused (i.e., if this is the second blood sample collected, the RBCs from the first sample are reinfused).

13. Clamp the cannula, attach a clean blunt-end needle and syringe containing heparinized saline to the cannula, unclamp the tubing, and flush the cannula with ~0.3 to 0.5 ml heparinized saline to thoroughly clear it of blood.

    The volume of saline used will depend on the length of the cannula.

    If multiple samples are to be collected with short intervals between collection times (e.g., every 10 min for 2 hr), then the flush syringe may stay connected to the cannula until the next sample is collected. If the interval between samples is 20 to 30 min or more, the cannula should be reattached to the swivel apparatus.

14. Repeat this process for every blood sample collected. Make sure that the cannula is free of blood and filled with heparinized saline at the end of each collection.

COMMENTARY

Background Information

With the recent passage of the Clean Water Act and the Food and Water Safety Act, the effects of endocrine disruptors on human and animal health has national and international attention. Endocrine disruption may be the planned mechanism of action in the case of a pharmaceutical agent or an unplanned side effect of a drug, an agricultural product, or an industrial chemical exposure. Whereas the deliberate disruption of an endocrine system has therapeutic utility, endocrine disruption can also be the underlying basis for infertility, cancer, or other disease. Therefore, although endocrine testing is not a required portion of a preclinical testing battery, it can certainly be an important aspect of drug development and continued safety evaluation.

The cannulated rodent model has been used since 1964 (Weeks and Davis, 1964), and improvements have been made throughout the last 25 years (Harms and Ojeda, 1974; McKenna and Bier, 1984; Dons and Havlik, 1986; MacLeod and Shapiro, 1988). This approach

for endocrine studies in rodents as well as large animals contributed significantly to our understanding of endocrine controls (i.e., negative and positive feedback). The data obtained with this model very clearly illustrated the dynamic changes that occur in peripheral blood concentrations (Coquelin and Desjardins, 1982; Ellis and Desjardins, 1982; MacLeod and Shapiro, 1988).

The process of defining an endocrine perturbation involves a multifaceted, data-dependent approach. In animals, the first clue might be an enlarged endocrine gland or disrupted estrous cycles. For example, in males, hypertrophy of the Leydig cells may occur after exposure to an antiandrogen, such as occurs with flutamide (Viguier-Martinez et al., 1983a,b; Simard et al., 1986). In females, menstrual or estrous cycle may be disrupted after exposure to estrogenic compounds. In this case, the vaginal cytology should reveal increased cornification. These endocrine biomarkers can easily be included in standard protocols and are helpful clues upon which to base the design of additional testing.

Technical approaches for endocrine assessments are similar in any subspecialty of endocrinology (i.e., reproductive, thyroid, adrenal, or pancreatic studies). Sensitive quantification methods such as the radioimmunoassay are available to measure hormone content in blood, urine, feces, or cerebral spinal fluid. Receptor binding assays, bioassays, and molecular measures are also useful biomarkers of endocrine disruption(s), but they will not be discussed here. Nonetheless, it should be possible at selected times during a standard preclinical protocol to collect samples for one or more specific endocrine biomarkers. Radioimmunoassay of blood hormones has great utility and could be done on single samples collected periodically during the protocol or at necropsy.

Intra-atrial cannulation can be used to establish the functional status of endocrine organs, to administer chronic treatments, or for other situations when an undisturbed, unstressed animal is required. Blood hormone studies using the cannulated rat model can be designed as the situation warrants. Two special experimental designs are discussed below.

Functional evaluation approaches include (1) the longitudinal endocrine baseline assessment (LEBA) used to evaluate the secretion profiles of individual hormones or of two or more related hormones, (2) the endocrine challenge test (ECT), and (3) a combination of the two tests. Each of these tests must be specifically designed for the endocrine system that is being tested based on endocrine homeostatic relationships. ECTs have been used for many years in human medicine and to a lesser extent in veterinary medicine. For example, if the pituitary-testicular controls are of interest, an ECT design would be as follows: (1) to test testicular response, a challenge with human chorionic gonadotropin (hCG) is given to stimulate testosterone release; (2) to determine the pituitary's functional capacity to release luteinizing hormone (LH) and follicle stimulating hormone (FSH), a challenge with gonadotropin releasing hormone (GnRH) is appropriate; and (3) to determine whether the hypothalamic synthesis and release of GnRH is operational, stimulation or inhibition of GnRH using hypothalamic neuronal controls such as dopamine, norepinephrine, and/or melatonin may be appropriate.

In an experiment, one or more of these tests would be used in three types of test animals: controls, test-compound treated (at one or more doses), and pair-fed animals (if test article caused a decreased weight gain of ≥10% because of decreased feed consumption in preliminary studies). The authors have developed and defined ECTs in rodents based on the dose of a trophic hormone required to stimulate a 50% maximal response of the target organ hormone (effective dose 50; ED_{50}). Initially, GnRH and hCG ECTs were developed in rodent research to assess endocrinopathies of the reproductive system (Fail et al., 1992, 1998).

To accomplish these challenge tests in an in vivo study, intra-atrial cannulation would be used to facilitate frequent collection of blood samples. With respect to a GnRH challenge, samples would be collected at −30, 0, 2, 15, 30, 45, 60, 120, 240 and 1440 min (0 represents the time of GnRH treatment). LH and FSH concentrations would be determined in these samples, and the percent response, or the absolute response, at 2 and 15 min compared between groups. (For other ECTs, the time of maximal response should first be determined.) The area under the response curve might also be of interest. To prevent dehydration and anemia, red blood cells (RBCs) are reinfused after blood plasma has been harvested.

Each approach used to assess endocrine function has its strengths and weaknesses. The authors' initial approach was a permanent tethering system (see Basic Protocol 1). This system is very useful for studies of short duration

(2 to 10 days). But patency for sampling is limited, because a flap or clot forms on the end of the cannula and blood can no longer be obtained (O'Farrell et al., 1996). In another useful variation without restraint, if acute sampling is the objective (≤24 hr), the exteriorized cannula is cut short, plugged with a copper plug, and allowed to rest on the animal's back out of reach until use. When samples are to be collected for a short period (1 to 2 hr), the plug is removed, and a metal tube is inserted into the cannula (on one end) and connected to a longer tubing (on the other end). For this approach, the animals must be watched closely to prevent chewing on the sampling tubing.

The authors' second method, the use of an indwelling vascular access port (see Basic Protocol 2), is necessary when long-term patency for sampling is the desired objective (10 to 60 days). The titanium port (e.g., from Instech Laboratories, SIMS Deltec, or Strategic Applications) allows collection of a single sample (while another person holds the animal) or the temporary attachment of the tether (using a jacket) for serial sampling. The port is placed subcutaneously in the intrascapular region. The vascular access port is an improvement on the old system in that it is locked physiologically, preventing loss of heparinized saline out of the cannula or seepage of blood into the cannula between sampling. This approach also minimizes clotting at the cardiac end of the cannula.

The vascular access port not only increases the length of patency for both sampling and infusion but also avoids long-term tethering of animals. Animals can be tethered temporarily, samples collected, and then the jacket and tether are removed while the animals are treated for some period (5 to 30 days). Finally, the animals are reattached to the tether and a second series of samples is collected from each animal. In this design each animal serves as its own control, reducing variation between animals with associated endocrine data.

Critical Parameters and Troubleshooting

In order to increase the chances of long-term patency, sterile technique, if possible, should be used during the entire surgical procedure. This is especially important when using the vascular access port. Surgical instruments should be sterilized between animals. The surgeon should wear sterile gloves and use a sterile drape for each animal whenever possible. Surgical gloves should be used and changed between animals and after an animal has been handled during the surgical procedure. The prepared portal and catheter should be placed on a sterile towel or drape prior to insertion into the animal. The surgeon and other technicians should refrain from handling the portal and catheter without wearing sterile gloves. Use aseptic technique whenever accessing the port post-operatively. Prior to blood sampling, sterilize jackets, tethers, and additional tubing, and use only sterile needles and syringes. Otherwise, there is the possibility of bacteria-induced clots (white blood cells) forming in the cannula.

During a long-duration study, animal growth is a concern. Be sure to place growth or tension loops under the skin at the ventral incision site when using the Preclinical Mini-Port. Care in choosing the strain of rat and the age at which surgery will take place will help minimize this complication. If the animal grows rapidly, there is the possibility that the cannula will be pulled from its original placement and sampling patency will be lost (usually infusion patency remains).

Care should be taken not to give the animal too much heparin during surgery. Some strains of rats are more sensitive to heparin than others. It is often advisable to use unheparinized saline during surgery (when checking cannula placement), and then to use the heparin/gentamicin saline to flush the cannula once it is in place. An animal with too much heparin will often bleed around its incisions and will be more likely to form hematomas at the tether button or portal site.

During blood sampling, do not remove >1 ml blood at each time point. Remove the minimal volume required to complete the work, and reinfuse resuspended RBCs whenever possible. By reinfusing the RBCs resuspended in saline, the animal's blood volume and hematocrit remain somewhat constant even though large amounts of blood and plasma have been removed over the total sampling period. RBCs can be damaged, however, as a result of all the processing. Thus, it is advisable to check hematocrit levels of the animals periodically. Hematocrit levels will not change immediately following blood transfusions or blood loss. Thus checking the hematocrit at the beginning and end of a sampling period will yield little difference in levels. Check the hematocrit on the first blood sample collected and again 24 hr later. Rats rarely show adverse clinical signs until their hematocrits are quite low (40% to 50% of normal). It would, however, be advis-

able to make sure that the hematocrits are within 10% to 20% of the original values before initiating a second sampling period (e.g., 1 or 2 days later).

Additional do's and don'ts during blood sampling include (1) making sure there is no air in the cannula and/or syringe when reinfusing RBCs or flushing through heparinized saline, (2) flushing saline or reinfusing RBCs relatively slowly to avoid a vascular system overload with a large bolus of solution, (3) avoiding leaving blood in the cannula for more than a few seconds (clotting occurs rather rapidly), and (4) avoiding using infusion solutions colder than room temperature.

Whether the permanent tether system or the vascular access port is used, if the cannula is patent for infusion but blood cannot be withdrawn, then there is the possibility that a small clot or flap may have formed at the tip of the cannula. Filling the cannula with a fibrinolytic agent, such as streptokinase or trypsin, for 24 hr may dissolve the clot. Often a fibrous sheath will form around the cannula. This has been determined to be composed of vascularized fibrous connective tissue and not fibrin (O'Farrell et al., 1996). Thus, fibrinolytic agents have little to no effect on it. It is best to flush the cannula with heparinized saline (in the case of the tether system) as often as possible, or to use a continuous infusion pump, to keep clots from forming. With the vascular access port, flushing the port every other day for the first week postsurgery is recommended. Generally, it is not necessary to check patency and flush the port and cannula more than once or twice a week after that.

Depending upon study design, the blood sampling procedure can be very labor intensive. If blood samples (with RBC reinfusion) are to be collected every 10 min, one person should be able to sample up to three animals (if all goes well). If 30 animals are being sampled at one time, then blood sampling personnel will number at least 10. At least two additional persons will be needed to continually process the blood samples during the sampling period. One or two people may be used to transport blood samples and reinfusion samples back and forth between the animal room(s) and the processing room. Another individual can provide technical and troubleshooting support to all other staff (backup).

The use of cannulated animals is particularly important when (1) stress hormones are being studied, (2) the effects of anesthesia are undesirable, (3) only one person is available for sampling, or (4) infusions are administered via computerized or mechanical pumps. With either approach (permanent tether or vascular port), blood samples can be withdrawn and/or treatments administered without handling the animal. This minimizes the stress response of hormones such as prolactin, corticosterone, oxytocin, and/or epinephrine, which are released when animals are restrained, anesthetized, frightened, or in pain (Suzuki et al., 1997).

The collection of samples from cannulated animals minimizes the release of these stress hormones and their impact on the hormones being studied. For example, norepinephrine and epinephrine concentrations were 2- to 8-fold lower in blood samples collected from jugular cannulas than in those collected from decapitated animals (Paulose and Dakshinamurti, 1987). Corticosterone response due to handling or stress was minimized (MacLeod and Shapiro, 1988). Cardiac response to the cannulation is resolved within 24 hr (Paulose and Dakshinamurti, 1987), and LH response to GnRH is normal within 2 days (Fail et al., 1992, 1998). FSH response may not be normal until 5 to 7 days after cannulation (P. Fail, unpub. observ.). Replacement of RBCs is used to maintain hematocrit in the normal range (MacLeod and Shapiro, 1988) for single samples taken over several days or during intense sampling windows such as for the ECT or LEBA (Fail et al., 1992).

Anticipated Results

The use of intra-atrial cannulation for serial sampling of unrestrained, untreated animals to illustrate endocrine secretion patterns is well established in the reproductive endocrinology literature and has significantly contributed to our understanding of endocrine signaling. These LEBAs are designed based on knowledge of the endocrine system being evaluated. For example, samples collected every 10 to 15 min during a 2- to 4-hr period can be used to determine profiles of a single hormone such as LH or thyroid stimulating hormone (TSH) and/or the relationship of two or more hormones (such as LH and testosterone, or TSH and thyroxine).

The authors (Fail et al., 1992, 1995, 1998, 1999) have collected endocrine data using both of these designs. The relationship of secretory patterns of LH to those of testosterone for untreated male rats in a LEBA is shown (Fig.

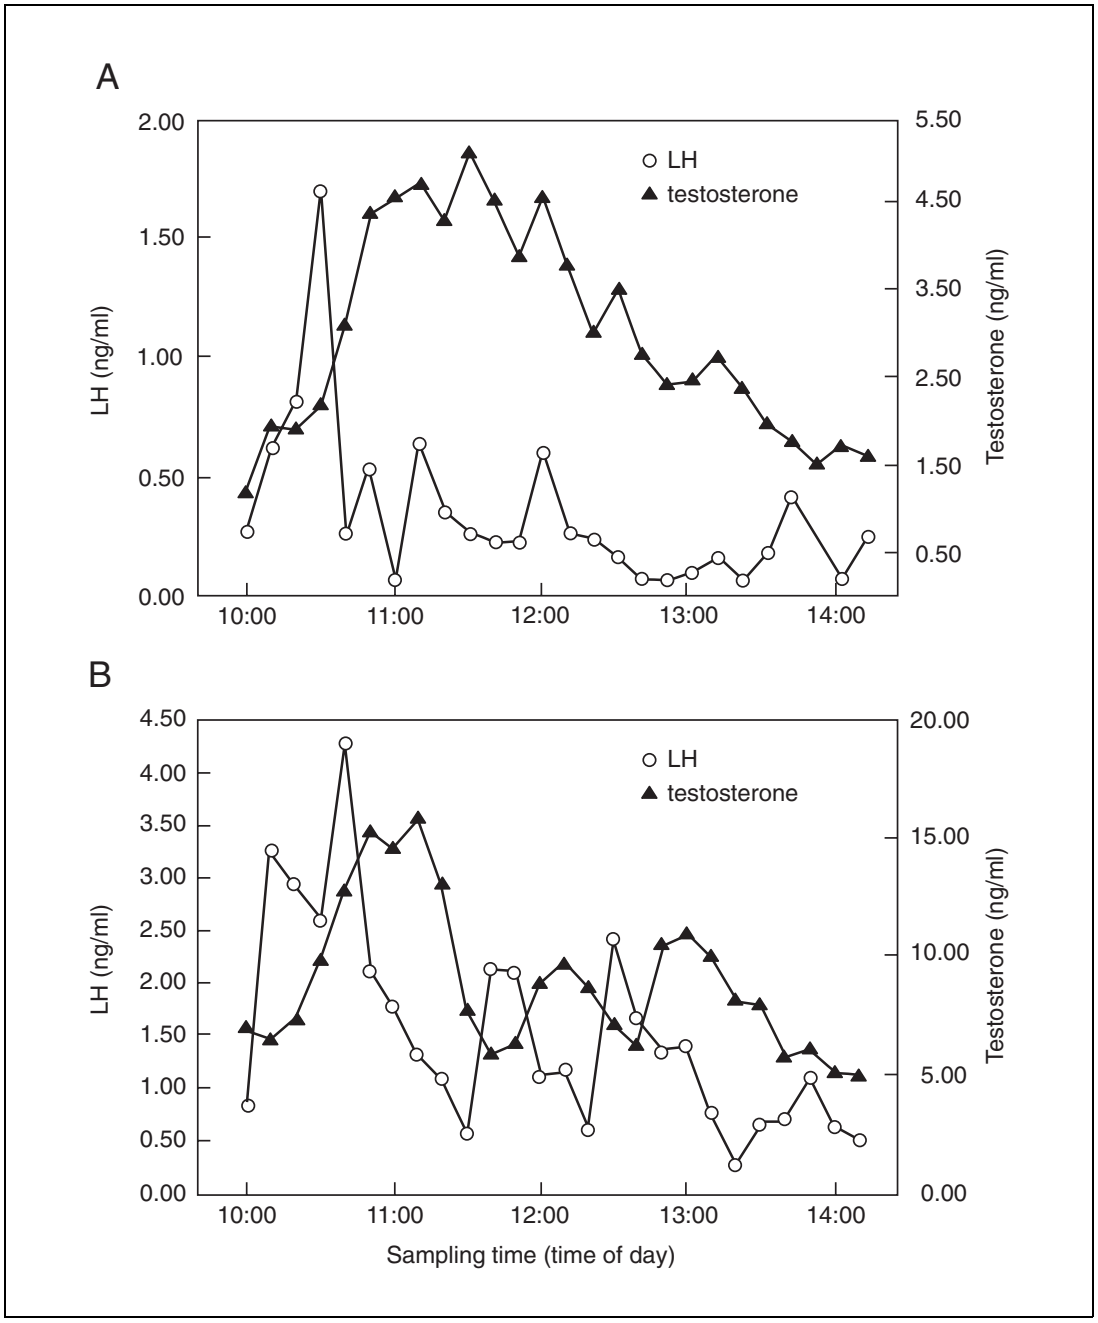

Figure 16.5.3 Longitudinal endocrine baseline assessment (LEBA) in two animals. Plasma luteinizing hormone (LH) and testosterone concentrations in a male Sprague Dawley rat were collected every 10 min during a 4-hr period. (**A**) Data are typical of a control (vehicle-treated) animal used for repeated sampling without endocrine challenge. The relationship of the two hormones within each time point and the prolonged response of testosterone to the LH spike is evident. In control animals, the LH spike lasted <30 min and evoked a broad plateau of testosterone release lasting >2 hr. (**B**) In animals treated with flutamide, LH concentrations were increased in amplitude and the spikes lasted longer than in controls. Testosterone response to LH, although it occurred, was of a shorter duration than for the control rat. Ten cannulated animals were prepared for each treatment group in this experiment, but the data were examined for individual animals, and typical curves are shown here. Data are from the authors' laboratory and are used with client's permission.

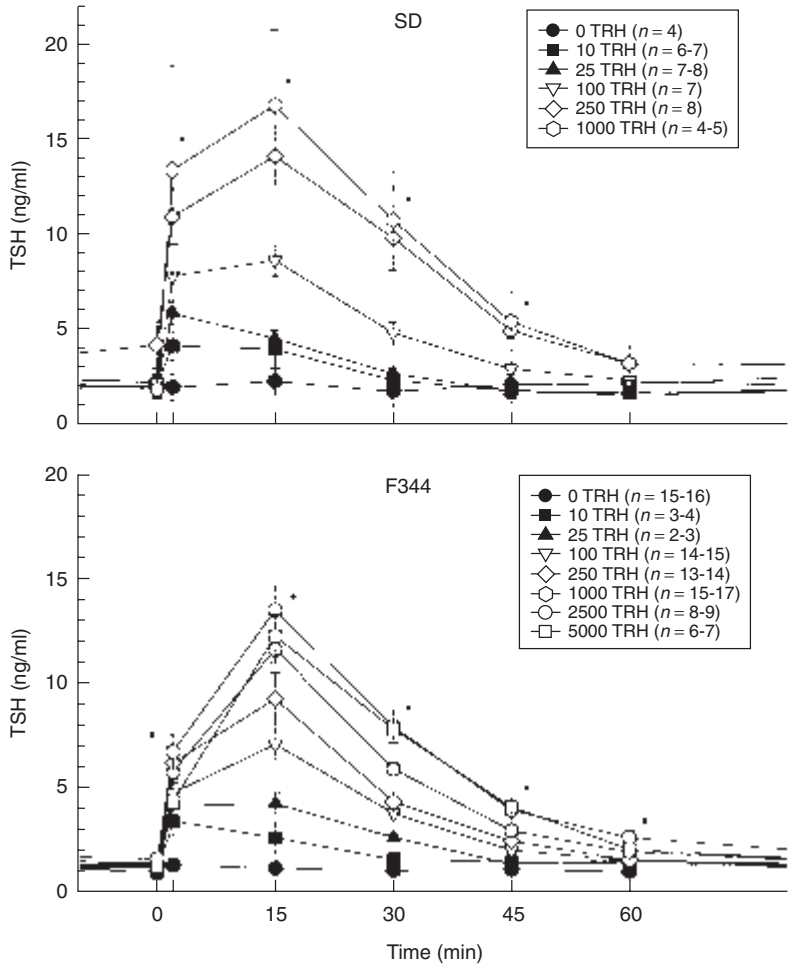

Figure 16.5.4 An endocrine challenge test (ECT) summarized for groups of animals. The response of thyroid stimulating hormone (TSH) to different concentrations of thyrotropin releasing hormone (TRH; dosage given in nanograms per 100 g) in male Sprague Dawley (SD) and Fisher 344 (F344) rats. In this ECT, an effective dose and duration of response was established. The difference in effective dose 50 (ED_{50}) for the two strains was established. Occasionally, samples could not be obtained from all animals for a specific time point. This is indicated by a range of *n* values. The lower number is the minimal number of animals represented in all points for that treatment. Asterisks indicate a statistically significant difference from controls within treatments ($p \leq 0.05$). Reprinted from Fail et al. (1999) with permission from Oxford University Press.

16.5.3A), and the data agree with those reported elsewhere (Ellis and Desjardins, 1982). The secretory patterns were changed for LH, FSH, and testosterone in males given flutamide (Fig. 16.5.3B). The authors also have ED_{50} data for LH, FSH, and testosterone after GnRH and hCG challenge in Sprague Dawley males, and for TSH, triodothyronine (T3), and thyroxine (T4) after thyrotropin releasing hormone (TRH) challenge (Fig. 16.5.4) in male Sprague Dawley and F344 rats.

Time Considerations

The total time for the cannulation protocol is short compared with that for the entire experiment. Planning should include the overall experimental plan. The total time will equal the sum of the following parts.

1. The development and design of the experiment requires 1 to 4 weeks depending on the available preliminary data and the knowledge of the endocrine system being evaluated. (An endocrine consultant should be used as needed.)

2. Animal Use Committee approval requires 1 to 4 weeks based on the frequency with which the committee meets. Also plan for Quality Assurance Unit approval of the experimental protocol if relevant.

3. Allow time for ordering supplies and materials; some materials are difficult to obtain or require assembly. The design will dictate whether vascular access ports are needed or if noncoring needles should be used for repeated access.

4. The surgery time per animal is based on the experience of the surgeon. Some animals will be more difficult to complete than others. If 30 animals are being used, allow 2 or 3 days. Sterilization of materials requires 1 to 7 days.

5. A recovery time of 7 days is recommended for indwelling (vascular access) ports. For an acute or short-term protocol, 2 days may be sufficient. The cannula should be flushed every other day during the recovery period.

6. The time required for sample collection depends on the experimental design. Allow 1 day for ECT and 1 day for LEBA studies. These times may be stretched out if all animals cannot be sampled during the same day (and same time regimen). Each technician can handle two to four animals simultaneously depending on the sampling regimen. The authors routinely handle 30 animals in a protocol using 10 to 14 technical staff. Allow 6 hr for a 4-hr LEBA.

7. Processing of the blood samples occurs simultaneously with sample collection. This includes the time needed to label and store the samples. Two technical staff are required.

Subsequent time considerations beyond the scope of these protocols include the sample radioimmunoassays (which require 2 days to 1 week per hormone and are hormone and sample number dependent), data management and statistical analysis (which require 2 to 4 weeks), and the generation of a study report (which requires 1 to 4 weeks, depending on the extent of the project and the use of good laboratory practices regulatory oversight).

Epididymal Sperm Count

Epididymal sperm count is a widely used, simple, and sensitive method for assessing the effects of male reproductive toxicants on the epididymis and/or testis. Usually the epididymis is divided into three parts: the caput, corpus, and cauda (Fig. 16.6.1). It is the epididymal cauda that is extensively used to perform epididymal sperm count. The method described in this unit is principally used for fresh tissue from rodents; however, the method can also be used for frozen epididymides with modifications.

Materials

PBS (*APPENDIX 2A*)
Necropsied male rats or mice, treated and control, euthanized
15 × 60–mm (rats) or 15 × 30–mm (mice) and 1.5 × 2.0–cm petri dishes
Slide warmer
13 × 100–mm test tubes and appropriate rack
Microscope: 10× and 40× objectives and 10× or 15× eyepieces
Necropsy board
0.1-mm-deep improved Neubauer hemacytometer and coverslips
No. 11 scalpel blades
60°C water bath
Gauze
Hand tally counter
Data collection system (i.e., hand-generated data form or computer-generated data collection system)

Additional reagents and equipment for using a hemacytometer (*APPENDIX 3B*)

NOTE: All protocols using live animals must first be reviewed and approved by an Institutional Animal Care and Use Committee (IACUC) and must follow officially approved procedures for the care and use of laboratory animals.

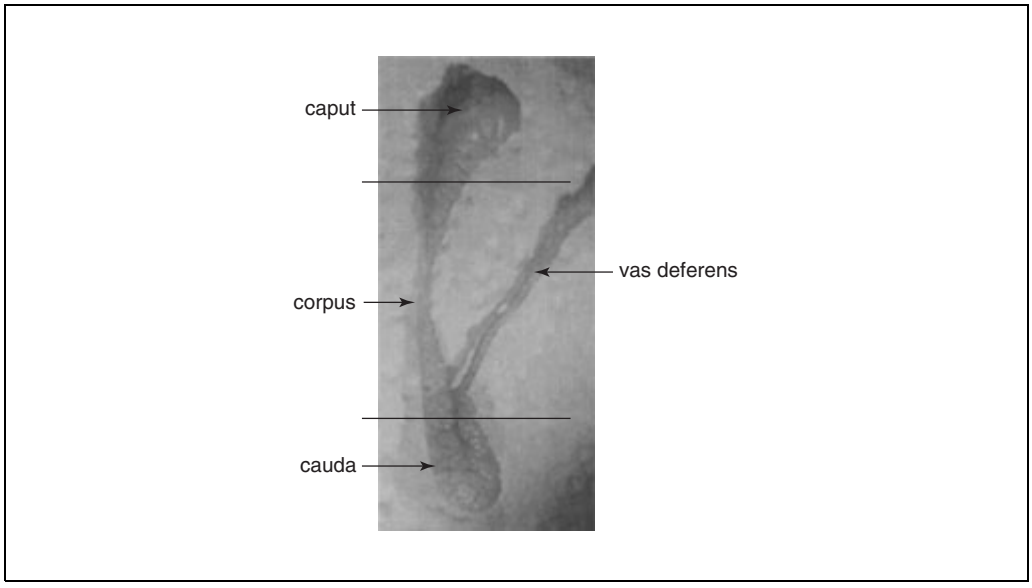

Figure 16.6.1 A rat epididymis and its three anatomic parts: caput, corpus, and cauda.

Contributed by Yefan Wang
Current Protocols in Toxicology (2002) 16.6.1-16.6.5

Prepare equipment

1. Label 15 × 60–mm (rats) or 15 × 30–mm (mice) petri dishes one for each animal, with the corresponding animal numbers. Fill with PBS (2 or 10 ml for mice or rats, respectively), and place on a slide warmer set at 35° to 37°C.
2. Equilibrate a water bath to ~60°C.

   If using a hot plate, use a glass beaker (100 ml) containing ~50 ml water.

   The purpose of the water bath is to kill motile sperm and allow an accurate count.
3. Label 13 × 100–mm test tubes, one for each animal, with the corresponding animal numbers. Add 2 ml PBS to each tube.
4. Turn the microscope on.
5. Clean a 0.1-mm-deep improved Neubauer hemocytometer and coverslips (both need to be cleaned between animals).

Prepare samples

6. Acquire the first necropsied male rats or mice, treated or control, euthanized by an approved method.
7. Place the animal on a necropsy board with the ventral side up. Open the abdominal cavity by making an ~5 cm incision in the lower right abdominal area. Pull out the right epididymis and testis by grasping the epididymal fat with a pair of forceps, leaving the vas deferens attached as a reference point (Fig. 16.6.1).
8. Isolate the epididymis from the testis and trim away fat. Place the entire epididymis on a flat surface. Procure the epididymal cauda by cutting ~1 mm down from the junction of the vas deferens and the epididymis cauda (see Fig. 16.6.1).
9. Measure and record the weight of the cauda in milligrams.
10. Place the cauda in a petri dish containing a known volume of PBS (2 or 10 ml for mice and rats, respectively) prewarmed to 35° to 37°C, and mince using two no. 11 scalpel blades to open the epididymal duct and release its contents. Swirl the petri dish several times to achieve a uniform sperm suspension.
11. After incubating at least 15 min at 35° to 37°C, mix the sperm suspension several times using a Pasteur pipet.
12. Using a 1-ml pipet, transfer 0.5 ml sperm suspension from the petri dish to a corresponding test tube containing 2 ml PBS, room temperature, avoiding transferring the epididymal tissue. Mix the tube by lightly tapping the bottom.
13. Place the test tube in a ~60°C water bath for ~1 min. Return the tube to the test tube rack and cool to room temperature.

Count sperm

14. Mix the diluted suspension, measure 10 µl with a micropipet, and load one side of the hemacytometer. Next, mix the suspension again by vortexing and load the other chamber. Place the loaded hemacytometer onto a clean 1.5 × 20–cm petri dish, bedded with a portion of moist gauze, for 2 min to allow the sperm to settle.
15. Place the hemacytometer on the microscope stage and focus on the top left secondary square (square no. 1; see Fig. A.3B.1 in *APPENDIX 3B*) of the tertiary square.
16. Count the number of sperm (entire structure) lying in the five secondary squares (nos. 1 to 5) and lying on or touching the top and left lines of the secondary squares (Fig.

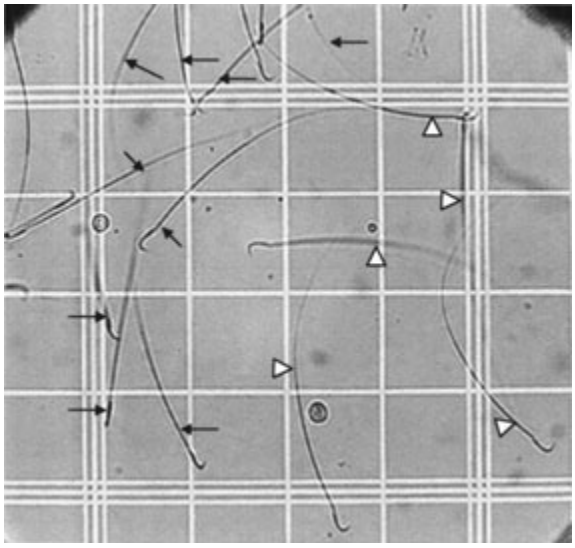

Figure 16.6.2 Actual microscopic photograph of the secondary square (area within the triple line border) of a hemacytometer (see Fig. A.3B.1 in *APPENDIX 3B*). The black arrows indicate the nine sperm that will be counted; five white arrows identify the sperm that will not be counted.

16.6.2). If there are less than 25 sperm in those five secondary squares, count the sperm in the entire tertiary square (all 25 secondary squares).

If any part of the sperm lies within or over the right and/or bottom lines, crossing right and bottom lines, it must be excluded from the count. If any part of the sperm lies within or over the left and/or top line, crossing either top or left line, that sperm must be counted.

There is one tertiary square on each side of the hemacytometer.

17. If clumped sperm are noted, reload and recount.
18. Record two counts for each animal on a hand tally counter and data collection system.
19. Calculate the total number of sperm per cauda epididymis based on the secondary count:

$$\text{Total sperm} = \text{mean count} \times \text{dilution factor}$$

where:

$$\text{Mean count} = (\text{count 1} + \text{count 2})/2$$

and

$$\text{dilution factor} = \frac{\text{total vol. PBS in dish}}{\text{transferred vol.}} \times \frac{\text{total vol. test tube}}{\text{vol. secondary square} \times \text{no. squares}}$$

For the protocol listed above, the transferred volume is 0.5 ml and the volume of a secondary square is 4×10^{-6} ml.

20. Calculate the epididymal sperm count per milligram cauda (sperm density):

Sperm density = (mean count × dilution factor)/cauda weight (mg) *or*

Sperm density = total number sperm per cauda/cauda weight (mg).

COMMENTARY

Background Information

The epididymis is a single, highly-coiled duct with functions that include reabsorption of the rete testis fluid, metabolism, epithelial cell secretions, sperm maturation, and sperm storage. The caput and the corpus play important roles in sperm maturation, with the cauda regarded as the site of sperm storage. The sperm require 1.8 to 4.9 days to move through the caput to the corpus epididymis and the travel time of sperm through the cauda ranges from 3.7 to 9.7 days among different species (Klassen, 1996). The first appearance of spermatozoa is detected in the caput at 45 days of age and in the cauda at 52 days of age, while the sperm population reaches the maximum in the caput at 72 days of age and in the cauda at 100 days of age. The sperm population is maintained beyond 450 days of age (Saksena et al., 1979). The number of sperm in the corpus and the caput epididymis is similar in sexually rested males and in males ejaculating daily. The number of sperm in the cauda epididymis may vary depending on the male's sexual activity (see Table 16.6.1).

Epididymal tissues are often obtained after a terminal sacrifice. This method can be modified and used on other species by adjusting the dilution. W.G. Kempinas (1988) recommends treating sperm suspensions with 0.05% collagenase for 20 to 60 min or 0.025% trypsin for 1 to 2 min at 34° to 37°C, which was found to result in a consistently homogeneous sperm sample. The Hamilton Thorne Biosciences Integrated Visual Optical System provides a fluorescent method of determining sperm concentration without the interference of detritus by

Table 16.6.2 Troubleshooting Guide for Sperm Count Errors

Problem	Possible cause	Solution
Count too low	Animals are too young (<60 days)	Use rats that are at least 60 days old
	Only a partial cauda was used	Refer to Fig. 16.6.1
	Settle time is too short (<2 min)	Use a timer (may help)
	Sharing cauda with sperm motility analysis	If possible, collect motility sample from vas deferens
	Incorrect dilution procedure	Review the dilution procedure
	Treatment effects reduced sperm output from the testis or speeds epididymal transit	Determine if a dose-related decrease is evident
Count too high	Cauda isolated with partial caput	Refer to Fig. 16.6.1
	Incorrect dilution procedure	Review the dilution procedure
	Clumping sample	Verify settle time and make dilution if necessary
Inconsistent count	Shorter settle time	Use a timer (may help)
	Clumping or nonhomogeneous sample	Mix well prior to sampling
	Inconsistent excision of the cauda	Refer to Fig. 16.6
	Underload or overload by using a Pasteur pipet	Switching to a micropipet might help

Table 16.6.3 Sperm Density and Total Number of Sperm per Cauda in Rodents[a]

Strain/species	Cauda sperm density (sperm/mg)[b]	Cauda sperm count[c]
CD-1 Mice	778.70 ± 331.718 (40)	16.35 ± 2.395 (40)
FVB Mice	470.90 ± 267.344 (53)	6.48 ± 3.726 (53)
C57BL/6 Mice	1376.49 ± 430.727 (19)	25.36 ± 5.728 (19)
Tg. AC Mice	437.44 ± 221.844 (42)	5.87 ± 3.268 (42)
CD-1 Rats	369.86 ± 114.480 (160)	145.06 ± 32.914 (160)
Fisher 344 Rat	702.00 ± 145.502 (30)	111.69 ± 26.251 (30)

[a]Values are given as mean ± std. dev. (sample size).

[b]Represents the sperm concentration (density) in cauda epididymis. Mean and std. dev. are given in thousands.

[c]Represents the total number of sperm stored in cauda epididymis. Mean and std. dev. are given in millions.

using IDENT STAIN, a DNA-specific fluorescent dye (Hamilton Thorne Research, 1989).

Another measurement that may be conducted with the remaining sperm suspension is preparing sperm suspension slides to perform sperm morphology evaluation.

Critical Parameters and Troubleshooting

As noted, this method is mainly a physical dilution process, so anything that affects the cauda weight and volume, and/or the homogeneity of suspension, consistency of sample collection, or counting will influence the results.

Table 16.6.2 presents some common problems encountered with these procedures, and their solutions.

Anticipated Results

The results, sperm density, and total number of sperm per cauda in a variety of strains of rodents, as determined in the author's laboratory, are listed in Table 16.6.3.

Time Considerations

The estimated processing time of epididymal sperm count samples is ~15 to 30 min per sample (necropsy time is not included).

Performing a Testicular Spermatid Head Count

The estimation of sperm production is an important parameter of male reproductive toxicology. One way to make the estimation is to count spermatid heads using a hemacytometer. The Basic Protocol describes this simple and reproducible method, which provides a good estimation of sperm production. The Support Protocol provides examples for calculating the testicular spermatid head concentration.

PERFORMING A TESTICULAR SPERMATID HEAD COUNT

BASIC PROTOCOL

This protocol describes procedures for preparing testes for homogenization, homogenizing a testis, loading the suspension onto a hemacytometer, and counting the spermatid heads using a compound microscope.

Materials

Frozen testes from mouse or rat (*UNIT 16.3*; Feldman and Seeley, 1988), frozen individually in scintillation vials on dry ice at −70°C or below
DMSO/saline solution (see recipe)
0.1% (w/v) trypan blue stain (see recipe)

125-ml Erlenmeyer flasks (for rats) or 12-ml test tubes (for mice)
Disposable weigh boats
Cyclone homogenizer with 20-mm (for rats) or 10-mm (for mice) rotor (VirTis)
Scalpel or razor blades
Microdissecting forceps (two pairs)
Homogenization vessels (50- to 100-ml for rats, 20-ml for mice; Jencons Scientific)
Lint-free wipes (e.g., Kimwipes)
10-, 50-, and 500-µl volumetric micropipettors
Hemacytometer with two chambers and coverslip
Compound microscope with 40× objective and 10× eyepiece
Cell counter

Prepare homogenizer

1. Label a 125-ml Erlenmeyer flask (for rats) or a 12-ml test tube (for mice) and a disposable weigh boat with identification corresponding to samples to be analyzed.
2. Turn on a cyclone homogenizer and set the homogenization duration to 1.0 min and rotor speed to 7500 rpm.
3. Secure a 20-mm (for rats) or a 10-mm (for mice) rotor in the homogenizer.

Prepare testis

4. Thaw a frozen testis for 2 to 3 min (for 1.5-g rat testis) or 1 min (for 0.1-g mice testis) in the labeled disposable weigh boat.
5. Make a shallow incision with a scalpel or razor blade in the tunica albuginea, the tough fibrous outer coat of the testis. Use a pair of microdissecting forceps to hold the testis.
6. Remove tunica and associated blood vessels from testis with a second pair of microdissecting forceps.

Contributed by Han Seung, Gary Wolfe, and Meredith Rocca
Current Protocols in Toxicology (2003) 16.7.1-16.7.6

7. Obtain the weight of the testis without tunica and associated blood vessels.

   A balance with three decimal places should be used for rats and one with four decimal places should be used for mice.

Homogenize testis

8. Transfer testis to an appropriate homogenization vessel.
9. Add 25 ml DMSO/saline solution for rat testis or add 5 ml DMSO/saline solution for mouse testis.
10. Drop rotor to 20 mm above the bottom of homogenization vessel for rat testis or to 10 mm above the bottom of homogenization vessel for mouse testis.
11. Homogenize testis 1 min at 7500 rpm.
12. Pour contents into the labeled 125-ml Erlenmeyer flask for rat testis or the 12-ml test tube for mouse testis.
13. Repeat steps 10 to 12 twice more for rat testis, first with another 25 ml and second with 50 ml DMSO/saline, adding both washes to labeled flask. Repeat only once more with 5 ml DMSO/saline for mouse testis.

    Alternatively, a smaller amount of DMSO/saline can be used, but further dilution will be necessary. For example, if only 25 ml DMSO/saline is used to make the homogenate, further dilution by a factor of 4 (i.e., adding 1 ml homogenate to 3 ml DMSO/saline) will be equivalent to a homogenate in a total volume of 100 ml DMSO/saline. When working with smaller volumes, however, any accidental losses in sample volume will have an even greater effect on the accuracy of the count; it is even more crucial that no spillage occurs.

14. Rinse homogenization vessel and rotor three times using deionized water.

    The inside of the rotor should be checked before rinsing. Occasionally the testis is stuck inside the rotor and does not get homogenized completely. In such an event, cut testis into two or three pieces with razor blade, and then rehomogenize with pooled 100 ml DMSO/saline (step 13), using 25 ml each for first and second washes and 50 ml for final wash. For mouse testis, use two 5-ml washes.

15. Dry homogenization vessel and rotor with lint-free wipes.

    The vessel and rotor are now ready for another sample.

Stain spermatid heads

16. Using an appropriate volumetric micropipettor, add 500 µl of 0.1% trypan blue into flask for a rat testis or add 50 µl of 0.1% trypan blue into test tube for a mouse testis.
17. Cover flask or test tube with Parafilm and vortex 5 sec at 2000 rpm. Stain ≥1 min.

    Although there is no upper time limit for staining, the homogenate will degrade after ~6 hr, making spermated counts unnecessarily harder.

Count spermatid heads

18. Vortex spermatid head suspension 10 sec and use a 10-µl micropipettor to load 10 µl suspension into a hemacytometer (Fig. A.3B.1) with coverslip already in place.
19. Let spermatid heads settle 5 min before counting.

    The suspension must not be allowed to evaporate. Placing the hemacytometer on moist gauze in a large petri dish will prevent evaporation of the suspension.

20. Place hemacytometer on the stage of a compound microscope so that both chambers can be viewed.

21. Set objective lens to 40× and focus on one of the counting chambers.

    Each hemacytometer contains two chambers. Each chamber has one tertiary square (Fig. A.3B.1).

22. Using a cell counter, count spermatid heads in first and last rows of secondary squares (a total of ten secondary squares) using a cell counter. Also count spermatid heads that are not touching any of the lines within secondary squares, as well as the spermatid heads touching bottom and right lines. Focus in and out of depth to count sperm not in focus. Record the number of spermatid heads.

    Trypan blue stains spermatid heads a light blue color.

23. Focus on the other counting chamber and repeat step 22.

24. Clean hemacytometer and its coverslip using wet lint-free wipes.

    Alternatively, the hemacytometer and the coverslip can be rinsed and then dried with a wipe.

    If the discrepancy between the two counts is >25% (i.e., the higher count is >125% of the lower count), the count should be repeated (steps 18 to 23). As an example, if the first count was 67 and the second count was 77, the second count is 15% higher than the first count: (77/67) × 100 = 1.149 or 15% higher. The count should also be repeated if any of the counts are <40 or >110. In the case of a repeated count only the two most recent counts are used to generate an average. Sperm samples with very high count (>150) can be diluted with DMSO/saline before recounting.

    Counts will generally range from 60 to 100 spermatids for a typical rat or mouse testis. Various factors such as low testis weight or incorrect homogenization volume can change the counts.

CALCULATING TESTICULAR SPERMATID HEAD CONCENTRATION

SUPPORT PROTOCOL

Each chamber of the hemacytometer is designed to hold 0.1 µl of solution in its tertiary square. The tertiary square is divided into 25 secondary squares, which are in turn divided into 16 primary squares. Thus each secondary square contains 0.004 µl. Because ten secondary squares are used for counting, 0.04 µl of suspension is used per chamber. The total volume of rat testis suspension is 100.5 ml, and mouse testis is 10.05 ml. Thus, the total number of spermatid heads in a rat testis is (mean count/0.00004 ml) × 100.5 ml. The total number of spermatid heads in a mouse testis is (mean count/0.00004 ml) × 10.05 ml.

Example 1: If counts for a rat were 75 and 79, or a mean count of (75 + 79)/2 = 77, then the total number of spermatid heads in the testis is (77/0.00004) × 100.5. This is equal to ~193 million spermatid heads. If the testis weighed 1.529 g, then there are 127 million spermatid heads per gram testis. The daily sperm production is then 20.7 million spermatids per gram testis per day or 31.7 million spermatids per testis per day, using 6.10 days as the time divisor (see Background Information; Oakberg, 1956).

Example 2: If the counts for a mouse testis were 69 and 76, or a mean count of (69 + 76)/2 = 72.5, then the total number of spermatid heads in the testes is (72.5/0.00004) × 10.05. This is equal to ~18.2 million spermatid heads. If the testis weighed 0.1016 g, then there are 179 million spermatid heads per gram testis. The daily sperm production is then 37.0 million spermatids per gram testis per day or 3.8 million spermatids per testis per day, using 4.84 days as the time divisor (see Background Information; Robb et al., 1978).

REAGENTS AND SOLUTIONS

Use Milli-Q-purified water or equivalent in all recipes and protocol steps. For common stock solutions, see ***APPENDIX 2A****; for suppliers, see* ***SUPPLIERS APPENDIX****.*

Dimethyl sulfoxide (DMSO)/saline solution

Place 18.00 g NaCl (0.9% final) in a 2-liter container. Add 1.60 liter water. Mix vigorously to dissolve NaCl. Add 200 ml DMSO (10% final). Bring to 2 liters with water. Store up to 30 days at room temperature.

This volume should be enough to suspend ~20 samples of rat testes or 200 samples of mice testes.

CAUTION: *DMSO can be very toxic because of its permeability.*

Trypan blue stain, 0.1% (w/v)

Mix together 10 mg trypan blue and 10 ml water. Stir until all crystals are dissolved. Store up to 1 year at room temperature.

The solution is a dark navy blue color. It may take a few minutes of stirring for all crystals to dissolve completely.

This volume should be enough for ~20 samples of rat testes or 200 samples of mice testes.

COMMENTARY

Background Information

The testis is a multicompartmental organ packed with highly convoluted tubules called seminiferous tubules. These tubules meet to form the rete testis. From the rete testis, ductuli efferentes connect to the epididymis where sperm mature and are stored. These tubules contain Leydig cells, Sertoli cells, spermatogonia, and other cells. Leydig cells secrete hormones such as testosterone. Sertoli cells secrete fluid into the lumen of the tubules. The testis is wrapped in a tough connective tissue called the tunica, which holds the seminiferous tubules together.

The seminiferous tubules are lined with spermatogonial stem cells known as A_0. A mitotic division of these cells gives rise to A_1 spermatogonial cells. These cells gradually displace toward the lumen by subsequent mitotic divisions. After six mitotic divisions, spermatogonial cells divide to produce primary spermatocytes. Further meiotic division produces secondary spermatocytes, and after another meiotic division, they form spermatids.

At the beginning, the heads of spermatids are round without remarkable morphology. However, they undergo a dramatic metamorphosis and become spermatozoa, which look like hooks. Toward the end of this metamorphosis, the nucleoprotein condenses and the cells become resistant to homogenization and detergent. The period during which cells are resistant to homogenization and detergent is referred to as the time divisor and is used to calculate the daily production of spermatids in a testis. The time divisor for rats is 6.10 and that of mice is 4.84 according to Oakberg (1956) and Robb et al. (1978), respectively. The overall duration of spermatogenesis within a testis is 52 days in rats and 36 days in mice.

An alternative method of estimating daily sperm production is by counting A_1 cells. A_1 cells are the spermatogonial cells derived from spermatogonial stem cells. By counting the A_1 cells, one can estimate the theoretical concentration of spermatids in a testis. Not all cells arising from A_1 cells, however, will become mature sperm. Also, this requires histological sampling. This method requires more time and materials and is more prone to error during preparation without better accuracy, as compared with the method of counting spermatid heads in testicular homogenates described here.

The epididymal sperm count (*UNIT 16.6*) provides quantitation of sperm that is stored and thus is available for ejaculation and fertility. Sperm is stored over a period of time, however, masking acute changes in the sperm production rate. Unlike epididymal sperm count, the testicular spermatid head count provides better quantitation of acute changes in sperm production, thus providing a better snapshot of changes in spermatogenesis within testes. This parameter can provide crucial information regarding reproductive toxicity of a test compound. Either an increase or decrease in the concentration of spermatid heads can indicate pathology. An increase in the spermatid head

concentration suggests that there is sperm retention (or inhibited sperm release; Ku et al., 1993; Linder et al., 1997). A decrease in the spermatid head concentration may be due to atrophy of the testis, changes in circulating hormones, loss of germ cell line, or physiological changes to Sertoli cells or Leydig cells. Histological examination may help clarify the underlying pathologic process (*UNITS 16.3 & 16.4*). Spermatid head count will not, however, provide any information about fertility without other parameters such as motility, morphology, and epididymal sperm counts.

There are two mixtures commonly used for homogenization. The authors prefer using DMSO/saline because of its shorter preparation time and longer expiration date. Another solution to suspend the spermatid heads is 0.9% (w/v) saline/0.1% (v/v) Triton X-100. This solution requires several hours to prepare and expires in weeks. Unlike saline/Triton X-100, DMSO/saline can be prepared within minutes, so as not to lose the capability of counting spermatid heads, and expires in 1 month.

The Basic Protocol describes a method that uses a hemacytometer to count testicular spermatid heads. An alternative method is to use a computer-assisted counting machine, such as the Hamilton Thorne 2030 (Hamilton Thorne Biosciences) or IVOS (Hamilton Thorne Biosciences). According to Centola (1996), the variability between samples is less when counts by the computer system are compared with manual ones, and counting error within a sample is comparable between the two methods.

Critical Parameters and Troubleshooting

Storage conditions

It is critical that the testes not be stored at −70°C for >6 months; for long-term storage (up to 12 months), they should be stored at −80°C or below. If the testes are not stored at −80°C or lower, they will be under risk of desiccation (freezer burn), a drying of the sample during storage in a freezer. Desiccation changes testicular weight, thus changing data for spermatids per gram testis.

Thawing

The purpose of thawing is to remove the parenchyma surrounding the testis. If the testis is not thawed sufficiently, it will make removal of the parenchyma difficult. If the testis is thawed too much, then there is a risk of removing a portion of the testis, decreasing the total number of spermatids per testis.

Homogenization

All the materials used during homogenization must be clean. Otherwise there will be cross-contamination between samples. Rinsing with deionized water three to four times will prevent cross-contamination between samples.

Consistency of counts

It is imperative for the person who counts the spermatids to be consistent. All the counts must be done in exactly the same manner. For example, if right and lower borders of secondary squares are included and not upper and left borders, then all the counts must include any spermatid heads touching lower and right borders, and they must exclude any spermatid heads touching upper and left borders of secondary squares.

Because only a small amount of the solution is used to count, the stained spermatids must be thoroughly suspended before loading the hemacytometer. Small deviations in the suspension will result in a great variability in the concentration of spermatids.

Also, it is important to focus in and out during counting. Because of the high magnification power of the microscope, the focal plane is rather shallow. Most of the spermatid heads will settle down on the hemacytometer, but some may stay suspended between the grids and the coverslip. Exclusion of these spermatid heads will underestimate the true concentration and renders the data inaccurate.

Data analysis

Repeating a spermatid head count if the higher count is >125% of the lower count is to prevent random abnormal sampling. Repeated counts ensure that an abnormally higher or lower count does not affect the mean of the group being analyzed. Counts of <40 spermatids are repeated to ascertain the values, because a change in a small number will make a more drastic change in the overall number. Counts of >110 spermatids are repeated to ensure accuracy of a dense field. It is harder to count when there are many overlapping spermatids in the field.

Anticipated Results

A typical count using the hemacytometer method described in this unit will yield between 60 to 100 testicular spermatid heads for rat or

mouse testis. According to a study conducted by Blazak et al. (1985) on the daily sperm production rate of Fischer 344 rats, a typical 20-week-old male rat has a testicular weight of 1.2 to 1.6 g/testis and produces 16 to 30 million sperm a day. With a time divisor of 6.10, a typical total spermatid head count for a rat testis will contain 185 million sperm.

In contrast, according to the same study, the daily sperm production rate of a typical 13-week-old male B6C3F1 mouse is 3.4 to 6.8 million per day, and its testis weighs 0.08 to 0.11 g. With a time divisor of 4.84 days, a typical total spermatid head count from a mouse testis is 24.1 million sperm.

Time Considerations

The whole procedure, including making solutions, will require 10 hr to perform spermatid head counts on 20 rat testes. The approximate time required for each step is as follows: solution preparation, 0.5 hr; setup and labeling flasks or tubes, 0.5 hr; sample preparation, 4 hr; spermatid head counts, 5 hr.

Transgenerational (In Utero/Lactational) Exposure to Investigate the Effects of Endocrine Disrupting Compounds (EDCs) in Rats

In this unit, timed-pregnant Sprague-Dawley rats are dosed daily during pregnancy and in some instances through lactation. At birth the number of pups/litter are counted and at 2 days of age, anogenital distance and body weight are recorded for all pups. When the pups are 13 days old, nipple and areolar retention are evaluated in females exposed to potential androgens or males exposed to potential antiandrogens. Pups are weaned at 21 to 28 days and housed in unisexual littermate groups of two to three pups/cage; the dams are sacrificed, and body weight and the number of implantation scars are recorded at this time. The onset of puberty is monitored by observing the age of vaginal opening in the females and the age of preputial separation in the males. Other endpoints that may be collected after puberty, if indicated, include estrous cyclicity and fertility in females after puberty, and ejaculated sperm counts, mating behavior, and fertility in males after sexual maturity (after 3 months). As soon as all necessary data have been collected, sexually mature rat offspring are necropsied and an extensive evaluation of the reproductive system is conducted.

The basic protocols recommended for transgenerational studies investigating the effects of EDCs on the reproductive system are: study design and exposure (see Basic Protocol 1); anogenital distance measurement (see Basic Protocol 2); assessment of areolae/nipple development (see Basic Protocol 3); detection of puberty (vaginal opening and preputial separation; see Basic Protocol 4); and necropsy, histology, and radioimmunoassays (see Basic Protocol 5).

NOTE: All protocols using live animals must first be reviewed and approved by an Institutional Animal Care and Use Committee (IACUC) and must conform to governmental regulations regarding the care and use of laboratory animals.

STUDY DESIGN

BASIC PROTOCOL 1

This protocol describes basic techniques for assigning timed-pregnant rats to treatment groups and administrating test compounds.

Materials

Individually housed timed-pregnant rats
Test compounds
Laboratory-grade corn oil (Sigma)

Balance, accurate to 0.1 g, that integrates the weight over several measurements (e.g., Sartorius IP65)
1-ml glass tuberculin syringe (BD)
1.5-in. × 18- or 20-G curved gavage needle (Popper and Sons)
25-G × 5/8-in. or 1/2-in. sterile needle (BD)
Saturated picric acid solution and envelope moistener or cotton swabs to apply picric acid to dams for treatment identification
Software such as Microsoft Excel or SAS (PC SAS or IBM Host on Demand) for calculating means and standard errors by treatment
FTP95 for transferring SAS output data sets to WordPerfect or Microsoft Word

Contributed by Joseph S. Ostby and L. Earl Gray Jr.
Current Protocols in Toxicology (2004) 16.8.1-16.8.16

Assign rats to treatment groups

1. On the morning when dosing is initiated, give a temporary cage number (cage cards numbered consecutively in pencil) to individually housed timed-pregnant rats and record their body weights.

2. After weighing, sort the rats by body weight from the lightest to the heaviest rat and assign treatment groups in the following manner:

   Randomly assign lightest rat to one treatment group
   Randomly assign next lightest rat to one of the remaining treatment groups
   Continue assigning rats in this manner until each treatment group contains one rat to form a block (block = a group of rats with similar body weights consisting of 1 rat/treatment group), which contains the lightest rats in the experiment.

3. Randomly assign a permanent cage number ranging from 1 through the total number of treatments to each rat in the first block. Assign the second block from the next lightest group of rats to treatment groups in a similar manner and give a permanent cage number ranging from the number equal to 1 plus the total number of treatment groups through the number equal to two times the total number of treatment groups in a random fashion. Thus, if the study has five treatment groups, the first block consists of the five lightest rats housed in cages 1 through 5 and the next block consists of the next five lightest rats housed in cages 6 through 10. Continue this procedure until all rats have been assigned to treatment groups and the number of blocks equals the number of rats/treatment group.

   This procedure minimizes potentially confounding experimental variables across treatment groups. The first block of rats (one rat/treatment group) representing the lightest rats in the experiment are placed on the first row(s) of the rack so that each rat is exposed to similar environmental conditions such as temperature, humidity, air flow, and light intensity. Likewise, the second block of rats will be placed on the next row(s) of the rack ensuring all rats in this block will also be exposed to similar environmental conditions.

4. After treatment assignment, calculate the mean body weights and standard errors for each treatment group to ensure that they are as similar as possible and not significantly different.

5. Once the rats have been assigned to treatment groups, give them an i.d. to identify their treatment group. Use picric acid to identify the treatment group.

   For example, rats could be marked as follows: left rear leg (LR), right rear leg (RR), left front leg (LF), right front leg (RF), back (B), both hind limbs (LRRR), both forelegs (LFRF), both left legs (LRLF), and both right legs (RRRF).

   Other means of marking the animals include ear tags, tail tattoos, or implantable transponders.

Prepare and administer dosing solutions

6. Prepare dosing formulations on the basis of microgram or milligram test compound/kilogram body weight/milliliter vehicle/day. Tare the dosing solution vial on a balance, add the calculated quantity of the test compound and record its weight, then add the necessary volume of the vehicle (laboratory-grade corn oil).

   After thorough mixing, further dilutions can be made from the original stock solution.

7. Weigh timed-pregnant rats and prepare the dose for gavage at 2.5 µl of the vehicle per gram body weight (2.5 ml corn oil/kg body weight; therefore, the volume administered to a 300- to 400-g pregnant rat would be 0.75 to 1 ml). Accurately measure this volume with a 1-ml glass tuberculin syringe.

A 1-ml dose is sufficient to allow most compounds to go into solution but does not exceed the stomach capacity of the rat.

Dose the timed-pregnant rats orally or inject subcutaneously (s.c.) with test compounds in a vehicle (e.g., laboratory-grade corn oil) depending on the chemical and its concentration (whether a solution or suspension).

Some compounds readily go into solution while others may require mixing for several days or even 1 week to form uniform suspensions. Suspensions must be stirred constantly while dosing and can be difficult to administer s.c. through small gauge needles. To avoid degradation of test compounds, avoid heating (to facilitate mixing) of dosing solutions unless chemical stability is assured. Depending upon solubility, a wide variety of other vehicles, other than corn oil, may be used.

8a. *For oral administration:* Dose orally by gently grasping the loose skin on the back and neck of the rat in such a manner that the head, neck, and back form a straight line. Gently insert a 1.5-in. × 18- or 20-G curved gavage needle into the left side of the oral cavity and down into the esophagus past the epiglottis (if any resistance is encountered, withdraw the needle and re-insert). To avoid discomfort and startling the rat, administer the dosing solution at a moderate rate and withdraw the needle along a path similar to the path used to insert the needle. Prior to oral dosing, the rats should be gently held in one hand and then held as described above to acclimate them to this type of restraint (since they are normally only picked up by their tails during cage changing).

Administration of compounds typically requires a health and safety research protocol. Prior to administration of these compounds the rats should be dosed for several days with water to acclimate them to this procedure and to reduce the possibility of the rat jumping while the compound is being administered. Rats undergoing rapid weight changes such as timed-pregnant rats should be weighed daily and the dose adjusted to body weight.

8b. *For subcutaneous administration:* Administer subcutaneous injections as microgram or milligram of the test compound/rat in a constant vehicle volume/day or microgram or milligram of the test compound/kilogram body weight/milliliter vehicle/day. Administer injections by placing the rat on a flat surface and gently grasping the loose skin on the back of the rat between the last three fingers and the heel of the hand and raise the skin on the neck with the thumb and index finger. Insert a 25-G × 5/8-in. needle into the raised skin on the neck below the thumb and index finger.

Once this is accomplished, the tip of the needle can be felt between the fingers, and injection can be confirmed by feeling the fluid flow into the injection site (the pressure produced even by microliter quantities can easily be detected in this manner). No more than ten rats should be injected with a single needle. Needles that are 25 or 27 G permit a moderate flow rate with corn oil (be aware that excessive plunger pressure may forcefully eject the needle and syringe contents) but are small enough to prevent excessive leakage at the injection site.

For example, potent steroidal androgens are administered at 0.1 to 10 mg per rat per day.

The optimum injection volume (~0.1 ml of the vehicle) can be accurately administered with a gas-tight microliter or a 1-ml tuberculin syringe, does not readily leak from the injection site due to excessive pressure, and is readily absorbed within 24 hours.

9. For the dosing described in steps 8a and 8b, use different dosing syringes and needles for each dose group to avoid contamination from residual material. Discard syringes on a daily basis, clean the gavage needles daily during the study and reuse but only for the same dosing solution.

10. Select exposure regime.

Exposure may be initiated on gestational day 8 (GD 8) prior to onset of fetal gonadal differentiation or on GD 14 near the onset of fetal testis steroid hormone synthesis (GD 1 = day of sperm positive smear). Exposure should continue through at least GD 18 to cover the primary period of reproductive tract development, but pups may also be exposed via the mother's milk through postnatal day (PND) 3 to encompass the period of sexual differentiation of the brain and central nervous system, or exposure may continue through the period of lactation. One final option would be to continue exposures to the pups after weaning using the same route and dosage levels given the dams.

BASIC PROTOCOL 2

MEASURING ANOGENITAL DISTANCE

The sexually dimorphic secondary sex characteristic in many mammalian species, anogenital distance (AGD; see Fig. 16.8.1), may be used to measure the degree of demasculinization of males as a consequence of developmental exposure to androgen receptor (AR) antagonists (e.g., vinclozolin, procymidone, flutamide, linuron, prochloraz, etc.), 5-alpha reductase inhibitors (finasteride), or compounds that inhibit steroidogenesis (some phthalates). Likewise, AGD is useful in measuring the degree of masculinization of females exposed during sexual differentiation to androgenic compounds such as testosterone or the anabolic growth stimulant trenbolone used in cattle.

AGD and body weight are normally measured in rats at birth or 2 days of age. As the animal grows, increased activity and variability in growth rates increase the variability of this measurement. However, decreased male AGD and increased female AGD observed in adult rats at necropsy demonstrates that endocrine disrupting compounds do permanently alter AGD.

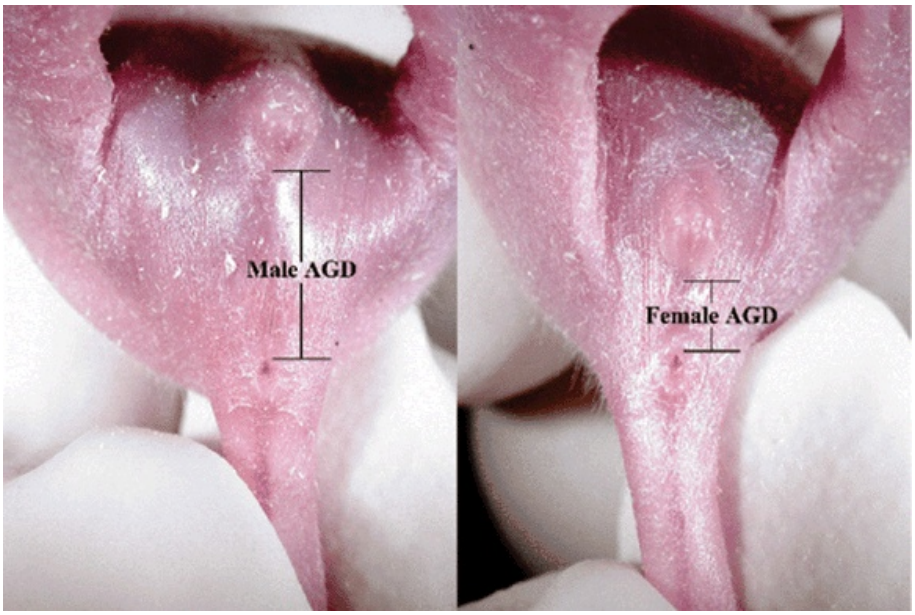

Figure 16.8.1 Anogenital distance in neonatal male and female SD rats. Photographs taken at the same magnification of perineal area of male and female siblings demonstrating the normal developmental effects of testicular androgens on AGD (the sexually dimorphic distance between the sex papilla and the anus). *This black and white facsimile is intended only as a placeholder; for full-color version of figure go to http://www.interscience.wiley.com/c_p/colorfigures.htm*

Studies conducted in the authors' laboratory that followed individual pups from birth to necropsy as adults have demonstrated there is a statistically significant correlation between AGD observed at birth and the presence of nipples in infant males, AGD at necropsy, as well as malformations observed when the rats were necropsied as adults. These results demonstrate that AGD is a reliable predictor of permanent alterations of the reproductive system that are not often apparent until the animal reaches sexual maturity. Similarly, increased AGD in female pups is associated with decreased numbers of nipples (as infants and adults) and malformations of the reproductive tract.

Materials

Sprague-Dawley or Long Evans pups at birth or on PND 2 and as adults
Dissecting microscope, 0.63× to 4× and 10-mm (0.1-mm divisions) ocular reticle (e.g., Leica MZ6)
1-mm stage micrometer (0.01-mm divisions)
Vernier caliper (0 to 150 mm with 0.1-mm divisions)
Two-place balance (e.g., Mettler PM2000)

1. Set a dissecting microscope fitted with a 10-mm ocular reticle (with graduated 0.1-mm divisions) at a magnification of ~1.5× and calibrate with a 1-mm stage micrometer (with graduated 0.01-mm divisions).

2. After the microscope has been set at ~1.5×, carefully adjust the magnification so that the 1-mm stage micrometer is exactly equal to 1.5 mm on the ocular reticle.

   A magnification of 1.5× has been determined to be the optimum magnification for obtaining the most accurate AGD measurement without being distracted by subtle pup movements.

3. After calibrating, raise the microscope ~4 to 6 in. using the coarse focus knob to allow the hands of the observer to rest comfortably on the stage while holding the pup. Position the perineal area of the pup in the focal plane and measure the distance between the posterior base of the sex papilla and the anterior anus using the ocular reticle. Record AGD along with the sex and body weight of the pup. Record the body weight to the nearest 0.01 g and record AGD to the nearest 0.1 scale on the micrometer (divide this measurement by 1.5, magnification = 1.5×, to obtain the actual AGD).

   At birth, AGD in male Sprague-Dawley or Long Evans rats is ~3 mm, while female AGD is ~50% smaller than the males or 1.5 mm.

4. At necropsy, measure AGD by placing the animal with the base of the tail on the edge of a table. Use the thumb to secure the tail to the side of the table and place the index finger above the phallus to maximally stretch the skin in the perineal area. Then, use a vernier caliper to measure the distance between the posterior base of the phallus and the anterior rim of the anus.

5. If pup body weight is significantly reduced by treatment, then adjust the AGD for body weight using body weight as a covariate in the statistical analysis.

   Since litter effects can occur particularly at this age, the data analyzed typically are litter means or n = number of litters/treatment unless it can be demonstrated that litter effects are not present in the data.

ASSESSING AREOLAE/NIPPLE DEVELOPMENT IN INFANT MALE AND FEMALE RATS

In the absence of testicular androgens, female rats develop areolae/nipples, while dihydrotestosterone induces regression or apoptosis of the nipple anlage. Thus, nipple development in male rats is a sensitive endpoint for evaluating the degree of demasculinization produced by in utero exposure to antiandrogenic compounds. Conversely, the partial or complete attenuation of areolae/nipples in female rats is useful in evaluating the masculinizing effects of androgenic compounds (see Fig. 16.8.2).

Although this endpoint is a sensitive indicator of endocrine disruptions, in 13-day-olds a small percent of the control males may have faint areolae. Therefore, it is recommended that prior to experimental data collection for this technique, and AGD as well, in experimental situations, researchers should practice collecting these data in pilot studies with both control and treated (testosterone propionate, TP, for females and vinclozolin for males) animals from several litters to establish a baseline for recording these data and to assure acceptable levels of reproducibility. If more than one observer is used in a study, then one must assure that there is a high degree of inter-observer reliability on these measures, and the study should be designed in a manner such that the treatment groups are split among different observers.

Due to the subjective nature of these endpoints, it is critical that the data are collected in a "blinded" manner, ensuring that the observer is not aware of the treatment group of each litter.

Because of the rapid development at this age, AGD and nipple data should be collected on all offspring at the same age in days over one 8-hr interval, by a single observer, if possible.

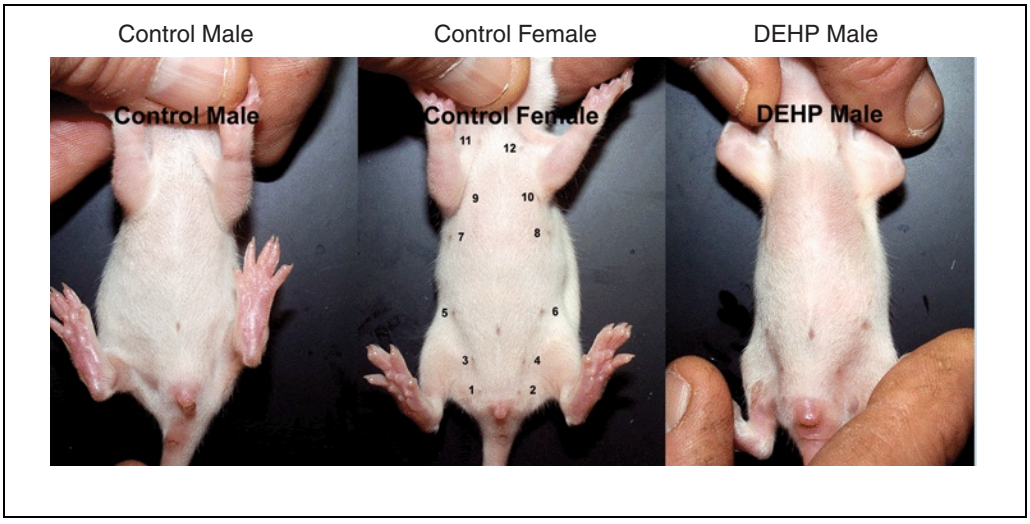

Figure 16.8.2 Areolas and nipples in infant male and female rats. Photographs taken when the pups were 14 days old showing a normal male without nipples, a normal female with twelve evenly spaced nipples (no. 9 not visible in photograph) and a male exposed to 750 mg of diethylhexyl phthalate from gestational 14 through postnatal 3. Some phthalate diesters such as diethylhexyl, benzylbutyl, and dibutyl phthalate inhibit fetal testosterone synthesis and thus prevent dihydrotestosterone from inhibiting development of the nipple anlage.
This black and white facsimile is intended only as a placeholder; for full-color version of figure go to http://www.interscience.wiley.com/c_p/colorfigures.htm

Materials

Infant male and female rats (e.g., Sprague-Dawley)
Bouins's fixative (see recipe)

Balance (e.g., Mettler PM2000)
Small animal clippers with size no. 40 clipper blade (Oster)

1. Collect areolae/nipple data shortly after control females develop prominent areolae/nipple buds but before the nipples are partially or completely hidden by rapid ventral hair growth (in Sprague-Dawley rats, this normally occurs when they are ~13 days old).

2. On PND 13, have an observer who is blind to treatment separate each litter by sex, determine the number of areolae/nipples, their position, and the body weight of the pup for each male or female in the litter, depending on the type of compound administered.

   If antiandrogens are administered, males exposed to antiandrogens are checked for nipple retention and females exposed to androgens are checked for nipple regression. The sex not checked for nipple development at 13 days can be counted and weighed together to determine average pup weight for that sex. Nipple data collection normally requires three technicians: an observer, a data recorder, and a technician responsible for removing and returning litters to their home cage.

3. Number the nipples to identify their location (female rats normally have twelve nipples, six symmetrical pairs, with the pairs distributed identically on all rats). For example, give nipples on the right side odd numbers (1, 3, 5, 7, 9, and 11) with no. 1 caudal and no. 11 cranial, and assign nipples on the left side even numbers (2, 4, 6, 8, 10, and 12), with no. 2 caudal and no. 12 cranial.

   Rats with nipple retention or regression can be given a unique picric acid i.d. when 13 days old and shaved and checked at necropsy to determine if abnormal nipple development observed persists into adulthood. Also, retained areolae/nipples in males may be scored as absent, faint, moderately developed, or prominent (female-like) and regressed areolae/nipples in females can be scored as normal, moderately faint, very faint, or absent.

4. At necropsy, shave the rats with small animal clippers and record the number of nipples/areolae. Fix retained or regressed nipples in Bouin's fixative and save for histological evaluation.

DETECTING PUBERTY—VAGINAL OPENING (VO) AND PREPUTIAL SEPARATION (PPS)

BASIC PROTOCOL 4

The onset of puberty in the rat can be evaluated by recording the body weight and age of the rat at vaginal opening (VO) or preputial separation (PPS). Although direct exposure from weaning through puberty may be the optimum period of time to alter this endpoint, in utero/lactational exposure can also impact puberty and consequently should be checked in transgenerational studies.

VO occurs when the rise in circulating ovarian hormones induces apoptosis of the vaginal membrane cells and development of the vaginal canal. The day of vaginal opening normally coincides with the day of first estrus and thus marks the initiation of the onset of estrous cyclicity in rats. The first few estrous cycles are typically longer and irregular after VO. VO is useful to identify/evaluate EDCs that accelerate (estrogen) or delay (antiestrogens, inhibitors of aromatase or inhibitors of hypothalamic-pituitary maturation) puberty in female rats. On occasion, females display a transient thread of tissue along the midline of the vaginal opening, which persists for several days or occasionally is

permanent. For this reason, the age and body weight at the onset of VO should be noted as well as the completion of VO, with dissolution of the thread, if present. The authors have found that female rats exposed in utero to Ah receptor agonists often display a permanent thread across the vaginal opening.

PPS in rats (complete manual retraction of the prepuce) occurs when increasing testicular androgen production produces cornification of the balano-preputial epithelial cells permitting the prepuce to retract along the length of the glans penis. The age at PPS is useful to identify antiandrogens which can delay puberty through altered development of the balano-preputial membrane (permanent incomplete PPS) or interfere with the normal rise in circulating androgens. Malformations such as incomplete PPS or hypospadias, which prevent accurate PPS data collection, are reported as a malformation when the adults are necropsied. Occasionally, males display a transient thread of tissue along the frenulum of the glans, which persists for several days or, on rare occasions, is permanent. For this reason, the age and weight at the onset of PPS should be noted as well as the completion of PPS, with the dissolution of the thread, if present. Also male rats with hypospadias may display a permanent thread on the glans or they are so malformed that PPS does not occur at all.

If time does not permit examining a large number of rats daily for VO or PPS, then the rats can be examined two or three times per week and the age of VO or PPS and body weight at puberty recorded. These data can then be analyzed and reported as the percentage of females or males which opened or separated on a given day for each treatment group.

Materials

Rats from litters of dams in treatment groups, approaching puberty
Balance for animal weight recorded to the nearest 0.01 g (e.g., Sartorius IP65) with integration capability to accurately weigh moving animals

Detect vaginal opening (VO)

1a. Check female rats daily for VO beginning at about PND 24, ~5 days prior to the onset of this landmark to ensure the day of VO is detected in all rats. Monitor each rat daily from then until the process is complete.

VO normally occurs in Sprague-Dawley and Long Evans rats between 29 and 35 days old (DOB = PND 1).

The index finger may be gently rubbed across the vaginal area to determine if the vaginal membrane is present or if the layer of dying cells are simply obscuring the vaginal opening.

2a. When VO is initiated and when complete, record the ages and body weights of each rat and calculate the mean ages and body weights for each treatment group, then check for statistical significance.

Detect preputial separation (PPS)

1b. Check male rats daily beginning at 35 to 37 days of age to ensure no rats have preputial separation. Apply gentle pressure to the prepuce to retract the prepuce and expose the glans penis.

PPS normally occurs in Sprague-Dawley and Long Evans rats between 39 and 45 days old (DOB = PND 1).

PPS is complete when the entire perimeter of the prepuce can be retracted evenly around the base of the glans penis.

2b. When PPS begins and when it is complete, record the ages and body weights of each rat and calculate the mean age, body weight, and standard errors by treatment group, and check for statistical significance.

NECROPSY

At 90 to 120 days of age, male and female Sprague-Dawley rats have reached sexual and physical maturity, therefore, this time frame represents the ideal time to evaluate their reproductive systems. Although the reproductive system of both males and females should be thoroughly evaluated when administering test compounds for the first time, the primary emphasis of each necropsy can be designed to focus on endpoints known or expected to be affected based upon previous in vitro/in vivo studies or on the results of data collected earlier in this study.

Materials

Male and female rats, 90 to 120 days old
CO_2

Bouin's fixative (see recipe)

Balance accurate to 0.1 g with integration capability for weighing rats (e.g., Sartorius IP65)
Rodent restraint cones (Harvard Apparatus)
Rodent guillotine
Vernier caliper (0 to 150 mm with 0.1-mm divisions)
Small animal clippers with size # 40 clipper blade (Oster) for shaving ventral surface to check areolae/nipples
Surgical instruments (Roboz): micro dissecting forceps (RS-5230 for grasping delicate tissues such as ventral prostate and RS-5236 for holding tougher tissue such as skin), micro dissecting scissors (RS-5852 for delicate dissections and RS-6814 for cutting tougher tissue such as skin) and hemostats (RS-7172 for clamping seminal vesicles)
Balance accurate to 0.0001 g for weighing tissues (e.g., Sartorius BP 121 S)

Perform male necropsy

The order of tissue dissection listed below is designed to minimize tissue dehydration and should facilitate accurate dissection in a timely manner.

1a. Weigh male rats, place in a restraint cone, and decapitate within 60 sec of removal from their cage. Collect the trunk blood for serum hormone analysis by radioimmunoassay.

2a. For external examination, shave the rat and examine for the presence of areolae/nipples and malformations of the external genitalia such as cleft prepuce, incomplete preputial separation, hypospadias (urethra opens along the underside of phallus rather than at the tip), or vaginal pouch. Measure anogenital distance at this time with a Vernier caliper, especially if it was affected at birth. Weigh the glans penis. Note if there are undescended, ectopic testes.

3a. Begin internal examination. Check for bladder stones (antiandrogens such as vinclozolin or procymidone increase the incidence of bladder stones), hydroureter, and obvious hydronephrosis resulting from back pressure on the kidneys. Check for undescended ectopic testes, which could be attached just below the kidneys to abdominal muscle wall by a cranial gonadal suspensory ligament or testes embedded in the abdominal muscle wall (ectopic). In the process of dissecting and weighing the tissues listed below, note any additional malformations.

4a. Dissect and weigh the ventral prostate; dissect (weighing is optional) the dorsolateral prostate from around the base of the seminal vesicles; and remove and weigh the seminal vesicles and coagulating glands after clamping the base of the seminal vesicles with hemostats to avoid leakage of seminal fluid. Note abnormalities such as infection, unusual coloration/texture, tissue adhesions, or missing or poorly

developed lobes of the seminal vesicles, coagulating glands, ventral or dorsolateral prostate and photograph if time permits.

The seminal vesicles can also be weighed dry after the seminal fluid is expressed and the tissue blotted dry.

5a. Withdraw the testes and epididymides from the scrotum and examine the gubernacular cords to ensure they are present and not elongated or filamentous (typically 4 to 8 mm in length), and dissect and weigh the testes and epididymides (see Fig. 16.8.3 and Fig. 16.8.4). Note any testicular/epididymal abnormalities such as undescended (also check for the presence of a cranial gonadal suspensory ligament) or ectopic testes (testis located in abdominal muscle wall), fluid-filled or hypoplastic or atrophic testes and epididymal hypoplasia or agenesis.

The testes can be saved for sonication resistant testicular sperm head counts or histology or both and the epididymides can be saved for whole, caudal, and caput plus corpus epididymal sperm counts or fixed for histology.

6a. Remove and weigh the Cowper's glands, and dissect and weigh the levator ani/bulbocavernosus (LABC), which loops around the colon and is attached at each end to the penile bulbs.

7a. Dissect and weigh nonreproductive tissues, which may be affected by EDCs. Include the pituitary, kidneys, adrenals, and liver. Weigh the brain and other tissues at this time.

It may also be helpful to slice the kidneys longitudinally to check for hydronephrosis and kidney stones.

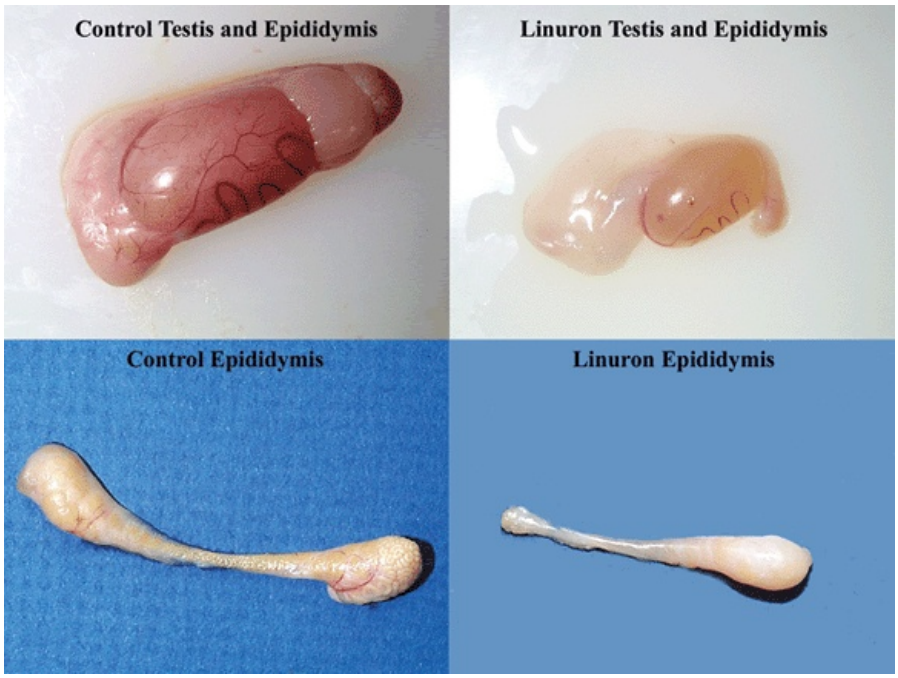

Figure 16.8.3 Testes and epididymides from control and in utero linuron-treated male rat offspring, necropsied as adults. Photographs in panels on the left show a control testis, epididymis and epididymal fat pad and the epididymis dissected from the testis with the fat removed. Panels on the right show a testis, epididymis and epididymal fat pad and the epididymis dissected from the testis with the fat removed, from a rat exposed in utero from gestational day 14 through 18 to 100 mg linuron/kg. Agenesis of the caput produces fluid pressure atrophy of the testis.
This black and white facsimile is intended only as a placeholder; for full-color version of figure go to http://www.interscience.wiley.com/c_p/colorfigures.htm

8a. Save all tissues weighed, especially tissues with gross malformations, and fix in Bouin's fixative for histological evaluation or process for other endpoints such as immunohistochemical staining.

Perform female necropsy

1b. Weigh females, anesthetize in CO_2, decapitate, and save the trunk blood for serum hormone analysis by radioimmunoassay.

2b. For external examination, shave the female rats and check for the absence/prominence of areolae/nipples (DHT inhibits development of nipples) and malformations of the external genitalia such as cleft phallus, vaginal threads, and absence of external vaginal opening (DHT inhibits development of lower vagina). Measure anogenital (AGD) and anovaginal distance (AVD) to calculate vaginal-genital distance (AGD-AVD), which decreases with exposure to androgens.

3b. Begin internal examination. Since androgens inhibit the development of the ovarian ligament, measure the kidney to ovary distance when females are exposed perinatally to suspected androgens. Androgens may also promote the development of male reproductive tissues such as prostatic tissue, seminal vesicles, penile bulbs with attached levator ani muscle, and Cowper's glands; note the presence of these tissues and photograph, if possible, and save for histological confirmation.

4b. Dissect and weigh the ovaries, and weigh the uterus with and without fluid (remove fluid by cutting each uterine horn open and blotting all fluid).

5b. Dissect and weigh the nonreproductive tissues—the pituitary, adrenals, kidneys (section each kidney to check for hydronephrosis), and liver.

6b. Save all tissues weighed, especially tissues with gross malformations, and fix in Bouin's fixative for histological evaluation or process for other endpoints such as immunohistochemical staining.

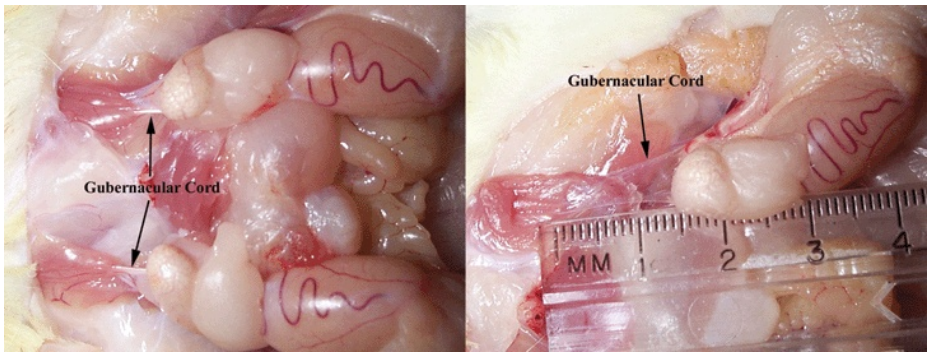

Figure 16.8.4 Gubernacular ligaments in control and phthalate ester–treated male rat offspring, necropsied as adults. Photographs showing a control rat with normal gubernacular cords (left panel) and a rat whose mother received received 750 mg diethylhexyl phthalate/kg from gestational day 14 through postnatal day 3 with a poorly developed gubernacular cord (right panel). Diethylhexyl, dibutyl, and benzylbutyl phthalate produced partial or complete agenesis of the gubernacular cord resulting in undescended testes in some rats, while other rats were observed with scrotal testes but absent or poorly developed, thin and elongated gubernacular cords.
This black and white facsimile is intended only as a placeholder; for full-color version of figure go to http://www.interscience.wiley.com/c_p/colorfigures.htm

DATA INTERPRETATION AND SUMMARY

Analyze AGD, areolar, nipple, pubertal landmark (VO or PPS), and organ weight data using litter means or a nested analysis that accounts for litter effects. If an overall ANOVA model analysis is significant, then use posthoc *t*-tests to compare dose groups to one another and the control group. Alternatively, use a one-tailed Dunnett's test to compare each treated group to the control group.

As these developmental reproductive toxicants (EDCs) produce characteristic syndromes, each containing a variety of effects, the data should be compiled in a manner that enables the investigator to determine what percentage of the offspring are normal and what percentage display any abnormality associated with the particular syndrome. For example, phthalate ester exposure in utero can induce any number of epididymal, testicular, gubernacular, internal sex organ, or external affects. Any animal displaying a morphological or histological alteration in any one of these tissues should be considered affected. If one of ten animals displayed epididymal agenesis, a second had a histological lesion of the epididymis, a third had testis agenesis, a fourth had seminiferous tubular agenesis, a fifth had agenesis of the gubernacular ligament, a sixth had agenesis of the ventral prostate, a seventh displayed hypoplasia of the right horn of the seminal vesicle, and an eighth had six permanent nipples, then it should be reported that 80% of the animals are adversely affected in this group. See Gray et al. 1994, 1997a or b, 2000; Lambright et al., 2000, and McIntyre et al. 2002 for examples of data presentation.

REAGENTS AND SOLUTIONS

Use Milli-Q-purified water or equivalent in all recipes and protocol steps. For common stock solutions, see ***APPENDIX 2A****; for suppliers, see* ***SUPPLIERS APPENDIX****.*

Bouin's fixative

3 liters saturated picric acid solution (Sigma)
1 liter 37% formaldehyde solution (Sigma)
200 ml glacial acetic acid (Sigma)
Store at room temperature in a fume hood; replace if a precipitate forms or at 4 months

CAUTION*: Upon drying, the picric acid solution will form a crystal residue that will ignite if sufficient heat or friction is applied. Any residue that forms on storage containers may be safely removed with a damp sponge.*

COMMENTARY

Background Information

Identification and comparison of the potency of endocrine disrupting compounds (EDCs) to natural ligands may be best accomplished using rapid in vitro screening assays such as receptor binding and transcriptional activation assays or short-term in vivo assays such as the Hershberger and uterotropic assay (Gray et al., 2002). In the authors' laboratory, the transgenerational protocol described has been used primarily to quantify and characterize the demasculinizing effects of antiandrogens in males or the masculinizing effects of androgens in females for compounds identified in these screening assays. Additionally, transgenerational exposure to EDCs such as androgen receptor (AR) antagonists or fetal testosterone synthesis inhibitors display unique profiles of malformations characteristic of their specific mechanism(s) of action (Gray et al., 1994, 1997a,b, 2000; Lambright et al. 2000; McIntyre et al., 2002).

Accurate oral or subcutaneous exposure is accomplished by administering the test compound on a milligram or microgram/kilogram body weight/milliliter vehicle/day basis and adjusting the dose daily according to body weight, which increases dramatically during the latter stages of gestation. Daily weighing also serves as a sensitive indicator of toxicity and consequently is monitored daily both on an individual basis and analyzed on a treatment group basis.

The sexually dimorphic androgen-sensitive perineal area between the anus and sex papilla (anogenital distance—AGD) provides a useful biomarker for quantitative evaluation of the fetal androgen status of a rat. Immunohistochemical staining demonstrates that androgen receptor expression in mesenchymal cells in the perineal and prepubic area first occurs on GD 19 (copulatory vaginal plug = GD 1) in male rats (Bentvelsen, 1995). AGD can be thought of as a phenotypic continuum between females (~1.5 mm) and males (~3 mm) in which developmental exposure of females to androgens masculinizes or increases female AGD, while developmental exposure of males to antiandrogens, feminizes or decreases male AGD. AGD at birth or PND 2 has been shown to correlate significantly with adult male urogenital malformations when the data analyzed are litter means. With the aid of a dissecting microscope fitted with an ocular reticle, neonatal AGD can be accurately measured to 0.1 mm and, if effected, this measurement should be repeated in the adult necropsy with the aid of vernier calipers.

Androgen receptor expression in mesenchymal cells of the nipple anlage is first demonstrated by immunohistochemical staining on GD 15 (vaginal plug = GD 1) in male rats and the presence of androgens (dihydrotestosterone) at this time promotes regression of the nipple anlage in both sexes (Bentvelsen, 1995). Consequently, recording the number of areolae/nipples at 13 days of age provides another sensitive endpoint for evaluating endocrine status of males potentially exposed to antiandrogens or females exposed to androgens during development. If the normal areolae/nipple phenotype is altered at this age, then at necropsy, the adults should be shaved, examined for the presence of areolae/nipples, and the tissues saved for histological evaluation.

Vaginal opening (VO) and preputial separation (PPS), which coincide with the rise in circulating estrogens or androgens, serve as indices of puberty in female and male rats, respectively. VO and PPS can be accelerated or delayed by hormonal manipulation and consequently provide useful endpoints for evaluating the hormonal status of animals exposed to potential EDCs (Korenbrot et al., 1977: Ojeda et al., 1976). For example, perinatal oral exposure to 200 mg of the AR antagonist, vinclozolin, from GD 14 through PND 3 (sperm + = GD 1) delayed preputial separation by 3 days (Gray et al., 1994), a single oral dose of 0.2 and 0.8 μg of 2,3,7,8-tetrachlorodibenzo-*p*-dioxin (TCDD) administered on GD 16 (sperm + = GD 1) delayed preputial separation by 1.5 and 3 days, respectively (Gray et al., 1997a), while 0.8 μg of 2,3,7,8 TCDD delayed vaginal opening by 1 day (Gray et al., 1997b).

At necropsy, sexually mature adult rats exposed perinatally to EDCs are examined externally to evaluate development of androgen-dependent tissues such as the perineal area and genital tubercle and tissues whose development are inhibited by androgens such as areolae/nipples. Permanent malformations of external tissues stimulated or inhibited developmentally by androgens in males include cleft prepuce/phallus, hypospadias, incomplete preputial separation, vaginal pouch, reduced glans penis weights, decreased anogenital distance, and nipples (Clark et al., 1990, 1993; Imperato-McGinley et al., 1992). Externally in females, androgens increase AGD, decrease the distance between the vagina and phallus, inhibit normal areolae/nipple development and prevent development of the lower vagina (Wolf et al., 2002). EDCs such as 2,3,7,8 TCDD decrease the distance between the urethral and vaginal openings, produce permanent vaginal threads (Gray et al., 1997b) and reduce glans penis weights (Gray et al., 1997a).

Internally, androgen-dependent tissues are examined for abnormal development, their weights are recorded and the tissues may be saved for histological evaluation. In male rats, these tissues should include the ventral prostate, seminal vesicles plus coagulating glands, testes, epididymides, and the levator ani/bulbocavernosus muscle complex. Other tissues that have been affected by EDCs in previous experiments and may be weighed, measured, or examined and saved for histology include the bulbourethral glands, gubernacular ligament, liver, kidneys, adrenals, dorsolateral prostate, bladder, and ureters (Gray et al., 1999; 2000). Additionally, malformations such as undescended or ectopic testis or the presence of cranial gonadal suspensory ligaments should be noted.

EDCs operating through different mechanisms of action produce different malformation profiles. AR antagonists such as vinclozolin target DHT-dependent tissue development including the ventral prostate and external genitalia and produce malformations such as permanent nipples, urinary bladder stones, ectopic testes, hypospadias, and vaginal pouches (Gray et al., 1994). In contrast, some EDCs, which inhibit fetal Leydig cell steroid and peptide hormone synthesis such as diethylhexyl phtha-

late (Parks et al., 2000), also induce malformations such as epididymal hypoplasia/agenesis and subsequent fluid pressure atrophy of the testes and undescended testes as a consequence of partial or complete agenesis of the gubernacular ligament (Gray et al., 2000; Kubota et al., 2001). Other EDCs such as linuron (Lambright et al., 2000) and prochloraz may alter reproductive development through several mechanisms of action (AR antagonism and steroid inhibition) and produce a profile of malformations intermediate between an AR antagonist and steroidogenesis inhibitor.

Critical Parameters and Troubleshooting

Ideally, test compound dosages should be selected to cover the full range of the dose-response curve with the lowest dose producing no or only minimal effects and the highest dose eliciting slightly less than maximal response without producing nonspecific, systemic maternal or neonatal toxicity. Generally, the highest dosage level should not induce a reduction in maternal weight >10%. Generally, litters are not culled and data collected on all offspring for each specific endpoint are used to provide the most accurate representation of the dose-response curve. If one is interested in subtle treatment-related changes in organ weights and somatic growth, the litters could be standardized to a litter size of 8 to 10 pups per litter. Because most data are analyzed as litter means (n = number of litters/treatment group), the number of litters/treatment group must be of sufficient size to ensure adequate statistical power. A typical study might consist of five treatment groups (a control and four different treatment groups) with eight dams/treatment group; this would potentially generate 500 offspring (100/treatment group).

Data for protocols in which data can be collected in 1 day, such as anogenital distance or nipple development at 13 days of age, should be collected one block at a time to minimize the effect of time on treatment and the data should be collected by only one observer who is blind to treatment. Likewise, data collection such as necropsy, which requires >1 day to complete, can be collected on one animal/litter for each treatment group in one block, again to minimize the effect of time/age on treatment and each technician should conduct the same tasks throughout the entire necropsy in order to reduce technician-to-technician variability for each specific endpoint.

Considerable attention should be given to assuring that the individuals involved are all adequately trained and follow similar procedures. If data on an endpoint like AGD or areolas must be collected by more than one technician, then the study director must ensure that the inter-observer reliability is high from training exercises; he also must avoid having one technician collect the data from the control group, while another collects the data from a treated group. All treatment/dose groups in a study should be run concurrently. If the whole experiment cannot be run at once, then it should be split into balanced complete block designs. While these comments might seem obvious, it has been known that investigators have had one technician collect the data on all the controls 1 month, while others collected the data on the treated groups at other times.

Anticipated Results

Perinatal exposure to EDCs such as antiandrogens or steroidogenic inhibitors may demasculinize males and reduce anogenital distance, induce female-like nipple development, delay preputial separation and inhibit normal development of the testes, epididymis, and sex accessory tissues such as the glans penis, ventral prostate, seminal vesicles/coagulating glands, bulbourethral glands, and levator ani/bulbocavernosus muscles in a dose-related fashion (Table 16.8.1).

In contrast, perinatal exposure to androgens can masculinize and defeminize the female offpsring resulting in increased anogenital distance, agenesis of areolae and nipples, agenesis of the lower vagina, absence of vaginal opening, hydrometrocolpus, and retained male tissues including the ventral prostate, seminal vesicles, and levator ani.

Time Considerations

Data collection for some endpoints such as anogenital distance at 2 days of age and areolae/nipple retention at 13 days of age, ideally, should be collected in 1 day by only one observer, while other protocols such as necropsy may be conducted over a considerably longer period such as 1 week or several weeks. Consequently the sample size (n = number of litters) should permit sufficient statistical power without jeopardizing data collection on all offspring at one time point. A study with five treatment groups and 8 to 10 dams/treatment or 100 to 120 offspring/treatment group should satisfy these criteria.

Table 16.8.1 Effects of Perinatal Vinclozolin on Male Offspring[a]

Observation	Percent affected[b]							
Dose (mg/kg/day)	0 (mean)	3	6.25	12.5	25	50	100	200
AGD reduction[c]	0 (3.43 mm)	7	4.2	9.1	14.7	24.9	35	50
Permanent nipples	0	1	2.6	3.6	5.4	50	100	100
Areolae/nipples in infants[d]	5	17	33	55	49	100	100	100
Ventral protstate gland size reduction[e]	0 (564 mg)	11	26	22	32	46	88	95
Hypospadiasis[e]	0	0	0	0	0	45	100	100
Vaginal pouch[e]	0	0	0	0	0	15	100	100
Ectopic testes[e]	0	0	0	0	0	0	20	50

[a]Combined data from Gray et al., 1994 and 1997.

[b]Perinatal oral maternal treatment with vinclozolin.

[c]Anogenital distance (AGD) was measured at PND 2.

[d]Areolae were observed at PND 13.

[e]Males were necropsied at full maturity as adults and organs were weighed and examined for structural malformations.

CHAPTER 17
Oxidative Stress

INTRODUCTION

Many chemical-induced toxic insults involve oxidative events as major components. Yet, we know that certain oxidative events are essential components of complex signaling processes in cell growth and regulation. Although natural antioxidants have essential roles in optima cellular functions and health, proper balance in both oxidative events and antioxidart functions remains to be fully elucidated. In this chapter, efforts are directed towards understanding and analyzing the oxidative events that appear crucial to toxicology. The formation and functions of protein sulfenic acids that are formed by oxidative processes are covered in an overview (*UNIT 17.1*). Sulfenic acids in proteins are formed upon reaction of cysteinyl thiols with oxidizing agents including mild oxidizing agents such as molecular oxygen and hydrogen peroxide. Topics covered in this overview include peroxide sensitivity, detection of nitrosative stress, participation of protein sulfenic acids in redox catalysis by antioxidant enzymes, in other catalytic functions and in transcriptional regulators. Examples of the role of protein sulfenic acids in catalysis and regulation are given including redox sensing mechanisms.

The measurement of protein sulfenic acid content is presented in *UNIT 17.2*. Notoriously difficult to identify due to their high reactivity, particularly outside the native protein environment, protein sulfenic acids are measured with techniques that are based upon this high degree of reactivity. Chemical modification methods are useful for sulfenic acid identification. Sulfenic acid can be trapped and detected using 7-chloro-4-nitrobenzo-2-oxa-1,3-diazole (NBD chloride), which reacts with both thiol groups and sulfenic acids in proteins but gives unique products that can be detected by their UV-visible spectra and mass spectrometry. An alternative utilizes a more reactive and less stable reagent 4-fluoro-7-nitrobenz-2-oxa-1,3-diazole (NBD fluoride). Another reagent, 2-nitro-5-thiobenzoic acid (TNB), reacts stoichiometrically with sulfenic acids for quantification. A fourth reagent, 5,5-dimethyl-1,3-cyclohexanedione (dimedone) reacts specifically with sulfenic acids but not thiol groups on proteins and relies on ESI-MS analysis for identification.

Oxidative stress and lipid peroxidation are implicated in chemical-induced cell injury/death. *UNIT 17.3* describes the adaptation of a fluorescence microplate reader for measuring tissue susceptibility to lipid peroxidation. Lipid peroxidation is initiated by Fe^{3+}-ADP in the presence ascorbate yielding oxidative products, including 4-hydroxy-2-nonenal, which form fluorescent products that are measured with a fluorescence microplate reader. Real-time measurement of a large number of samples for their susceptibility to lipid peroxidation is possible with this procedure.

Oxidative stress is a part of many disease states and may result from the accumulation of metals by tissues. Transition metals, including iron and copper, are widely studied for the many types of associated oxidative reactions. *UNIT 17.4* describes methods for in situ localization of nonenzymatic peroxidase-like activity of tissue-bound transition metals. A significant improvement over existing methods is an enhanced sensitivity based on the application of hydrogen peroxide and diaminobenzidine (DAB) for the detection of iron. An alternate protocol for the detection of redox-active transition metals is given

Contributed by Donald J. Reed
Current Protocols in Toxicology (2005) 17.0.1-17.0.2

as is a support procedure that utilizes selective chelating agents to evaluate the relative contributions of iron and copper to the redox activity.

An important measure of oxidant stress is the quantification of lipid peroxidation products. *UNIT 17.5* is an overview of the formation of lipid peroxidation products with emphasis on those products formed from the oxidation of ubiquitous arachidonic acid. This overview includes a discussion of the biochemistry of F2-isoprostanes as well as their utility as markers of oxidant stress. Mechanisms of formation of isoprostanes, their quantification in vitro, in vivo, and in animal models of oxidant stress are described. A major topic is the formation of F2-Isoprostanes in human diseases including atherosclerotic cardiovascular disease and Alzheimer's disease. The quantification of F2-isoprostanes in tissue lipids by gas chromatography/mass spectrometry as a measure of oxidant stress is the main protocol in *UNIT 17.6*. An alternative protocol is the extraction of lipids from phospholipid-containing biological fluids. The protocol for quantification F2-isoprostanes by GC/negative ionization MS is extremely sensitive with a lower limit of detection in the range of 1 to 5 picograms. An example is given for the analysis of F2-isoprostanes in plasma obtained from a rat 4 hour after treatment with carbon tetrachloride. A discussion of critical parameters and troubleshooting along with anticipated results are included in this protocol.

Oxidant stress leading to biological oxidative damage includes the formation of protein-centered radicals. *UNIT 17.7* describes a new technology that utilizes several protocols of immuno-spin trapping for the detection of protein-centered radicals. The spin trap being utilized is 5,5-dimethyl-1-pyrroline N-oxide (DMPO which, under proper conditions, can form stable DMPO-protein radical-derived nitrone adducts that are detected and identified by immuno-spin trapping with an antiserum against DMPO. A basic protocol describes the procedure for the production and detection of hemoprotein-centered radicals by immuno-spin trapping ELISA. A second basic describes the preparation and immunoblot analysis of DMPO-protein radical-derived nitrone adducts. Because *UNIT 17.7* focuses on a new technology, a detailed discussion of critical parameters and troubleshooting along with anticipated results are included in this protocol.

Donald J. Reed

Formation and Functions of Protein Sulfenic Acids

Sulfenic acids (R-SOH) are the simplest oxy-acids of organic sulfur and, unlike with higher sulfur oxidation states, sulfinic ($R-SO_2H$) and sulfonic ($R-SO_3H$) acids, they are inherently unstable and highly reactive (Hogg, 1990). Considerable insight has been gained through studies of small molecules wherein the sulfenic acid moieties have been stabilized by steric, hydrogen-bonding, and/or electronic factors. Recent progress in the identification and analysis of cysteine-sulfenic acids formed within proteins has also added to the understanding of the forces that contribute to their stabilization (Claiborne et al., 2001). Cysteine sulfenic acids, as reversibly oxidized products of peroxide, peroxynitrite, or NO-mediated oxidation of cysteinyl thiols, are outstanding candidates as players in redox regulation, an area of intense investigation in recent years (Poole et al., 2004). Indeed, protein sulfenic acids are involved in multiple ways in oxidative and nitrosative stress as (1) redox centers or catalytic intermediates in enzymes, (2) reversibly oxidized sensors of peroxide or NO levels in regulatory proteins, and (3) intermediates in the irreversible damage to cysteinyl residues caused by overoxidation of these amino acids.

Sulfenic acids in proteins have been notoriously difficult to identify due to their reactivity, particularly outside of their native protein environment. Early evidence supporting the formation and stabilization of sulfenic acids in two proteins, glyceraldehyde-3-phosphate dehydrogenase and papain, relied only on indirect methods for their identification (Allison, 1976). Over the last decade, the growing number of proteins known to form sulfenic acids of functional significance and the improvement in definitive identification via structural and chemical techniques have greatly enhanced recognition of their importance in biological systems. Hopefully, with the tools now available, the widespread biological significance of these cysteine modifications will be further clarified.

FORMATION, REACTIVITY, AND DETECTION OF CYSTEINE SULFENIC ACIDS IN PROTEINS

Sulfenic acids in proteins are formed upon reaction of cysteinyl thiols with mild oxidizing agents. Even molecular oxygen can act as an oxidant of protein thiols (termed autooxidation), although the rate of this reaction is insignificant in the absence of catalytic quantities of metals (particularly iron and copper; Torchinsky, 1981). Oxidizing agents of greatest biological significance are peroxides, including hydrogen peroxide, organic hydroperoxides, and peroxynitrite, and nitric oxide and/or its derivatives. All of these agents participate in cell signaling and have been shown to convert protein thiols to sulfenic acids. The reactivity of particular cysteinyl thiols toward these molecules is controlled by their respective protein environments. Important factors include accessibility of the thiol toward these agents and the proximity of other important amino acid side chains, which may interact with the thiol group or with the oxidant or its product. Most reactive are cysteine residues with relatively low pK_a values (below the typical value of ~8.5 for an unperturbed cysteine thiol), which are stabilized as the nucleophilic thiolate anion at neutral pH. Proximity to basic amino acids that stabilize the negative charge on the thiolate therefore promotes the oxidation of given cysteine residues.

Peroxide Sensitivity

Other factors are clearly involved, as well. Documented reactivities of thiolate anions with hydrogen peroxide, for example, range from ~20 M^{-1} sec^{-1} for protein tyrosine phosphatases to 10^5 to 10^6 M^{-1} sec^{-1} for cysteine-dependent peroxidases, such as peroxiredoxins and enterococcal NADH peroxidase (Poole et al., 2004). OxyR, a bacterial transcriptional regulator with exquisite sensitivity toward hydrogen peroxide, also exhibits peroxide reactivity within this range, at ~2×10^5 M^{-1} sec^{-1} (Åslund et al., 1999). A likely important active site feature in these peroxide-sensitive sites is the proximity of a general acid catalyst to protonate the poor RO^- leaving group of the hydroperoxides, although no such catalyst has as yet been identified in these proteins. Although some of these features in proteins are coming to light, understanding the molecular basis for redox sensitivity toward oxidants of given cysteinyl residues is still at an early stage.

Another mechanism for enhancement of cysteine reactivity toward peroxides, coordination of the cysteine sulfur to a metal, has re-

Contributed by Leslie B. Poole
Current Protocols in Toxicology (2003) 17.1.1-17.1.15

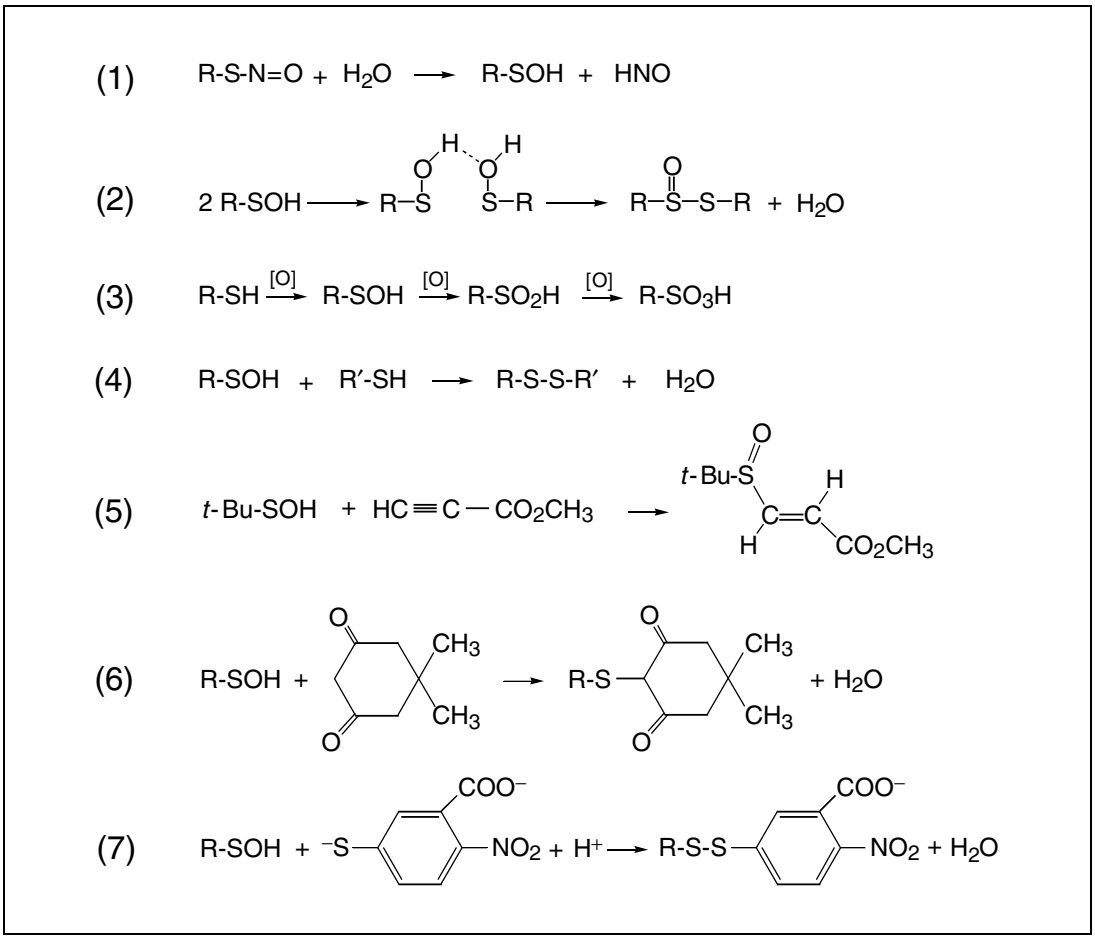

Figure 17.1.1 *(continues on right)* Chemical reactions relevant to the redox chemistry of sulfenic acids.

cently been characterized as well. In one heat shock protein from *Escherichia coli*, Hsp33 (Graumann et al., 2001), cysteinyl residues coordinated to zinc were shown to react with hydrogen peroxide, resulting in disulfide-bond formation. Furthermore, release of the bound metal concomitant with disulfide bond formation is an essential part of the activation of this protein. This mechanism likely also applies to the iron-coordinated cysteinyl residues within the peroxide-sensitive transcriptional repressor PerR from *Bacillus subtilis* (Mongkolsuk and Helmann, 2002). Although cysteine sulfenic acid formation was not demonstrated in these cases, its formation as an intermediate leading to disulfide bond formation is a plausible hypothesis. Such metal-enhanced reactivity of cysteine thiols may also be relevant to the sensitivity of Fe-S clusters toward oxidative damage (e.g., in aconitase and fumarase; Costa Seaver and Imlay, 2001). The release of the Fe(II) under conditions where H_2O_2 is already present undoubtedly exacerbates the deleterious effects of Fe-S center breakdown. Such cysteine-coordinated metal centers can thus serve as peroxide sensors, as well (Mongkolsuk and Helmann, 2002).

Nitrosative Stress and Sulfenic Acids

Several important players in nitrosative stress, including nitric oxide, S-nitrosoglutathione, and the product of nitric oxide and superoxide, peroxynitrite ($OONO^-$), deserve special attention as modifiers of cysteine thiols. Although the pathways through which nitric oxide modifies cysteinyl residues are complex, NO and its derivatives have been shown to modify free cysteine residues to give the S-nitrosothiol (R-SNO) and/or sulfenic acid (R-SOH) products or, in the presence of additional thiols, mixed disulfide bonds (Stamler and Hausladen, 1998; Marnett et al., 2003). Interestingly, when human glutathione reductase was inactivated with S-nitrosoglutathione (GSNO), the active-site cysteine residue proximal to the flavin (Cys63) was oxidized to a stable sulfenic acid and the interchange cysteine (Cys58) was linked through a mixed disulfide bond to glutathione (Becker et al., 1998). Oxidation of protein thiol groups to sulfenic,

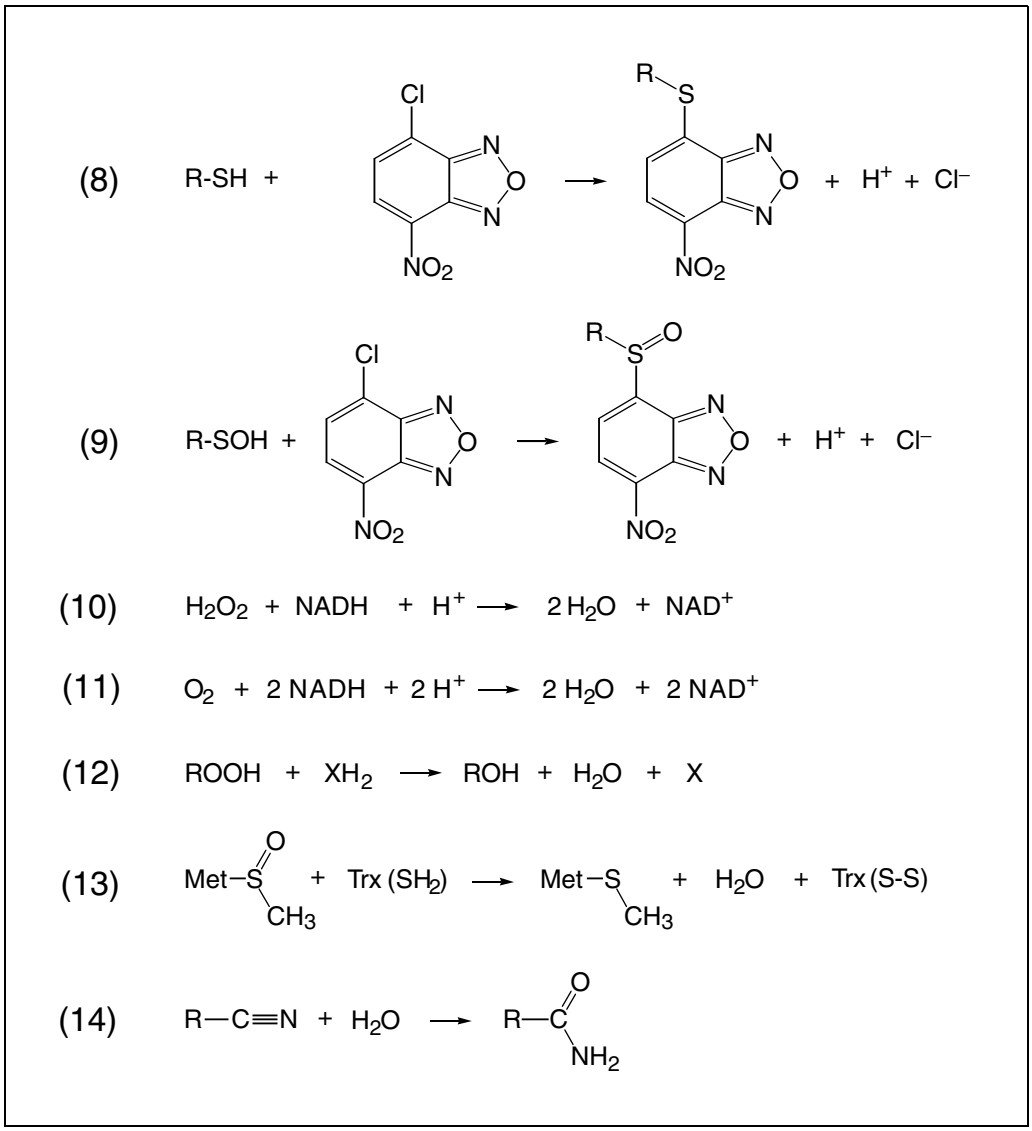

Figure 17.1.1 *(continued)*

sulfinic, and sulfonic acids has also been observed to occur subsequent to S-nitrosothiol generation, suggesting that these oxyacids are produced by initial hydrolysis of the nitrosothiol groups to generate the protein sulfenic acid and HNO, the one electron reduced form of NO (Fig. 17.1.1, reaction 1; Poole et al., 2004).

The sulfenic acid can then be further oxidized or condensed with reduced glutathione (GSH) or other thiol groups to form a mixed disulfide. Here again, factors stabilizing S-nitrosothiols, particularly those which preferentially yield either Cys–SNO or Cys–SOH products, are relatively poorly understood.

Chemistry of Sulfenic Acids

Once formed, sulfenic acids are intrinsically unstable due to their chemical reactivity but can be stabilized in the protein environment. The chemistry of sulfenic acids in small molecules and proteins, which has been reviewed elsewhere (Allison, 1976; Hogg, 1990; Claiborne et al., 2001), is summarized below in terms of the relevant reactions in which they participate and the forces which stabilize cysteine sulfenic acids in proteins.

Self condensation

Based on small molecules as model compounds, the greatest propensity of sulfenic acids is to undergo self-condensation via a hydrogen-bonded dimeric intermediate to yield a thiosulfinate linkage (Fig. 17.1.1, reaction 2).

This irreversible condensation reaction highlights a remarkable feature of sulfenic acids: the displacement of $^{-}$OH from one sulfur by the direct attack of the other demonstrates

their participation as both nucleophiles and electrophiles in chemical reactions. Given the intermediate which must be formed to promote this reaction, steric hindrance (preventing the close approach of two sulfenic acid moieties) and sulfenate anion stabilization (disfavoring generation of the hydrogen bonding network) are thus important factors in sulfenic acid stability in these molecules.

Oxidation, reduction, and trapping

Sulfenic acids have generally been considered transient intermediates in the oxidation of thiols to sulfinic ($R\text{-}SO_2H$) or sulfonic ($R\text{-}SO_3H$) acids (Fig. 17.1.1; reaction 3) and in the formation of disulfide bonds from free thiols (Fig. 17.1.1, reaction 4).

While sulfenic acids are readily reduced back to the thiol state with the chemical reductants dithiothreitol (DTT) or arsenite (which is reportedly unable to reduce disulfide bonds; Torchinsky, 1981), sulfinic acids are only reducible by such agents at very low pH (i.e., <4; Finlayson et al., 1979) and the oxidation to sulfonic acids is irreversible. The reactivity of sulfenic acids with both alkenes and alkynes (Allison, 1976; Hogg, 1990) has been used as the basis for the chemical trapping of unstable sulfenic acids formed, for example, upon thermolysis of sulfoxides. During thermolytic decomposition of di-*tert*-butyl sulfoxide, addition of methyl propiolate allowed for adduct formation with the *tert*-butyl-SOH product (Fig. 17.1.1, reaction 5), proving its formation (Shelton and Davis, 1973).

Reaction with nucleophiles

Sulfenic acids also react with nucleophiles such as benzylamine and cyanide. Adduct formation with 5,5-dimethyl-1,3-cyclohexanedione (dimedone) (Fig. 17.1.1, reaction 6) has been used as a diagnostic tool for demonstrating sulfenic acid formation in proteins (Allison, 1976).

Reaction with aromatic disulfides

The suggestion that sulfenic acids can react with aromatic disulfides (Torchinsky, 1981, p. 52) has been borne out by the demonstration of their reactivity with 5,5′-dithiobis(2-nitrobenzoic acid) (DTNB), a reagent typically considered to be thiol-specific (Poole and Ellis, 2002). Although the reaction of DTNB with sulfenic acids is complex and substoichiometric due to the additional reactivity of the 2-nitro-5-thiobenzoic acid (TNB) product with sulfenic acids (Fig. 17.1.1, reaction 7), this observation argues for caution in interpreting thiol contents as measured by DTNB reactivity in cases where sulfenic acids may also be present.

Identification of Sulfenic Acids in Proteins

For identification of sulfenic acids in proteins, recent developments in crystallographic and NMR approaches have led to important advances (Claiborne et al., 2001). In cases where these techniques have not been applicable, however, sulfenic acid identification has relied on several complementary protein chemical methods, as described in detail in the following unit (*UNIT 17.2*).

TNB and dimedone

Taking advantage of the unique reactivity of sulfenic acids toward the chromophoric thiol reagent TNB, quantitation of accessible sulfenic acids can be accomplished by monitoring the decrease in A_{412} as the mixed disulfide bond forms (Fig. 17.1.1, reaction 7).

As described above, dimedone reactivity also implies the presence of sulfenic acid (Fig. 17.1.1, reaction 6), although this product lacks any distinguishing spectral features and must be monitored either by incorporation of the radiolabeled reagent or by the mass increase imparted by adduct formation (Allison, 1976).

NBD chloride

Recent efforts taking advantage of the intrinsic nucleophilicity of sulfenic acids have led to the development of the thiol reagent 7-chloro-4-nitrobenzo-2-oxa-1,3-diazole (NBD chloride) as a diagnostic tool for sulfenic acid identification. Although NBD chloride reacts with both thiols (Fig. 17.1.1, reaction 8) and sulfenic acids (Fig. 17.1.1, reaction 9) at neutral pH, the adduct generated has distinct spectral features depending on the presence or absence of the sulfenate-derived oxygen.

The protein-S-NBD adduct has characteristic UV-visible (λ_{max} = 420 nm) and fluorescence (λ_{ex} = 422 nm, λ_{em} = 527 nm) properties which are readily distinguished from those of the nonfluorescent protein-S(O)-NBD adduct (λ_{max} = 347 nm; Fig. 17.1.2). The latter product is also larger by 16 amu as measured by electrospray ionization mass spectrometry (ESI-MS; Fig. 17.1.3). Whether the NBD adduct formed with the sulfenic acids is a sulfoxide or sulfenate ester was not established by these studies, although arguments supporting sulfoxide formation have been made based

partly on the acid stability of the product (Claiborne et al., 2001).

Direct detection by ESI-MS

One final note on sulfenic acid detection in proteins should be made. Where protein subunit molecular weights are sufficiently small and relatively gentle nondenaturing conditions are employed (e.g., ammonium bicarbonate buffer), ESI-MS techniques may allow for direct detection of the sulfenic acid oxygen and resolution of this species from the thiol or further oxidized R-SO_2H- and R-SO_3H-containing species (Fuangthong and Helmann, 2002). Typically, however, adventitious overoxidation of the sulfenic acid to exclusively yield the sulfonic acid (R-SO_3H) product is observed, particularly where acetonitrile and formic acid must be added for detection of the ionized protein (Ellis and Poole, 1997b).

Stabilization

As alluded to above, protein sulfenic acids, once formed, can (1) be stabilized within the protein environment, (2) react with nearby protein thiols or exogenous thiol groups to form disulfide bonds, (3) be further oxidized to sulfinic and/or sulfonic acids by oxidants such as molecular oxygen, peroxides, or peroxynitrite, or (4) be directly reduced back to the thiol state. Critical factors in the stabilization of protein sulfenic acids have been described previously (Allison, 1976) and are continuing to be refined in light of recent structural data (Claiborne et

al., 2001). One important factor in sulfenic acid stabilization in proteins is the absence of proximal thiols. Other factors may include proximity of suitable hydrogen-bond acceptors to the sulfenic acid hydrogen or the stabilization of the deprotonated sulfenate base. An apolar and/or inaccessible microenvironment for sulfenic acids in proteins also provides a stabilizing environment. Where sufficiently accessible, sulfenic acids will likely react with the high concentrations of GSH within the cells of most organisms, a process known as glutathionylation or glutathiolation. Note that the thiol-disulfide interchange of a protein thiol with glutathione disulfide (GSSG) can also yield this product without the intermediacy of sulfenic acid. Susceptibility toward overoxidation involving reaction with excess peroxide is also controlled by structural and electronic factors, although again, few details of the molecular mechanisms involved are clear.

FUNCTIONS OF PROTEIN SULFENIC ACIDS

Because both sulfenic acids and the disulfide bonds that may ensue following SOH formation are reducible back to the thiol state, these species are highly suited as catalytic redox centers or as redox-sensitive regulatory components within enzymes and transcription factors. The phenomenon of redox regulation includes a wide variety of redox sensors which modulate protein function in response to changing environmental signals, intracellular signals, or both (Bauer et al., 1999; Marnett et al., 2003). Hydrogen peroxide and NO, as important cellular redox signals, have the propensity to generate stable cysteine sulfenic acids and disulfide bonds in proteins with redox-sensitive cysteinyl residues. With recently improved methodology for identifying sulfenic acid formation in proteins, the stage is set for the application of these approaches to the identification of protein sulfenic acids of functional significance. Based on current knowledge, the following represents a brief review of the catalytic and regulatory roles played by sulfenic acids in proteins.

Sulfenic Acid Participation in Redox Catalysis by Antioxidant Enzymes

NADH peroxidase

The first identified and best characterized naturally-occurring sulfenic acid in a protein is that of NADH peroxidase, a flavoprotein expressed in some lactic acid bacteria, which acts as a functional substitute for catalase in these heme-deficient organisms (Claiborne et al., 2001). In this protein, cysteine sulfenic acid represents the stable, oxidized form of the active site generated on reaction with its oxidizing substrate, hydrogen peroxide, during catalysis (Fig. 17.1.1, reaction 10 and Fig. 17.1.4, Scheme 1).

The cysteine sulfenic acid is then directly reduced back to its activated thiolate form (protein-S^-) via electrons from NADH provided via the proximal isoalloxazine of the tightly bound FAD.

Initial evidence supporting identification of this stable sulfenic acid came in part from the fact that only a single cysteine was present per subunit, and no intersubunit disulfide bond was formed on oxidation with peroxide (Poole and Claiborne, 1989). In the last decade, structural data obtained by cryocrystallography and ^{13}C-NMR have fully confirmed the presence of this unusual redox center (Claiborne et al., 2001). As observed in the X-ray crystal structure, the cysteine sulfenic acid (Cys42-SOH = Cyo42) is stabilized through H-bonding interactions of both S_γ and O_δ with the nearby FAD (3.3 – 3.6 Å) and a neutral histidine (~3.4 Å between Cyo42-O_δ and His10 $N_{\varepsilon 2}$), interactions which may serve to stabilize the sulfenate base. The relatively apolar microenvironment, its very limited solvent access, and the lack of any other cysteinyl residues in the protein all serve to stabilize this redox center in NADH peroxidase.

NADH oxidase

Another flavoprotein with homology to NADH peroxidase (44% identity between the two proteins from *Enterococcus faecalis*), NADH oxidase, has also been identified as a sulfenic acid–containing protein with mechanistic similarities to the NADH peroxidase (Claiborne et al., 2001). In this case, oxygen is fully reduced by four electrons to water (Fig. 17.1.1, reaction 11), and evidence strongly supports the generation of a flavin C(4a)-hydroperoxide intermediate (FADHOOH) formed on reaction of the reduced flavin with oxygen (Claiborne et al., 2001).

Although active site asymmetry in the dimeric enzyme has complicated the kinetic and structural analyses of NADH oxidase, it seems clear that the sulfenic acid of this protein is in quite a similar environment and playing an identical mechanistic role as that of the related NADH peroxidase (Claiborne et al., 2001). Thus, the Cys-SOH formed on oxidation of the active site cysteine by the peroxyflavin is rere-

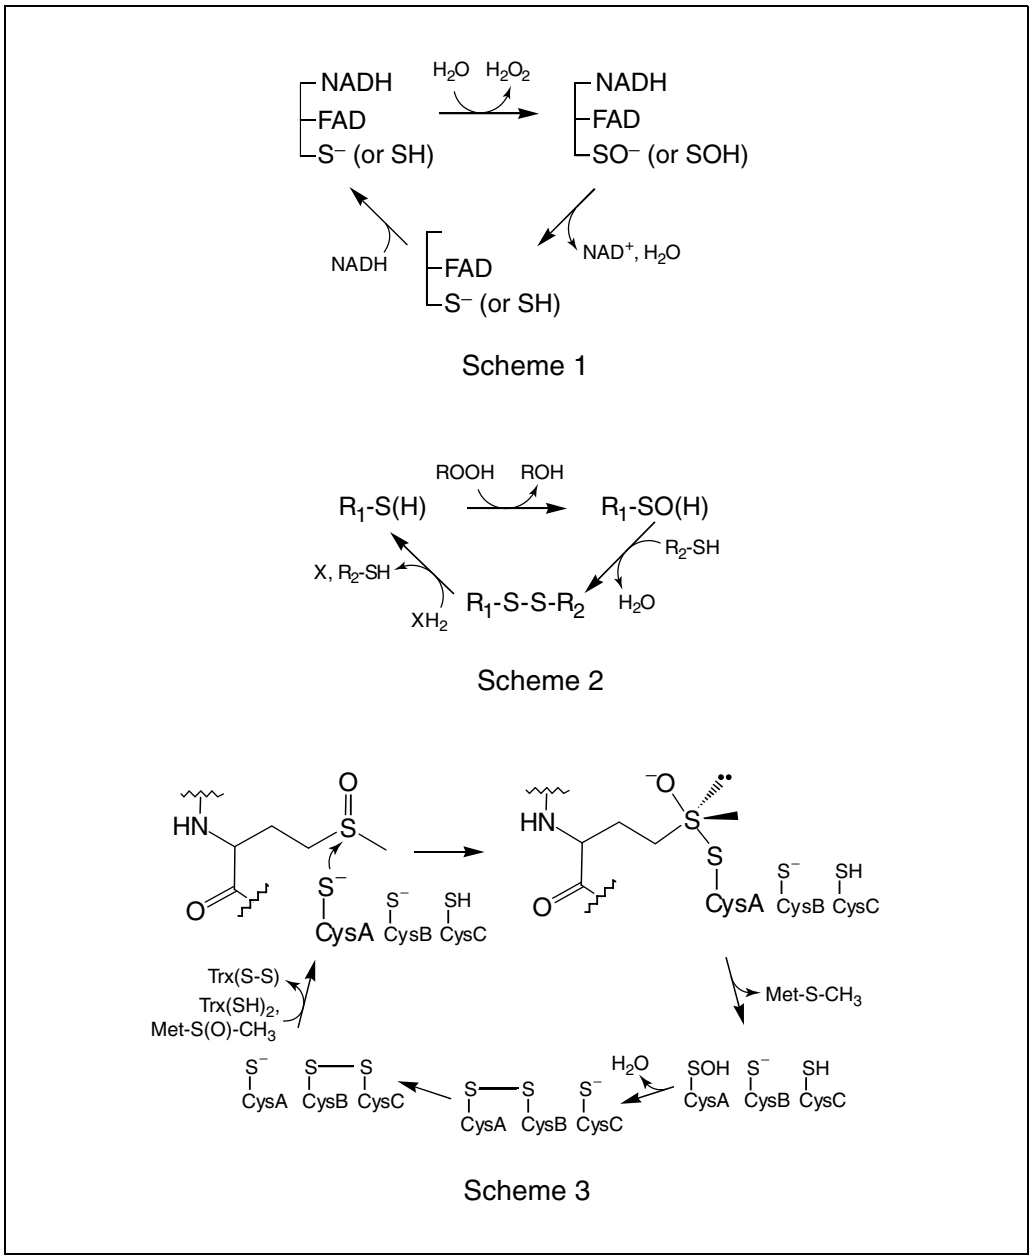

Figure 17.1.4 Reaction schemes involving protein sulfenic acids.

duced by NADH with the flavin playing an intermediary role in electron transfer between the two as in Scheme 1 (Fig. 17.1.4).

Peroxiredoxins

Over the last ~15 years, a ubiquitous family of peroxidases, named the peroxiredoxins (Prxs), has been identified which relies on a chemistry similar to that of the NADH peroxidase in catalyzing the cysteine-dependent reduction of peroxides (Fig. 17.1.1, reaction 12).

Prokaryotic and eukaryotic Prxs generally reduce a wide variety of peroxides, including hydrogen peroxide, organic hydroperoxides, and peroxynitrite, and are expressed at high levels in many cell types (Wood et al., 2003a). In bacteria, Prxs such as AhpC from *Escherichia coli* are essential for maintaining the low levels of hydrogen peroxide required for sustained growth (Costa Seaver and Imlay, 2001). The presence of up to six different subtypes of Prxs in mammalian cells also helps regulate levels of hydrogen peroxide, a mediator of cytokine-induced signal transduction (Hofmann et al., 2002). At least one Prx, PrxI, also known as heme-binding protein 23 (HBP23) and proliferation-associated gene (PAG), also interacts directly with and inhibits *c*-Abl, a nonreceptor tyrosine kinase. Thus, these proteins are important not only in protec-

tion against oxidative stress but also in regulation of cell signaling, with demonstrated roles in such processes as proliferation, differentiation, and apoptosis.

Prx classes

Prxs can be structurally and functionally divided into three classes known as the typical 2-Cys Prxs, the atypical 2-Cys Prxs and the 1-Cys Prxs (Wood et al., 2003a). Whereas Prxs in all three classes catalyze the reduction of hydroperoxides to yield a sulfenic acid at the conserved active site cysteine (Fig. 17.1.4, Scheme 2), the mechanism for recycling of the sulfenic acid to regenerate the activated thiolate differs among the three classes.

1-Cys Prxs: In 1-Cys Prxs, the sulfenic acid likely reacts with a small molecule thiol prior to reduction with a second molecule of the reductant, although the identity of the electron donor is as yet unclear (Fig. 17.1.4, Scheme 2; $XH_2 = R_2SH$ and the product is R_2-S-S-R_2 in this case).

2-Cys Prxs: In 2-Cys Prxs, the thiol which condenses with the nascent sulfenic acid comes from another cysteine group in the protein, either on the same subunit as the peroxidatic cysteine (atypical 2-Cys Prxs) or, more commonly, from an adjacent subunit of the head-to-tail homodimer (typical 2-Cys Prxs). The electron donor required for recycling of 2-Cys Prxs generally includes a reduced pyridine nucleotide (NADH or NADPH), a flavoprotein disulfide reductase (thioredoxin reductase, AhpF, trypanothione reductase, or lipoamide dehydrogenase) and an additional CXXC-containing protein or module (thioredoxin, the N-terminal domain of AhpF, tryparedoxin, or AhpD; Wood et al., 2003a).

2-Cys Prx to 1-Cys Prx: Prior to 1998, the strongest evidence for cysteine sulfenic acid involvement in Prx-catalyzed peroxide reduction came from the studies of a mutant of *Salmonella typhimurium* AhpC, C165S, in which the second cysteine had been removed by mutagenesis, leaving only the peroxidatic Cys46 (Ellis and Poole, 1997a,b). This enzyme exhibited full peroxidatic activity toward cumene hydroperoxide in the presence of excess NADH and AhpF, showing that it had effectively been converted to a 1-Cys Prx. Reactivity of the oxidized active site cysteinyl group toward TNB and dimedone was demonstrated as part of the proof of sulfenic acid production on peroxide treatment of this mutant. Reactivity of the thiol and sulfenic acid forms of this mutant toward NBD chloride was also studied, as described above, and it was this work that resulted in the development of a new protocol for the trapping and identification of cysteine sulfenic acids in proteins (Ellis and Poole, 1997b).

Prx structures

Structure of hORF6: In 1998, the 2.0 Å crystal structure of the C91S mutant of a human 1-Cys Prx, hORF6, demonstrated the sulfenic acid at the active site (Cys47-SOH = Cyo47) of this enzyme, as well (Choi et al., 1998). At least some of the environmental features known to stabilize protein sulfenic acids are also present in the hORF6 (PrxVI) structure. Solvent access to the Cyo47, which lies at the bottom of an active site pocket, is restricted. A nearby His (His39) is within H-bonding distance (3.0 Å) of the Cyo47-S_γ, and the only other cysteine in the protein (Cys91, mutated to Ser in the mutant studied by X-ray crystallography) is ~17 Å away.

Other Prx structures: Since the report of the hORF6 structure, six structures of reduced, oxidized, and overoxidized 2-Cys Prxs have been reported (Wood et al., 2003a,b). The most important findings are that the typical 2-Cys Prxs must undergo considerable structural rearrangements around the peroxidatic cysteine at the active site and the resolving cysteine in the C-terminal tail of the partner subunit in order to form the disulfide bond of the oxidized proteins. Typical 2-Cys Prxs also form strong decamers as pentameric arrangements of homodimers $[(\alpha_2)_5]$ in their reduced, but not oxidized (disulfide-bonded) forms.

Prx inactivation and signaling

As Prxs are intimately involved in the cellular control of H_2O_2 levels, they play an obvious role in modulating peroxide-linked redox signaling pathways. Thus, mechanisms by which Prx activities are regulated, reportedly including oligomerization, phosphorylation, proteolysis, and overoxidation of the active site cysteine, presumably dictate the ability of H_2O_2 to act as a second messenger (Poole et al., 2004). The phenomenon whereby Prxs are inactivated by their own substrate at the active site Cys-SOH is particularly striking; in fact, eukaryotic Prxs are significantly more sensitive (by ~110-fold) toward inactivation by H_2O_2 than are their bacterial counterparts (Wood et al., 2003b). The Cys-SOH, which persists longer in the eukaryotic versions of the 2-Cys Prxs prior to disulfide bond formation, therefore acts as a peroxide-sensitive switch in higher organisms.

Interestingly, the product of Cys-SOH oxidation in Prxs, the stabilized cysteine sulfinic acid, turns out not to be irreversibly oxidized in vivo. At least some eukaryotic cell types express a sulfinic acid reductase capable of reversing Cys-SO_2H formation in some Prxs (Poole et al., 2004).

Methionine sulfoxide reductases

Function: One hallmark of oxidative damage to proteins by reactive oxygen and nitrogen species is the oxidation of methionine residues to asymmetric methionine sulfoxides (epimeric R and S forms). Repair enzymes that can catalytically reduce these oxidized amino acids back to their original form using electrons from thioredoxins (Fig. 17.1.1, reaction 13) have been identified recently from bacterial and eukaryotic sources (Weissbach et al., 2002).

These peptide methionine sulfoxide reductases (Msrs) are therefore responsible for the reversal of such oxidative damage, suggesting that methionine oxidation, like reversible cysteine oxidation, may even be an important player in redox signaling. There is a growing list of proteins and peptides whose biological activities are affected by the oxidation of methionine residues (e.g., α-1-proteinase inhibitor, a voltage-gated K^+ channel, and calmodulin); the observation that Msrs can restore activity to at least some of these oxidized proteins supports a regulatory role for these enzymes (Weissbach et al., 2002).

Mechanism: Of interest in the context of this discussion is the intermediacy of a cysteine sulfenic acid (or, in some cases, the corresponding selenenic acid of selenocysteine-containing enzymes) in the catalytic cycle of Msrs (Boschi-Muller et al., 2000). During turnover, an essential, conserved cysteine at the active site (CysA) acts as the nucleophile and attacks the sulfur of the methionine sulfoxide, leading to the formation of a trigonal-bipyramidal intermediate (Fig. 17.1.4, Scheme 3; Boschi-Muller et al., 2000; Weissbach et al., 2002).

Collapse of the intermediate generates the restored methionine product and a sulfenic acid at the active site cysteine. Condensation with CysB to form a disulfide bond and a series of thiol-disulfide exchange reactions with CysA, B, and C in Msrs and the two cysteines of the thioredoxin electron donor results in reactivation of the enzyme for another turnover. The primary evidence for the intermediary cysteine sulfenic acid comes from the TNB and dimedone reactivity of the intermediate generated when only CysA is present (Boschi-Muller et al., 2000).

Other Catalytic Functions of Cysteine Sulfenic Acids in Proteins

Before leaving the topic of sulfenic acids important in catalysis, several systems distinct from the antioxidant enzymes presented above, yet depending on sulfenic acids for function, should also be noted. These proteins include nitrile hydratase, with a cysteine sulfenic acid at the active site, and human serum albumin, where sulfenic acid generation has been linked to the catalytic reduction of platinum drugs.

Nitrile hydratase

This enzyme from *Rhodococcus* sp. N-771 contains nonheme iron and catalyzes reaction 14 of Figure 17.1.1, a chemistry critical to the industrial production of acrylamide.

In the 1.7-Å X-ray crystal structure of the NO-inhibited enzyme published in 1998 (Nagashima et al., 1998), Cys112 was oxidized to a sulfinic acid (Cys112-SO_2H) and Cys114 to a sulfenic acid (Cys114-SOH). These two residues, along with Cys109-SH, act as ligands to the bound Fe(III). Oxygen atoms from each of the two oxidized cysteine residues also protrude above the equatorial plane of the Fe(III) ligand field and are within 2.8 to 3.0 Å of the NO nitrogen. Recent data has shown the essentiality of the oxidation of both cysteine residues in generating active enzyme (Murakami et al., 2000). Together, these data support catalytic roles for both Cys-SOH and Cys-SO_2H in this unusual active site, although the Cys-SOH is not undergoing changes in its redox state during the catalytic cycle.

Human serum albumin and activation of Pt(IV) drugs

Oxidation of Cys34 in human serum albumin (HSA) by the NO donor diethylamine nonoate was shown to result in the generation of the sulfenic acid form of this residue based on its reactivity with dimedone and GSH (DeMaster et al., 1995). This observation took on new significance with the more recent finding that Cys34-SH catalyzes the reduction of the iodide analogue of the anticancer drug cisplatin (*cis*-$[Pt(IV)Cl_2(NH_3)_2]$). During reaction of HSA with $[Pt(en)(OH)_2I_2]$, Cys34-SH was oxidized to the sulfenic acid and subsequently to higher oxidation states, likely through the intermediacy of the sulfenyl iodide at Cys34 (Cys34-SI; Kratochwil et al., 1999). The formation of the sulfenic acid at Cys34 was supported by NBD-modification and ESI-MS analyses. The importance of this observation lies in the fact that Pt(IV) anticancer drugs

undergo reductive activation in blood plasma, where HSA-Cys34 represents the major thiol (Claiborne et al., 2001). In vivo, the formation of the sulfenic acid at Cys-34 of HSA may be reversible, and its formation in the context of Pt(IV) drug activation may represent a sort of catalytic cycle for this abundant serum protein.

Redox Regulation Through Reversible Cysteine Sulfenic Acid Formation in Enzymes

An important role for sulfenic acids in proteins is in the regulation of activity in enzymes for which they are not part of the catalytic mechanisms. In particular, enzymes with an essential cysteinyl residue at their active site can be susceptible to this modification and inactivated by it. As long as the oxidation stops at the level of sulfenic acid or disulfide bond formation, enzymatic activity can be restored by a chemical reductant. Reduction in vivo will also occur as long as a pathway exists whereby a cellular reductant (typically reduced thioredoxin, GSH, or glutaredoxin) can carry out this reaction. Examples of enzymes shown to be inactivated by sulfenic acid formation and reactivated by chemical reduction include papain (Allison, 1976), glyceraldehyde-3-phosphate dehydrogenase (GAPDH; Allison, 1976; Ishii et al., 1999), and NO-inhibited GSSG reductase (Becker et al., 1998), as mentioned earlier. Given their importance in signal transduction pathways, two additional types of enzymes undergoing reversible peroxide- or NO-mediated inactivation through cysteine sulfenic acid formation, protein tyrosine phosphatases and cathepsin K, are discussed in more detail below. It should be noted again that enzymes that are glutathionylated as part of their reversible inactivation may also first be oxidized to sulfenic acids and then condense with GSH; this modification pathway has been observed, for example, for protein tyrosine phosphatases (Barrett et al., 1999). Indeed, reaction with one molecule of GSH can be viewed as the first step in reactivation which is followed by reaction with a second molecule of GSH, GSSG formation and regeneration of the active enzyme. This process is analogous to the reaction mechanism of glutathione peroxidases, where the chemical analog of cysteine sulfenic acid, the selenenic acid (Cys-SeOH), is regenerated with two molecules of GSH.

GAPDH

In the case of GAPDH, cysteine sulfenic acid formation inhibits one activity but also imparts a new enzymatic activity (Allison, 1976). As mentioned above, oxidation of GAPDH leads to stable sulfenic acid formation. In its thiol form, Cys149 of GAPDH from *Bacillus stearothermophilis* catalyzes the production of 1,3-bisphosphoglycerate. On oxidation to Cys149-SOH by hydrogen peroxide (Schmalhausen et al., 1999) or nitric oxide (Ishii et al., 1999), the modified enzyme does not catalyze the dehydrogenase reaction but instead participates directly in the hydrolytic decomposition of D-glyceraldehyde-3-phosphate through a new acyl phosphatase activity. Thus, this redox switch not only turns the activity of this glycolytic enzyme on and off, it also converts the enzyme to a form with a distinctly different catalytic activity.

hBCATm

It should also be noted that peroxide-sensing, regulatory dicysteinyl centers such as those within CXXC motifs are also likely to be converted to the disulfide form through intermediary sulfenic acid formation. For example, human mitochondrial branched-chain aminotransferase (hBCATm), a pyridoxal phosphate–dependent enzyme which does not require a cysteine residue in its catalytic mechanism, is completely inhibited by disulfide bond formation at a CXXC redox center proximal to the active site (Conway et al., 2002). Reaction of one of the cysteine residues, Cys315, with peroxide forms Cys315 sulfenic acid as the first step in the process, as established recently by combined mutagenesis and chemical modification studies (Conway, Poole, and Hutson, unpub. observ.). The proximity of the other cysteine thiol (Cys318) in the wild-type enzyme then leads to disulfide bond formation, and reversal of this oxidation by DTT reactivates the enzyme.

Protein tyrosine phosphatases

It is increasingly clear that cellular redox status has an important role to play in numerous signal transduction pathways, including those involving growth factors and tyrosine phosphorylation. For example, the src family protein tyrosine kinase Lck becomes highly phosphorylated on tyrosines when T lymphocytes are incubated with hydrogen peroxide, a phenomenon attributed to the oxidative inactivation of protein tyrosine phosphatases (PTPases; Nakamura et al., 1997). Several reports have confirmed the oxidation of the essential active site cysteine of PTPases such as VHR and PTP1B to a stable sulfenic acid by hydrogen peroxide

treatment, a reversible modification which inactivates these enzymes and can therefore lead to hyperphosphorylation of their target proteins (Denu and Tanner, 2002). The competitive inhibitor phosphate protected against peroxide-mediated inactivation, 2-mercaptoethanol reversed the effect of the hydrogen peroxide, and NBD chloride modification gave a clear indication of sulfenic acid formation, in spite of the contributions to the spectra of the NBD adducts of the other three cysteine residues (Denu and Tanner, 1998). Oxidation of the active site cysteine of PTP1B was also shown to occur in vivo on growth factor stimulation of cultured cells (Lee et al., 1998). In this study, reactivation of the peroxide-inhibited PTP1B ensued on treatment with either reduced thioredoxin or GSH. As noted above, glutathionylation is also observed for PTPases (Barrett et al., 1999), consistent with their oxidative conversion to sulfenic acid–containing proteins followed by condensation with and rereduction by GSH. Crystallographic studies of inactivated PTPases revealed a surprising new derivative of Cys-SOH; in these structures the main-chain nitrogen of an adjacent Ser residue is covalently linked to the sulfenyl sulfur, forming a stable, yet reducible, sulfenyl-amide at the active site (Salmeen et al., 2003). With PTPases as targets for reversible inactivation by hydrogen peroxide, sulfenic acid formation in one class of enzymes can have a big effect on signal transduction pathways involving a large number of other regulatory proteins.

Cathepsin K

Cathepsin K, a cysteine-dependent protease homologous with papain, is thought to play a key role in bone resorption as a result of its collagenolytic activity (Percival et al., 1999). It is expressed at high levels in bone-resorbing osteoclasts and may be responsible for the reduction in bone resorption which results from treatment with NO and NO donors. Indeed, cathepsin K activity of the purified protein or of the protein expressed in cultured cells was inhibited by treatment with GSNO or NOR-1, another NO donor; the activity of the GSNO-treated enzyme was largely regenerated by DTT treatment. Treatment with GSNO led to glutathionylation as shown by mass spectrometry; this technique also indicated the presence of sulfinic or sulfonic acid forms of the active site Cys25 following NOR-1 treatment. Cotreatment of cathepsin K with both NOR-1 and dimedone led to formation of the dimedone adduct, indicating that sulfenic acid was likely formed as an intermediate during the oxidation of Cys25 by one or both compounds. These findings compare nicely with earlier studies of sulfenic acid formation and stabilization in the closely related protease papain (Allison, 1976) and support an important role for sulfenic acid formation in cathepsin K as a mechanism by which NO exerts its inhibitory effect on bone resorption.

Redox Regulation Involving Cysteine Sulfenic Acid Formation in Transcription Factors

As for enzymes, a number of transcriptional regulators sense changes in redox status or peroxide levels specifically through oxidative modifications to Cys-SH. In many cases, the precise linkage between oxidation state of a critical thiol and transcriptional activity is as yet poorly characterized. For example, sulfenic acid generation at the conserved Cys-154 of Fos and the related Cys-278 of Jun, the two protein components of AP-1, was hypothesized more than a decade ago (Abate et al., 1990) but still has not been firmly established. Still, the location of these single cysteine residues within the long recognition helix and in very close proximity to the site of interaction with DNA (Chen et al., 1998a), and considerable data highlighting the importance of maintaining that cysteine in a reduced state for full transcriptional activation (Xanthoudakis and Curran, 1996), argue strongly for a role in regulation by sulfenic acid generation in these proteins. Furthermore, data were presented ruling out disulfide bond formation in oxidized AP-1 (Abate et al., 1990), and the naturally-occurring mutation of Cys278 to a Ser in *v*-Jun both removes its redox regulation and enhances its DNA binding and therefore cell transformation capability, leading to the designation of this mutation as a gain-of-function mutation (Abate et al., 1990; Xanthoudakis and Curran, 1996). A similar situation exists for the E2 protein of bovine papillomavirus-1. A conserved Cys (Cys340 in BPV-1 E2) also exhibits interaction with the DNA target as observed in the 1.7-Å X-ray crystal structure (Hegde et al., 1992). Through mutagenesis analyses of this and two other Cys residues in the recognition helix, it was shown that only Cys 340 is required for inactivation by diamide, a thiol-oxidizing agent (McBride et al., 1992). In this case, mutations of Cys340 to Ser and Ala also gave reduced DNA binding affinities (by ~50% and ≥90%, respectively),

arguing for the requirement of the free thiol at Cys340 for effective binding. Again, sulfenic acid formation has not been directly proven but has a high likelihood of playing an important role in redox regulation involved in the pathogenesis of these DNA tumor viruses.

The case for sulfenic acid–dependent redox regulation for several other transcriptional regulators, OxyR, OhrR, and NF-κB, is stronger, and each of these is covered in more detail below.

OxyR

The bacterial transcription factor OxyR was identified in 1985 and shown to act as a direct sensor of hydrogen peroxide, also transducing the signal to activate the transcription of a number of antioxidant proteins, including the peroxiredoxin system proteins AhpF and AhpC in *E. coli* and *S. typhimurium* (Storz and Imlay, 1999). Early investigations led to the suggestion that sulfenic acid formation might be involved in the activation of OxyR; subsequent mutagenesis studies have supported that notion, as primarily Cys199, but to some extent also Cys208, are required for peroxide activation (Kullik et al., 1995). In MALDI-TOF analyses of tryptic fragments, evidence was noted for thiosulfinate generation (ostensibly from condensation between sulfenic acids) in the oxidized form of a mutant lacking Cys208, supporting peroxide-mediated oxidation of Cys199 (Zheng et al., 1998). Disulfide bond formation between Cys199 and Cys208, as would be expected following Cys199-SOH formation if the two residues are close enough, was indeed observed after activation of OxyR with hydrogen peroxide (Zheng et al., 1998). Recent X-ray crystallographic data including 2.7- and 2.3-Å structures, respectively, for both reduced and oxidized forms of OxyR indicates a very large conformational change imparted to the protein upon disulfide bond formation (Choi et al., 2001). In fact, the two cysteine thiols are some 17 Å apart in the structure of the reduced protein, a situation similar to that observed for the Prxs wherein the two Cys sulfurs are brought together for disulfide bond formation through significant conformational changes (Wood et al., 2003a). A recent report has revisited cysteine modification in OxyR and concluded that Cys oxidation by hydrogen peroxide primarily results in sulfenic acid formation at Cys199 and not disulfide bond formation; other modifications such as nitrosation and glutathionylation of Cys199 were also observed in vivo and found to activate the protein in vitro, as well (Kim et al., 2002). Although the relative contributions of sulfenic acid and disulfide-bonded forms of OxyR in vivo are currently a matter of debate (Poole et al., 2004), rapid formation of sulfenic acid at Cys199 by hydrogen peroxide is clearly critical to the peroxide response.

OhrR

The best evidence for a functional cysteine sulfenic acid generated by peroxide modification of a transcriptional regulator has been reported for OhrR of *Bacillus subtilis*. OhrR in its reduced form represses transcription of the *ohrA* organic peroxide resistance gene and is representative of a family of peroxide sensors identified in both gram positive and negative organisms (Mongkolsuk and Helmann, 2002). The protein from *B. subtilis* has only one cysteine per subunit, which is conserved among other family members, and exposure to peroxides leads to the reversible oxidation of this residue (Cys15) to a sulfenic acid and derepression of *ohrA* transcription (Fuangthong and Helmann, 2002). Formation of the sulfenic acid was documented by spectral analysis of the NBD chloride–modified protein as well as direct observation of this and higher oxidized species ($-SO_2H$ and $-SO_3H$) by ESI-MS. DTT reversibility of the peroxide-mediated oxidation argues that this overoxidation is probably not of significance under most conditions, however. S-thiolation, in this case with cysteine or the thiol group of coenzyme A (*B. subtilis* does not contain glutathione), may also occur in vivo as part of the activation and/or rereduction process. Interestingly, other OhrR family members, including OhrR from *Xanthomonas campestris*, also likely sense peroxides through sulfenic acid formation at this conserved cysteine, although in at least some cases intramolecular disulfide bond formation may also ensue, much like the peroxide-sensing mechanism employed by OxyR (Panmanee et al., 2002).

NF-κB

Activity of the inducible transcription factor NF-κB is modulated, in part, by cellular redox status; oxidative and nitrosative stresses as well as treatment with thiol alkylating agents all lead to an inhibition of its DNA-binding activity (Marnett et al., 2003). These effects have been attributed to modification of a cysteine residue (Cys62) that lies within an electropositive en-

vironment, enhancing its susceptibility toward oxidation. The 2.9-Å crystal structure of the p65/p50 heterodimer in complex with the intronic enhancer DNA of the immunoglobulin light-chain gene also demonstrates the proximity of Cys62 to its target DNA (Chen et al., 1998b). Reported modifications to the cysteinyl residue on treatment with reactive oxygen or nitrogen species have included intra- or intermolecular disulfide bonds formation, nitrosation, and glutathionylation (Marnett et al., 2003). In a recent report, sulfenic acid formation was also detected in addition to glutathionylation at Cys62, even though the oxidizing conditions used were imparted by varying the ratio of GSH to GSSG incubated with the protein (Pineda-Molina et al., 2001). While the relative contributions of all of these modifications to the redox regulation of NF-kB in vivo will require further investigation, it is clear that sulfenic acid formation at Cys62 in NF-kB is a critical component of the redox sensitivity of its function.

SUMMARY

Sulfenic acid formation in enzymes and transcriptional regulators is now well documented and is clearly an important component of redox catalysis and signalling in many systems. While Cys-SOH can itself be a stabilized redox form in these proteins, it can also readily react with proximal thiol groups of other cysteines or external agents to form disulfide bonds. Both sulfenic acids and disulfide bonds are reducible by cellular thiols back to the thiol state and, as such, are appropriately suited for roles in both redox regulation and catalysis. On the other hand, cysteine sulfenic acids lie on the pathway toward oxidative inactivation through formation of cysteine sulfinic and sulfonic acids, forms which may themselves play functional roles in redox sensing. Given the increasing number of proteins shown to form sulfenic acids of functional significance, it seems likely that the application of chemical and structural methods to detect these species in other systems will continue to increase our appreciation for the diverse roles they play in biological phenomena.

Measurement of Protein Sulfenic Acid Content

Cysteine sulfenic acids in proteins are of considerable biological interest as important players in redox catalysis and redox regulation, yet they have been notoriously difficult to identify due to their high reactivity, particularly outside their native protein environments. Where sulfenic acids are stabilized within proteins, factors contributing to their stability include the lack of proximal thiols, nearby hydrogen-bonding and/or basic side chains to stabilize the protonated or deprotonated sulfenic acid, and restricted access to solvent (see overview, *UNIT 17.1*). Direct observation of sulfenic acids within proteins has been possible only with crystallography, often requiring low-temperature cryotechniques to avoid overoxidation, and NMR using ^{13}C-cysteine-labeled protein (Claiborne et al., 1999). Electrospray ionization mass spectrometry (ESI-MS) can be successful for direct detection of the additional oxygen of the sulfenic acid (Fuangthong and Helmann, 2002), but more often it leads to detection only of the sulfonic acid form (Cys-SO_3H) generated through overoxidation of the sulfenic acid of interest (Ellis and Poole, 1997a).

The protocols outlined in this unit describe three chemical modification methods useful for sulfenic acid identification. The first reagent, 7-chloro-4-nitrobenzo-2-oxa-1,3-diazole (NBD chloride), reacts with both thiol groups and sulfenic acids in proteins at pH 7, but in each case the reactions give unique products that can be distinguished by their UV-visible spectra and by their masses (with the NBD-sulfenate adduct being 16 amu larger than the NBD-thiol adduct; see Basic Protocol 1). As an alternative, NBD chloride can be replaced by 4-fluoro-7-nitrobenz-2-oxa-1,3-diazole (NBD fluoride), a less stable reagent which reacts more quickly with thiols and sulfenic acids and gives the same products (see Alternate Protocol). The second reagent, 2-nitro-5-thiobenzoic acid (TNB), made from 5,5′-dithiobis(2-nitrobenzoic acid) (DTNB) and 1,4-dithio-DL-threitol (DTT), reacts stoichiometrically with sulfenic acids resulting in the loss of its bright yellow color, thereby allowing for accurate quantitation of R-SOH groups by spectroscopy as well as ESI-MS (see Basic Protocol 2). The third reagent, 5,5-dimethyl-1,3-cyclohexanedione (dimedone), reacts specifically with sulfenic acid, but not thiol, groups on proteins. Unfortunately, the product does not exhibit any distinguishing visible absorbance properties; therefore, proof of modification by dimedone generally relies on ESI-MS analysis, as the radiolabeled reagent is not commercially available (see Basic Protocol 3). Of the three, only the dimedone modification is not reversed by the reductant DTT, making the latter a particularly useful reagent for subsequent tryptic digestion and peptide analysis (see Support Protocol 3). If conversion of a given protein thiol group to a sulfenic acid (see Support Protocol 1) is accompanied by a spectral change, titration of the enzyme with buffers at different pH values may allow for the determination of the pK_a of that sulfenic acid (see Basic Protocol 4). Functional properties of a given protein may also be affected by sulfenic acid formation and/or modification and may be tested as well (see Support Protocol 2).

SULFENIC ACID TRAPPING AND DETECTION USING NBD CHLORIDE

BASIC PROTOCOL 1

This method is most useful in demonstrating sulfenic acid formation where this species is accessible to modification and is the only cysteine thiol or sulfenic acid present, accessible, or both. In cases where accessibility is the problem, denaturants can be used. If more than one accessible cysteine thiol and/or sulfenic acid is present per subunit, modification may still allow for the demonstration of sulfenic acid using difference spectra.

Contributed by Leslie B. Poole
Current Protocols in Toxicology (2003) 17.2.1-17.2.20

The sulfenic acid is generated by the method of choice, typically treatment with stoichiometric hydrogen peroxide, *t*-butyl hydroperoxide, or cumene hydroperoxide (see Support Protocol 1), then trapped by reaction with NBD chloride. Once the excess free reagent is removed from the modified protein by ultrafiltration, the presence of thiol- or sulfenate-adducts with NBD can be assessed by UV-visible spectroscopy and/or mass spectrometry.

Materials

Putative sulfenic acid–containing protein, purified and in neutral pH buffer
Neutral pH buffer: 25 mM potassium phosphate (pH 7.0)/1 mM EDTA, or equivalent pH ≤7 buffer
100 mM NBD chloride in DMSO (see recipe)
Acetonitrile
Formic acid

Ultrafiltration unit of appropriate MWCO (e.g., Millipore Centricon, Orbital Biosciences Apollo, Vivascience Vivaspin)
UV-visible scanning or diode-array spectrophotometer
Electrospray ionization mass spectrometer (ESI-MS) or access to a fee-for-service facility
Software for comparing observed and predicted mass (e.g., Calculate pI/MW tool; *http://www.expasy.ch*)

Additional reagents and equipment for preparing proteins containing sulfenic acid (see Support Protocol 1) and determination of protein concentration by a non-NBD affected assay

Prepare protein

1. Prepare at least 1 ml of a 15 μM (monomer or target thiol group concentration) solution of the putative sulfenic acid–containing protein in neutral pH buffer (i.e., pH ≤7) using the method described in this unit (see Support Protocol 1) or by other methods established by functional analyses.

   For example, in a typical reaction, add 3 μl of 8 mm hydrogen peroxide to 0.5 ml of 45 μM protein (see Support Protocol 1).

Modify with NBD chloride

2. To the protein of interest, with or without oxidant pretreatment, add a small volume of 100 mM NBD chloride, either directly or through the sidearm of the anaerobic cuvette. Incubate 10 to 30 min at room temperature.

   More reagent gives a faster reaction, allowing pseudo-first-order kinetics to be followed by any spectral changes observed; therefore, for most experiments, an excess of at least 10-fold NBD over protein-thiol and sulfenic-acid groups is desirable. Thus, continuing with the example in step 1, after oxidation, add 3 μl NBD chloride solution and incubate 10 to 30 min at room temperature. After modification, the protein in the cuvette can be exposed to air for the ultrafiltration step.

Analyze modified protein by spectroscopy

3. Transfer the protein-NBD solution to an ultrafiltration unit of appropriate molecular weight cutoff (MWCO). Remove the unreacted NBD chloride by washing with neutral pH buffer through repeated cycles of concentration and dilution (e.g., concentrate to 50 μl and redilute with 5 ml buffer two to three times) according to manufacturer's instructions.

   Attention must be made to the stated MWCO of the device so that the protein of interest will be retained. With each concentration cycle, the flow-through solution (filtrate) is removed and fresh neutral pH buffer is added to dilute the protein again, for a total of two to three concentration/redilution cycles.

Either Centricon ultrafiltration units, which allow 2 ml to be concentrated to 40 to 50 µl, or larger units offered by several other suppliers (e.g., Orbital Biosciences or Vivascience), which allow 6 to 7 ml to be concentrated to ~10 to 50 µl, can be used. In the case of the latter, the ability to concentrate more solution at once and to use swinging bucket rotors rather than fixed-angle rotors can speed up the washing process.

Alternatively, the modified protein without ultrafiltration can be isolated by HPLC in tandem with injection into a mass spectrometer.

4. Check for the presence of free NBD in the filtrate by determining the absorbance at 343 nm. Repeat steps 3 and 4 until no free reagent is detected (i.e., A_{343} is <0.02).

5. *Optional.* For best quantitation, assess the protein concentration using a protein assay that is not affected by the presence of the NBD—e.g., the Detergent-Compatible (DC) Protein Assay Kit from Bio-Rad.

   The A_{280} (APPENDIX 3G) now has a contribution from the presence of NBD and therefore cannot be used to determine the protein concentration. Colorimetric assays monitoring wavelengths beyond 500 nm may work (APPENDIX 3G).

6. Remove the concentrated protein from the ultrafiltration unit and bring to approximately the original concentration with neutral pH buffer, assuming there has been no loss of protein during the ultrafiltration step (protein recovery from the ultrafiltration devices can be tested independently with unmodified protein).

7. Perform a spectral scan from ~250 to 700 nm to allow for the assessment of the nature of the modification.

   Thiol adducts with NBD give a peak at 420 nm with an extinction coefficient of 13,000 M^{-1} cm^{-1} (Birkett et al., 1970). Sulfenic acid adducts with NBD give a peak at 347 nm with a similar extinction coefficient (Ellis and Poole, 1997a).

Prepare the modified protein for ESI-MS

8. Wash the modified protein sample at least three times (complete concentration and redilution) with water as described in step 3 to remove excess reagent and buffer components.

9. Prepare 1 nmol modified protein in 100 µl water. Add an equal volume of acetonitrile and 2 µl formic acid before injection. Analyze by ESI-MS.

   This amount of sample is far above that required for the analysis by most modern ESI-MS instruments. Optimization of sample analyses may involve changing the acetonitrile concentration and/or using a volatile buffer such as ammonium bicarbonate instead of water during the washing step (Fuangthong and Helmann, 2002).

   Alternatively, the modified protein without ultrafiltration can be isolated by HPLC in tandem with injection into the mass spectrometer. Once prepared for mass spectrometry, samples are generally stable at −20°C for weeks prior to analysis (at least in the absence of the acetonitrile and formic acid).

   Using this approach, the NBD adduct prepared from the thiol form of the protein will exhibit a mass 16 amu less than that prepared from the sulfenic acid form. NBD itself contributes 164 amu to the mass of the protein.

10. Compare the obtained mass with the predicted mass using a program that takes into account the natural abundance of all isotopes in the protein.

ALTERNATE PROTOCOL

SULFENIC ACID TRAPPING AND DETECTION USING NBD FLUORIDE

This method can be utilized to generate an NBD adduct with protein cysteine sulfenic acids which can then be followed by UV-visible spectroscopy and/or ESI-MS as described above (see Basic Protocol 1). The only difference between this and the Basic Protocol is that 100 mM NBD fluoride (see recipe) rather than NBD chloride is used as the chemical modification agent. The reactivity of NBD fluoride is approximately ten times greater than that of NBD chloride (as described in the handbook from Molecular Probes), allowing for more rapid modification. Note that NBD fluoride should be freshly made and used as soon as possible given its reactivity and instability. The incubation time with this reagent can be decreased relative to that needed for NBD chloride (step 2), and the ultrafiltration step should be performed very quickly after modification (steps 3 and 4).

BASIC PROTOCOL 2

QUANTITATION OF SULFENIC ACID FORMATION BY REACTION WITH TNB

In order to quantify cysteine sulfenic acids in proteins, this method takes advantage of the thiol reactivity of sulfenic acids and the resulting formation of mixed disulfide bonds with TNB, a chromophoric thiol-containing reagent generated by reduction of DTNB. The TNB reagent must be tested just before use to ensure that there is no excess of DTT or DTNB (see Reagents and Solutions). Assessment of the extent of reaction can be made immediately by monitoring the decrease in A_{412}. Further proof of disulfide bond formation is obtained by isolation of the TNB-labeled protein through ultrafiltration, analysis of spectral properties of the modified protein, and release of the protein-associated TNB by DTT treatment. TNB-labeled protein can also be digested by trypsin and peptides separated by HPLC and monitored for the presence of the TNB label.

Materials

Putative sulfenic acid–containing protein, purified and in neutral pH buffer (pH 7)
Neutral pH buffer: 25 mM potassium phosphate (pH 7.0)/1 mM EDTA, or other pH 7 to 7.5 buffer
4 mM TNB solution (see recipe)
100 mM DTT (see recipe)
Ultrafiltration unit of appropriate MWCO (e.g., Millipore Centricon, Orbital Biosciences Apollo, Vivascience Vivaspin)

Additional regents and materials for preparing proteins containing sulfenic acid (see Support Protocol 1), determining protein concentration, determining the identity of the labeled peptide (optional; see Support Protocol 3), and assay of protein function (optional; see Support Protocol 2)

Prepare protein

1. Prepare at least 1 ml of a 15 μM (monomer concentration) solution of the (putative) sulfenic acid–containing protein in neutral pH buffer (i.e., pH 7 to 7.5) using the method described in this unit (see Support Protocol 1) or by other methods established by functional analyses.

Modification with TNB

2. To the protein of interest, with or without oxidant pretreatment, add a small volume of 4 mM TNB either directly or through the sidearm of the anaerobic cuvette and incubate at room temperature. Monitor the decrease in A_{412} until the spectral changes are complete (usually within 2 to 5 min, if accessible).

At long incubation times (>20 to 30 min), TNB can air oxidize, a process that must be taken into account using appropriate control reactions.

A two- to three-fold excess of reagent can be used, keeping in mind that the quantitation of sulfenic acids will be most accurate where the total A_{412} of TNB added is 1.0 or slightly less (i.e., within the linear range of the spectrophotometer), and the absorbance change upon adding the reagent to the protein is >0.1.

3. Read the A_{412} of a blank consisting of neutral pH buffer containing the same concentration of TNB as the sample.
4. Calculate the sulfenic-acid content of the protein as follows.
   a. Subtract the final A_{412} value of the modified sample (step 2) from the A_{412} of the blank (step 3).
   b. Using the extinction coefficient 14,150 M^{-1} cm^{-1} (Riddles et al., 1979), convert this value to concentration of sulfenic acid–containing residues.
   c. Divide by the protein concentration to obtain the sulfenic acid content of the protein.

Excess peroxide and at least some other oxidants also react with TNB over time; if present, these oxidants should be added to control reactions without protein to assess the contribution of this reaction.

Isolate TNB-labeled protein

5. Transfer the reaction mixture to an ultrafiltration unit of appropriate molecular weight cutoff (MWCO). Remove unreacted TNB by washing with neutral pH buffer through repeated cycles of concentration and dilution (e.g., concentrate to 50 µl and redilute with 5 ml buffer two to three times) according to manufacturer's instructions.

Attention must be made to the stated MWCO of the device so that the protein of interest will be retained. With each concentration cycle, the flow-through solution (filtrate) is removed and fresh neutral pH buffer is added to dilute the protein again, for a total of two to three concentration/redilution cycles.

Either Centricon ultrafiltration units, which allow 2 ml to be concentrated to 40 to 50 µl, or larger units offered by several other suppliers (e.g., Orbital Biosciences or Vivascience) which allow 6 to 7 ml to be concentrated to ~10 to 50 µl, can be used. In the case of the latter, the ability to concentrate more solution at once and to use swinging bucket rotors rather than fixed-angle rotors can speed up the washing process.

6. Check for the presence of free TNB in the filtrate by determining the absorbance at 412 nm. Repeat steps 5 and 6 until no free reagent is detected (i.e., A_{412} is <0.02).
7. Remove the concentrated protein from the ultrafiltraton unit and bring to approximately the original concentration with neutral buffer. Transfer the solution to a quartz cuvette.
8. *Optional.* For best quantitation, assess the protein concentration using a protein assay that is not affected by the presence of the TNB—e.g., the Detergent-Compatible (DC) Protein Assay Kit from Bio-Rad.
9. *Optional.* If identification of the labeled peptide is important, perform a tryptic digest and analyze as described (see Support Protocol 3).

Release TNB from the modified protein

10. Add a 10- to 100-fold excess of 100 mM DTT, monitoring the spectral changes from 280 to 600 nm until complete (i.e., until no change is detected).

The increase in A_{412} is used to assess the amount of TNB released from the isolated, modified protein. The calculation is basically the same as in step 4 except that the A_{412} after DTT treatment is higher than before.

11. *Optional.* If regeneration of the thiol group(s) in the protein is expected to restore or alter the functional properties of the protein, perform an appropriate assay to determine this (see Support Protocol 2), with or without an additional ultrafiltration step (see step 5), depending mostly on the potential for the excess DTT to interfere with the assay.

BASIC PROTOCOL 3

MODIFICATION AND DETECTION OF PROTEIN SULFENIC ACIDS WITH DIMEDONE

Reactivity of proteins with dimedone is diagnostic for the presence of cysteine sulfenic acids. This reaction is not monitored by spectral changes but rather by the mass increase observed on modification of the sulfenic acid. Where localization of the incorporated dimedone is of interest, tryptic digests followed by HPLC and mass spectrometric analyses can be used to identify modified peptides and/or residues (see Support Protocol 3).

Materials

Putative sulfenic acid–containing protein sample, purified and in neutral pH buffer (pH 7)

Neutral pH buffer: 25 mM potassium phosphate (pH 7.0)/1 mM EDTA, or other buffer at pH 7

100 mM dimedone (see recipe)

Ultrafiltration unit of appropriate MWCO (e.g., Millipore Centricon, Orbital Biosciences Apollo, Vivascience Vivaspin)

Electrospray ionization mass spectrometer (ESI-MS) or access to a fee-for-service facility

Software for comparing observed and predicted mass (e.g., Calculate pI/MW tool; *http://www.expasy.ch)*

Additional reagents and materials for preparing proteins containing sulfenic acid (see Support Protocol 1) and determining the identity of the labeled peptide (optional; see Support Protocol 3)

Prepare protein

1. Prepare at least 200 µl of a 15 µM (monomer concentration) solution of the (putative) sulfenic acid–containing protein in neutral pH buffer (i.e., pH ≤7) using the method described in this unit (see Support Protocol 1) or by other methods established by functional analyses.

Modify with dimedone

2. To the protein of interest, with or without oxidant pretreatment, add a 100-fold excess of 100 mM dimedone either directly or through the sidearm of the anaerobic cuvette. Incubate 1 to 2 hr at 25°C.

Prepare modified protein for ESI-MS

3. Transfer the reaction mixture to an ultrafiltration unit of appropriate molecular weight cutoff (MWCO). Remove the unreacted dimedone and buffer components by washing thoroughly (at least three times) with water through repeated cycles of concentration and dilution (e.g., concentrate to 50 µl and redilute with 6 ml water three to four times) according to manufacturer's instructions.

Attention must be made to the stated MWCO of the device so that the protein of interest will be retained. With each concentration cycle, the flow-through solution (filtrate) is removed and deionized water is added to dilute the protein again, for a total of at least three concentration/redilution cycles.

Either Centricon ultrafiltration units, which allow 2 ml to be concentrated to 40 to 50 µl, or larger units offered by several other suppliers (e.g., Orbital Biosciences or Vivascience), which allow 6 to 7 ml to be concentrated to ~10 to 50 µl, can be used. In the case of the latter, the ability to concentrate more solution at once and to use swing-out bucket rotors rather than fixed-angle rotors can speed up the washing process.

Alternatively, the modified protein without ultrafiltration can be isolated by HPLC in tandem with injection into a mass spectrometer.

4. Prepare 1 nmol modified protein in 100 µl water. Add an equal volume of acetonitrile and 2 µl formic acid before injection. Analyze by ESI-MS.

   This amount of sample is far above that required for the analysis by most modern ESI-MS instruments. Optimization of sample analyses may involve changing the acetonitrile concentration and/or using a volatile buffer such as ammonium bicarbonate instead of water during the washing step (Fuangthong and Helmann, 2002).

   Alternatively, the modified protein without ultrafiltration can be isolated by HPLC in tandem with injection into the mass spectrometer. Once prepared for mass spectrometry, samples are generally stable at –20°C for weeks prior to analysis (at least in the absence of the acetonitrile and formic acid).

   Using this approach, only peptides containing a cysteine sulfenic acid will form adducts with dimedone. Dimedone itself contributes 140 amu to the mass of the protein.

5. *Optional.* If identification of the labeled peptide is important, perform a tryptic digest of the isolated modified protein and analyze as described (see Support Protocol 3).

DETERMINATION OF THE PROTEIN SULFENIC ACID DISSOCIATION CONSTANT (pK_a)

BASIC PROTOCOL 4

In some cases, proteins containing sulfenic acids may exhibit a low extinction absorbance band (ε_{max} of ~320 to 370 nm) due to the presence of the deprotonated sulfenate species (Poole and Ellis, 2002), as has been observed previously in small molecules (Tripolt et al., 1993). In these cases, lowering of the pH to protonate this group will result in the disappearance of this absorbance band. Titration of this absorbance can be used to determine the pK_a value of the cysteine sulfenic acid within the protein. Depending on the extinction coefficient for this absorbance and on the pH stability properties of the protein, large amounts of the protein containing the stable sulfenic acid and a stopped-flow spectrophotometer are optimal for this determination.

Materials

Citrate/phosphate buffer (pH from 3 through 7.6)/1 mM EDTA (see recipe)
Protein, purified and in 10 mM neutral pH buffer (e.g., potassium phosphate buffer diluted to 10 mM)

UV-visible spectrophotometer and/or stopped-flow spectrophotometer
3 to 5 ml syringes

Additional reagents and materials for preparing proteins containing sulfenic acid (see Support Protocol 1) and determining the identity of the labeled peptide (optional; see Support Protocol 3)

Prepare sample

1. Prepare at least a 150 µM (monomer concentration) solution of the (putative) sulfenic acid–containing protein in 10 mM neutral pH buffer (i.e., pH ~7) using the method described in this unit (see Support Protocol 1) or by other methods established by functional analyses.

2. To observe the expected absorbance change and determine the feasibility of this experiment, mix the protein with an equal volume of high and low pH citrate/phosphate buffers (e.g., pH 4 and 7.6) and record the UV-visible spectral change from 250 to 400 nm (should be immediate).

If the near UV absorbance band is lost at low pH, the following experiment is feasible.

In the case of the sulfenate anion of the C165S mutant of AhpC, maximal absorbance was at 367 nm (Poole and Ellis, 2002).

Conduct rapid mixing (pH jump) experiment

3. Set the monochromator wavelength of the spectrophotometer at the λ_{max} for the protein sulfenate peak (e.g., 367 nm in the case above).

4a. *For a stopped-flow spectrophotometer:* Load the sulfenic acid–containing protein into a 5-ml syringe and one of the buffers (i.e., high or low pH) into another. Rapidly mix the protein and buffer solutions and acquire data at the peak wavelength for 10 sec. Repeat each point ten times or more, controlling for instrument drift by frequently checking the absorbance of buffer alone.

Keep the sample volume as low as possible to minimize protein consumption (although protein may be recovered from this nondestructive procedure at pH values where the protein is stable). Any formation of precipitated protein or any conformational changes resulting from the pH change may, however, confound the results. The use of the stopped-flow spectrophotometer allows for the absorbance changes that ensue after the rapid pH change to be measured before any slower pH-dependent denaturation occurs. Data analysis to determine the pK_a is performed as described below.

4b. *For a standard spectrophotometer:* If a stopped-flow spectrophotometer is unavailable, hand mix the buffer and protein and measure the absorbance at the peak wavelength as rapidly as possible with a standard spectrophotometer.

For rapid mixing, the phosphate/citrate buffer can be added to the protein in the cuvette, a piece of Parafilm held tightly over the cuvette with the index finger, and the solution mixed rapidly (yet gently) as it is poured from top to bottom in the cuvette several times.

5. Plot absorbance versus pH, averaging all data which overlay at a given pH. If the expected sigmoidal curve is observed, fit data to the following equation:

$$y = \frac{\left(A \times 10^{x}\right) + \left(B \times 10^{\mathrm{pK_a}}\right)}{10^{x} + 10^{\mathrm{pK_a}}}$$

where A is the absorbance at high pH, B is the absorbance at low pH, and y is the absorbance at pH x.

SUPPORT PROTOCOL 1

PREPARATION OF SULFENIC ACID-CONTAINING PROTEIN

Susceptible protein thiol groups are oxidized to sulfenic acids by the addition of even mild oxidants including hydrogen peroxide, organic hydroperoxides, hypochlorous acid, peroxynitrite, S-nitrosoglutathione, and other NO-generating or NO-derived signaling molecules. This oxidation may be stoichiometric or may require an excess of the oxidant, and anaerobiosis may or may not be necessary. This protocol describes the use of peroxides as the oxidant but is generally applicable to use of the other oxidants, as well.

Materials

Protein solution
Argon or oxygen-free nitrogen (optional)
Neutral pH buffer: 25 mM potassium phosphate (pH 7.0)/1 mM EDTA, or other buffer at pH 7 or lower
Peroxide of choice—e.g., 8 mM H_2O_2 or cumene hydroperoxide (see recipes)
100 mM DTT (see recipe)
Anaerobic cuvette assembly (Williams et al., 1979) or small pear-shaped flask with stopcock

1. Determine if anaerobic conditions are necessary for the protein solution being used.

   Preparation of the sulfenic acid form of the target cysteinyl residue(s) on the protein may or may not require anaerobic conditions for stabilization. If the oxygen reactivity of this species is unknown, use anaerobic conditions.

   If the protein sulfenic acid can be detected by one of the Basic Protocols (1 to 3) when generated under anaerobic conditions, but the sulfenic acid content of the protein decreases quickly after shifting to aerobic conditions, then preparation and initial modification steps of the sulfenic acid–containing protein should be conducted anaerobically.

2. *Optional.* If anaerobic conditions are necessary, place the protein solution in an anaerobic cuvette assembly or small pear-shaped flask with stopcock, and, over a period of 20 to 30 min total and using approximately ten to twenty cycles with gentle rocking, flush with argon or nitrogen followed by gentle vacuum.

3. To the protein solution, add a stoichiometric amount of the peroxide of choice (e.g., 8 mM H_2O_2 or cumene hydroperoxide).

   Excess peroxide may also be added, although there is a risk of thiol overoxidation beyond the sulfenic acid oxidation state. For cysteine-based peroxidases (e.g., NADH peroxidase and peroxiredoxins) and at least one peroxide-sensitive transcriptional regulator (OxyR), this reaction is very fast ($\geq 10^5$ M^{-1} sec^{-1} second-order rate constant); however, it is generally much slower and varies greatly for other protein thiol or thiolate groups. As a result, no clear statement can be made as to the length of time required for the incubation of the protein with the peroxide (this should be treated as a variable). For example, continue treatment for 2 min to 24 hr at 4° or 25°C.

4. Perform a wavelength scan from 250 to 400 nm. Determine if any spectral changes due to addition of peroxide are present.

   Any spectral signature can provide both a way to monitor sulfenic acid formation and a way to discriminate between protonated and deprotonated forms of the sulfenic acid for pK_a determination (see Basic Protocol 4). However, for observations of such low-extinction coefficient spectral changes, the protein needs to be at very high concentration ($\geq$ 80 μm).

FUNCTIONAL ANALYSES OF THE MODIFIED PROTEIN

SUPPORT PROTOCOL 2

If a free thiol group is required for the functional activity of the protein under investigation, either modification of that group with NBD chloride or oxidation of the thiol group to sulfenic acid followed by NBD chloride or TNB modification should block its activity. Whether or not oxidation to the sulfenic acid itself alters the protein's activity depends on the function of this modification. In cysteine-based peroxidases, the sulfenic acid is a naturally occurring intermediate during turnover and is therefore catalytically active as long as the reductant being used will reduce this species and overoxidation to inactive sulfinic and sulfonic acids forms does not occur preferentially. In at least some peroxide-sensitive transcriptional regulators, the sulfenic acid form represents an important functional form, either activating or derepressing transcription from genes related to oxidative stress protection (see *UNIT 17.1*). In these cases an assay for transcriptional activation is appropriate. In protein tyrosine phosphatases, the active site cysteine is reversibly inhib-

ited by conversion to the sulfenic acid form. Therefore, an assay for phosphatase activity using a model phosphorylated peptide can be used for these proteins. It is of great interest to test the consequences of modification and/or oxidation of target cysteines in active sites of enzymes or binding sites of transcriptional regulators.

If the protein sulfenic acid is known to be stable toward air (or at least stable over the 10 to 30 min during which the functional analyses is performed; see Support Protocol 1), the assay of interest can be carried out aerobically. The air stability of the chemically-modified proteins is not a problem, although in these cases, an exogenous chemical has been added to the protein to give a non-native modification. For NBD- or TNB-modified protein, the thiol(ate) group is restored by DTT treatment (excess reagents may need to be removed by ultrafiltration prior to carrying out the functional assay). Dimedone modification of sulfenic acids is not reversed by DTT treatment.

SUPPORT PROTOCOL 3

TRYPTIC DIGESTION OF MODIFIED PROTEINS

To determine the peptide or even residue of the protein modified by one of the reagents described above, chemical modification of the protein can be followed by tryptic digestion and isolation and analysis of the peptides. The dimedone modification is best for this analysis due to its irreversibility, although its lack of distinguishing spectral features is a disadvantage.

Materials

Modified protein (see Basic Protocols 1, 2, or 3)
50 mM NEM (see recipe)
10 M urea or 8 M guanidine hydrochloride (see recipes)
100 mM Tris·Cl buffer, pH 8.0 (*APPENDIX 2A*) or 100 HEPES, pH 7.6 (see recipe)
100 mM calcium chloride (1.11 g anhydrous $CaCl_2$ in 100 ml water; store up to several weeks at room temperature)
TPCK-treated trypsin (see recipe)
10 mM EGTA
100 mM DTT

95° or 60°C waterbath
HPLC equipped with a C18 reversed-phase column, solvents for peptide isolation (e.g., 0.1% v/v trifluoroacetic acid, 70% v/v acetonitrile with 0.08% trifluoroacetic acid)
Electrospray ionization mass spectrometer (ESI-MS) or access to a fee-for-service facility

1. *Optional.* If the NBD-, TNB-, or dimedone-modified protein has additional cysteine thiol groups, use alkylation to block by adding 50 mM NEM to a 100-fold excess and incubating 1 hr at room temperature.

2. Prepare a small volume (≤200 µl) containing ~1 mg isolated, modified, blocked (if necessary) protein and 8 M urea or 6 M guanidinium hydrochloride. Optionally, incubate 15 to 20 min at 95°C or 45 to 60 min at 60°C to ensure denaturation.

3. Once the sample has cooled, add sufficient 100 mM Tris·Cl, pH 8.0, or, if the sample is NBD-labeled, 100 mM HEPES, pH 7.6, to lower the denaturant concentration to ≤1 M. Add 1/100 vol of 100 mM calcium chloride (1 mM final).

   If NBD- or TNB-labeled protein is used, the conditions for trypsin digestion can be pretested to ensure that the label remains covalently attached to the protein (reductants remove both labels and cannot be used, and amine groups can react with and remove the NBD moiety).

4. Add TPCK-treated trypsin to a protease/protein ratio of 1:100 to 1:40 (w/w). Incubate 12 hr at 37°C. Add a second aliquot of TPCK-treated trypsin and incubate another 12 hr.

   Shorter incubation times may also suffice.

5. *Optional.* To monitor the progress of the digestion, remove small aliquots of the reaction mixture and analyze using one of the following techniques: reversed-phased HPLC, MALDI-TOF mass spectrometry, SDS- or Tris-Tricine-PAGE.

6a. *For storage:* Freeze samples at −20°C and store up to 2 weeks.

6b. *For immediate use:* Inactivate the trypsin by adding sufficient acetic acid to lower the pH to <4, or by adding 10 mM EGTA to chelate calcium.

7a. *To analyze by absorbance (for NBD- and TND-labeled proteins only):* Analyze digested peptides by HPLC and absorbance using the following procedure:

   a. To an aliquot of digested peptide, add 1/10 vol of 100 mM DTT.

   b. Separate the digested peptides by HPLC, with and without DTT treatment, using an appropriate column and gradient.

      For example, use a C18 or C8 column and a linear gradient over 60 to 100 min from 0% to 60% solvent B (70% acetonitrile/0.08% trifluoracetic acid) with the balance being solvent A (0.1% trifluoracetic acid). Monitor the absorbance at 347 or 420 nm for NBD-treated samples, or 325 nm for TNB-treated samples. Peptide elution is typically monitored at 215 nm where the peptide bonds absorb strongly and the contributions of solvents A and B are appropriately balanced.

      For further analysis of these peptides, additional purification using a more shallow gradient should be carried out.

   c. For TNB- and NBD-labeled samples, identify labeled peptides by comparing HPLC chromatograms of the tryptic digest with the same digest sample treated with DTT (step a) before separation on HPLC. (DTT treatment will remove the chromophore and may shift the retention time of the peptide).

7b. *To analyze by ESI-MS:* Perform reversed-phase HPLC as described (step 7a, substep b) in tandem with ESI-MS on digests. Identify labeled residues by the added mass. Repeat steps 1 to 6 with unlabeled protein and analyze by HPLC in tandem with ESI-MS to verify labeling.

   Where only a single cysteine is encoded within that peptide, further localization is unnecessary. Additional analysis by MS-MS using collision-induced fragmentation can also be used to determine the sequence and location of the labeled cysteine. Alternatively, the peptide can be subjected to Edman degradation to determine the position of the blocked cysteine, although its identification may rely only on the absence of an identifiable peak at the position of the modified cysteine.

REAGENTS AND SOLUTIONS

Use Milli-Q-purified water or equivalent for all recipes and protocol steps. For common stock solutions, see ***APPENDIX 2A****; for suppliers, see* ***SUPPLIERS APPENDIX****.*

Citrate/phosphate buffer

To 245 ml water, add 9.61 g citric acid (~200 mM final), 7.10 g dibasic sodium phosphate (~200 mM Na_2HPO_4 final), and 93 mg disodium EDTA. Measure the pH, which should be ~3. Slowly drip in a solution of 1 M sodium hydroxide (4.0 g in 100 ml) to raise the pH, and remove ~10-ml aliquots at each desired pH value (about every 0.2 pH units). Store the aliquots up to 1 month at room temperature, but recheck pH of each before each use.

This allows for mixing of the sulfenic acid-containing protein with strong buffers at various pH values to determine the pK_a of the protein-associated sulfenic acid (Basic Protocol 4).

Cumene hydroperoxide, 8 mM

Prepare a stock solution containing 20 µl cumene hydroperoxide solution (80% stock from Sigma, aliquots stored at −20°C for up to one year) and 980 µl dimethyl sulfoxide (DMSO). Prepare a 15× dilution of the stock solution in water to give a final concentration of ~8 mM. Prepare fresh daily.

Dimedone, 100 mM

To 1 ml DMSO add 14 mg dimedone (Sigma-Aldrich). Aliquot and store up to several months at −20°C.

DTNB, 5 mM

Prepare a 100 mM stock solution by dissolving 0.198 g of 5,5′-dithiobis(2-nitrobenzoic acid) in 5 ml DMSO. Aliquot and store up to several months at −20°C. Before use, dilute the stock DTNB solution 20-fold into 25 mM phosphate buffer, pH 7 (*APPENDIX 2A*).

Standardize the working solution by diluting 3 µl in 0.5 ml 25 mM phosphate buffer. While monitoring the A_{412}, add 8-µl aliquots of 0.5 mM DTT, pausing between each addition until the spectral changes are complete. When the A_{412} no longer increases with additional DTT, use the maximal A_{412} to calculate the DTNB concentration using an ε_{412} value of 14,150 M^{-1} cm^{-1} for TNB (the solution resulting from the combination of DTNB and DTT), and the fact that 2 moles of TNB are released per mole DTNB (Riddles et al., 1979).

DTT, 100 mM

Dissolve 154 mg of 1,4-dithio-DL-threitol (DTT) in 10 ml water. Store in aliquots up to 2 weeks at −20°C.

Standardize the DTT by first performing the standardization of DTNB (see recipe). To calculate the DTT concentration, use the titration breakpoint from a plot of A_{412} versus volume of DTT added to determine the volume of DTT required to titrate the known amount of DTNB.

DTT has two thiols per molecule, therefore its concentration is equivalent to the concentration of DTNB with which it reacts.

Guanidine hydrochloride, 8 M

To ~4 ml water add 7.64 g guanidine hydrochloride (ultrapure; Sigma-Aldrich). Warm solution and add water to fully dissolve and bring volume to 10 ml total. Store up to several months in a tightly sealed bottle at room temperature.

HEPES, 100 mM (pH 7.6)

To 90 ml of water, add 2.38 g HEPES and dissolve. Add 1 M sodium hydroxide dropwise to bring the pH to 7.6, then add water to bring the final volume to 100 ml. Store up to several weeks at room temperature.

Hydrogen peroxide, 8 mM

Dilute ~182 µl of a 30% solution (stored at 4°C) into 250 ml water. Make fresh daily.

For standardization of hydrogen peroxide, prepare solutions of 10 mg/ml *o*-dianisidine in methanol and 1 mg/ml horseradish peroxidase (HRP) in an appropriate buffer—e.g., 25 mM potassium phosphate (pH 7.0)/1 mM EDTA or other buffer at pH 7; store these solutions up to 1 month or more at 4°C in the dark. Add 10 µl of the 10 mg/ml *o*-dianisidine solution and 2 to 10 µl of the 8 mM (putative) peroxide solution to 0.9 ml 25 mM phosphate buffer, pH 7 (*APPENDIX 2A*)/0.1% Triton X-100. Bring to 0.99 ml with deionized water. Use this solution to blank a spectrophotometer at 460 nm, then add 10 µl of the 1 mg/ml HRP solution to the cuvette. Monitor

continued

the A_{460} change which is complete within a few seconds. Use $\varepsilon_{460} = 11{,}300\ M^{-1}\ cm^{-1}$ for oxidized *o*-dianisidine and dilution factors to compute peroxide concentration. Use three to four different volumes of the hydrogen peroxide solution to be tested and added linear regression to determine the change in A_{460} per microliter (the slope of the line) to obtain an accurate concentration: slope/11,300 × cuvette path length in centimeters = millimolar concentration of hydrogen peroxide.

NBD chloride, 100 mM

To 1 ml DMSO, add 20 mg 7-chloro-4-nitrobenzo-2-oxa-1,3-diazole (NBD chloride). Store aliquots up to several weeks protected from light at −20°C.

Determine the concentration of the solution by first making a 20-fold dilution of the stock into 25 mM phosphate buffer, pH 7 (*APPENDIX 2A*), and then adding 16 µl of this diluted NBD chloride solution to 1.0 ml methanol. Use a glass pipet rather than micropipettor to measure out the methanol and avoid leakage. Measure the A_{336}. Use an ε_{336} of 9800 $M^{-1}\ cm^{-1}$ and the dilution factor to calculate the concentration of the stock.

NBD chloride is called 4-chloro-7-nitrobenz-2-oxa-1,3-diazole by Molecular Probes; this reagent is also available from other suppliers like Sigma-Aldrich. Another abbreviation for the compound is Nbf-Cl.

NBD fluoride, 100 mM

To 100 µl DMSO, add 1.8 mg of 4-fluoro-7-nitrobenz-2-oxa-1,3-diazole (NBD fluoride; Molecular Probes). Keep protected from light at room temperature, and use within several hours after it is prepared (do not store at −20°C as for NBD chloride).

Determine the concentration of the solution by first making a 20-fold dilution of the stock into 25 mM phosphate buffer, pH 7 (*APPENDIX 2A*), and then adding 16 µl of this diluted NBD fluoride solution to 1.0 ml methanol. Use a glass pipet rather than a micropipettor to measure the methanol and avoid leakage. Measure the A_{328}. Use an ε_{328} of 8000 $M^{-1}\ cm^{-1}$ and the dilution factor to calculate the concentration of the stock.

NEM, 50 mM

To 1 ml DMSO, add 6.3 mg *N*-ethylmaleimide (NEM). Aliquot and store up to a few weeks at −20°C.

If knowledge of the exact concentration of this solution is important, standardize by first preparing a 1:20 dilution of 100 mM DTT (see recipe) and then adding 6 µl of this dilution to 1 ml of 25 mM phosphate buffer, pH 7 (*APPENDIX 2A*). Add 14 µl of a 1:20 dilution of the NEM stock. Incubate 30 min at room temperature, then add 15 µl of 0.25 mM DTNB, diluted from the 5 mM working solution (see recipe). The loss of thiol groups corresponds to the amount of NEM added, allowing for calculation of the concentration of the stock solution. Therefore the concentration of NEM in the final test solution is equal to the A_{412} of the control (without NEM) minus the A_{412} in the presence of NEM divided by the ε_{412} value of 14,150 $M^{-1}\ sec^{-1}$ for TNB.

TNB solution, 4 mM

To a dark-colored microcentrifuge tube (or a tube wrapped with aluminum foil) containing 0.84 ml of 25 mM phosphate buffer, pH 7, add 80 µl of 100 mM stock DTNB (see recipe) and 80 µl of 100 mM DTT (see recipe). The solution will turn dark orange. Store up to 1 week at −20°C.

continued

Determine the concentration of TNB by adding 7.5 µl of the TNB solution to 0.5 ml phosphate buffer, measuring the A_{412}, and calculating the concentration using an ε_{412} of 14,150 M^{-1} cm^{-1} for TNB (Riddles et al., 1979). Add 1 µl of 100 mM or 2 µl of 5 mM DTNB (see recipe) and observe any increase in A_{412}. If there is an increase, calculate the amount of DTNB that should be added to the stock TNB solution to bring it to the maximum A_{412} but not beyond. This amount will be equal to 1/2 the concentration of TNB generated (according to the increased A_{412} divided by the ε_{412} of 14,150 M^{-1} sec^{-1}) taking into account the relevant dilutions factions and the volume of the TNB stock. Perform the same test using 100 mM DTT instead of DTNB, adding more DTT to the TNB stock solutions if necessary, as calculated for the needed addition above.

The reagent is properly prepared if addition of neither dithiothreitol nor DTNB leads to an increase in A_{412}. This reagent tends to air oxidize and should be tested every few hours for DTNB formation (readjust with additional DTT as needed).

TPCK-treated trypsin

Prepare a stock solution of 1 mg TPCK-treated trypsin (Worthington Biochemical) in 100 µl of 1 mM HCl (8.5 µl concentrated HCl in 100 ml water), or as indicated by the manufacturer. Aliquot and store up to several months at −70°C if necessary, but do not subject to multiple freeze/thaw cycles.

The best grades of trypsin available (e.g., sequencing-grade trypsin from Promega) include modified forms of trypsin that do not undergo self-digestion and are therefore active longer during the digestion (and don't generate contaminating peptides from the trypsin, itself). Immobilized trypsin (Pierce Biotechnology) can also be used so that the digestion can be stopped by centrifugation and removal of the supernatant to a separate tube.

Note that for digestion of 1 mg of the target protein using a protease/protein ratio of 1:50, 2 µl of the prepared trypsin solution is added.

Urea, 10 M

To ~4 ml of water add 6.01 g urea (ultrapure; Sigma-Aldrich). Warm the solution and add water to fully dissolve and bring to 10 ml final volume. Store 1 to 2 days at room temperature.

COMMENTARY

Background Information

The procedures described herein allow for the detection and measurement of sulfenic acids in proteins by chemical means and do not require the specialized approaches of crystallography or NMR. The intrinsic instability of sulfenic acids makes them inherently difficult to work with; mass spectrometry can theoretically be used to demonstrate the single oxygen added to the cysteine and/or protein, but without use of a trapping agent, only the further oxidized sulfinic (R-SO2H) and/or sulfonic (R-SO3H) acid species are typically observed. With NBD modification, the sulfenate oxygen is incorporated into the product, and subsequent mass spectrometry allows for its demonstration. The other two methods, TNB and dimedone modification, result in the loss of the oxygen but indicate the presence of the sulfenic acid in the protein simply by their ability to react with it.

Modification with NBD chloride

As described above, NBD modification may be the best way to trap and demonstrate sulfenic acids in proteins. In fact, access to a mass spectrometer is not required as the product of NBD reaction with sulfenic acids has a distinctive spectral signature with the peak shifted some 73 nm with respect to that generated on reaction with thiol groups. Because this peak is shifted only ~4 nm from that of the free reagent, however, the protein must be washed free of excess reagent before the spectral signature of the covalently-attached NBD can be discerned. This very slight spectral perturbation on modification of sulfenic acids by NBD limits the ability to follow the course of the reaction spectroscopically, although with sufficient protein and only a small excess of reagent, this may be possible. On the other hand, modification of thiols by NBD chloride is readily monitored

spectroscopically and can be used to determine the rate of modification and the extent of the reaction without subsequent washing steps. Note that rates of modification for thiol versus sulfenic acid groups by NBD chloride appear to be similar, as reported earlier by Ellis and Poole (1997a). NBD chloride may not be the reagent of choice if there are additional accessible thiol groups in the protein that may obscure the spectral signature of the R-S(O)-NBD adduct. Reactivity of NBD chloride toward other amino acid side chains can occasionally cause problems in these analyses, as well; however, the adducts with amino or tyrosyl groups are typically formed only at higher pH and have distinct spectral properties (i.e., λ_{max} of 382 and 480 nm for NBD adducts with tyrosines and amines, respectively; Ghosh and Whitehouse, 1968; Aboderin and Boedefeld, 1976; Miki, 1985). In some cases, NBD adducts with thiol groups have been shown to migrate to proximal amine groups of lysine (e.g., Senior et al., 1998), and this process may occur with the NBD adducts of sulfenic acids, as well.

Modification with NBD fluoride

The alternative protocol (see Alternate Protocol) describes the use of NBD fluoride as a replacement for NBD chloride. Since the product formed is identical, all the advantages and disadvantages described above for NBD chloride modification are relevant to this reagent as well. NBD fluoride has the advantage of reacting more quickly with thiol and sulfenic acid groups but has the related disadvantage of being rather unstable in solution and considerably more expensive than NBD chloride. Additionally, uncharacterized spectral changes also occur during the modification reaction, but the modified protein, once washed free of unbound reagent, still has the same appearance as that generated with NBD chloride.

Modification with TNB

Reactivity with TNB is very useful as the spectral changes that ensue allow for immediate quantitation of sulfenic acid content. Subsequent to this reaction, covalent modification of the protein with TNB can be confirmed upon washing, spectral analysis, and release of the bound TNB by DTT treatment. The major disadvantage of using this reagent is its tendency to air-oxidize, and any DTNB present in the solution can react with other thiol groups in the protein and cause an *increase* in the absorbance at 412 nm. TNB can also react with excess peroxides or other oxidants that may remain in the solution, and this reactivity may obscure the reaction of interest. This must therefore be accounted for by control reactions conducted in the absence of protein.

Modification with dimedone

Dimedone reacts only with sulfenic acids in proteins, a reaction considered diagnostic for these species. It is also not reversed by DTT treatment and is therefore particularly useful for peptide analysis following digestion of the modified protein by trypsin. Unfortunately, however, dimedone as a label has no distinguishing spectral features and thus requires the use of mass spectrometry to establish its incorporation. An advantage is that, because dimedone does not react with thiols, it can be added before or at the same time as the oxidant is added and may therefore allow for trapping of the sulfenic acid as it is formed and before it becomes further oxidized to the sulfinic and sulfonic acids. This could be particularly useful for systems where the sulfenic acid is formed rather slowly, and further oxidation of this species occurs readily.

Reversibility of modification

As noted above, NBD and TNB modifications of sulfenic acids are both reversible by addition of DTT, returning the target cysteine to the reduced (thiol) state. This can allow for restoration of function which may be shown in subsequent experiments. At the same time, the reversibility of these modifications may complicate the use of tryptic digests to verify the site of modification, although TNB- and NBD-modified peptides have in some cases been isolated successfully (Chae et al., 1994; Jeong et al., 2000).

Determination of pK_a

If spectral properties of the sulfenic acid–containing protein allow for the determination of the pK_a as described (see Basic Protocol 4), this relatively simple method of assessing this parameter can be a major advance, as only a few pK_a values for sulfenic acids, particularly within proteins, have been reported (Claiborne et al., 1999; Poole and Ellis, 2002). Unfortunately, such a spectral feature may not be observed, especially if other chromophores are present in the protein. The procedure requires large quantities of protein in which the sulfenic acid has been stably generated, but it is nondestructive as long as the protein is stable in the buffers at various pHs.

Critical Parameters

Before any of the spectral analyses can be performed, it must be clear that there is enough protein available to give absorbance changes that are sufficient for quantitative analysis (i.e., >0.1). In the case of the dimedone treatment, which doesn't rely on spectral analyses, the requirement for protein may be less, as the amount used must be sufficient for identification of the modification by ESI-MS.

The chemical modification reagents, if used in excess, do not necessarily have to be standardized by spectral titrations with model reagents unless there are problems with the modification or exact amounts are required. However, the oxidant levels used to generate the sulfenic acid in the first place may be quite critical. For addition of a stoichiometric amount of hydrogen peroxide, for example, exact quantitation of the hydrogen peroxide concentration by the HRP assay is an important first step. As has been mentioned above, the TNB reagent is particularly prone to air-oxidation and must be checked for the presence of excess DTNB or DTT every 2 hr or so. Loss of protein during ultrafiltration can be a major source of error, so it is advantageous to test in advance for the recovery of a given protein with the specific ultrafitration device to be used. Finally, it is helpful, particularly with the NBD modification methods, to know in advance how many accessible thiols are in the protein. This can be done by adding a 10-fold excess of DTNB and observing the rise in A_{412} over time, until completion of the reaction. The amount of TNB released is directly proportional to the number of reactive thiols present in the protein. However, reactivity and accessibility of given protein thiols to particular reagents can be different.

For pK_a determination, the pH values of all phosphate/citrate buffer solutions used should be measured on the day the analysis is performed.

Troubleshooting

Choice of modifying reagent

Where multiple thiol groups are present, only one of which is oxidant sensitive, the demonstration of sulfenic acid formation by NBD chloride modification may require the use of difference spectroscopy to clearly identify the 347 nm peak of the R-S(O)-NBD adduct. In these cases, quantitation will likely suffer as well. Other possibilities are to compare the modified spectra with those obtained when the cysteine of interest has been mutated to a serine. Alternatively, the cysteinyl thiols that obfuscate the analysis can themselves be removed by mutagenesis to serines (assuming that such changes do not affect the normal function of the protein). If there is a way to reversibly block only the cysteine of interest (e.g., by sulfenic-acid formation, then reaction with 1 mole reduced glutathione or TNB for each mole cysteine), this can be done initially, followed by alkylation of the remaining cysteine thiols by a reagent such as *N*-ethylmaleimide. If the rereduced enzyme is fully functional, then effects and detection of sulfenic acid formation at the target cysteine can be analyzed for the preblocked protein using the NBD chloride method without interference by the other cysteine thiols. Another approach could be to use the sulfenic acid–containing protein preblocked with dimedone, then reacted with NBD chloride to generate the control spectrum with only the interfering cysteine thiols modified for comparison with the spectrum of the modified protein containing the sulfenic acid as well as the additional thiols. If the problem is too great, then dimedone (and ESI-MS analysis) rather than NBD chloride should be used.

Use of denaturants

With all of the chemical modification methods for detecting sulfenic acids, the presumption is that the target sulfenic acids are accessible to reaction by these reagents. Where modification reactions are unsuccessful, lack of accessibility may be the problem (even if the corresponding thiol group is accessible toward DTNB and NBD chloride modification, the sulfenic acid moiety may not be accessible due to conformational changes or other differences). In these cases, addition of denaturants may be necessary for trapping of the sulfenic acid to take place (e.g., see modification of NADH peroxidase as reported in Ellis and Poole, 1997a). Denaturants can include guanidine hydrochloride (GuHCl), urea, or SDS, although urea may itself react with NBD chloride. Low amounts (0.5 to 2 M) of urea or GuHCl can be tried first, or, if necessary, higher amounts (4 to 6 M) can be used. In these cases, it is best if the modifying reagent is already present when the denaturant is added, since denaturation of the protein can also promote autoxidation of the sulfenic acid (the denaturant solution can also be bubbled with nitrogen or argon for 20 min before addition to remove oxygen). During ultrafiltration to remove excess reagent, the continued presence of some

amount of the denaturant (e.g., 2 M GuHCl), as is compatible with the ultrafiltration device being used, may be necessary to avoid protein precipitation. One adverse effect of denaturation could be to expose additional cysteinyl thiol groups if the protein has them; in this case, dimedone may be the reagent of choice. Proteins can be analyzed by spectroscopy in the presence of the denaturant but must be freed of denaturant for ESI-MS analysis and may be best analyzed using reversed-phase HPLC linked to ESI-MS analysis.

Interfering lysines

Where modification of the sulfenic acid by NBD chloride is successful, but the NBD group migrates to a proximal lysine side chain over time (as noted by the decrease in A_{347} and increase in A_{480}), one approach may be to preblock accessible amino groups of lysine using amine-specific reagents such as succinimidyl esters (see the handbook from Molecular Probes). Then, once the NBD modification of the sulfenic acid is complete, there should be no further migration of the NBD group and the full absorbance increase at 347 nm can be observed. Again, if the identity of the lysine group is known or suspected, mutagenesis can be used to change this lysine group to a different amino acid, provided this mutation does not also result in a change in the functional properties of the protein.

Poor ESI-MS resolution

The possibility also exists that, if there is insufficient resolution due to the large size of the target protein and/or the quality of data obtained from the mass spectrometer, a mass difference will be obtained for the NBD-modified sulfenic acid product that is less that the full 16 amu expected (relative to the NBD-thiol adduct). This may indicate only partial conversion of the protein to the sulfenic acid prior to modification and an inability to resolve the R-S-NBD and R-S(O)-NBD products by mass spectrometry. One solution is to allow the oxidation of the thiol group to proceed for a longer time or with more oxidant prior to NBD chloride modification. Alternatively, dimedone could be the preferred modification agent, as it gives a much greater mass shift on modification.

Anticipated Results

Modification with NBD

For modification reactions with NBD chloride (or NBD fluoride), the thiol form of the protein will generate a peak for the NBD adduct with a maximum at 420 nm, while the sulfenic acid form, once washed free of excess reagent, will exhibit a maximal absorbance at 347 nm, with the 347 nm peak rising concomitant with a decrease at 420 nm (Fig. 17.1.2). If multiple cysteine residues are present, demonstration of the 347 nm peak may be improved by using difference spectroscopy (Fig. 17.2.1), although quantitation will likely suffer under these conditions. ESI-MS analyses will indicate that the R-S(O)-NBD adduct is 16 amu larger than the R-S-NBD adduct (Fig. 17.1.3), and the R-S(O)-NBD adduct will be nonfluorescent, unlike the R-S-NBD adduct (λ^{ex}_{max} = 422 nm, λ^{em}_{max} = 527 nm). NBD itself accounts for an additional mass of 164 amu.

Modification with TNB

Modification of sulfenic acid–containing proteins with TNB will result in the stoichiometric incorporation of the TNB into the protein, as judged by the decrease in the A_{412} relative to that expected from the dilution of the TNB reagent into buffer lacking protein. Conversion of this A_{412} decrease to the concentration of TNB consumed using the extinction coefficient for TNB and dividing that result by the protein concentration will yield the sulfenic acid content of the protein. On isolation of the TNB-modified protein by ultrafiltration, the spectrum of the modified protein will have a peak at ~325 nm corresponding to the TNB-mixed disulfide bond formed at the cysteine of interest (Ellis and Poole, 1997b). Addition of DTT to this solution will then result in the isosbestic decrease in this peak and increase in the TNB peak with its absorbance maximum at 412 nm (Fig. 17.2.2). If no protein is lost during ultrafiltration, this is a second opportunity to quantitate the TNB modification of the protein. The quantitative decrease in A_{412} upon TNB modification can be used as an assay method for sulfenic acid generation during oxidant titration of the protein (e.g., as in Figure 4 of Poole and Ellis, 2002) or for sulfenic acid generation over time in the presence of excess oxidant, although reactivity of the TNB with the oxidant in the absence of protein must be considered in the latter case.

Modification with dimedone

Reaction of the sulfenic acid in the protein with dimedone will result in a 140-amu increase in mass. Dimedone modification should also eliminate the functionality of the cysteine residue and will block any additional attempts

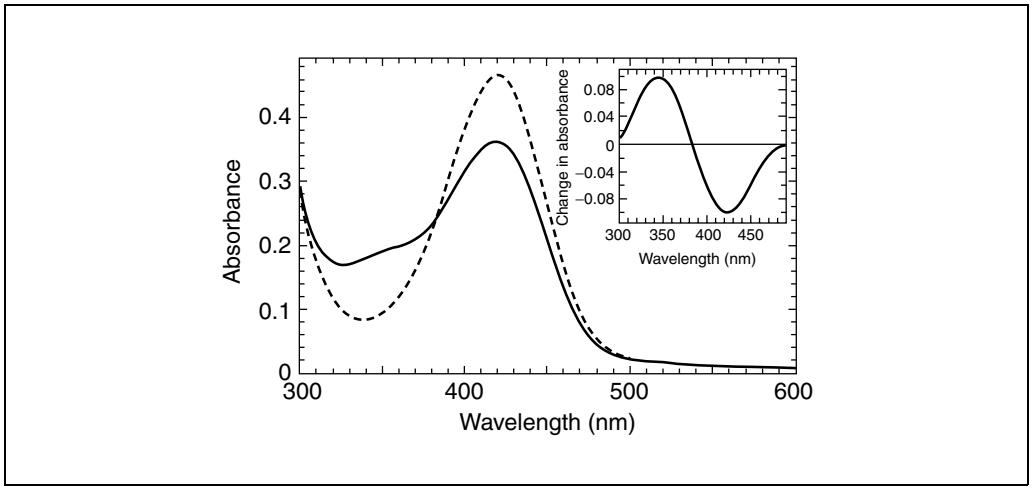

Figure 17.2.1 Hypothetical UV-visible spectra for NBD adducts of reduced and oxidized forms of a protein with three additional reactive cysteine thiol groups. As in Figure 17.1.1, spectra correspond to the R-S-NBD product (dotted line) and the products, including R-S(O)-NBD, after NBD chloride modification of the protein in which one of the four cysteine residues has been oxidized to a sulfenic acid (solid line). The inset represents the difference spectrum calculated by subtracting the spectrum of the fully reduced and modified form of the protein from that of the oxidized, modified form.

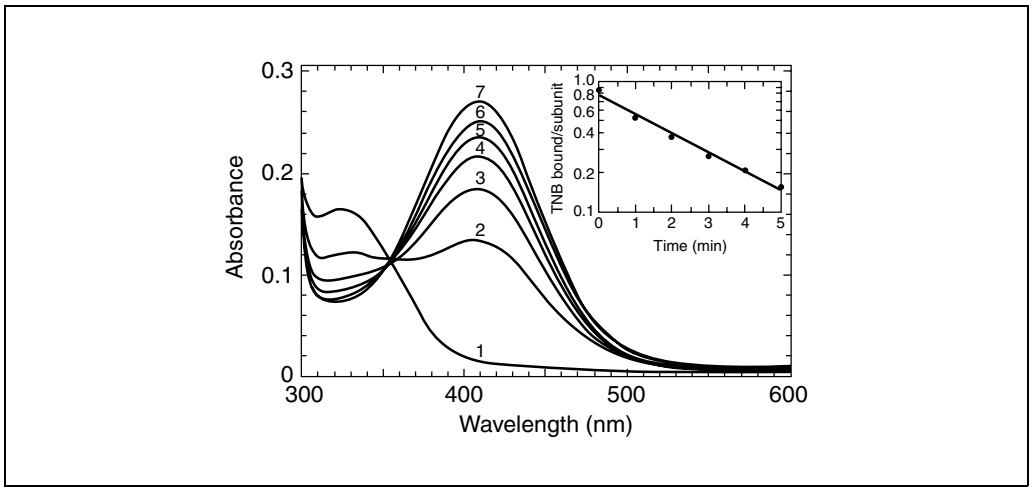

Figure 17.2.2 Reduction of TNB-labeled C165S AhpC by DTT. The TNB-labeled enzyme generated by TNB treatment of the protein oxidized by a stoichiometric amount of hydrogen peroxide was isolated by ultrafiltration with Centricon CM-30 concentrators, then treated with a 10-fold excess of DTT. Shown are spectra before (1), and after addition of DTT for 1, 2, 3, 4, 5 and 30 min (spectra 2 to 7, respectively). The inset represents a semilogarithmic plot of the change in absorbance, converted into units of TNB/subunit, versus time. to modify this group with NBD chloride (as a cross-confirmation of the target of these reagents as the sulfenic acid).

Determination of pK$_a$

If there are observable differences between the absorbance of the deprotonated sulfenate base at higher pH values and the absorbance of the protonated sulfenic acid at lower pH values (Fig. 17.2.3), then a fit of the absorbance versus pH data to the equation given in Basic Protocol 4 will allow for the determination of the pK$_a$ of the sulfenic acid (Fig. 17.2.4). In several small molecules, pK$_a$ values for the stabilized sulfenic acids have ranged from 4.8 to 6.3 (Claiborne et al., 2001), while a pK$_a$ of ~6.1 has been determined for one protein sulfenic acid so far (Poole and Ellis, 2002).

Time Considerations

For most of the chemical modification procedures, once the reagents are prepared and the protein concentration is determined, the generation of the sulfenic acid and reaction with

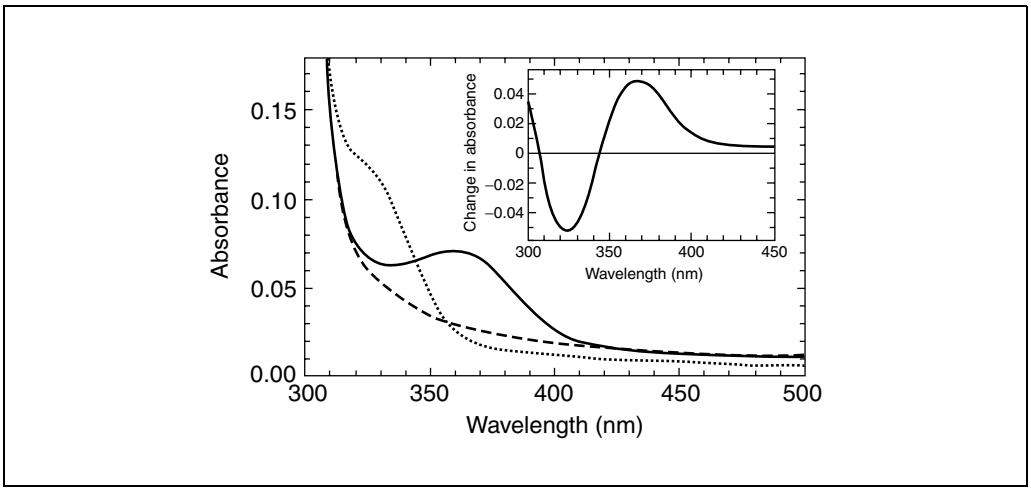

Figure 17.2.3 Spectral properties of thiol(ate) (Cys46-SH or Cys46-S^-), sulfenate (Cys46-SO^-), and sulfenic acid (Cys46-SOH) forms of C165S AhpC from *Salmonella typhimurium*. Spectra of the mutant enzyme (200 μM) at pH 7.0 in the absence (dotted line) or presence (solid line) of 1.1 equivalent of H_2O_2 are shown. The dashed spectrum represents the Cys46-SOH form of the enzyme at pH 4.6. The inset depicts the difference spectrum between the Cys46-S(H) and Cys46-SO^- forms of C165S AhpC. Figure 17.2.4 Hypothetical determination of pK_a value for a protein sulfenic acid given absorbance values determined in various pH buffers. Given an experiment similar to that described (see Basic Protocol 4), representative data are shown for absorbance values at 367 nm versus pH of a sulfenic acid–containing protein (~50 μM) with a pK_a of ~6.1. The fitted curve is obtained using the equation given in the protocol.

the modifying agent is complete within <1 to 2 hr. Ultrafiltration may take 20 min to 3 hr, depending on the particular device and the molecular weight cutoff (lower cutoff, slower filtration). The pK_a determination itself takes about 1 to 3 hr, with preparation and/or pH measurement of the citrate/phosphate buffers requiring 1 to 2 additional hr. Tryptic digests are carried out for 12 to 24 hr, and each HPLC run takes ~90 to 120 min.

Fluorescence Microplate Reader Measurement of Tissue Susceptibility to Lipid Peroxidation

BASIC PROTOCOL

Oxidative stress and lipid peroxidation have been implicated as important mechanisms for chemical-induced cell injury/death and the development of numerous disease states. The enrichment and maintenance of cellular antioxidant defense systems are potential strategies to prevent toxic oxidative damage. It is therefore important to estimate or monitor the susceptibility of biological samples to lipid peroxidation. Susceptibility to lipid peroxidation is determined by several factors, such as fatty acid composition and antioxidant levels present in membranes. As numerous antioxidants are present in cells, it is technically difficult to analyze biological specimens for each one. This unit describes a fluorescence microplate reader–based assay to measure the susceptibility of tissue samples by exposing them to an initiator and measuring the length of time to the start of lipid peroxidation. The lipid peroxidation reaction is initiated by addition of Fe^{3+}-ADP chelator in the presence of a low concentration of ascorbate. The by-products of lipid peroxidation, such as 4-hydroxy-2-nonenal, can subsequently react with amines of amino acids (e.g., glycine) to form fluorescent products that are measured with a fluorescence microplate reader. This assay allows the rapid monitoring of the susceptibility to lipid peroxidation in a large number of samples in real time.

Materials

Tissue, cells, or subcellular organelles
50 mM potassium phosphate buffer, pH 7.4 (see recipe)
Glycine/ascorbate solution (see recipe)
Initiator solution (see recipe), fresh

Sonicator
Flat-bottomed 96-well microplates (Rainin Instrument)
Cytofluor 4000 fluorescence multiwell microplate reader (PerSeptive Biosystems) with temperature control

Suspend samples

1. Sonicate biological samples (i.e., tissue, cells, or subcellular organelles) in 1 ml of 50 mM potassium phosphate buffer, pH 7.4, at a setting that evenly distributes the tissue into solution in ~5 to 15 sec. Keep all preparations on ice until use.

   The amount of sample used varies depending on the source of samples (see Table 17.3.1).

   Avoid buffers and reagents that may quench fluorescence (e.g., Triton, SDS) or that may chelate iron).

2. Add 90 µl of the sample to an allocated well on a flat-bottomed 96-well microplate. Add 100 µl glycine/ascorbate solution.

Measure fluorescence

3. Determine background fluorescence (one cycle) of each well using the following settings on a Cytofluor 4000 fluorescence multiwell microplate reader at 37°C:

Excitation:	360/40 nm
Emission:	460/40 nm
Gain:	90.

Table 17.3.1 Optimal Assay Conditions and Results for Different Biological Samples

Biological sample[a]	Sample amount (mg protein/well)	Initiator concentration (ADP mM/Fe^{3+} μM)	Lag time (min)[b]	Rate (AFU/min)[b]
Liver homogenate[c]	0.1	1/25	10 ± 3.0	10.1 ± 0.3
Liver mitochondria[c]	0.1	1/25	38 ± 10	14.1 ± 1.0
Liver inner mitochondrial membrane[c]	0.1	1/25	15 ± 3	21.4 ± 4.4
Brain	0.1	1/25	12 ± 1	18.8 ± 1.8
Kidney	0.1	1/25	12 ± 1	9.0 ± 1.7
Heart	0.4	4/100	10 ± 3	14.9 ± 2.2
Skeletal muscle	0.5	1/25	13 ± 8	25.0 ± 0.3

[a]All tissues were obtained from Sprague-Dawley rats. Ground tissue was suspended into 50 mM potassium phosphate buffer, pH 7.4, and sonicated for 5 sec. The tissue suspension was used for assay.

[b]Data are the mean ± standard error of three determinations.

[c]Liver homogenates, mitochondria, and inner mitochondrial membranes were isolated as described by Hovius et al. (1990) with modifications.

4. Add 10 μl fresh initiator solution to each well. Read immediately at 37°C and every 5 min for 60 cycles, for a total of 300 min.
5. Save the data and perform lag-time or maximal-rate analysis after completion of the reading.

Perform maximal-rate analysis

6. To determine rate of the propagation phase (Fig. 17.3.1), in the software that comes with the microplate-reader, open the kinetics option of Post Processing from the Cytofluor window.
7. Set the Window Size (i.e., range) for the rate to be calculated based on the second phase of the curve. Visually look at the kinetic curve and decide the number of points on the second phase of the curve that will be used for this calculation. Type the number into the Window Size. If necessary, modify the number of window-size points for the kinetic curve of other wells in the microplate to obtain an accurate rate for each sample.

   For example, thirteen window-size points were chosen in Fig. 17.3.1.

8. Click on the desired cell to cause the Maximal Rate measurement for the chosen number of observations in the range to be plotted and the equation for the line, max rate, correlation coefficient (r^2), and window size to appear (Fig. 17.3.1).

Obtain lag time

9. Calculate the lag time (x) from the rate equation (step 7) using the fluorescence value at the intersection of the rate line with the x axis as the Y value (for example, 1000 in Fig. 17.3.1).

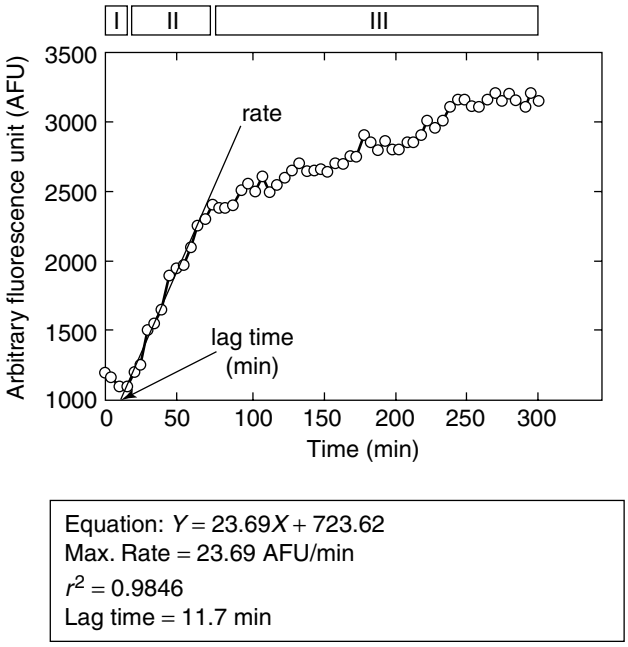

Figure 17.3.1 Kinetic profile of fluorescence during lipid peroxidation. The kinetic curve indicates three phases: (I) a latency phase, (II) a propagation phase, and (III) a termination phase. Lag time (i.e., time from commencement of the assay to the start of lipid peroxidation) can be determined by the latency phase or propagation phase via the equation shown. The maximal rate—i.e., slope expressed in arbitrary fluorescence units (AFU)/min—is also calculated via the equation.

REAGENTS AND SOLUTIONS

*Use Milli-Q-purified water or equivalent for all recipes and protocol steps. For common stock solutions, see **APPENDIX 2A**; for suppliers, see **SUPPLIERS APPENDIX**.*

Glycine/ascorbate solution

Prepare ascorbate stock solution by weighing 7.93 mg L-ascorbic acid and adding 1 ml of 200 mM glycine buffer (see recipe). Vortex to dissolve. Add 300 µl ascorbate stock solution to 14.7 ml of 200 mM glycine buffer (see recipe) and mix. Prepare fresh.

Glycine buffer, 200 mM

Dissolve 1.50 g glycine in 100 ml of 100 mM potassium phosphate buffer, pH 7.4 (see recipe). Store up to 6 months at 4°C.

Initiator solution

Weigh 2.7 mg ferric chloride hexahydrate ($FeCl_3 \cdot 6\ H_2O$) and add 1 ml water to dissolve. Weigh 17.5 mg of sodium adenosine 5′-diphosphate (ADP) from a bacterial source and dissolve in 1.9 ml of 50 mM potassium phosphate buffer, pH 7.4 (see recipe). Just prior to use, mix the ADP solution with 0.1 ml of the ferric chloride solution.

The concentration used depends on the source of biological samples being evaluated (see Table 17.3.1). For instance, higher concentrations of ADP and $FeCl_3 \cdot 6\ H_2O$ may be required for certain tissues. For most cases, the final concentrations are 1 mM ADP and 25 µM ferric chloride.

Potassium phosphate buffer (pH 7.4), 100 mM

Dissolve 13.6 g monobasic potassium phosphate (KH_2PO_4) in 1 liter water and 17.4 g dibasic potassium phosphate (K_2HPO_4) in 1 liter water. Mix 200 ml of the monobasic solution with 800 ml of the dibasic solution. Store up to 1 year at 4°C.

COMMENTARY

Background Information

Overwhelming evidence indicates that reactive oxygen species (ROS) and subsequent lipid peroxidation play critical roles in the pathogenesis of numerous clinical disease states, including drug/toxicant-induced cell injury/death. Unsaturated lipids in biological membranes are susceptible to peroxidation by ROS or free radicals. This lipid peroxidation may result in impairment of membrane properties and functions such as a decrease in membrane fluidity, inactivation or release of membrane-bound components (e.g., receptors and enzymes), and an increase in nonspecific permeability. To protect against the potentially damaging effects from ROS, cells are well equipped with a comprehensive set of antioxidant systems, which include enzymes such as superoxide dismutase, catalase, glutathione peroxidase, and glutathione reductase, macromolecules such as albumin, ceruloplasmin, ferritin, and thioredoxin, and a number of low-molecular-weight antioxidants including ascorbic acid, α-tocopherol, β-carotene, ubiquinol, glutathione, methionine, uric acid, and bilirubin. As oxidative stress is an imbalance between pro-oxidants and antioxidants, favoring oxidation, it is frequently important to determine the cellular antioxidant capacity or susceptibility of tissue to lipid peroxidation.

Since multiple antioxidants are normally present in cells, it is technically difficult to measure the level of each individual antioxidant in biological samples as well as to interpret the significance of these concentrations in terms of preventing oxidative damage. In vivo, antioxidants probably do not exert their effect alone, but rather act in combination with other antioxidants. Such interactions may lead to differences in total antioxidant capacity (Niki and Noguchi, 2000). For example, two antioxidants may interact with each other to produce a synergistic effect. It is known that vitamin E acts as a primary antioxidant, and resultant vitamin E radicals can regenerate vitamin E in the presence of vitamin C, ubiquinol, or glutathione. On the other hand, antioxidants may serve as pro-oxidants under certain conditions. Both vitamins C and E can reduce metal ions and have been shown to accelerate the oxidation of liposomes and low-density lipoprotein (LDL). In fact, β-carotene dietary supplementation at 20 mg per day increased the incidence of lung cancer in male smokers in one prospective trial (Woodford and Whitehead, 1998). Therefore, the assessment of total cellular membrane antioxidant status is important to estimate the tissue's capacity to resist oxidative stress in vivo and in vitro.

The antioxidant status of cellular membranes is also a valuable functional measure of experimental and clinical antioxidant supplementation. The addition of antioxidants to in vitro or in vivo systems does not guarantee that the administered antioxidant has been delivered in a functional form to a particular tissue, cell, or subcellular fraction of interest. This is especially true for lipophilic antioxidants such as vitamin E. For example, the authors have recently shown that the addition of D-α-tocopherol or D-α-tocopheryl acetate to hepatocyte suspensions results in high levels of these compounds in cells, mitochondria, and microsomes as determined by HPLC analyses (Fariss et al., 2001). However, functional antioxidant measurements of these tissues (using the fluorescence microplate reader assay) indicate that the vitamin E present was not functional and most likely represents clusters of lipophilic vitamin E adhered to cellular membranes (Fariss et al., 2001). In contrast, the same hepatocytes treated with D-α-tocopheryl succinate were protected against toxic oxidative stress, which appears to be related to the rapid uptake of tocopheryl succinate in cells and mitochondria followed by the rapid release of functional tochopherol (Fariss et al., 2001). This unique ability of tochopheryl succinate to serve as a rapid delivery system for functional tochopherol has also been observed following acute in vivo administration. As shown in Table 17.3.2, not all vitamin E derivatives are equal in terms of rapid delivery of functional tochopherol to tissue, mitochondria, and inner mitochondrial membranes. Based on these studies (using the microplate reader assay) and those demonstrating enhanced in vitro and in vivo cytoprotection with tocopheryl succinate treatment, the

Table 17.3.2 Effects of Single Administration of Tocopherol and Tocopheryl Esters on Liver Samples[a]

Tissue/treatment	Tocopherol (nmol/mg protein)	Tocopheryl ester (nmol/mg protein)	Lag time (min)	Rate (AFU/min)

α-Tocopheryl succinate	0.22 ± 0.05	3.86 ± 0.79	106 ± 49	15.3 ± 0.2

[a]Abbreviation: ND, not detectable.

[b]Rats were administered a single dose (i.p.) of vehicle (olive oil) or 0.19 mmol/kg of α-tocopherol, α-tocopheryl acetate, or α-tocopheryl succinate. After 18 hr, liver homogenates and subcellular fractions were isolated as described by Hovius et al. (1990) with modifications. Tocopherol and tocopheryl ester levels were then determined by HPLC assay (Fariss et al., 1989). Data are the mean ± std. error; the sample size is 3 to 5 rats.

authors conclude that the enrichment of mitochondrial and inner mitochondrial membrane with functional tochopherol is a critical event in tochopheryl succinate cytoprotection against toxic oxidative stress.

Antioxidant capacity can be estimated by direct measurement of the ability of biological samples to scavenge free radicals or by their susceptibility to lipid peroxidation. Several methods have been developed to assess the total antioxidant capacities of biological samples such as blood plasma, other body fluids, and plant extracts; the methods are mainly based on the ability of these biological samples to scavenge free radicals, or to chelate the transition metals (Ghiselli et al., 2000). These methods include the ferric reducing ability of plasma (FRAP; Benzie and Strain, 1996), total radical trapping parameter (TRAP; Wayner et al., 1985), trolox equivalent antioxidant capacity (TEAC; Re et al., 1999), oxygen radical absorbance capacity (ORAC), total oxyradical scavenging capacity (TOSC), and cycle voltammetry (CV) assays (Chevion et al., 2000). Although these methods can provide useful information, especially with the assessment of low-molecular-weight water-soluble antioxidants in particular, they may have some difficulties in assessing certain antioxidants. For example, protein antioxidants like superoxide dismutase were not suitable for the assessment with such assays (Yu and Ong, 1999). In addition, such assays may underestimate the antioxidant capability for antioxidants acting as iron chelators, such as albumin (Yu and Ong, 1999). Furthermore, most of these assays are limited to determining the total antioxidant capacity in plasma or serum, but not in tissue. In contrast, the fluorescence microplate reader assay reported here has the distinct advantage of assessing the antioxidant capacity of tissues, cells, and subcellular fractions. However, this fluorescence assay is not useful for serum or plasma, as the peroxidation of this tissue does not produce a strong fluorescent signal (apparently insufficient polyunsaturated fatty acids are present to produce reactive aldehydes and fluorescence). Another important advantage of this fluorescence microplate reader assay is in determining the functional antioxidant contributions of lipophilic antioxidants such as tocopherol. Unfortunately, this fluorescence assay's ability to assess the antioxidant contributions of water-soluble, non-enzymatic and enzymatic antioxidants has not been determined.

Other methods for evaluation of antioxidant capacity include the assessment of the susceptibility to lipid peroxidation (Tirmenstein et al., 1998; Cervato et al., 1999), which is the strength of the fluorescent assay reported here. Lipid peroxidation is probably the most extensively investigated process induced by free radicals. A number of assays exist for determining lipid peroxidation based on several different biochemical endpoints. One of the common methods is the thiobarbituric acid reactive substances (TBARS) assay, which is known to detect malondialdehyde (MDA) and other monofunctional aldehydes. However, most of these assays require considerable sample preparation and analysis time. Samples either need to be extracted with organic solvents or dissolved in SDS; furthermore, the assay is not in real-time.

The fluorescence microplate reader assay reported here has numerous advantages. First, assay procedures and sample preparations are rapid, inexpensive, and simple. Second, it allows the rapid monitoring of lipid peroxidation in real time using a large number of biological samples, including tissue, cells, and subcellular fractions. To clearly illustrate the advantages of this fluorescence microplate reader assay over the traditional TBARS assay, consider the time and expense required to analyze the samples in Table 17.3.2 for antioxidant capacity or susceptibility to lipid peroxidation. Using the microplate reader assay, these samples can be analyzed in a single 8-hr day by placing each sample (~5 samples per treatment and subcellular fraction for a total of 60 samples to be analyzed) in individual wells of the 96-well microplate, adding the appropriate buffer and initiator of lipid peroxidation, and reading each well for fluorescence in the plate reader for 300 min. (The microplate reader automatically reads the fluorescence of each well every 5 min.) In contrast, these same samples would take ~6 days to analyze for susceptibility to lipid peroxidation by the TBARS assay. Each sample (only 20 samples/day can be analyzed) is incubated in a glass scintillation vial with the appropriate buffer and initiators of lipid peroxidation, and an aliquot of this solution is collected every 15 min for 3 hr for TBARS analysis (12 aliquots for TBARS analysis per tissue sample). Accordingly, using the TBARS assay, it would take 3 full days to analyze all 60 tissue samples in this experiment (Table 17.3.2) and at least another 3 days to analyze the 720 aliquots for TBARS levels. Thus the advantages of this fluorescence microplate reader assay for determining a tissues' susceptibility to lipid peroxidation are substantial.

For the most part, the authors have found good agreement between the TBARS assay and the fluorescence microplate reader assay in assessing the susceptibility of biological samples to lipid peroxidation (Tirmenstein et al., 1998). However, the assay has disadvantages as well. For example, the microplate reader assay cannot be used for quantification of amounts of lipid peroxidation produced, since the identity of the fluorophore is not known. Regardless of the methods used for measuring lipid peroxidation, the susceptibility of biological samples to lipid peroxidation can be estimated by adding lipid peroxidation initiators in the assay system and measuring the commencement time of lipid peroxidation or maximal rate of second propagation phase.

To initiate the production of pro-oxidants in antioxidant capacity assays, numerous initiator systems have been used, such as hydrogen peroxide alone or coupled with horseradish peroxidase, 2,2′-azobis(2-amidinopropane)dihydrochloride (AAPH), 2,2′-azinobis(3-ethylbenzothiazoline 6-sulfonate) (ABTS), 2′-azobis(2,4-dimethylvaleronitrile) (AMVN), and inorganic iron or copper, given alone or in a chelated form. After examining several of these initiators, Fe^{3+}/ADP was selected for the susceptibility to lipid peroxidation assay. It is known that inorganic iron in certain chelated forms is capable of promoting free-radical-mediated peroxidation of membrane lipids. In addition, Fe^{2+}/ADP or Fe^{3+}/ADP-ascorbate has been extensively studied and used as an in vitro model. The mechanism of iron-induced lipid peroxidation is hydroxylradical–production related via the Fenton reaction. The transition metal iron reacts with oxygen to produce superoxides, which can be dismutased by superoxide dismutase to form hydrogen peroxides. Hydrogen peroxides undergo Fenton reaction in the presence of ferrous iron (Fe^{2+}) to form hydroxyl radicals ($OH^{\cdot}$; Fig. 17.3.2). Lipid peroxidation is initiated by this free radical and the chain reaction is promoted to the generation of lipid alkyl radicals (L·), followed by the formation of a lipid peroxyl radical (LOO·) due to the interaction with oxygen. LOO· eventually converts to LOOH via hydrogen abstraction from neighboring allylic bonds (Fig. 17.3.2). Lipid peroxides in the presence of ferrous iron are converted to lipid alkoxyl radicals (again by the Fenton reaction) which degrade and fragment (again with the help of iron) to form a wide variety of reactive aldehyde products, including

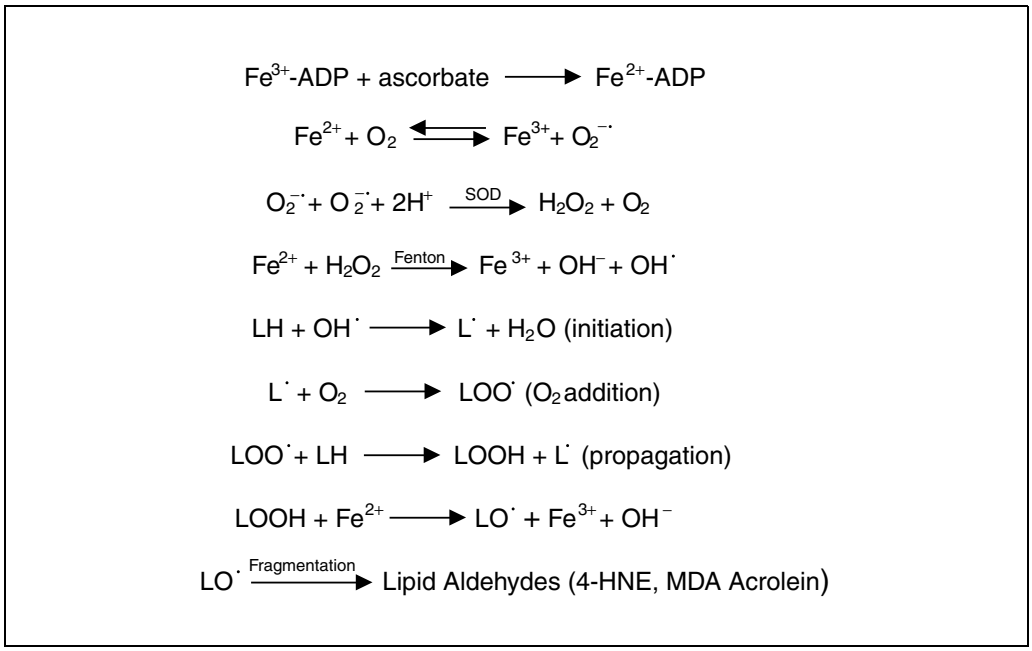

Figure 17.3.2 Fe^{2+}/Fe^{3+} initiation of generation of hydroxyl radicals and lipid peroxidation products.

4-hydroxy-2-nonenal, MDA, and acrolein. Amino acids, especially basic amino acids such as glycine, histidine, lysine, and arginine, can strongly react with the α, β-unsaturated carbonyl groups of these by-products to form fluorescence adducts. Such a process is believed to cause or at least be associated with numerous clinical conditions, including the formation of lipofuscin and ceroid pigments during aging, amyloid β-peptide plaques during Alzheimer's disease, Lewy bodies in Parkinson's disease, and the formation of advanced glycation end products (AGE)–associated protein adducts in diabetic complications such as nephropathy. The authors have experimented briefly with the use of other initiators in the assay, such as AAPH and Fe/H_2O_2, but found that the initiator Fe/ADP results in the greatest fluorescence signal and reproducibility in a wide variety of biological specimens (Tirmenstein, pers. comm.).

Critical Parameters and Troubleshooting

Both the lag time and maximal rate of propagation phase can be used for estimation of susceptibility to lipid peroxidation. Extended lag time or lowered maximal rate suggests increased tissue antioxidant capacity or decreased susceptibility to lipid peroxidation. Lag time is the most valuable parameter used in this assay. The area under the curve (AUC) may be an alternative way to describe the antioxidant capacity since both changes in lag time and maximal rate will significantly affect this parameter. All these values can be readily obtained from the array (Fig. 17.3.3).

This method was originally developed and used for the determination of the susceptibility of rat liver and its subcellular organelles to lipid peroxidation. In terms of use for other biological samples, a few factors should be considered. First, the quantity of antioxidants in plasma, brain, kidney, heart, lung, and liver, as well as their peroxidizable lipids are different. For example, the formation of MDA in rat liver mitochondria was 12-fold higher than those of cardiac mitochondria with the same iron/ascorbate system (Wiswedel et al., 1989). Therefore, selecting the correct amount of tissue and the concentrations of lipid peroxidation initiator are critical to ensure that the sample is peroxidized in the time frame of the assay. For example, with heart tissue, a greater amount of tissue and higher concentrations of lipid peroxidation initiator are required (see Table 17.3.1). The use of plasma or serum in this assay has not been successful, presumably due to the low level of unsaturated lipid in this biological specimen, thus limiting the ability to generate a detectable fluorescence signal.

Background fluorescence is increased slightly after 5 hr of incubation with the lipid peroxidation initiator as described (see Basic

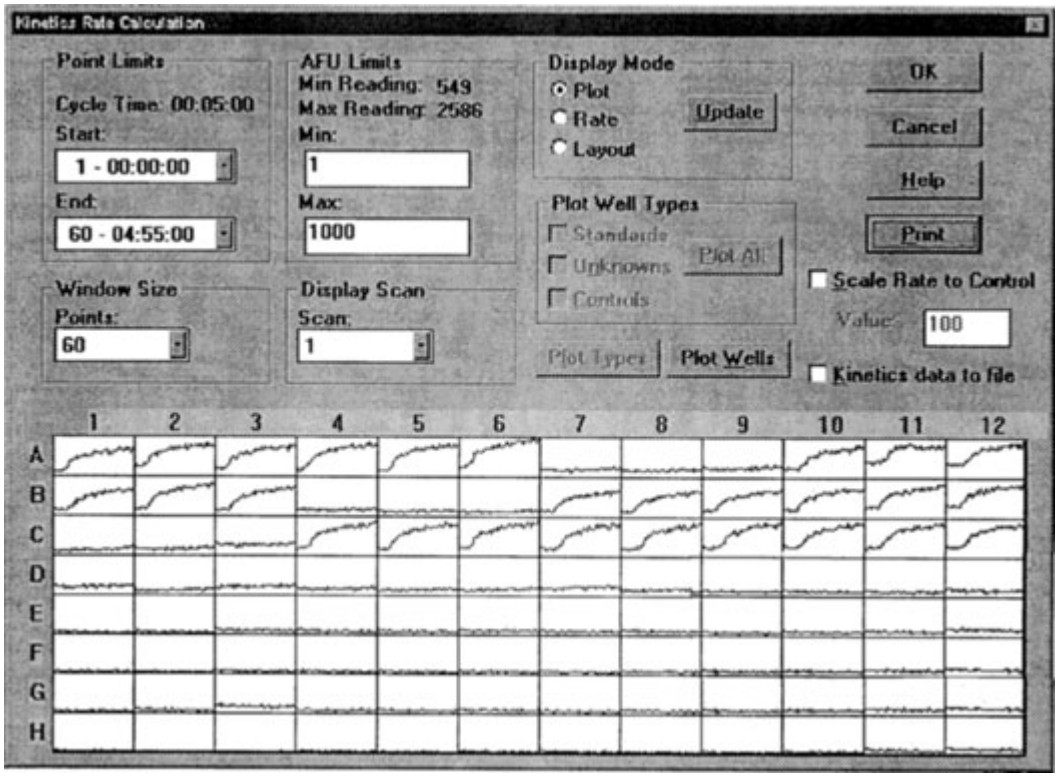

Figure 17.3.3 Kinetic traces of fluorescence for lipid peroxidation in isolated hepatic mitochondrial membrane induced by Fe^{3+}-ADP/ascorbate. The mitochondrial samples were isolated from rats administered (i.p.) either vehicle (traces A1-A3, A10-A12, B7-B9, C4-C6), tocopheryl acetate (A4-A6, B1-B3, B10-B12, C7-C12), or the Tris salt of tocopheryl succinate (A7-A9, B4-B6, C1-C3), 18 hr prior to isolation.

Protocol) but lacking biological samples. The results also indicate that the increase in fluorescence with incubation time only occurs in incubations containing ascorbate, ADP, ferric chloride, and glycine. If any one of these compounds is omitted from the incubation solution, no increase in fluorescence is detected. In general, the concentration of ascorbate is also important in determining whether it is pro-oxidant (reducing iron) or antioxidant. Ascorbate at higher concentrations acts as an antioxidant, but lipid peroxidation (MDA) production by Fe^{3+}/ADP was largely potentiated at lower concentrations of ascorbate. In the present assay, a final concentration of 450 mM ascorbate was used. The lag time can be shortened by increasing the concentration of ferric chloride/ADP, and thus varying the concentration of ferric chloride is an effective way of controlling lag time.

Metal chelators such as EDTA or EGTA are commonly used during sample preparation, such as fractionation of homogenates, mitochondria, and microsomes from tissue. These chelators can form complexes with iron and inhibit lipid peroxidation. Therefore, isolated fractions should be completely washed with non-EDTA or -EGTA buffer. Other considerations should also be taken into account during the studies of the antioxidant capacity of vitamin E esters, such as tocopheryl succinate. It has been shown that tocopheryl succinate can be taken up rapidly by the cells and incorporated into the membrane where it is hydrolyzed into tocopherol by membrane-bound esterase (Fariss et al., 2001). Thus, during the microplate reader assay, esterase inhibitors should be added in order to avoid any hydrolysis of tocopheryl succinate in the samples. A recent study by the authors showed that thenoyltrifluoroacetone is a potent inhibitor of esterase activity and it effectively inhibits the hydrolysis of tocopheryl succinate without affecting the measurement of susceptibility to lipid peroxidation (Zhang and Fariss, 2002). The addition of 25 μM thenoyltrifluoroacetone (final concentration) is recommended in these studies.

Anticipated Results

Figure 17.3.1 shows the kinetic profile of lipid peroxidation with a 5-hr incubation time. Typically, three phases are observed: (I) the initial latency phase, followed by (II) a second propagation phase, and finally (III) a termination phase. Lag time can vary depending on the source of tissues and concentration of lipid peroxidation initiator used. With the current assay method (see Basic Protocol), the lag time for different tissues ranged from 10 to 40 min and maximal rates from 10 to 25 AFU/min (Table 17.3.1).

As mentioned previously, the authors' laboratory has a long-term interest in the protective role of vitamin E derivatives, including tocopherol, tocopheryl acetate, and tocopheryl succinate. Tocopherol is a chain-breaking antioxidant and is known to react with a variety of free radicals, in particular peroxyl radicals Due to its lipophilic property, tocopherol does not rapidly accumulate in hepatic mitochondria. The authors and others have found that tocopheryl succinate is far more effective than tocopherol in protecting isolated hepatocytes against many different toxic oxidative changes, presumably via enriching mitochondria with tocopherol (Fariss et al., 2001). Recent in vivo studies by the authors showed that a single dose of 0.19 mmol/kg (~100 mg/kg) tocopheryl succinate i.p. can rapidly enrich not only rat hepatocytes, but most importantly, mitochondria and inner mitochondrial membranes, which consequently results in a decrease in their susceptibility to lipid peroxidation as compared with samples from vehicle control animals. The decrease in susceptibility to lipid peroxidation with this treatment provides important evidence that the measured enrichment of tocopherol in these mitochondrial fractions is functioning as an effective antioxidant. For example, as illustrated in Table 17.3.2 for mitochondria, the lag time (elapsed time between addition of initiator to the sample and the onset of lipid peroxidation, as measured by an increase in fluorescence in this assay) for samples isolated from vehicle control rats is very short, ~41 min. with a rate of 15.0 AFU/min. This rapid onset of lipid peroxidation (fluorescence) indicates that this sample is highly susceptible to lipid peroxidation. By contrast, hepatic mitochondria isolated from rats pretreated with tocopheryl succinate were completely resistant to the induction of lipid peroxidation, as indicated by a lag time of >300 min (maximum incubation time) and no measurable rate (an increase in fluorescence was not observed in this sample). Interestingly, pretreatment of rats with tocopherol or tocopheryl acetate did not significantly alter the susceptibility of their hepatic mitochondria to lipid peroxidation (with lag times and rates similar to those observed for vehicle control, Table 17.3.2). Decreased tissue susceptibility to lipid peroxidation in these studies correlated well with enhanced tocopherol levels in these samples. These results confirm that the assay is a reliable way to assess the total antioxidant status in tissue. It is interesting to note however, that unlike mitochondria, the inner mitochondrial membrane was not completely protected from the susceptibility to lipid peroxidation following tocopheryl succinate administration in vivo (Table 17.3.2), even though these two mitochondrial fractions were enriched with identical levels of tocopherol. These results can be explained by the greater cardiolipin content of inner mitochondrial membrane (as compared with mitochondria) and the well-known enhanced susceptibility of this inner mitochondrial membrane–specific phospholipid to lipid peroxidation (Lesnefsky et al., 2001).

Time Consideration

The total time required for this assay is ~6 hr. Sonication of samples and preparation of lipid peroxidation initiator can be finished within 1 hr.

In Situ Localization of Nonenzymatic Peroxidase-Like Activity of Tissue-Bound Transition Metals

The protocols described below pertain to detection of tissue iron using the DAB-enhanced Perls method (see Basic Protocol) as well as the general detection of redox-active transition metal ions without the introduction of any metal-containing reagents (see Alternate Protocol). In the latter case, use of the MBTH/*o*-phenylenediamine method in the absence of H_2O_2 pretreatment permits the selective visualization of endogenous enzymatic peroxidase-like activity, whereas use of DAB following the H_2O_2 pretreatment permits the visualization of endogenous nonenzymatic redox-active metals. Whether the staining reflects mainly iron or mainly copper can be ascertained by noting whether it is attenuated more by preincubation with increasing concentrations of the iron-selective chelator deferoxamine or by increasing concentrations of the copper-selective chelator diethylenetriaminepentaacetic acid (DTPA), as described in the Support Protocol. These methods do not permit one to distinguish other redox-active metals such as chromium, and possibly manganese, whose contributions cannot be excluded. Noting an inhibitory effect of prior incubation with chelating agents is further evidence that the DAB staining reflects adventitiously bound redox-active metals rather than enzymatic activity, because the latter is refractory to chelators.

A key advance represented by the protocols provided below is an enhanced sensitivity arising from the recognition that standard formalin fixation detracts from detection of metal-based redox activity, which is not the case with the fixative used in the protocols below (methacarn; 60:30:10 methanol/chloroform/acetic acid; see Reagents and Solutions), as verified by limited studies using nonfixed tissue.

DETECTION OF IRON

BASIC PROTOCOL

Iron can be detected in freshly isolated, paraffin-embedded tissue sections fixed in the absence of formalin, using potassium ferrocyanide and 3,3′-diaminobenzidine tetrahydrochloride (DAB).

Materials

Fresh tissue of interest
Fixative solution (see recipe)
30%, 50%, 70%, 80%, 95%, and 100% (v/v) ethanol
Xylene
Paraffin
50 mM Tris·Cl, pH 7.6 (*APPENDIX 2A*)
7% (w/v) potassium ferrocyanide solution (see recipe), freshly prepared
DAB/H_2O_2 solution (for Basic Protocol; see recipe), freshly prepared
Permount mounting medium (e.g., Fisher)

Tissue-embedding cassettes (Omnisette; Fisher)
Paraffin-embedding system or machine (e.g., TBS ATPI Automated Tissue Processor; Fisher)
Microtome
Superfrost Plus microscope slides (Fisher)
Coplin jars

Contributed by Lawrence M. Sayre, Peggy L.R. Harris, George Perry, and Mark A. Smith
Current Protocols in Toxicology (2004) 17.4.1-17.4.8

Humified chamber (storage container with sealable lid, lined with moistened paper towels and containing elevated surface on which to place slides) or container designed for immunohistochemical incubations
3-cc BD disposable syringes (Fisher)
0.22-μm Millex-GS syringe filters (Millipore)
Coverslips

Prepare tissue

1. Dissect the tissue sample.
2. Place an ~0.5-cm^3 sample of tissue in a tissue-embedding cassette and immerse in 50 ml of fixative solution. Incubate overnight at 4°C
3. Remove sample from fixative and place in 50% ethanol.
4. Using a histology paraffin-embedding system/machine, dehydrate sample through an ascending ethanol series and carry out paraffin embedding as follows:

   70% ethanol for 40 min at 40°C
   80% ethanol for 40 min at 40°C
   95% ethanol for 40 min at 40°C
   100% ethanol for 40 min at 40°C
   100% ethanol for 40 min at 40°C
   100% ethanol for 1 hr 10 min at 40°C
   xylene for 40 min at 40°C
   xylene for 40 min at 40°C
   paraffin for 40 min at 60°C
   paraffin for 1 hr at 60°C
   paraffin for 40 min at 60°C.

   Follow the manufacturer's suggested operating guidelines, but run the machine without formalin, thus avoiding the standard formalin fixative step at the beginning.
5. Once a paraffin block is obtained, cut 6-μm sections using a microtome and place the sections on Superfrost Plus microscope slides. Dry sections on the slide overnight at 37°C
6. Rehydrate sections by immersing in the following solutions in Coplin jars at room temperature for the indicated lengths of time.

   xylene for 10 min
   xylene (fresh) for 10 min
   100% ethanol for 10 min
   95% ethanol for 10 min
   70% ethanol for 10 min
   50% ethanol for 10 min
   30% ethanol for 10 min
   50 mM Tris·Cl, pH 7.6, for 10 min
   50 mM Tris·Cl, pH 7.6 (fresh) for 10 min.

Stain for iron

7. Apply enough freshly made 7% potassium ferrocyanide solution to cover the section. Place slide in humidified chamber and incubate 1.5 to 2 hr at 37°C or overnight at 4°C.
8. Rinse slide in 50 mM Tris·Cl, pH 7.6, for 10 min.

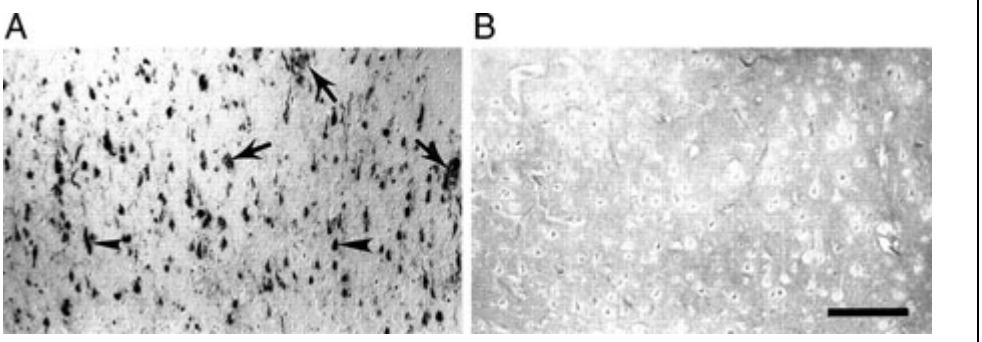

Figure 17.4.1 Histochemical detection of iron in Alzheimer's disease (**A**) compared with control case (**B**) shows striking association of iron with neurofibrillary tangles (arrowheads) and senile plaques (arrows) characteristic of the Alzheimer's disease brain. Scale bar = 200 μm.

9. Develop signal by covering the section with freshly prepared DAB/H_2O_2 solution (using a 3-cc syringe and 0.22-μm syringe filter to filter the DAB/H_2O_2) and leaving the solution on the section for 5 min.
10. Dehydrate sections by immersing in the following solutions (ascending ethanol series) in Coplin jars at room temperature for the indicated lengths of time:

    30% ethanol for 10 min
    50% ethanol for 10 min
    70% ethanol for 10 min
    95% ethanol for 10 min
    100% ethanol for 10 min
    xylene for 10 min.

11. Apply coverslip to slide using Permount.

    A dark brown precipitate, easily visualized by light microscopy, will form at sites containing iron (Fig. 17.4.1). Time consideration—approximately 4.5 to 18 hr.

DETECTION OF REDOX-ACTIVE TRANSITION METALS

ALTERNATE PROTOCOL

Redox activity, a key feature of non-sequestered transition metals (e.g., iron, copper) provides a key enhancement to metal localization studies.

Additional Materials *(also see Basic Protocol)*

Peroxide/methanol: add 4 ml of 30% hydrogen peroxide to 36 ml of 100% methanol; prepare fresh daily
DAB/H_2O_2 solution (for Alternate Protocol; see recipe), freshly prepared
MBTH/*o*-phenylenediamine/H_2O_2 solution (see recipe), freshly prepared

1. Dissect, fix, dehydrate, embed, and section sample; place sections on slides and dry overnight (see Basic Protocol, step 1 to 5).
2. Rehydrate sections (and optionally inactivate endogenous peroxidases) by immersing in the following solutions in Coplin jars at room temperature for the indicated lengths of time:

    xylene for 10 min
    xylene (fresh) for 10 min
    100% ethanol for 10 min

95% ethanol for 10 min
peroxide/methanol for 30 min (optional; to inactivate endogenous peroxidase activity)
70% ethanol for 10 min
50% ethanol for 10 min
30% ethanol for 10 min
50 mM Tris·Cl, pH 7.6, for 10 min
50 mM Tris·Cl, pH 7.6, for 10 min.

3. *Optional:* Perform chelation to titrate away endogenous metals to determine the source of activity (i.e., metal) and to verify the specificity of the finding (see Support Protocol).
4. Using a 3-cc syringe and 0.22-μm syringe, apply enough freshly made DAB/H_2O_2 solution to cover the section.
5. To an adjacent section on the same slide or a section on a second slide, using a 3-cc syringe and 0.22-μm syringe filter to filter the MBTH/*o*-phenylenediamine solution, apply MBTH/*o*-phenylenediamine solution for comparison purposes.
6. Place slides in a humidified chamber and incubate 1.5 to 2 hr at room temperature.
7. Rinse slides in 50 mM Tris·Cl, pH 7.6, for 10 min.
8. Dehydrate sections by immersing in the following solutions (ascending ethanol series) in Coplin jars at room temperature for the indicated lengths of time:

   30% ethanol for 10 min
   50% ethanol for 10 min
   70% ethanol for 10 min
   95% ethanol for 10 min
   100% ethanol for 10 min
   xylene for 10 min.

9. Apply coverslip to slide using Permount.

   A dark brown precipitate will form at sites containing redox activity.

SUPPORT PROTOCOL

CHELATION OF METALS FOR CONTROLS

After the tissue sections have been hydrated, a chelation step may be performed to selectively remove individual endogenous metals. A serial dilution of DEF (which selectively removes iron) and DTPA (which selectively removes copper) can be used, starting with a 0.1 M concentration and doing successive 1:10 dilutions with water (0.01 M and 0.001 M). Although higher concentrations of either chelator will remove all metals, a determination of the relative effectiveness of the chelators at lower concentration may permit an assessment of which metal ions are most responsible for the redox activity.

Additional Materials *(also see Basic Protocol and Alternate Protocol)*

0.1 M DEF stock: Weigh 65.68 mg deferoxamine (DEF; Sigma) and add 1 ml H_2O
0.1 M DTPA stock: Weigh 39.33 mg diethylenetriaminepentaacetic acid (DTPA; Sigma) and add 1 ml H_2O

1. After performing the rehydration series in step 2 of the Alternate Protocol, remove the slides from the Tris·Cl buffer, and apply either DEF or DTPA to appropriate sections at the desired concentration (e.g., serial dilutions of 0.1, 0.01, and 0.001 M).

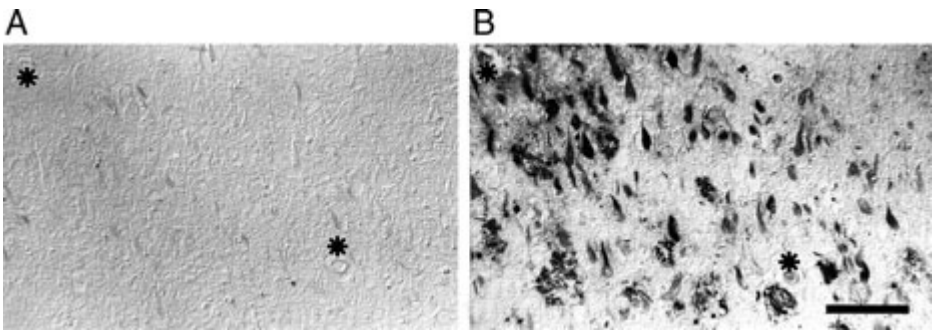

Figure 17.4.2 Lesion-associated iron (see Fig. 17.4.1) could be completely stripped with deferoxamine (**A**) but readily rebound to the same sites following incubation with iron(III) citrate and iron(II) chloride (**B**). Asterisks indicate landmark blood vessels in adjacent sections. Scale bar = 100 μm.

2. Incubate overnight at room temperature in humidified chamber.
3. Rinse extensively with 50 mM Tris·Cl, pH 7.6, prior to continuing the detection procedure (see Alternate Protocol, step 4).

Typical results are shown in Figure 17.4.2.

REAGENTS AND SOLUTIONS

Use Milli-Q-purified water or equivalent for the preparation of all solutions and in all protocol steps. For common stock solutions, see ***APPENDIX 2A****; for suppliers, see* ***SUPPLIERS APPENDIX****.*

DAB/H_2O_2 solution (for Alternate Protocol)

Weigh 5 mg of 3,3′-diaminobenzidine tetrahydrochloride (DAB). Add 6 ml 50 mM Tris·Cl, pH 7.6 (*APPENDIX 2A*), and 672 μl of 30% hydrogen peroxide, then mix. Prepare immediately before use.

Final concentrations: 0.75 mg/ml DAB/3% H_2O_2.

DAB/H_2O_2 solution (for Basic Protocol)

Weigh 5 mg of 3,3′-diaminobenzidine tetrahydrochloride (DAB). Add 6.67 ml 50 mM Tris·Cl, pH 7.6 (*APPENDIX 2A*), and 3.36 μl of 30% hydrogen peroxide, then mix. Prepare immediately before use.

Final concentrations: 0.75 mg/ml DAB/0.015% H_2O_2.

Fixative solution

Mix 300 ml methanol, 150 ml chloroform, and 50 ml glacial acetic acid to give a final volume of 500 ml. Store in a glass bottle at 4°C until needed.

Final concentrations: 60:30:10 (v/v/v) methanol/chloroform/acetic acid.

MBTH/o-phenylenediamine/H_2O_2 solution

Stock solutions:

3 *mg/ml MBTH:* Weigh 3 mg of 3-methyl-2-benzothiazolinone hydrazone (MBTH; Sigma) and add 1 ml of 50 mM Tris·Cl, pH 7.6 (*APPENDIX 2A*).

2 *mg/ml o-phenylenediamine:* Weigh 2 mg of *o*-phenylenediamine and add 1 ml of 50 mM Tris·Cl, pH 7.6 (*APPENDIX 2A*).

continued

Working solution:
Mix the following immediately before use:
125 µl of 3 mg/ml MBTH
125 µl of 2 mg/ml *o*-phenylenediamine
50 µl of 30% hydrogen peroxide
200 µl of 50 mM Tris·Cl, pH 7.6 (*APPENDIX 2A*)

Potassium ferrocyanide solution, 7%

Weigh 0.7 g $K_4Fe(CN)_6 \cdot 3H_2O$ into a graduated cylinder. Add 5 ml water and 300 µl concentrated hydrochloric acid. Mix, then bring to a final volume of 10 ml. Prepare immediately before use.

COMMENTARY

Background Information

Many disease states are associated with tissue accumulation of metals. This accumulation can reflect unusually high tissue levels of metal-storage proteins such as ferritin (iron) and ceruloplasmin (copper), or metal transporters such as transferrin (iron) and the copper-transporting ATPase implicated in Wilson's disease. When such proteins become saturated, free metal ions are released into plasma and, at least in the case of iron, may result in deposition of simple inorganic forms of the metal, such as Fe_2O_3. A number of techniques have been used for quantitation of tissue metals, including atomic absorption spectroscopy, magnetic resonance imaging, X-ray microanalysis, and laser microprobe mass analysis (LAMMA). For semiquantitative determination of tissue metals, however, various histochemical methods have always seen greater use on account of their convenience (Bancroft and Stevens, 1982; Pearse, 1985). Specificity of the latter methods for individual metals relies on the use of metal ion-specific chelating agents and often requires prior release of metals from their protein-binding sites by treatment with trichloroacetic acid or HCl.

The most popular method for histochemical detection of iron has been Perls' method (Perls, 1867; Thompson, 1966), which relies on the formation of the deep blue mixed-valent ($Fe^{2+}Fe^{3+}$) cyano complex known as Prussian blue. Usually, this technique localizes ferric iron that can be mobilized by treatment with ferrocyanide, though reaction of ferricyanide with Fe^{2+} gives the same complex (Parmley et al., 1978). A later development of this method was to take advantage of the fact that Prussian blue is especially active in catalyzing the H_2O_2-dependent oxidation of 3,3′-diaminobenzidine (DAB), the latter serving as the most commonly used chromogenic substrate for peroxidase. This so-called enhanced Perls' method (Nyguyen-Legros et al., 1980) has been widely applied to the histochemical localization of total iron (ferritin, transferrin, and free iron) in brain and other tissues as a function of aging and disease (Conner et al., 1990). The advantage of using DAB is that its oxidation yields an insoluble brown polymer deposited at the sites of enzyme localization and readily detected by microscopy.

Nonetheless, with application of H_2O_2 and DAB becoming the most generally used chromogenic method for immunohistochemical studies that involve the (horseradish) peroxidase-antiperoxidase (PAP) method or direct use of horseradish peroxidase–linked secondary antibodies, it has been important to eliminate any endogenous peroxidase activity in the tissue by prior treatment with H_2O_2 at a concentration (usually one part 3% H_2O_2 diluted with four parts methanol) that inactivates such enzymatic activity (Sternberger, 1986). Without the H_2O_2 pretreatment, any endogenous peroxidase-like activity would interfere. Indeed, the H_2O_2-dependent oxidation of peroxidase substrates such as DAB or 3,3′,5,5′-tetramethylbenzidine (TMB) has been directly used to localize endogenous peroxidase activity in neural tissue (Svensson et al., 1984). The key point here is that such activity can represent either authentic enzymatic (peroxidase or catalase) activity or nonenzymatic "pseudo"-peroxidase activity of adventitiously bound redox-active transition metal ions. A distinction between the two can be ascertained only by studies that probe the conditions under which the peroxidase-like activity persists. Thus, when the activity shows a pH dependence reminiscent of a particular heme enzyme, can be blocked by prior treatment with sodium azide (Schaermeyer, 1992) or 3-amino-1,2,4-triazole, or can be eliminated

by heating, such as occurs in the case of staining of peroxisomes (Schipper et al., 1990a), the interpretation has been in terms of endogenous enzyme activity. On the other hand, when staining is independent of pH, heat, or the presence of inhibitors (Schipper et al., 1990b), as has been found for astrocyte mitochondria in the aging brain (Schipper et al., 1998), the interpretation has been in terms of nonenzymatic redox activity. In the latter regard, concomitant use of X-ray microanalysis has provided evidence for localization of both iron (presumed to be nonenzymatic heme iron on the basis of lack of reaction with Prussian blue; Schipper et al., 1990a) and copper (Brawer et al., 1994).

The authors' studies revealed the presence of H_2O_2-dependent DAB oxidizing activity in the neurofibrillary pathology of Alzheimer disease (Sayre et al., 2000). Since this activity was not attenuated by prior exposure of the tissue sections to peroxidase-inactivating levels of H_2O_2, the interpretation was in terms of nonenzymatic redox-active transition metals. Nonetheless, to demonstrate that the level of H_2O_2 being used was sufficient to inactivate endogenous enzymatic peroxidase activity, a method was needed for detecting the latter which was independent of the use of DAB. A range of studies on the effect of added iron- and copper-selective chelating agents on the intrinsic ability of these metals to mediate H_2O_2-dependent DAB oxidation suggested, at least in the case of copper, that a key facet of this reaction was the ability of DAB to enter into bidendate coordination with Cu^{2+}. Thus, the authors found that simple transition metal complexes were incapable of mediating the H_2O_2-dependent oxidation of noncoordinating peroxidase substrates such as TMB. This would suggest that TMB is an ideal reagent for selective detection of enzymatic peroxidase activity in the face of redox-active free metal ions that are detected by DAB (Trojanowski et al., 1983). Indeed, the discrepancy between DAB staining and TMB staining observed by others (Svensson et al., 1984) most likely reflects the redox activity of nonenzymatic transition metals. The authors, however, were unable to observe a reproducible tissue staining using TMB. On the other hand, they found that a 1:1 mixture of 3-methyl-2-benzothiazolinone hydrazone (MBTH) and *o*-phenylenediamine, which, like TMB, gave a negative result with H_2O_2 in the presence of simple transition metal complexes, permitted the observation of endogenous enzymatic peroxidase activity. The reaction in this case involved an oxidative coupling (Ngo and Lenhoff, 1980) to generate an insoluble material similar to that seen using DAB. Staining using the MBTH/*o*-phenylenediamine reagent, albeit weak, was eliminated by the H_2O_2 pretreatment, unlike the DAB staining, confirming that the latter reflected nonenzymatic redox activity (Sayre et al., 2000).

Critical Parameters and Troubleshooting

The most important factor to ensure success is the fixative. The tissue should not be exposed to any aldehyde-containing fixative, e.g., formalin or formaldehyde. If this does occur, the methods will only show a limited stain or not work at all. Also, the potassium ferrocyanide, MBTH, and DTPA solutions should be made just prior to use so that they do not become oxidized and lose any of their strength. In any event, if the staining of the sample is weak, a longer incubation with the solutions may be needed. It is possible to incubate the samples overnight in the working solutions at 4°C to increase the stain intensity, or even at room temperature overnight, although this may increase the background of the stain. Occasionally, a precipitate forms when the DAB is applied to the samples. Once on the sections, it is difficult to remove; however, a more thorough filtering of freshly made DAB solution should correct this for future stains.

Anticipated Results

A brown precipitate, easily visualized by light microscopic techniques, will form at the sites containing iron (see Basic Protocol) or redox activity (see Alternate Protocol). Representative results are shown in Figures 17.4.1 and 17.4.2.

Time Considerations

After the tissue samples have been embedded in paraffin and sections cut (which will take 1 day), the procedure should take ~5 hr (or 48 hr if an overnight incubation is required).

F_2-Isoprostanes as Markers of Oxidant Stress: An Overview

Lipid peroxidation, the oxidation of cellular lipids, is a central feature of oxidant stress, a phenomenon that has been increasingly implicated as causative in numerous pathological conditions. Lipid peroxidation products are frequently used to quantify oxidative injury, and can be assessed by a number of methods that include the measurement of either primary or secondary peroxidation end products. The development of specific, reliable, and non-invasive methods for measuring oxidative stress in humans is of fundamental importance for establishing the role of free radicals in human diseases. Primary end products of lipid peroxidation include conjugated dienes and lipid hydroperoxides, while secondary end products include thiobarbituric reactive substances (TBARS), gaseous alkanes, and a group of prostaglandin (PG) F_2-like products termed F_2-isoprostanes (F_2-IsoPs; Halliwell and Grootveld, 1987; Morrow et al., 1990a). Quantification of these various compounds has proven highly useful for the study of free radical–mediated lipid peroxidation in in vitro model systems. However, the F_2-IsoPs appear to be a significantly more accurate marker of oxidative stress in vivo in humans and animals than other compounds (Liu et al., 1999; Morrow and Roberts, 1999; Fam and Morrow, 2003). The biochemistry of F_2-IsoPs, as well as considerations regarding their utility as markers of oxidative stress will be discussed herein.

MECHANISM OF FORMATION OF ISOPROSTANES

IsoPs are PG-like compounds formed from the peroxidation of arachidonic acid, a ubiquitous polyunsaturated fatty acid (Morrow et al., 1990a; Morrow and Roberts, 1999). Unlike PGs, which are formed via the action of the cyclooxygenase enzymes, F_2-IsoPs are formed non-enzymatically as a result of the free radical–mediated peroxidation of arachidonic acid. Figure 17.5.1 outlines the mechanism by which IsoPs are generated. Following abstraction of a bis-allylic hydrogen atom and the addition of a molecule of oxygen to arachidonic acid to form a peroxyl radical, endocyclization occurs and an additional molecule of oxygen is added to form PGG_2-like compounds. These unstable bicycloendoperoxide intermediates are then reduced to the F_2-IsoPs. Based on this mechanism of formation, four F_2-IsoP regioisomers are generated (see Fig. 17.5.1; Morrow et al., 1990a,b; Morrow and Roberts, 1999). Compounds are denoted as 5-, 12-, 8-, or 15-series regioisomers depending on the carbon atom to which the side chain hydroxyl is attached; the authors have proposed a nomenclature system based on this feature (Taber et al., 1997). An alternative system for the IsoPs has been proposed by FitzGerald and colleagues in which the abbreviation iP is used for isoprostane, and regioisomers are denoted as III to VI based upon their structure (Rokach et al., 1997). IsoPs that contain F-type prostane rings are isomeric to $PGF_{2\alpha}$ and are thus referred to as F_2-IsoPs. It should be noted that IsoPs containing alternative ring structures (such as those resembling PGD_2/E_2 and PGA_2/J_2) can also be formed by this mechanism (Chen et al., 1999; Reich et al., 2001a). F_2-IsoPs, however, have been the most studied class of IsoPs and, because of their stability, afford the most accurate measure of oxidative stress (Liu et al., 1999).

An important structural distinction between IsoPs and cyclooxygenase-derived PGs is that the former contain side chains that are predominantly oriented *cis* to the prostane ring while the latter possess exclusively *trans* side chains (Morrow et al., 1990a,b). A second important difference between IsoPs and PGs is that IsoPs are formed in situ esterified to phospholipids and are subsequently released by a phospholipase(s) (Liu et al., 1999; Morrow and Roberts, 1999), while PGs are generated only from free arachidonic acid.

QUANTIFICATION OF F_2-ISOPROSTANES

Over the past 12 years, several methods have been developed to quantify the F_2-IsoPs. The authors' laboratory uses a gas chromatographic/negative ion chemical ionization mass spectrometric (GC/NICI MS) approach employing stable isotope dilution (Morrow and Roberts, 1999). For quantification purposes, the F_2-IsoP, 15-F_{2t}-IsoP, and other F_2-IsoPs that co-elute with this compound are measured. Other investigators quantify different F_2-IsoP isomers, as discussed subsequently

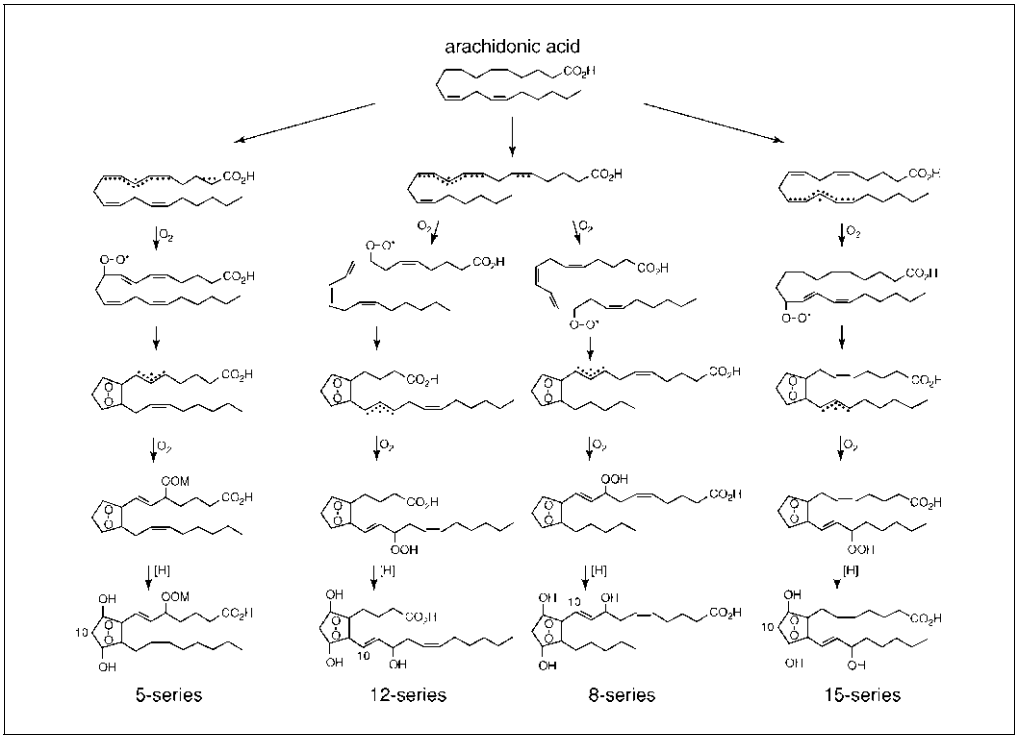

Figure 17.5.1 Mechanism of formation of the F_2-isoprostanes. Four regioisomers are formed, each consisting of eight racemic diastereomers. Stereochemistry is not indicated.

(Rokach et al., 1997). Several internal standards are available from commercial sources to quantify the IsoPs. These include [$^2H_4$]15-F_{2t}-IsoP ([$^2H_4$] 8-iso-$PGF_{2\alpha}$) and [$^2H_4$]-$PGF_{2\alpha}$. The advantages of mass spectrometry over other approaches include its high sensitivity and specificity, which yield quantitative results in the low picogram range. Its drawbacks are that it is labor intensive and requires considerable expenditures on equipment.

Several alternative mass spectrometric assays have been developed by different investigators including FitzGerald and colleagues (Rokach et al., 1997; Pratico et al. 1998a). As with the authors' assay, these methods require solid-phase extraction with a C18 column, TLC purification, and chemical derivatization. Furthermore, IsoPs are quantified using isotope dilution NICI GC/MS but the assay measures F_2-IsoP isomers other than 15-F_2-IsoP. These methods appear to be comparable to the authors' in terms of utility. In addition, a number of liquid chromatographic MS methods for F_2-IsoPs have been recently developed; these require less sample preparation (Liang et al., 2000; Bohnstedt et al., 2003), but the sensitivity and reliability of these for the analysis of IsoPs in complex biological samples is unknown.

Alternative methods have been developed to quantify IsoPs with immunological approaches (Morrow et al., 1999a). Antibodies have been generated against 15-F_{2t}-IsoP and at least three immunoassay kits are commercially available. A potential drawback of these methods is that limited information is currently available regarding their precision and accuracy. In addition, little data exist comparing IsoP levels determined by immunoassay to those determined by mass spectrometry. Analogous to immunological methods to quantify cyclooxygenase-derived PGs, it might be predicted that immunoassays for IsoPs will suffer from a lack of specificity (Roberts and Morrow, 2000). Furthermore, the sensitivity and/or specificity of these kits may vary substantially between manufacturers. However, while mass spectrometric methods of IsoP quantification are considered the "gold standard," immunoassays have expanded research in this area because of their low cost and relative ease of use.

F_2-ISOPROSTANES AS AN INDEX OF OXIDANT STRESS

Measurement of F_2-IsoPs In Vitro

To demonstrate the utility of quantifying F_2-IsoPs as an index of oxidant stress, it is necessary to compare the formation of these compounds with other known indices of oxidant stress using established in vitro models of oxidant stress. The formation of F_2-IsoPs has been compared to malondialdehyde (MDA), one of the most commonly used measures of lipid peroxidation that utilizes Fe/ADP/ascorbate-induced peroxidation of rat liver microsomes (Longmire et al., 1994). Both F_2-IsoP and MDA (measured as thiobarbituric acid reacting substances) formation increased in parallel in a time-dependent manner and correlated with the loss of arachidonic acid and with increasing oxygen concentrations up to 21%. Although the formation of F_2-IsoPs correlated with other measures of lipid peroxidation in this in vitro model, the authors have reported that quantification of F_2-IsoPs is far superior to measurements of MDA as an index of lipid peroxidation in vivo (Longmire et al., 1994).

It is hypothesized that the oxidation of low density lipoprotein (LDL) in vivo converts it to an atherogenic form, which is taken up by macrophages in the vessel wall. Subsequent activation of these cells likely plays an important role in the development and progression of atherosclerotic lesions in humans (Steinberg et al., 1989). Thus, the authors have performed studies examining the formation of F_2-IsoPs in LDL that is oxidized to determine whether measurement of F_2-IsoPs esterified to lipoproteins may provide an approach to assess lipoprotein oxidation in vivo (Lynch et al., 1994). In these studies, either plasma lipids or purified LDL from humans was peroxidized with Cu^{2+} or the water-soluble oxidizing agent 2,2-azo-bis(2-amidinopropane) (AAPH; Lynch et al., 1994), and the formation of F_2-IsoPs was compared to other markers of lipid peroxidation including formation of cholesterol ester hydroperoxides, phospholipid hydroperoxides, loss of antioxidants, and changes in the electrophoretic mobility of LDL. In plasma oxidized with AAPH, increases in the formation of F_2-IsoP paralleled increases in lipid hydroperoxide formation and occurred only after depletion of the antioxidants ascorbate and ubiquinol-10. In purified LDL that was oxidized, formation of F_2-IsoPs again correlated with increases in lipid hydroperoxides and increases in the electrophoretic mobility of LDL and occurred only after depletion of the antioxidants α-tocopherol and ubiquinol-10. Similar findings have been reported by others (Gopaul et al., 1994; Pratico and FitzGerald, 1996).

Taken together, these in vitro studies suggest that quantification of F_2-IsoP correlates with other established indices of oxidative stress, and serves as a useful marker of lipid peroxidation.

Measurement of F_2-IsoPs In Vivo

It has been previously recognized that one of the greatest needs in the field of free radical research is a reliable non-invasive method to assess lipid peroxidation in vivo in humans (Roberts and Morrow, 2000). In this respect, most methods available to assess oxidant stress, which are adequate for in vitro purposes, have suffered from a lack of sensitivity and/or specificity or are unreliable when applied to complex biological fluids and tissues. However, a substantial body of evidence indicates that measurement of F_2-IsoPs in body fluids such as plasma provides a reliable approach to assess lipid peroxidation in vivo and represents a major advance in the ability to assess oxidative stress status in animals and humans (Morrow and Roberts, 1997; Roberts and Morrow, 2000). Normal levels of F_2-IsoPs have been defined in human biological fluids such as plasma and urine. (Liu et al., 1999; Morrow et al., 1999a; Morrow and Roberts, 1999). It is important to note that quantities of these compounds exceed those of cyclooxygenase-derived PGs by at least an order of magnitude, suggesting that IsoPs are a major pathway of arachidonic acid disposition. Further, levels of F_2-IsoPs are sufficient to be detected in every normal biological fluid that has been assayed including plasma, urine, bronchoalveolar lavage fluid, cerebrospinal fluid, and bile (Morrow et al., 1999a).

The finding of significant levels of F_2-IsoPs in normal animal and human biological fluids and tissues indicates there is ongoing lipid peroxidation that is incompletely suppressed by antioxidant defenses, even in normal humans and animals, lending support to the hypothesis that the normal aging process is due to enhanced oxidant damage of relevant biological molecules over time. In this regard, previous studies have suggested that IsoP levels in normal mice and humans increase with age (Rokach et al. 1997; Roberts and Reckelhoff, 2001), although another report refutes this (Feillet-Coudray et al., 1999).

An attractive possibility suggested by these findings is the measurement of F_2-IsoPs in urine as an index of systemic or whole body oxidant stress integrated over time. However, the measurement of free F_2-IsoPs in urine can be confounded by the potential contribution of local IsoP production in the kidney, although the extent to which this occurs is unclear (Morrow and Roberts, 1997; Morrow et al., 1999a; Roberts and Morrow, 2000). In light of this issue, the primary urinary metabolite of 15-F_{2t}-IsoP has previously been identified to be 2,3-dinor-5,6-dihydro-15-F_{2t}-IsoP, and a highly sensitive and accurate mass spectrometric assay to quantify this molecule has been developed (Roberts et al. 1996; Morrow et al., 1999b; Morales et al., 2001). Thus, the quantification of 2,3-dinor-5,6-dihydro-15-F_{2t}-IsoP may represent a truly non-invasive, time-integrated measurement of systemic oxidation status that can be applied to living subjects.

Formation of Isoprostanes in Animal Models of Oxidant Stress

F_2-IsoPs have also proven highly valuable in studying oxidative injury in vivo in many animal models of disease. Administration of carbon tetrachloride ($CC1_4$) intragastrically to rats is a well-established model of oxidative injury, causing severe free radical–induced damage to the liver and other organs. Esterified levels of F_2-IsoPs in liver tissue increase by 200-fold within 1 hr of CCl_4 treatment and subsequently decline over 24 hr (Morrow et al., 1992), while plasma free and lipid-esterified IsoP concentrations increased after liver levels up to 50-fold in a dose-dependent manner. Administration of the antioxidant lazaroid U78517 to CCl_4-treated animals significantly blunted the enhanced formation of F_2-IsoPs in this model (Morrow and Roberts, 1997).

As a second example, F_2-IsoP formation has been employed to study the toxicity of diquat, a dipyridyl herbicide. Diaquat undergoes redox cycling in vivo, generating large amounts of the superoxide anion and causing hepatic and renal injury in rats. This effect is markedly augmented in animals deficient in selenium (Se), a trace element that is required for the enzymatic activities of glutathione peroxidase and other antioxidant proteins. To study whether lipid peroxidation occurs in this model, levels of F_2-IsoPs were quantified in plasma and tissues from Se-deficient rats following diquat administration. Se-deficient rats administered diquat showed 10- to 200-fold increases in plasma F_2-IsoPs, with the primary sites of IsoP generation being the kidney and liver (Awad et al., 1994). Further studies disclosed that the extent of tissue injury and IsoP formation directly correlated with the degree of Se depletion (Burk et al., 1995).

The measurement of F_2-IsoPs can also be employed to examine the oxidation status of transgenic animals. For instance, Pratico et al. (1998b) demonstrated that apolipoprotein E–deficient mice, which developed severe atherosclerotic disease, also showed marked increases in plasma F_2-IsoP levels. Dietary supplementation with the antioxidant α-tocopherol prevented the increase in plasma F_2-IsoP levels, and reduced atherosclerosis in these animals. Increases in F_2-IsoPs have been observed in animal models of disease in nearly every organ. Using the brain as an example, increased F_2-IsoP levels have been described in mice subjected to a vast array of neurological insults, including amyloid precursor protein overexpression (Pratico et al. 2001), intracerebroventricular lipopolysacharide injection (Montine et al., 2002a), kainate-induce seizures (Patel et al., 2001; Montine et al., 2002a), and cerebral ischemic injury (Marin et al., 2000). Taken together, these studies suggest that quantification of F_2-IsoPs in animal models of oxidant injury represents an accurate method to assess lipid peroxidation in vivo.

F_2-ISOPROSTANE FORMATION IN HUMAN DISEASES

From the above examples, measurement of IsoPs appears to be a reliable index of lipid peroxidation in vivo and thus potentially provides a tool to assess the role of oxidative stress in the pathophysiology of human disease. Elevations of IsoPs in human body fluids and tissues have been found in a diverse array of human disorders (Table 17.5.1). For purposes of this brief review, the authors have chosen to discuss IsoP formation in several human diseases in which their generation has been examined in some detail, namely atherosclerosis and Alzheimer's disease. For a more detailed discussion of these and other disorders, the reader is referred to the cited references in Table 17.5.1.

Atherosclerotic Cardiovascular Disease

The association between various risk factors for atherosclerosis and enhanced IsoP generation has been extensively explored, and it was found that IsoP formation is increased in humans with these risk factors. These data suggest that enhanced oxidant stress may play a role in the development of atherosclerosis, although the mechanisms involved have not been

Smoking	Morrow et al., 1995

elucidated. Although trials with antioxidants have generally failed to show benefit in the prevention of heart disease in humans, there is still considerable evidence to support the hypothesis that oxidative stress is intimately involved in atherosclerosis.

A link between cigarette smoking and the risk of cardiovascular disease is well established (Kannel, 1981). However, the underlying mechanism(s) for this effect is not fully understood. The gaseous phase of cigarette smoke contains a number of oxidants and exposure of LDL to the gaseous phase of cigarette smoke in vitro induces oxidation of the LDL lipids (Frei et al., 1991). Thus, the hypothesis that smoking induces an oxidative stress by examining F_2-IsoP levels in plasma from smokers was explored. Ten individuals who smoked heavily (>30 cigarettes/day) and ten age and sex matched non-smoking normal volunteers were studied (Morrow et al., 1995). Plasma concentrations of free and esterified F_2-IsoPs were significantly elevated in the smokers compared to the non-smokers ($p = 0.02$ and $p = 0.03$, respectively). In all subjects, levels of F_2-IsoPs both free in the circulation and esterified to plasma lipoproteins were significantly reduced following 2 weeks of abstinence from smoking ($p = 0.03$ and $p = 0.02$, respectively). The occurrence of enhanced formation of IsoPs in smokers has also subsequently been confirmed in studies by other groups (Reilly et al., 1996). Collectively, these findings suggest strongly that smoking causes an oxidative stress and the observation that smokers have elevated levels of F_2-IsoPs esterified in plasma lipids also supports the hypothesis that the link between smoking and risk of cardiovascular disease may be attributed to enhanced oxidation of lipoproteins.

It has been well established that patients with hypercholesterolemia have an increased

risk for the development of atherosclerosis. Thus, it was of interest to determine whether levels of F_2-IsoPs are increased in patients with this condition.

Levels of F_2-IsoPs esterified in plasma lipids were determined in patients with polygenic hypercholesterolemia (Roberts and Morrow, 1999). Levels in patients with hypercholesterolemia were found to be significantly increased by a mean of 3.4-fold (range 1.7- to 7.5-fold) above levels measured in normal controls ($p < 0.001$). Interestingly, in these patients, there was no correlation between levels of F_2-IsoPs and serum cholesterol, triglycerides or LDL-cholesterol. In addition, plasma arachidonic acid content was measured in these patients and normal controls. Again, no correlation between IsoP and arachidonate levels was found. Thus, these data suggest that the finding of high levels of F_2-IsoPs in patients with hypercholesterolemia is not due simply to the presence of more lipid, i.e., arachidonic acid substrate. Rather, it is suggested that hypercholesterolemia is associated with enhanced oxidative stress. The underlying basis for this observation, however, remains unclear. Interestingly, a report also found that the urinary excretion of F_2-IsoPs was also increased in patients with Type II hypercholesterolemia by a mean of 2.5-fold, which was suppressed by ~60% with vitamin E treatment (600 mg/day; Davi et al., 1997).

Patients with diabetes are known to have an increased incidence of atherosclerotic vascular disease. Furthermore, the formation of F_2-IsoPs has been found to be induced in vascular smooth muscle cells by hyperglycemia (Natarajan et al., 1996). Thus, a link between enhanced oxidative stress in vivo and diabetes has been explored. Gopaul et al. (1995) reported a mean 3.3-fold increase in free F_2-IsoPs in plasma from diabetic patients compared to non-diabetic healthy control subjects. A later report demonstrated that plasma F_2-IsoP levels increased significantly within 90 min during acute hyperglycemia in type 2 diabetic patients (Sampson et al., 2002). In addition, Davi et al. (1999) reported that elevated urinary F_2-IsoP levels in diabetic patients could be suppressed by vitamin E supplementation or glycemic control.

High plasma levels of homocysteine are an independent risk factor for cardiovascular disease (Boushey et al., 1995). The mechanism by which hyperhomocysteinemia induces atherosclerosis is not fully understood but promotion of LDL oxidation has been suggested. The relationship between total plasma concentrations of homocysteine and F_2-IsoPs in 100 Finnish male participants in the Antioxidant Supplementation in Atherosclerosis Prevention study has been explored (Voutilainen et al., 1999). The mean plasma total homocysteine and F_2-IsoP concentrations were 11.1 μmol/liter and 29.6 ng/liter, respectively. The simple correlation coefficient for the association between plasma concentrations of homocysteine and F_2-IsoPs was 0.40 ($p < 0.0001$). Plasma concentrations of F_2-IsoPs increased linearly across quintiles of homocysteine levels. The finding of a positive correlation between plasma concentrations of F_2-IsoPs and homocysteine supports the suggestion that the mechanism underlying the link between high homocysteine levels and risk for cardiovascular disease may be attributed to enhanced lipid peroxidation.

In accordance with the LDL oxidation hypothesis of atherosclerosis, levels of F_2-IsoPs should be higher in atherosclerotic plaques than in normal vascular tissue. To address this issue, levels of F_2-IsoPs were measured in fresh advanced atherosclerotic plaque tissue removed during arterial thrombarterectomy ($n = 10$) and compared with levels measured in normal human umbilical veins removed from the placenta immediately after delivery ($n = 10$) (Gniwotta et al., 1997). Levels of F_2-IsoPs esterified in vascular tissue normalized to both wet weight and dry weight were significantly higher in atherosclerotic plaques compared to normal vascular tissue. When the data was normalized to arachidonic acid content, the F_2-IsoP/arachidonic acid ratio was about four-fold higher than the ratio in normal vascular tissue ($p = 0.009$). This finding indicates that unsaturated fatty acids in atherosclerotic plaques are more extensively oxidized than lipids in normal vascular tissue. These observations are also in accord with data from FitzGerald and colleagues who have shown increased amounts of F_2-IsoPs in human atherosclerotic lesions including the localization of F_2-IsoPs in atherosclerotic plaque tissue to foam cells and vascular smooth muscle cells (Pratico et al., 1997).

Alzheimer's Disease

Oxidative stress has been implicated in the pathogenesis of numerous neurodegenerative conditions, including Alzheimer's Disease (AD). Regional increases in oxidative damage and lipid peroxidation have been described in brain tissue obtained post mortem from patients with AD (Markesbery, 1997). Similarly,

F_2-IsoP levels are significantly elevated in affected regions of post-mortem brain samples from AD patients as compared to controls (Reich et al., 2001a). However, an objective index of oxidative damage associated with AD that can be assessed in living patients is lacking. Such a biomarker could be vital for understanding the role of oxidative damage in AD patients by permitting repeated evaluation of disease progression or responses to therapeutic interventions. Toward such a goal, the authors obtained post-mortem ventricular fluid from eleven patients with a pathological diagnosis of AD and eleven control patients, in order to evaluate F_2-IsoP levels in cerebrospinal fluid (CSF; Montine et al., 1998). All subjects participated in a rapid autopsy protocol such that fluid was collected within 3 hr of death. F_2-IsoP levels were significantly increased in ventricular fluid from AD patients (72 ± 7 pg /ml, mean $\pm$ S.E.M.) compared to CSF from control individuals (46 ± 4 pg/ml, $p < 0.01$), and correlations were identified between increases in IsoP levels and higher Braak stage and decreased brain weight, two indices of AD severity. In a larger study, the authors have shown that CSF F_2-IsoP level correlates with the extent of pathological neurodegeneration but not with density of neuritic plaques or neurofibrillary tangles (Montine et al., 1999a; Reich et al., 2001b).

Subsequently, the authors undertook a study to examine CSF F_2-IsoP levels in living patients with probable AD (Montine et al., 1999b). CSF was obtained from the lumbar cistern in 27 patients with AD and 25 controls without neurodegenerative disorders matched for age and gender. In keeping with post-mortem studies, lumbar CSF levels of F_2-IsoPs were significantly increased (31.0 ± 2.6 pg/ml) in AD patients compared to control subjects (22.9 ± 1.0 pg/ml, $p < 0.05$). Pratico et al. (2000) have also observed increased F_2-IsoPs in CSF of patients with probable AD, as well as in patients with mild cognitive impairment (MCI), a condition which precedes symptomatic dementia in AD (Pratico et al., 2002). However, this group also reports increased F_2-IsoPs in plasma and urine of both MCI and AD patients, though the authors' laboratory and others have not been able to detect these changes in peripheral F_2-IsoPs (Montine et al., 2002b; Bohnstedt et al., 2003). Taken together, these studies suggest that quantification of IsoPs in cerebrospinal fluid of patients with Alzheimer's disease may be of use as an intra vitum index of disease progression or as a tool to monitor response to therapy.

CONCLUSIONS

The discovery of IsoPs as products of non-enzymatic lipid peroxidation has been a major breakthrough regarding the quantification of oxidant stress in vivo. The quantification of these molecules has opened up new areas of investigation regarding the role of free radicals in human physiology and pathophysiology, and appears to be the most useful tool currently available to explore the role of free radicals in the pathogenesis of human disease. Although considerable information has been obtained since the initial discovery of IsoPs, much remains to be understood about the role of these molecules as markers of oxidant stress. It is anticipated that additional research in this area will continue to provide important insights into the role of oxidative stress in human disease.

Quantification of F_2-Isoprostanes by Gas Chromatography/Mass Spectrometry as a Measure of Oxidant Stress

This unit outlines methods to assess lipid peroxidation associated with oxidant injury in vivo by quantifying concentrations of either esterified or free F_2-isoprostanes (F_2-IsoPs). Quantification of these compounds overcomes many of the shortcomings associated with other assays of oxidant stress, especially in humans in vivo. Thus, measurement of F_2-IsoPs likely represents an important advancement in the ability to assess the role of oxidative stress in human disease (Fam and Morrow, 2003). The techniques employed for the analysis of F_2-IsoPs from biological sources that are detailed herein utilize mass spectrometric approaches. Procedures are outlined for the analysis of both F_2-IsoPs esterified to tissue phospholipids (see Basic Protocol 1) and free F_2-IsoPs (see Basic Protocol 2). In addition, quantification of F_2-IsoPs esterified in plasma lipids is also detailed (see Alternate Protocol).

NOTE: All inorganic solvents should be high purity HPLC or GC grade. All reagents/chemicals should be ACS certified or equivalent grade.

QUANTIFICATION OF F_2-ISOPROSTANES IN TISSUE LIPIDS

BASIC PROTOCOL 1

F_2-IsoPs from biological sources can only be quantified as free compounds using gas chromatography (GC)/mass spectrometry (MS) (Morrow and Roberts, 1999) Thus, to measure levels of these compounds esterified to phospholipids, the phospholipids are first extracted from the tissue sample and subjected to alkaline hydrolysis to release free F_2-IsoPs. Free F_2-IsoPs are then quantified using the same procedure for the measurement of free compounds in biological fluids (see Alternate Protocol). This protocol outlines the extraction and hydrolysis of F_2-IsoPs from tissue lipids.

The assay described herein is applicable to all animal and human tissues and cell samples. Preparation of phospholipid-containing biological fluids, such as plasma, differs slightly (see Alternate Protocol). To measure free F_2-IsoPs from low-protein fluids (such as urine or low-serum cell medium) that do not require lipid extraction, see Basic Protocol 2.

Materials

Fresh or frozen tissue
Folch solution (see recipe)
Butylated hydroxytoluene (BHT; Aldrich)
Nitrogen or argon source
0.9% (w/v) aqueous sodium chloride (NaCl; high purity; EMD Biosciences) prepared in ultrapure water
Methanol (high-quality; Burdick and Jackson or VWR Scientific) containing 0.005% (v/v) BHT
15% (w/v) aqueous potassium hydroxide (KOH pellets; high purity; EMD Biosciences) prepared in ultrapure water
1 N HCl (American Chemical Society certified or equivalent grade)
50-ml conical, polypropylene centrifuge tubes
Blade homogenizer (PTA 10S generator, Brinkman Instruments)
Table-top centrifuge
Analytical evaporation unit (Organomation Associates)
37°C water bath

Contributed by Erik S. Musiek and Jason D. Morrow
Current Protocols in Toxicology (2005) 17.6.1-17.6.9

1. Weigh out 0.05 to 1 g of either fresh tissue or tissue frozen at −70°C.

   If the sample weighs <0.15 g, the volume of Folch solution in step 2 and the volume of aqueous NaCl in step 5 can be reduced by half.

2. Add tissue to 20 ml of ice-cold Folch solution containing 0.005% (v/v) BHT in a 50-ml centrifuge tube with cap. Keep on ice.

   Polypropylene tubes are recommended, as polystyrene is not resistant to chloroform.

3. Homogenize tissue with blade homogenizer 30 sec at maximum speed or until fully homogenized. Keep on ice.

4. Purge airspace in centrifuge tube with nitrogen or argon, then cap. Let solution stand 1 hr at room temperature to allow maximal extraction of lipids from ground tissue. Shake tube occasionally for several seconds during this period of time.

5. Add 4 ml of 0.9% aqueous NaCl. Vortex or shake vigorously for 1 min at room temperature.

6. In a table-top centrifuge, centrifuge 10 min at 800 × *g*, room temperature, to separate aqueous and organic layers.

   Following centrifugation, a semi-solid protein layer should have formed between the upper (aqueous) and lower (organic) layers.

7. After centrifugation, carefully pipet off top aqueous layer and discard. Remove the lower organic layer carefully from under the intermediate semi-solid protein aqueous layer and transfer to a 50-ml conical centrifuge tube. Evaporate under nitrogen stream in an analytical evaporation unit to dryness.

8. Hydrolyze F_2-IsoPs from phospholipids by adding 4 ml methanol containing 0.005% BHT and vortex to resuspend lipids, then add 4 ml of 15% aqueous KOH. Purge tube with nitrogen and cap.

   If sample originally weighed <0.15 g, lipid extract can be resuspended in 1 ml methanol containing 0.005% BHT, to which 1 ml of 15% aqueous KOH is added.

9. Incubate mixture 20 min in a 37°C water bath.

10. After incubation, acidify the mixture to pH 3.0 with 1 N HCl. Then dilute the mixture to 80 ml with ultrapure water (pH 3.0) in preparation for extraction of free F_2-IsoPs (see Alternate Protocol).

    It is important to dilute the methanol in this solution to ≤5% to ensure proper column extraction of F_2-IsoPs in the subsequent purification procedure.

ALTERNATE PROTOCOL

EXTRACTION OF LIPIDS FROM PHOSPHOLIPID-CONTAINING BIOLOGICAL FLUIDS

The technique used to extract F_2-IsoP-containing phospholipids from biological fluids, e.g., plasma, differs somewhat from methods used for tissue. The authors have found that arachidonic acid in plasma is much more susceptible to autoxidation during lipid extraction than arachidonate in tissue samples. Thus, to suppress ex vivo oxidation of arachidonic acid in plasma, triphenylphosphine (TPP), in addition to BHT, is added to the Folch solution (Morrow and Roberts, 1999).

Additional Materials *(also see Basic Protocol 1)*

Biological fluid, e.g., plasma
Triphenylphosphine (TPP; Aldrich)
0.043% (w/v) magnesium chloride ($MgCl_2$; high purity; EMD Biosciences) in ultrapure water

1. Add 1 ml of biological fluid to 20 ml ice-cold Folch solution containing 0.005% BHT and 5 mg TPP in a 50-ml centrifuge tube. Shake vigorously for 2 min.
2. Add 10 ml of 0.043% $MgCl_2$ and shake vigorously for 1 min. Centrifuge 10 min at 800 × *g*, room temperature.
3. Separate lower organic layer from other layers and transfer to a new 50-ml centrifuge tube.
4. Dry organic layer at room temperature under nitrogen in an analytical evaporator unit.
5. Proceed immediately to hydrolysis procedure (see Basic Protocol 1, step 8).

QUANTIFICATION OF F_2-ISOPS

BASIC PROTOCOL 2

Quantification of F_2-IsoPs by GC/negative ion chemical ionization (NICI) MS is extremely sensitive with a lower limit of detection in the range of 1 to 5 pg using a deuterated internal standard with a [$^2H_0$] blank of <5 ppt (Morrow and Roberts, 1999) Thus, it is usually not necessary to assay >1 to 3 ml of a biological fluid or a lipid extract from >50 to 100 mg of tissue. Furthermore, because urinary levels of F_2-IsoPs are high (typically >1 ng/ml), 0.2 ml of urine was found to be more than adequate to quantify urinary F_2-IsoPs (Morrow et al., 2001). The following assay procedure that is described and summarized in Figure 17.6.1 is the method used for analysis of free F_2-IsoPs in plasma but is equally adaptable to other biological fluids and hydrolyzed lipid extracts of tissues (see Basic Protocol 1).

Materials

Fluid or tissue extract, hydrolyzed
1 N HCl
[$^2H_4$] 15-F_2-IsoP (8-iso-$PGF_{2\alpha}$) internal standard (Cayman Chemical)
C18 Sep-Pak column (Waters)
Methanol (high purity; Burdick and Jackson, VWR Scientific)
pH 3 water (ultrapure filtered, adjusted to pH 3 with ACS-grade HCl)
Heptane (high purity; Burdick and Jackson, VWR Scientific)
Ethyl acetate (high purity; Burdick and Jackson, VWR Scientific)

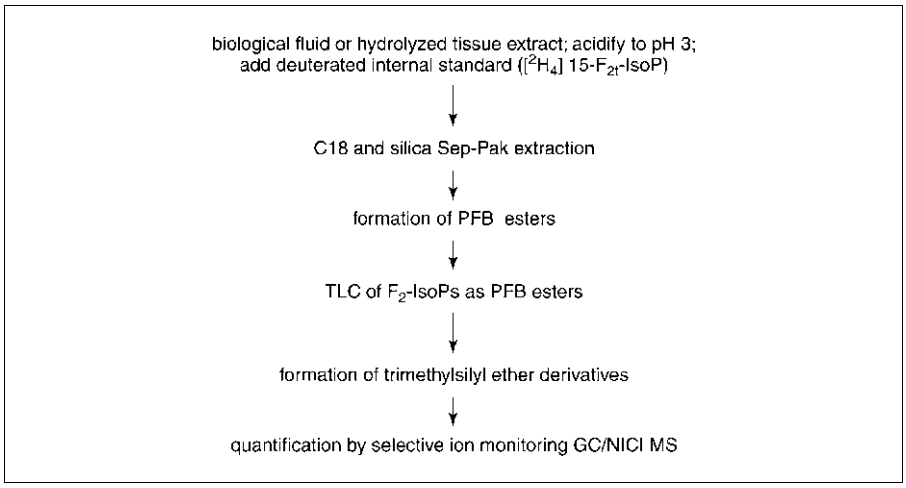

Figure 17.6.1 Outline of the procedures used for the extraction, purification, derivatization, and mass spectrometric analysis of F_2-IsoPs from biological sources.

Na_2SO_4 (anhydrous)
Silica Sep-Pak column (Waters)
10% (v/v) pentafluorobenzyl bromide (PFBB; Sigma-Aldrich) in acetonitrile
10% (v/v) *N*,*N*′-Diisopropylethylamine (DIPE; Sigma-Aldrich) in acetonitrile
Chloroform with ethanol (high purity; Burdick and Jackson, VWR Scientific)
Ethanol (high purity; Burdick and Jackson, VWR Scientific)
$PGF_{2\alpha}$ methyl ester (Cayman Chemical)
10% phosphomolybdic acid (Sigma) solution in ethanol
N,*O*-bis(trimethylsilyl)trifluoroacetamide (BSTFA; Supelco)
Dimethylformamide (DMF; Aldrich)
Undecane (Aldrich)

10-ml disposable plastic syringes
20-ml glass scintillation vials
5-ml Reacti-Vials (Pierce Scientific)
Analytical evaporation unit (Organomation Associates)
37°C water bath
Glass TLC tank and TLC paper
TLC plates (LK6B silica; Whatman)
90°C oven
Dessicator
1.5-ml microcentrifuge tubes
Gas chromatograph/mass spectrometer with capabilities for negative ion chemical ionization (NICI) mass spectrometry (model 6890N, Agilent Technologies or equivalent)
Capillary gas chromatography column (DB-1701, Fisons)

Prepare sample and apply on column

1. Acidify hydrolyzed extract to pH 3 with 1 N HCl.
2. Add 1 to 5 nmol of deuterated [$^2H_4$] 15-F_2-IsoP (8-iso-$PGF_{2\alpha}$) internal standard and vortex.
3. Precondition one C18 Sep-Pak column connected to a 10-ml disposable plastic syringe per sample with 5 ml methanol and then 7 ml pH 3 water.
4. Apply acidified sample mixture to the preconditioned Sep-Pak column.

   Care must be taken when applying the sample to the column to avoid loss of IsoPs. The sample should be pushed through the column at ∼1 to 2 ml/min, such that individual drops emerge from the Sep-Pak. Slightly more vigorous fluid flow is acceptable during the subsequent wash and elution steps, though a steady stream is not recommended.

Wash and elute column

5. Wash column first with 10 ml pH 3 water and then with 10 ml heptane.
6. Elute F_2-IsoPs from column with 10 ml of 50:50 (v/v) ethyl acetate/heptane into a 20-ml glass scintillation vial.
7. Add 5 g anhydrous Na_2SO_4 to the vial and swirl gently.

   This step removes residual water from the eluate.

8. Precondition silica Sep-Pak column with 5 ml ethyl acetate.
9. Apply eluate to silica Sep-Pak in the same manner as in step 3.
10. Wash cartridge with 5 ml ethyl acetate, then elute F_2-IsoPs from silica Sep-Pak with 5 ml of 1:1 (v/v) ethyl acetate/methanol into a 5-ml Reacti-Vial.

11. Evaporate eluate under nitrogen in an analytical evaporation unit.

Samples can be safely stored for up to 1 week at −20°C.

Prepare sample for TLC

12. Convert F_2-IsoPs to pentafluorobenzyl esters (which facilitates GC/MS analysis) by adding 40 µl of 10% PFBB in acetonitrile and 20 µl 10% DIPE in acetonitrile to the Reacti-Vial, vortex briefly, and incubate for 20 min in a 37°C water bath.

13. Prepare TLC tank by adding 97 ml chloroform, 3 ml ethanol, and TLC paper to saturate the tank, and allow to equilibrate for 30 min.

14. Dry sample thoroughly under nitrogen in an analytical evaporation unit in a fume hood and resuspend material in 50 µl methanol. Vortex briefly.

Perform TLC

15. Prewash a silica TLC plate with 90:10 (v/v) ethyl acetate/ethanol. Dry the plate 10 min in a 90°C oven then cool in a dessicator prior to sample application. Apply sample mixture to a lane on the prewashed silica TLC plate. For a TLC standard, apply ~2 to 5 µg of the methyl ester of $PGF_{2\alpha}$ to another TLC lane.

Avoid applying sample to the first 1 cm of the plate (preloading area).

16. Chromatograph to 13 cm. Visualize the TLC standard by spraying the lane with a 10% phosphomolybdic acid solution in ethanol and heating on a hot plate.

Only spray and heat the plate containing the $PGF_{2\alpha}$ standard, not the sample-containing plates. A single band will appear, which can be measured to determine the area to be scraped on the sample-containing plates.

17. Scrape silica from the TLC plate in the region of the methyl ester of $PGF_{2\alpha}$ (R_f = 0.18) and adjacent areas 1 cm above and below.

Extract isoprostanes

18. Place silica in a 1.5-ml microcentrifuge tube and add 1 ml ethyl acetate to extract isoprostanes. Vortex vigorously for 30 sec, then microcentrifuge 3 min at 13,000 rpm at room temperature.

19. Remove the ethyl acetate and place it in a new 1.5-ml microcentrifuge tube, taking care not to disrupt the silica pellet.

Samples can be safely stored for up to 1 week at −20°C.

20. Dry under nitrogen, then add 20 µl BSTFA and 7 µl DMF to residue to covert to trimethylsilyl ether derivatives for GC/MS analysis.

21. Vortex well and incubate sample 20 min at 37°C, then dry reagents under nitrogen.

22. Resuspend in 20 µl undecane and vortex briefly.

Undecane is stored over calcium hydride to prevent water accumulation.

Sample is now ready for mass spectrometric analysis and should be analyzed within 24 hr.

Perform mass spectrometry

23. For quantification of F_2-lsoPs by GC/NICI MS analysis, use an Agilent 6890N mass spectrometer with a computer interface. Chromatograph F_2-IsoPs on a 15-meter DB1701 fused silica capillary column. Program the column temperature from 190°C to 300°C at 20°C/mm. Use methane as the carrier gas for NICI at a flow rate of

1 μl/min. Set the ion source temperature to 250°C, the electron energy to 70 eV, and the filament current to 0.25 mA. Monitor for endogenous F_2-IsoPs using the carboxylate anion m/z 569 (M-181, loss of $CH_2C_6F_5$).

The corresponding carboxylate anion for the deuterated intemal standard is m/z 573.

In the authors' experience, the indicated column produces excellent separation of individual regioisomers compared to other columns.

REAGENTS AND SOLUTIONS

Use ultrapure (triply distilled) water or equivalent in all recipes and protocol steps. For common stock solutions, see ***APPENDIX 2A****; for suppliers, see* ***SUPPLIERS APPENDIX****.*

Folch solution

Combine 2 volumes of high-purity chloroform (containing ethanol as a preservative) with 1 volume of high-purity methanol, both available from Burdick and Jackson or VWR Scientific. Cool to 4°C. Store in dark in a brown bottle to prevent light degradation. Store up to 1 month at −20°C.

COMMENTARY

Background Information

Free radicals derived primarily from oxygen have been implicated in the pathophysiology of a wide variety of human diseases including atherosclerosis, cancer, neurodegenerative disorders, and even the normal aging process (Halliwell and Gutteridge, 1990). Much of the evidence for this, however, is indirect or circumstantial, largely because of limitations of methods that are available to quantify free radicals or the products they produce in biological systems. This is a particular problem when non-invasive approaches are used to assess oxidant injury in animals or humans (Halliwell and Grootveld, 1987; DeZwart et al., 1999).

Measures of lipid peroxidation are frequently utilized to implicate free radicals in pathophysiological processess. These measurements include quantification of short-chain alkanes, malondialdehyde, or conjugated dienes. Each of these, however, suffers from problems related to specificity and sensitivity, especially when utilized to quantify oxidant stress in vivo. Further, artifactual generation of these lipid peroxidation products can occur ex vivo, and factors such as endogenous metabolism can affect levels of compounds measured (DeZwart et al., 1999).

In 1990, the authors reported that a series of prostaglandin (PG)F_2-like compounds, termed F_2-isoprostanes (F_2-IsoPs), are produced in vivo in humans by a non-cyclooxygenase free radical–catalyzed mechanism involving the peroxidation of arachidonic acid (Morrow et al., 1990). Formation of these compounds initially involves the generation of four positional peroxyl radical isomers of arachidonic acid; these undergo endocyclization to PGG_2-like compounds that are subsequently reduced to PGF_2-like compounds. Four F_2-IsoP regioisomers are formed, each of which can theoretically be comprised of eight racemic diastereomers.

The authors have accumulated a large body of evidence that suggests that quantification of F_2-IsoPs represents a reliable and useful approach to assess lipid peroxidation and oxidant stress in vivo (see also *UNIT 17.5*). They readily increase in animal models of oxidant stress. Further, concentrations of F_2-IsoPs are present that are easily detected in normal human and animal biological fluids such as plasma and urine (Roberts and Morrow, 2000; Fam and Morrow, 2003). This allows the definition of a normal range, which permits an assessment of small increases in the formation of F_2-IsoPs in settings of mild oxidant stress. In addition, F_2-IsoPs can be detected in virtually every type of biological fluid analyzed thus far including plasma, urine, cerebrospinal fluid, bile, lymph, bronchoalveolar lavage fluid, and synovial fluid (Morrow et al., 2001). Levels of these compounds are also detectable in all types of tissues examined to date. These include liver, kidney, stomach, brain, lung, vascular tissue, muscle, and heart. Thus, the fact that F_2-IsoPs are detectable in various tissues and fluids provides the opportunity to assess the formation of these compounds at local sites of oxidant injury. Finally, F_2-IsoPs are increased in a number of human disorders associated with enhanced oxidant stress (Roberts and Morrow, 2000; Fam and Morrow, 2003).

The precursor of the F_2-IsoPs is arachidonic acid. The vast majority of arachidonic acid present in vivo exists esterified to phospholipids. Previously, the authors reported the novel finding that F_2-IsoPs are initially formed in situ from arachidonic acid esterified to phospholipids and then subsequently released in the free form by phospholipases (Morrow et al., 1992). This observation provides the basis for an important concept regarding the assessment of isoprostane formation in vivo in that when isoprostane generation is quantified, total production of F_2-IsoPs may be more accurately assessed by measuring levels of both free and esterified compounds. Furthermore, the fact that F_2-IsoPs are formed in situ in phospholipids can be utilized in an advantageous way to assess oxidant injury in specific animal or human organs by analyzing levels of these compounds esterified in phospholipids from tissue biopsy specimens obtained for diagnostic purposes.

Critical Parameters and Troubleshooting

Considerable care must be taken when harvesting and handling samples to prevent the artifactual ex vivo generation of F_2-IsoPs (Morrow and Roberts, 1997). F_2-IsoPs can be generated artifactually in arachidonate-containing biological fluids that remain >2 hr at room temperature, or stored at −20°C. However, storage of samples at −70°C prevents ex vivo oxidation and maintains sample integrity for at least 5 years. Ex vivo formation of F_2-IsoPs does not occur if samples are processed immediately after procurement or if BHT (and TPP in the case of arachidonate-rich fluids such as plasma) is added to the organic solvent during lipid extraction (Morrow and Roberts, 1997). Hydrolysis of lipids in tissues or biological fluids should be performed immediately after lipid extraction to avoid potential autoxidation of arachidonate contained in the phospholipids. In addition, artifactual generation of F_2-IsoP can also occur during sample preparation if reagents contain significant trace metal contamination. Thus, reagents should be of very high purity. The quality of water used during lipid extraction is extremely important. The authors routinely use triply distilled water or its equivalent. Finally, all glassware and plasticware should be rinsed with ultrapure (triply distilled) water prior to use (Morrow and Roberts, 2002).

During sample workup, there are several points in the assay during which tissue or fluid extracts can be safely stored overnight at −70°C. These include (1) following elution from the silica Sep-Pak in Basic Protocol 2, step 10, and (2) following extraction from silica after TLC purification in Basic Protocol 2, step 19.

A common problem encountered when performing this assay occurs after derivatization of F_2-IsoPs to trimethylsilyl ethers. These derivatives are readily hydrolyzed upon exposure to very small amounts of water. Loss of the trimethylsilyl ethers will result in a lack of detectable signal at the correct molecular weight when analyzed by MS. Should this occur, the sample should be dried under nitrogen and rederivatized and analyzed immediately.

Quantification by GC/negative ion chemical ionization (NICI) MS is an extremely sensitive method to quantify the F_2-IsoPs (Morrow and Roberts, 1999). The lower limits of detection of F_2-IsoPs is in the range of 1 to 5 pg using a deuterated standard with a blank of <5 ppt. Thus, it is not necessary to assay >1 to 3 ml of a fluid such as plasma, 0.2 ml urine, or 50 to 100 mg tissue.

It should be noted that the method outlined herein is one of several GC/MS techniques that have been developed by investigators to quantify F_2-IsoPs. The other assays utilize very similar purification and derivatization approaches although they quantify different F_2-IsoP regioisomers including $iPF_{2\alpha}$-I and $iPF_{2\alpha}$-VI (Lawson et al., 1998; Pratico et al., 1998). In addition, IsoPs can be quantified by liquid chromatography/MS and immunoassay although neither of these methods may be as sensitive or accurate as GC/MS (Fam and Morrow, 2003; Liang et al., 2003).

Anticipated Results

Figure 17.6.2 shows the selected ion current chromatogram obtained from the analysis of F_2-IsoPs in plasma from a rat after treatment with CCl_4 to induce an oxidant stress. The series of peaks in the upper m/z 569 selected ion current chromatogram represents different endogenous F_2-IsoPs. This pattern of peaks is virtually identical to that obtained from all other biological fluids and tissues that the authors have examined to date. In the lower m/z 573 chromatogram, the single peak represents the [$^2H_4$] 15-F_{2t}-IsoP internal standard that was added to the plasma sample. For quantification purposes, the peak denoted by an asterisk (*), which co-elutes with the 15-F_{2t}-IsoP internal standard, is routinely measured. Using the ratio of the intensity of this peak to that of the internal standard, the concentration of F_2-IsoPs was calculated to 742 pg/ml, ~36-fold above normal. The normal plasma

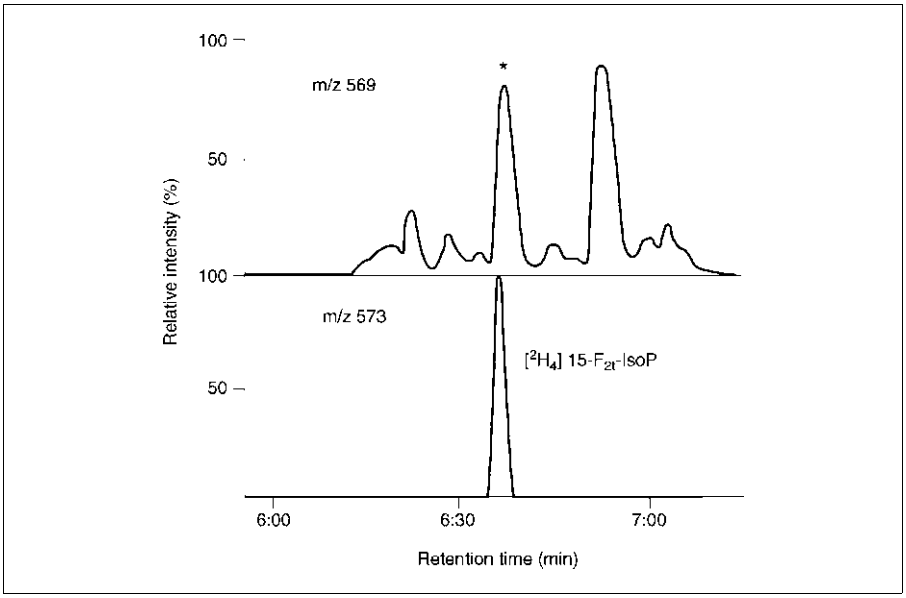

Figure 17.6.2 Analysis of F_2-IsoPs in plasma obtained from a rat 4 hr after treatment with CCl_4 (2 ml/kg orogastrically) to induce endogenous lipid peroxidation. The m/z 569 ion current chromatogram represents endogenous F_2-IsoPs. The m/z 573 ion current chromatogram represents the [$^2H_4$] 15-F_{2t}-IsoP internal standard. The peak in the upper chromatogram represented by the asterisk (*) is the one routinely used for quantification of the F_2-IsoPs. The concentration of F_2-IsoPs in the plasma using the asterisk (*) peak for quantification was calculated to be 742 pg/ml.

concentration of F_2-IsoPs in rats is 22 ± 4 pg/ml (mean ± 1 SD) and in normal human plasma is 35 ± 6 pg/ml (mean ± 1 SD) The reader is referred to previously published data for normal levels of F_2-IsoPs in other biological fluids and tissues (Morrow et al., 2001). Quantification of the F_2-IsoPs based on the intensity of the asterisk (*) peak shown in Figure 17.6.2 is highly precise and accurate. The precision is ± 6% and the accuracy is 96%.

Time Considerations

In general, 15 to 20 samples per day can be processed by an experienced investigator. Lipid extraction and hydrolysis of this number of samples requires ~3 hr, Sep-Pak purification requires ~1.5 hr, drying, derivatization, and TLC purification require ~2 hr, and extraction, drying, and silylation require 1 hr. Mass spectrometric analysis is automated and each sample requires ~15 min of machine time.

Immuno-Spin Trapping: Detection of Protein-Centered Radicals

Protein-centered radicals are involved in biological oxidative damage induced by drugs, environmental hazards, and cellular reactive oxygen species. They can be generated by, among others, hydrogen peroxide (H_2O_2)-induced hemoprotein- or metal-catalyzed protein oxidations (Fig. 17.7.1). Because of their paramagnetic properties, these radicals can be detected and analyzed by direct electron spin resonance (ESR; also known as electron paramagnetic resonance, EPR). After a few microseconds or seconds, via mechanisms that are not completely understood, they decay to diamagnetic species (ESR-silent species).

In the presence of spin traps, such as 5,5-dimethyl-1-pyrroline *N*-oxide (DMPO), protein-centered radicals can be trapped to form DMPO-protein radical adducts in which the formation of a new covalent linkage between the spin trap and the protein-centered radical preserves their free radical character. These radical adducts have a longer half-life than their parent radicals, thus DMPO-protein nitroxide radical adducts can also be characterized and studied by ESR. However, after a few seconds or minutes these species also decay to ESR-silent species by reduction or oxidation reactions to hydroxylamine or nitrone adducts, respectively, with preservation of the covalent bridge but not their paramagnetic properties.

In an oxidizing environment, DMPO-protein nitroxide radical adducts decay to stable DMPO-protein radical–derived nitrone adducts, which can be detected and identified by immuno-spin trapping. This new technology combines the specificity and sensitivity of both spin trapping and antigen-antibody interaction and is based on the detection of the nitrone moiety in DMPO-protein radical–derived nitrone adducts by using an antiserum against DMPO (Fig. 17.7.1).

Some of the advantages of using immuno-spin trapping rather than ESR and ESR-spin trapping to detect protein-centered radicals are: (1) the feasibility of applying this technology in any research, clinic, or academic laboratory without needing complicated equipment or specialists in physical chemistry and quantum mechanics, (2) the small quantity of sample required (microgram), and (3) the possibility of detecting more than one protein-centered radical in the same system and determining their approximate molecular weights. Moreover, day-to-day immuno-spin trapping is proving to be a

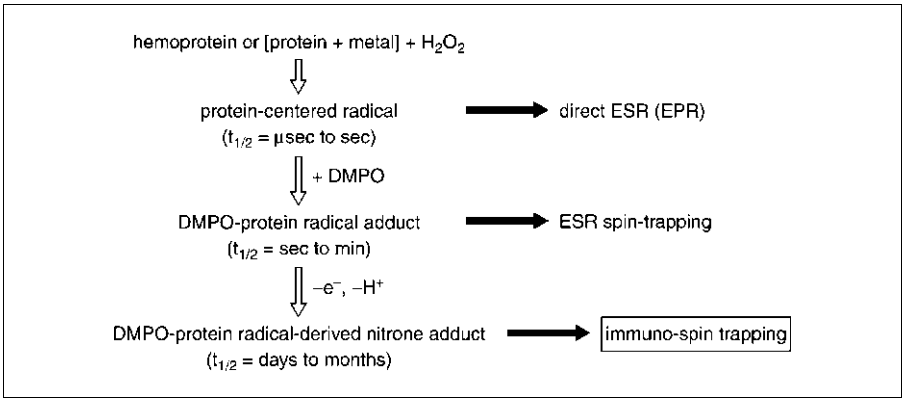

Figure 17.7.1 Detection of hydrogen peroxide (H_2O_2)-induced protein-centered radicals.

Current Protocols in Toxicology (2005) 17.7.1-17.7.18

simple, reliable, affordable, sensitive, and specific approach to detecting protein-centered radicals in situ and in real time in vitro, ex vivo, and in vivo, and it could be a powerful tool in toxicological research.

In this unit, protocols for the production and immuno-spin trapping detection of H_2O_2-induced horse heart metmyoglobin (metMb)- and human oxyhemoglobin (oxyHb)-DMPO radical–derived nitrone adducts are described (see Basic Protocols 1 and 2). Immuno-spin trapping assays include enzyme-linked immunosorbent assay (ELISA; *UNIT 18.7*) and immunoblotting to detect and characterize protein-centered radicals as their DMPO-protein radical–derived nitrone adducts.

BASIC PROTOCOL 1

PRODUCTION AND DETECTION OF HEMOPROTEIN-CENTERED RADICALS BY IMMUNO-SPIN TRAPPING ELISA

Enzyme-linked immunosorbent assay (ELISA; *UNIT 18.7*) is a heterogeneous—i.e., requires separation between bound and unbound material in some step(s)—immunochemical technique that allows simultaneous screening of many samples (Tijssen, 1985). In this technique, antigens (nitrone adducts) are bound under alkaline conditions at the bottom of a 96-well microtiter plate through hydrophobic interactions. After coating, unbound material is removed by a wash step with a buffer containing detergent and an inert protein to remove any nonspecific interactions. This step allows removal of any non-protein nitrone adducts that can interfere with the detection of protein nitrone adducts. This represents one of the most important advantages of heterogeneous assays like ELISA compared to homogeneous assays such as ESR-spin trapping.

After the wash step, the first antibody is added. After incubation, nonspecific bound and unbound antiserum is removed by two or three wash steps followed by addition of the secondary antibody labeled with an enzyme. Then, after further incubation, unbound and weak nonspecific interactions are removed by two or three wash steps. Finally, immuno-complexes are detected by adding enzyme substrates that produce luminescence or soluble-colored products that can be detected and measured.

Materials

Metmyoglobin (metMb; USB)
Oxyhemoglobin (oxyHb; Apex Biochemicals)
H_2O_2 (Alfa Aesar)
Chelex-treated sodium phosphate buffer, pH 7.7 (see recipe)
5,5-Dimethyl-1-pyrroline *N*-oxide (DMPO; Alexis Biochemicals)
Chelex-treated sodium phosphate buffer, pH 7.4, containing 1 mM diethylenetriaminepentaacetic acid (DTPA)
PD-10 desalting columns (Amersham Biosciences)
Catalase solution (100 or 500 IU, Roche Applied Bioscience)
Coating buffer (see recipe)
Wash buffer (see recipe)
Blocking buffer (see recipe)
Primary antibody solution (see recipe)
Secondary antibody solution (see recipe)
Chemiluminescence substrate for ELISA (see recipe)
37°C incubator with agitator
96-well white microtiter plates (e.g., Greiner Bio-One, PGC)
Automated microtiter plate washer (optional)
Multichannel pipettor
Luminescence reader for microtiter plates or strips (optional)

Table 17.7.1 Extinction Coefficients of Reagents

Reagent (abbreviation)	Supplier	Extinction coefficient
DMPO[a]	Alexis Biochemicals	$\varepsilon_{228} = 7800\ M^{-1}\ cm^{-1}$
H_2O_2	Alfa Aesar	$\varepsilon_{240} = 43.6\ M^{-1}\ cm^{-1}$
Metmyoglobin (metMb)	USB	$\varepsilon_{406} = 154\ mM^{-1}\ cm^{-1}$
Oxyhemoglobin (oxyHb)[b]	Apex Biochemicals	$\varepsilon_{541} = 13.8\ mM^{-1}\ cm^{-1}$

[a]Purified by vacuum sublimation at room temperature and stored under an argon atmosphere at −70°C.

Prepare DMPO-protein radical-derived nitrone adducts (i.e., sample to analyze)

1. Prepare hemoprotein [metmyoglobin (metMb) and oxyhemoglobin (oxyHb)] solutions by completely dissolving metMb or diluting oxyHb in 500 µl of Chelex-treated sodium phosphate buffer, pH 7.7, at room temperature. Pour solutions of metMb and oxyHb through PD-10 desalting columns to eliminate any preservatives and collect the colored eluate. Immediately before use, prepare 10× stock solutions of the reagents necessary to produce DMPO-protein radical-derived nitrone adducts (e.g., hemoprotein, H_2O_2, and DMPO) by using known extinction coefficients (see Table 17.7.1). Prepare all stock solutions in Chelex-treated sodium phosphate buffer and keep on ice until use.

   MetMb and oxyHb solutions are brown and red solutions, respectively. Hemoprotein stock solutions can be stored for 1 day at 4°C before use without significant variation in results.

   Typical reagent concentrations used in immuno-spin trapping experiments can be found in Figures 17.7.2 to 17.7.6 (also see Anticipated Results).

2. Prepare the reaction mixture by adding 30 µl of a 10× stock solution of hemoprotein (metMb or oxyHb) to 210 µl Chelex-treated sodium phosphate buffer containing 1 mM DTPA, at room temperature. Then, add 30 µl of 10× DMPO stock solution and start reaction by adding 30 µl of freshly prepared 10× H_2O_2 stock solution.

3. Incubate reaction mixture 1 hr at 37°C with agitation. Stop reaction by removing excess H_2O_2 with 10 µl of 100 IU/ml catalase solution.

   Under these conditions DMPO-protein radical-derived nitrone adducts are formed and are ready to be measured by ELISA.

   After the chemical reaction and before analysis, it is prudent, but not necessary, to eliminate excess reagent (e.g., DMPO and H_2O_2) by dialysis using a membrane with a cut-off appropriate for the molecular weight of the protein under analysis. Dialysis of the reaction mixture (300 µl) may be performed using a 0.1- to 0.5-ml Slide-A-Lyzer dialysis cassette (Pierce) against 2 liters of Chelex-treated sodium phosphate buffer, pH 7.4, containing 1 mM DTPA at 4°C with three changes of buffer.

   After stopping the reaction with catalase or elimination of reagent excess by dialysis, DMPO-protein radical-derived nitrone adducts can be stored up to 3 weeks at 4°C or up to 6 months at –20°C.

   Protein-centered radicals have been detected in many systems containing protein-redox active metals and peroxides. Consequently, careful selection of the conditions for preparing the nitrone adducts is a key factor for success.

Bind DMPO-protein radical-derived nitrone adducts to ELISA plates

4. Add 190 µl coating buffer and 10 µl (~0.5 to 3 µg proteins) experimental and control samples to each well of a 96-well white microtiter plate. Incubate plate 60 min at room temperature to allow samples to bind to the plate.

High protein binding microtiter plates are recommended. The authors use 96-well white microtiter plates.

Typically, 0.5 to 3 μg of protein are used for ELISA analysis of DMPO-protein radical–derived nitrone adducts.

5. Wash plate one time with 300 μl wash buffer in each well and incubate plate for 10 min at room temperature. Remove wash buffer.

   For more reproducible results, the authors recommend using multichannel pipettors and an automated microtiter plate washer. However, if an automated plate washer is not available, washing steps can be performed as follows without significant variations in the results: add 300 μl of wash buffer to each well and incubate the plate for 5 min in an orbital shaker. Remove the wash buffer by aspirating with a multichannel pipettor, being careful not to touch the bottom of the wells, or by inverting and shaking the plate. Repeat wash buffer addition, incubation, and evacuation two or three additional times. Remove the excess wash buffer from the last wash step by inverting the plate on paper towels. Do not let the plate dry.

6. Add 200 μl blocking buffer to each well and incubate the microtiter plate 60 min at room temperature.

7. Repeat step 5.

Detect antigen

8. Add 200 μl primary antibody solution to each well and incubate 60 min at 37°C to allow the antibodies to recognize and bind to the DMPO-protein radical–derived nitrone adducts.

9. Repeat step 5 three times.

   This step removes the unbound primary antibody.

10. Add 200 μl of the secondary antibody solution and incubate microtiter plate 60 min at 37°C to allow the secondary antibody to recognize and bind to the primary antibody.

11. Repeat step 5 three times.

Detect antigen-antibody complexes

12. Add 200 μl chemiluminescence substrate for ELISA and read immediately in a microtiter plate reader equipped with a luminometer.

    Alternatively, other chromogenic substrates for alkaline phosphatase can be used and the absorbance detected by studying the absorbance of its soluble product.

BASIC PROTOCOL 2

PREPARATION AND IMMUNOBLOT ANALYSIS OF DMPO-PROTEIN RADICAL–DERIVED NITRONE ADDUCTS

The authors use ELISA to quantify protein radical–derived nitrone adduct generation, but to study and identify any structural effect on the protein (e.g., aggregation or fragmentation), immunoblot analysis, which also provides an approximate molecular weight for the DMPO-protein radical–derived nitrone adduct(s), is used. Although less sensitive than ELISA, immunoblotting is the only immunochemical analysis that allows for the investigation of more than one protein-centered radical adduct in the same system (see Anticipated Results) or in complex mixtures such as cellular environments (Ramirez et al., 2003) or tissue homogenates (Detweiler et al., 2002). Once protein-centered radicals are detected, the corresponding band in gels stained by Coomassie blue can be cut, digested, and analyzed by mass spectrometry to identify the protein and even the residue where DMPO is bound, i.e., where the radical was produced (Deterding et al., 2004).

Materials

Metmyoglobin (metMb; USB)
H_2O_2 (Alfa Aesar)
Oxyhemoglobin (oxyHb; Apex Biochemicals)
5,5-Dimethyl-1-pyrroline *N*-oxide (DMPO; Alexis Biochemicals)
Chelex-treated sodium phosphate buffer, pH 7.4, containing 1 mM diethylenetriaminepentaacetic acid (DTPA)
PD-10 desalting columns (Amersham Biosciences)
Catalase solution (100 or 500 IU, Roche Applied Bioscience)
4× NuPage LDS sample buffer (Invitrogen)
10× NuPAGE sample reducing agent (Invitrogen)
4% to 12% NuPAGE Novex Bis-Tris gel (1.0-mm, 10-well; Invitrogen)
Running buffer (see recipe)
Nitrocellulose membranes (0.45-μm pore size, Invitrogen)
Transfer buffer (see recipe), cold
0.1% (w/v) Ponceau S red in 4% (v/v) acetic acid
Blocking buffer (see recipe)
Wash buffer (see recipe)
Primary antibody solution (see recipe)
Secondary antibody solution (see recipe)
TBS, pH 9.6 (see recipe)
Chemiluminescence substrate for westernblots (see recipe)
1-Step NBT/BCIP reagent (Pierce)

37°C incubator with agitator
70° to 80°C water bath
Mini electrophoresis system (e.g., XCell SureLock Mini-Cell system, Invitrogen)
Mini-gel blot module (e.g., XCell II Blot Module, Invitrogen)
X-ray film (e.g., CL-XPosure film, Pierce)

Prepare DMPO-protein radical-derived nitrone adducts (i.e., the sample to analyze)

1. Prepare 10× stock solutions of reagents [i.e., metmyoglobin (metMb), oxyhemoglobin (oxyHb), DMPO, and H_2O_2]. Completely dissolve metMb or dilute oxyHb solution in 500 μl of Chelex-treated sodium phosphate buffer, pH 7.4, at room temperature. Pour solutions of metMb and oxyHb through PD-10 desalting columns (equilibrated with distilled water) to eliminate any preservatives and collect the colored eluate. Immediately before use, prepare ten times concentrated stock reagent (hemoproteins, H_2O_2, and DMPO) solutions than the final concentrations required in the reaction mixture (see Fig. 17.7.4) in Chelex-treated sodium phosphate buffer by using known extinction coefficients (see Table 17.7.1) and keep on ice until used.

   MetMb and oxyHb solutions are brown and red, respectively. These hemoprotein solutions can be stored for 1 day at 4°C before use without significant variation in results.

2. Prepare the reaction mixture in disposable 1.5-ml microcentrifuge tubes. Add 30 μl of 10× stock solution of hemoprotein (metMb or oxyHb) to 210 μl Chelex-treated phosphate buffer containing 1 mM DTPA at room temperature. Then add 30 μl of 10× stock DMPO solution and start reaction by adding 30 μl of freshly prepared 10× H_2O_2 stock solution.

3. Incubate reaction mixture 1 hr at 37°C with agitation. Stop reaction by removing excess H_2O_2 with 10 μl of 500 IU/ml catalase solution.

   Under these conditions, DMPO-protein radical-derived nitrone adducts are formed and are ready to be resolved by SDS-PAGE.

It is recommended to eliminate excess reagent (i.e., DMPO and H_2O_2) by dialysis. Dialysis of the reaction mixture (300 μl) is performed using a 0.1- to 0.5-ml Slide-A-Lyzer dialysis cassette (Pierce) against 2 liters of Chelex-treated sodium phosphate buffer, pH 7.4, containing 1 mM DTPA at 4°C with three changes of buffer.

After stopping the reaction with catalase or eliminating reagent excess by dialysis, DMPO-protein radical-derived nitrone adducts can be stored for 3 weeks at 4°C or up to 6 months at –20°C.

Protein-centered radicals have been detected in many systems containing protein-redox active metals and peroxides. Consequently, careful selection of the conditions for preparing the nitrone adducts is a key factor for success.

Prepare sample to resolve by SDS-PAGE

4. Mix 30 μl of reaction mixture, 10 μl of 4× NuPage LDS sample buffer, and 4 μl of 10× NuPAGE sample reducing agent.

   In place of the NuPAGE sample reducing agent, 4 μl of fresh 0.5 M dithiotreitol (DTT) solution can be used with similar results.

5. Heat the sample 7 to 10 min in a 70° to 80°C water bath, and then let it cool to room temperature.

6. Load 10 μl sample per lane of a 4% to 12% NuPAGE Novex Bis-Tris gel.

   The ten-well, 1-mm, 4% to 12% NuPAGE Novex Bis-Tris gels are appropriate for separation of proteins between 3 and 100 kDa and resolve well for proteins used in this protocol. Careful selection of gels is a key factor in successful immuno-spin trapping.

   For better standard-molecular-weight band visualization, the authors add 1 to 3 μl of 1× SeeBlue Plus2 pre-stained standard (Invitrogen) to the first and middle lanes of the gel.

7. Perform protein separation using an electrophoresis system under continuous voltage conditions for 40 min at 200 V with running buffer. Remove the running buffer and add distilled water to cool the gel.

   This step in the procedure permits easier handling of the gel during the following steps.

8. Remove glass or plastic from the gel, cut a piece of nitrocellulose membrane for orientation, and place on top of the gel. Remove any bubbles between membrane and gel by submerging under cool (0° to 4°C) transfer buffer.

   CAUTION: *Acrylamide compounds are neurotoxic and carcinogenic for laboratory animals and humans; consequently, gloves and adequate safety practices must be followed to avoid exposure.*

9. Blot proteins onto nitrocellulose membrane by using a nitrocellulose membrane filter paper sandwich. Perform the transfer in a mini-gel blot module for 20 to 30 min at 40 V.

   Under the buffer conditions used in this process, proteins will migrate from the negative electrode to the positive electrode.

   Those who are unfamiliar with blotting may refer to the NuPAGE Bis-Tris gel instruction manual, where clear instructions on how to assemble the blotting sandwich are provided. This booklet is included in every box of NuPAGE gels and can also be found on the manufacturer's Web site (see Internet Resources).

Stain protein on membrane

10. Transfer the membrane to a clean tray or dish (e.g., weigh boats, pipet tip boxes, or other) and rinse with distilled water.

    To minimize the volume of stains, buffers, and antibody solutions, it is convenient that the tray or dish is only slightly larger than the membrane.

11. Incubate the membrane with 0.1% Ponceau S red in 4% acetic acid for 10 to 30 sec. Wash the membrane with distilled water until red bands (i.e., indication of proteins) appear on a white background, which can then be scanned or photographed.

    The red bands on the membrane will disappear during the blocking process.

    This staining allows for observation of any defects in the blotting process such as poor blotting or diffusion of proteins on the membrane. Usually, the latter is due to the poor quality of sponges used in the transfer sandwich. If this occurs, the authors recommend using new sponges. Sponges should not be used for >20 blotting processes.

    Before immunoblotting, membranes can be stored dry for weeks between pages of a book, or in water if the immunostaining is started the next morning. If stored dry, it is important to rehydrate the membrane for at least 30 min in distilled water at room temperature.

Detect DMPO-protein radical-derived nitrone adducts on membrane by immunoblotting

12. Incubate the membrane with enough volume of blocking buffer to cover the membrane 60 min at room temperature. Remove blocking buffer.

    Typically, the authors use 25 ml of reagents. In the following steps, use enough volume of buffers and solutions to cover the membrane.

13. Cover the membrane with wash buffer and incubate for 10 min at room temperature. Remove wash buffer.

14. Incubate the membrane with primary antibody solution 60 min at room temperature.

15. Repeat step 13 three times.

16. Incubate the membrane with secondary antibody solution 60 min at room temperature.

17. Repeat step 13 three times. After removal of the last wash buffer, cover the membrane with TBS, pH 9.6.

    Incubation of the membrane after the last wash with TBS, pH 9.6, will increase the activity of alkaline phosphatase with a consequent increase in detection sensitivity.

Develop antigen-antibody complexes by using ECL

18. Remove the membrane, place it face up onto a piece of plastic, add 5 ml chemiluminescence substrate for western blots, and incubate for 2 min in the dark.

19. Remove excess reagent by wicking with paper towels without touching the membrane and place the membrane between two pieces of plastic.

    The authors use office plastic folders.

20. Remove the bubbles remaining between the plastic and membrane by rolling with a pipet or pressing them onto a paper towel.

    This procedure also ensures the complete removal of excess liquid.

21. In a dark room, expose membrane to X-ray film.

    Exposure time may vary from a few seconds to a few minutes (or longer), depending upon the amount of antigen to be detected.

22. Develop the X-ray film.

    If desired, the same membrane can be used for colorimetric development of the antigen-antibody complexes (optional).

23. Scan or photograph the membrane to make a permanent record of the results.

Develop antigen-antibody complex by using one-step NBT/BCIP reagent (optional)

Sometimes unexpected problems can occur due to failure of the X-ray film, equipment, or developing reagents. NBT/BCIP development is also a way to keep a good record, but is not necessary.

24. (*Optional*) For membrane used for luminescent development, wash three times, 5 min each, in distilled water with agitation. Finally, wash with 25 ml TBS, pH 9.6, for 5 min.

25. (*Optional*) Add 10 ml 1-Step NBT/BCIP reagent, incubate 15 min or until purple bands are clearly visible, then stop the reaction by washing three times, 5 min each, with distilled water.

26. Scan or photograph the membrane to make a permanent record of the results.

CAUTION: *Use gloves and laboratory clothes when developing antigen-antibody complexes by either method as the reagents can be toxic and carcinogenic.*

REAGENTS AND SOLUTIONS

Use Milli-Q-purified water or equivalent in all recipes and protocol steps. For common stock solutions, see ***APPENDIX 2A****; for suppliers, see* ***SUPPLIERS APPENDIX****.*

Blocking buffer

100 ml coating buffer (see recipe)
2 ml gelatin from cold water fish skin (45% v/v, Sigma)
Mix until total dissolution.
Prepare 1 hr before use to ensure total solubilization

Alternatively, 2.5% (w/v) bovine serum albumin and 2.5% (w/v) casein in coating buffer or SeaBlock (Pierce) can be used without significant variation in results.

Chelex-treated sodium phosphate buffer, 0.1 M (pH 7.4)

Weigh 5 g of Chelex 100 resin (Bio-Rad) in a 1-liter beaker and add 1 liter of water with a magnetic stirrer, stir the resin at low speed (to avoid damaging the resin) for 2 hr at 4°C. Allow the resin to sediment and remove the water. Resuspend the resin in 1 liter of distilled water and allow the resin to wash overnight at 4°C. Repeat this procedure one more time for 2 hr. Then filter the suspension using a 0.45-μm filter and wash the resin with 1 liter of 0.1 M sodium phosphate buffer, pH 7.4, to adjust pH. Filter the excess buffer and add the washed resin to 1 liter phosphate buffer and stir with a magnetic stirrer at slow speed overnight at 4°C. On the next day, filter the treated phosphate buffer to eliminate the resin and add 1 ml of 100 mM DTPA solution (stock) to the filtrate to make 1 liter of Chelex-treated sodium phosphate buffer, pH 7.4, containing 1 mM DTPA.

Chemiluminescence substrate

For ELISA:
Add 50 μl CDP-star (Roche Applied Science) to 50 ml TBS, pH 9.6 (see recipe). Prepare immediately before use in buffer at room temperature and mix well.
For western blot:
Add 50 μl CDP-star to 50 ml TBS, pH 9.6 (see recipe) and 100 μl Nitro-Block II (Tropix). Prepare immediately before use in buffer at room temperature and mix well.

Coating buffer

1.59 g sodium carbonate (Na_2CO_3)
2.93 g sodium bicarbonate ($NaHCO_3$)

continued

0.20 g sodium azide (NaN_3)
Dissolve in 900 ml distilled water, adjust to pH 9.6 with NaOH or HCl and make up to 1 liter
Store up to 1 month at room temperature

In some cases, antigens bound under neutral conditions, such as distilled water or phosphate buffer, give lower backgrounds than bicarbonate buffer. The authors recommend that the coating buffer be optimized to produce the highest signal/background ratio.

Primary antibody solution

Dilute primary anti-DMPO (Alexis Biochemicals, Cayman Chemicals, and Oxford Biomedical Research) antibody 1:5000 in wash buffer (see recipe). Dilute the antiserum immediately before use.

Running buffer

50 ml 20× NuPAGE MES SDS running buffer (Invitrogen)
850 ml distilled water
Prepare immediately before use

Secondary antibody solution

Dilute secondary ImmunoPure goat anti-rabbit IgG (specific to Fc) antibody, alkaline phosphatase–conjugated (Pierce) 1:5000 in wash buffer. Dilute the antiserum immediately before use.

IMPORTANT NOTE: Hemoproteins and metal-protein complexes can catalyze the reduction of H_2O_2 and oxidation of peroxidase substrates with the production of nonspecific signals in ELISA and western blot analysis. Consequently, secondary antiserum conjugated to peroxidases will produce high unspecific signals that are not associated with antigen-antibody interaction, but related to the peroxidase activity of the hemoprotein or metal-protein under analysis.

Tris-buffered saline, 10× (pH 7.4)

30 g TRIZMA base
80 g NaCl
2 g KCl
800 ml distilled water
Adjust to pH 7.4 with concentrated HCl. Bring to 1 liter, and filter sterilize into 100-ml flasks
Store up to 1 month at room temperature

Tris-buffered saline, pH 9.6 (TBS, pH 9.6)

In 800 ml distilled H_2O, add the following:
32 g NaCl
0.8 g KCl
12 g Tris
Adjust to pH 9.6 with 1 M HCl
Bring up to 1 liter with H_2O
Sterilize by filtering through a 0.45-μm filter
Store up to 1 month at room temperature

Transfer buffer

800 ml distilled water
50 ml 20× NuPAGE transfer buffer (Invitrogen)
100 ml methanol
1 ml antioxidant
Add distilled water to make 1 liter
Prepare immediately before use

Wash buffer

100 ml 10× TBS (see recipe)
900 ml distilled water
2 ml cold-water fish gelatin
0.5 ml Tween 20 (USB)
Mix until total dissolution
Store at 4°C and let it reach room temperature before use

Alternatively, 0.25% (w/v) BSA plus 0.25% (w/v) casein acid hydrolyzate in 1× TBS and 0.05% (v/v) Tween 20 can be used in place of fish gelatin.

COMMENTARY

Background Information

A growing field of evidence suggests that free radicals and particularly protein-centered radicals are involved in aging, pathophysiology, and toxicological processes (Berlett and Stadtman, 1997; Dean et al., 1997; Mason, 2000; Hawkins and Davies, 2001). A free radical is an atom or group of atoms possessing one unpaired electron. The unpaired electron gives these species paramagnetic properties that make them suitable for detection by electron spin resonance (ESR). However, because of the high reactivity of protein-centered radicals, they are generally stable for only microseconds to seconds before they decay to ESR-silent species.

In the spin-trapping technique, a reactive radical ($R^{\bullet}$) adds across the double bond of a diamagnetic spin trap (S = T) to form a much more stable free radical, a radical adduct (R-S-$T^{\bullet}$), which can then be examined by electron spin resonance (ESR; Mason, 2000).

$$R^{\bullet} + S = T \rightarrow R\text{-}S\text{-}T^{\bullet}$$

The most popular of these spin traps is 5,5-dimethyl-1-pyrroline *N*-oxide (DMPO).

When DMPO traps a protein-centered radical, a nitroxide radical adduct is formed with a covalent bond between DMPO and the protein (Davies and Hawkins, 2004). This species conserves the unpaired electron of the parental protein-centered radical, resulting in another paramagnetic species that can be studied by ESR (Davies and Hawkins, 2004). The specificity of the reaction between a nitrone spin trap and protein-centered radicals has already made spin trapping with ESR detection the most universal, specific tool for the detection of free radicals (Mason, 2000) and protein-centered radicals (Clement et al., 2001; Davies and Hawkins, 2004) in biological systems. However, ESR and ESR-spin trapping require extensive knowledge of mathematics and physical chemistry and also require complicated equipment, which has limited their application in biomedical laboratories.

The radical adduct is a paramagnetic species that decays (seconds to minutes) by oxidation or reduction to ESR-silent species by mechanisms still not well understood. Although the oxidation of nitroxide radical adducts to the corresponding ESR-silent nitrone adduct has not been well studied (Mason, 2004), once the ESR signal has decayed, nitrone adducts are evidence of earlier radical reactions (Deterding et al., 2004).

Clearly, it would be advantageous to detect markers of protein radical formation without using ESR. A potential alternative to ESR was suggested by flow injection electrospray ionization mass spectrometry (ESI/MS) of the reaction products of myoglobin with H_2O_2 and DMPO. This analysis, performed after the ESR signal disappeared, demonstrated the presence of a myoglobin-derived product with a mass increase of 111 Da. This species corresponded to the addition of DMPO minus two hydrogen ions as expected for the formation of a covalent bond between Mb and DMPO (Detweiler et al., 2002). The persistence of the covalent bond after the radical character of the adduct was lost suggests that the oxidized form, the nitrone moiety, could form the basis of an antigen (Mason, 2004).

The nitrone group does not exist in nature, thus eliminating the possibility of a false-positive from endogenous cellular components. It should be highly antigenic, as is the related nitro group (Mason, 2004). Moreover, the site of DMPO attachment to the protein is a specific marker for where the radical resided. Consequently, an antiserum that recognizes DMPO was developed in the authors' laboratory (Detweiler et al., 2002). To facilitate antiserum production, a DMPO derivative containing an octanoic acid (OA) tail was synthesized, and this DMPO-OA was conjugated to a carrier protein chicken egg albumin for the immunization of rabbits. After the immunization

Table 17.7.2 Troubleshooting Guide to Immuno-Spin Trapping

Problem	Possible cause	Solution
No nitrone adducts are detected by ELISA in a solution of a hemoprotein with peroxidase activity, DMPO, and H_2O_2	No amino acid-centered radical was formed as is the case with horseradish peroxidase	Check if the protein radical has previously been detected by ESR and/or ESR-spin trapping with DMPO. Study a known system to obtain training.
High background/signal ratio in ELISA	Inappropriate blocking buffer	Probe with another blocking protein such as dry milk, casein/BSA, or SeaBlock solution (Pierce).
	DMPO was not purified	Use purified DMPO.
	High amount of protein added to well, producing high nonspecific antiserum binding.	Add a lower amount of protein to each well (typically 0.5 to 3 μg protein/well are enough).
	High nonspecific binding	Increase the number of washes or increase Tween-20 concentration in the washing buffer to 0.1%.
H_2O_2-concentration dependence in the nitrone adducts was observed by ELISA but not by immunoblot analysis	It is possible that DMPO binds nonspecifically to protein radicals formed at the high temperatures used to prepare samples for reducing blots	Dialyze samples before mixing with the sample buffer.
No protein-centered radicals are observed in immunoblot analysis but they were detected by ELISA	Nitrone epitope was modified by the reducing agent	Run the SDS-PAGE under non-reducing conditions or change the reducing agent. The use of 2-ME as a reducing agent (see Anticipated Results; Fig. 17.7.2B) is not recommended.
Diffuse band pattern was observed	If SDS-PAGE was well done, as confirmed by protein staining of the gel, it could be due to a low blot quality; this must be checked immediately after the transfer by using the temporary stain procedure described in the immunoblot protocol	Change sponges, check blotting apparatus in special electrodes.

regime, the rabbits were bled and the serum containing anti-DMPO polyclonal antibodies was collected (Detweiler et al., 2002). This antiserum has been used to develop immuno-spin trapping (Ramirez et al., 2003) and it is commercially available from Alexis Biochemicals, Cayman Chemicals, and Oxford Biomedical Research.

Initially, this antiserum was successfully used to detect myoglobin-centered radicals in supernatant obtained from rat heart homogenate (Detweiler et al., 2002). Later immuno-spin trapping was applied in the study of protein-centered radicals generated in hemoglobin treated with peroxynitrite (Romero et al., 2003), ketoprofen/UV-A irradiation (He et al., 2003), and H_2O_2 (Ramirez et al., 2003; Deterding et al., 2004). The H_2O_2-induced DMPO-hemoglobin adducts were detected by immuno-spin trapping (Ramirez et al., 2003), and then the exact localization of the radical sites where DMPO was bound to Hb was determined using LC/MS and MS/MS analysis of proteolytic fragments (Deterding et al., 2004). Recently, a lactoperoxidase-centered, thiol-dependent radical was also detected by immuno-spin trapping in incubations containing lactoperoxidase, thiols, and DMPO (Guo et al., 2004). Hypochlorite-induced DMPO-cytochrome *c* adducts have also been reported (Chen et al., 2004).

Critical Parameters and Troubleshooting

Mixing unpurified DMPO with oxyHb or metHb, in the absence of H_2O_2 produced protein aggregation detectable as dimers (~32 kDa) in reducing SDS-PAGE and high

background in ELISA and immunoblot experiments. These background and aggregation patterns were abolished when catalase was added before the addition of DMPO, suggesting that H_2O_2 is a contaminant present in commercial DMPO preparations (Ramirez and Mason, unpub. observ.). Before DMPO is used as a spin trap, it is appropriate to purify it by vacuum sublimation and store it in 50-µl aliquots under an argon atmosphere at −70°C. It is important that no protein radical–derived nitrone adducts or aggregation be observed when purified DMPO is incubated for 1 to 2 hr with hemoproteins.

On the other hand, when compounds such as reducing thiols are added to the analysis mixture, they have effects not associated with their metal-chelating abilities, and in these systems, they can modify nitrone adducts to immuno-spin trapping silent species (see the effect of 2-ME on DMPO-Hb radical–derived nitrone adducts) or even produce DMPO-trappable protein-centered radicals (Guo et al., 2004).

Because of the heating procedure required before SDS-PAGE separation, the nitrone adducts or the spin trap may react with the protein and thiols, i.e., under reducing

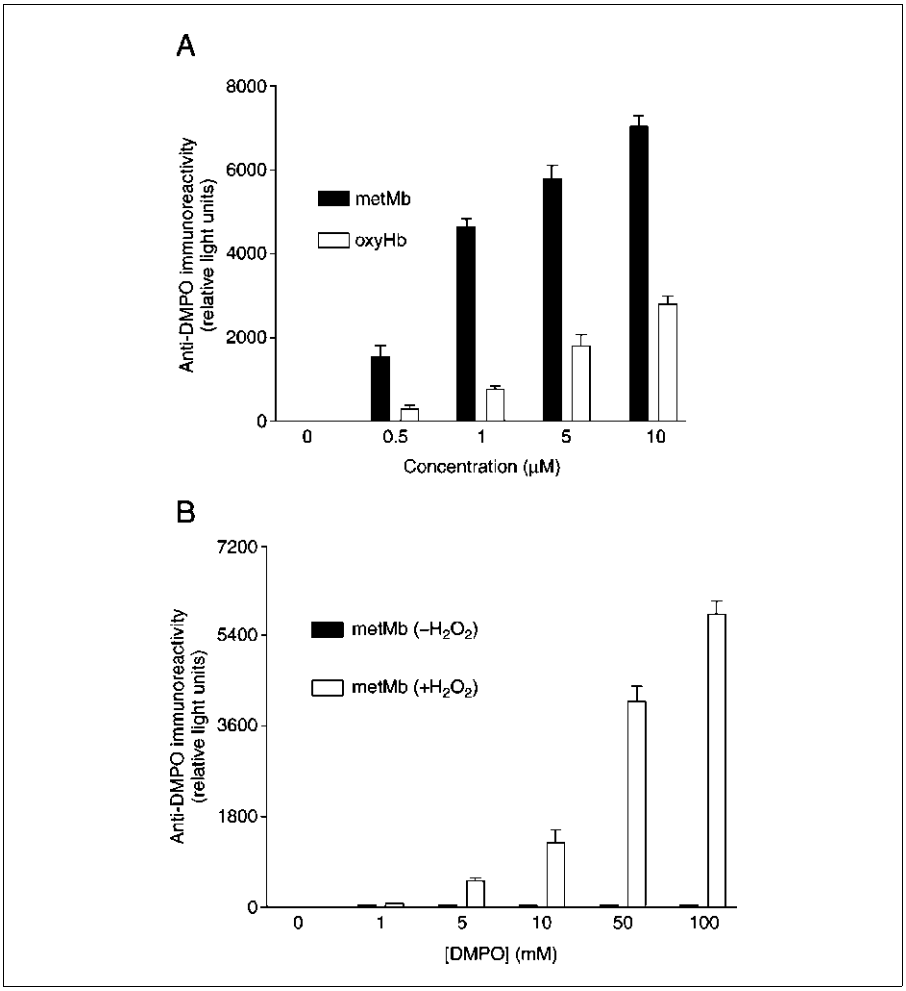

Figure 17.7.2 Detection of myoglobin (Mb) and hemoglobin (Hb) radical–derived nitrone adducts by immuno-spin trapping. (**A**) Reaction mixture contained 50 mM DMPO, 10 µM H_2O_2, and varying concentrations of metMb or oxyHb (as heme); (**B**) Reaction mixture contained 5 µM metMb (as heme), 5 µM H_2O_2, and varying concentrations of DMPO. Reactions were performed in 100 mM Chelex-treated sodium phosphate buffer, pH 7.4, containing 1 mM DTPA. After a 1-hr incubation at 37°C the excess H_2O_2 was removed by adding 50 IU catalase. Protein-radical–derived nitrone adducts were determined by ELISA (see Basic Protocol 1). Data show mean values ± S.E. from three experiments performed in triplicate.

conditions. In this case, sample dialysis prior to electrophoresis is sufficient to prevent false-positive results. Detailed analysis of parameters that can affect immunoassays can be found in immunoassay manuals (Tijssen, 1985).

See Table 17.7.2 for a guide on troubleshooting immuno-spin trapping.

Anticipated Results

The incubation of heme proteins with weak peroxidase activity such as hemoglobin (Hb), myoglobin (Mb), and cytochrome c with H_2O_2 produces protein-centered radicals that have been detected and characterized by direct ESR and ESR-spin trapping. With a very low concentration of H_2O_2, i.e., 10 μM, Hb- or Mb-centered radicals were produced and detected as DMPO-protein radical–derived nitrone adducts by ELISA (Fig. 17.7.2A). Even a low concentration of metMb (0.5 μM) produced significant amounts of DMPO-protein radical–derived nitrone adduct as detected by ELISA. As hemoprotein concentration

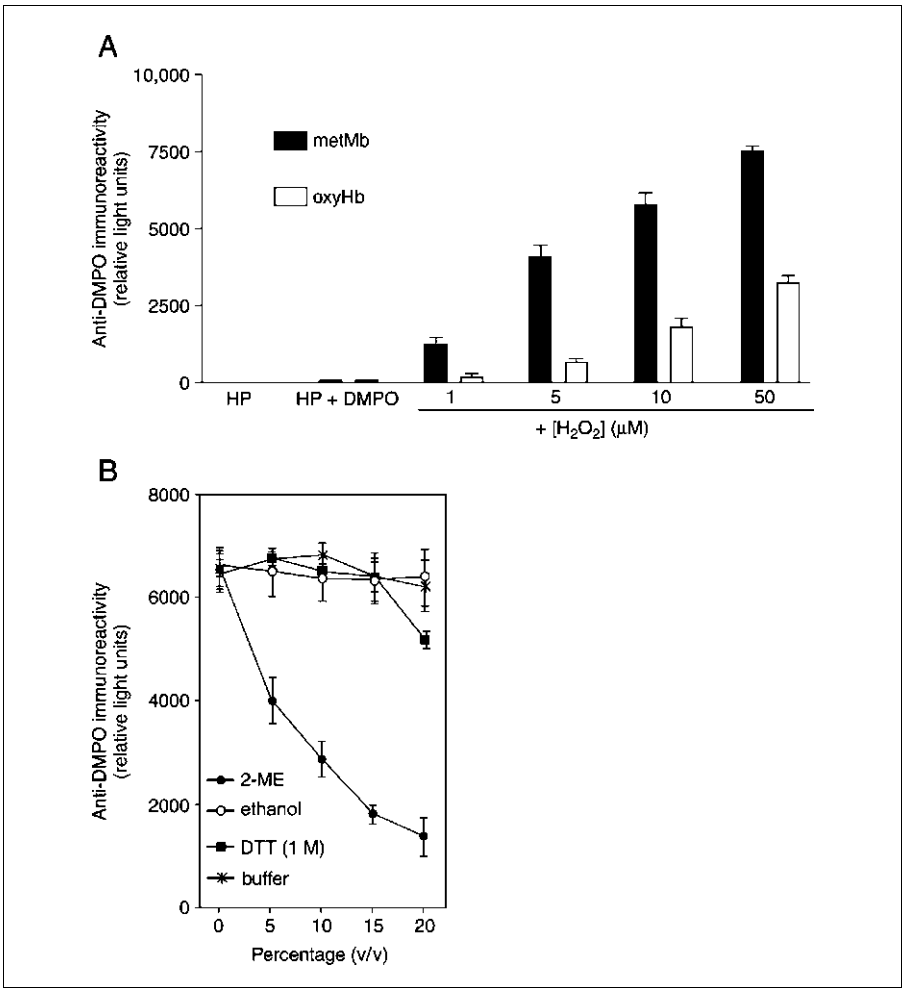

Figure 17.7.3 Detection of Hb- and Mb-centered radicals by immuno-spin trapping assays. (**A**) 5 μM hemoproteins (HP, as heme) were incubated with 50 mM DMPO and varying concentrations of H_2O_2 in 100 mM Chelex-treated sodium phosphate buffer, pH 7.4, containing 1 mM DTPA. (**B**) 10 μM oxyHb was reacted with 10 μM H_2O_2 and 50 mM DMPO in 100 mM Chelex-treated phosphate buffer containing 100 μM DTPA. Reaction was performed 1 hr at 37°C and stopped by adding 50 IU catalase. Then the reaction mixture was incubated 10 min at 37°C with different percentages of 2-mercaptoethanol (2-ME, stock 14 M), its chemical structural analog ethanol, DTT (1 M), or phosphate buffer to correct for changes in volume. Nitrone adducts were determined in 10 μl of the reaction mixture by ELISA (see Basic Protocol 1). Data show mean values ± S.E. from three experiments carried out in triplicate and in three separate experiments.

increases, generation of nitrone adducts rises steadily (Fig. 17.7.2A). Mb always produces more nitrone adducts than Hb or cytochrome *c* (data not shown), and metHb produces more adducts than oxyHb (Fig. 17.72A).

The amount of nitrone adducts detected by ELISA depends on the concentration of DMPO available to trap radical sites in the protein (Fig. 17.7.2B). The authors do not recommend the use of higher concentrations of DMPO because it may suppress hydrophobic binding of the protein to the ELISA microtiter plate or bind non-covalently to the protein during sample preparation for SDS-PAGE. If higher concentrations of DMPO must be used, try dialyzing the sample before processing by ELISA or immunoblotting. If purified DMPO is used, no hemoprotein radical–derived nitrone adducts should be detected when H_2O_2 is omitted (Fig. 17.7.2B, closed bars). It is also important to conduct control experiments in which one of the components is omitted.

Previously, hemoglobin-centered radicals were detected by direct ESR and ESR-spin trapping using millimolar concentrations of H_2O_2, which do not represent physiological conditions. With the immuno-spin trapping assay and ELISA, a significant amount of Mb radical–derived nitrone adduct can be detected with H_2O_2 concentrations as low as 1 μM. No DMPO-protein radical–derived nitrone adducts were detected when hemoprotein, DMPO, or H_2O_2 was omitted in the reaction mixture. In general, the production rate of DMPO-protein radical–derived nitrone adduct increases with hemoprotein (Fig. 17.7.2A), DMPO (Fig. 17.7.2B) and H_2O_2 (Fig. 17.7.3A) concentration.

Preliminary observations showed that immunoblot analysis of Hb radical–derived nitrone adducts obtained after protein separation under non-reducing conditions (i.e., without thiols) gave a higher signal/background ratio than those obtained after protein separation under reducing conditions (i.e., adding 10% v/v 2-mercaptoethanol during sample preparation). The authors hypothesized that this excessive background was due to the reaction

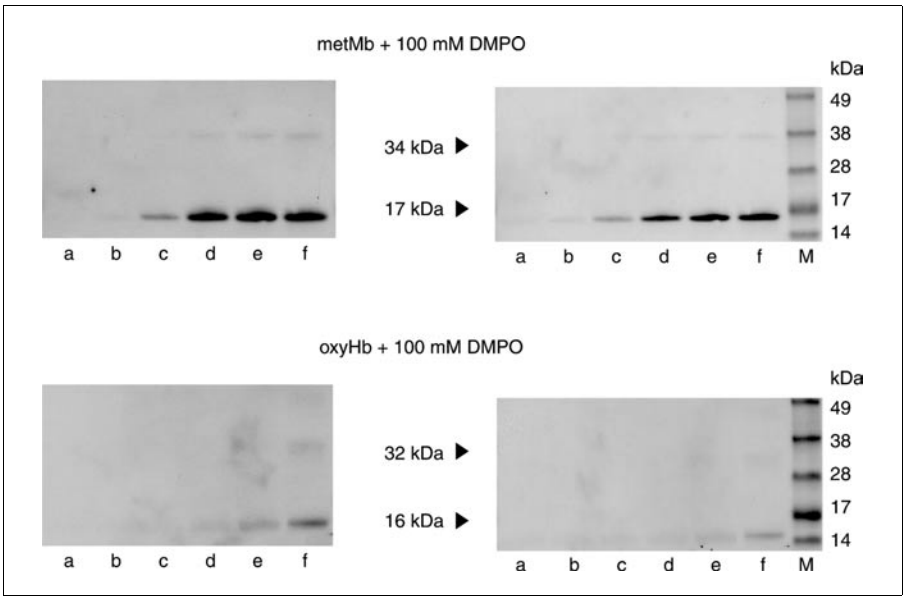

Figure 17.7.4 Immuno-spin trapping detection of hemoprotein radical–derived nitrone adducts by immunoblot analysis. The reaction contained 10 μM hemoprotein (metMb or oxyHb), with 0, 0.5, 1, 5, 10, and 50 μM H_2O_2 (lanes a through f, respectively) in the presence of 100 mM DMPO in 100 mM Chelex-treated sodium phosphate buffer, pH 7.4. Reactions were performed 1 hr at 37°C and stopped by adding 50 IU catalase. The reaction mixture was separated by SDS-PAGE and nitrone adducts were detected by immunoblotting and enhanced chemiluminescence (ECL) development (left membranes). The membranes were then washed with distilled water and incubated with 5 ml BCIP/NBT One-Step reagent until purple bands appeared on a white background (right membranes). The membranes were washed with distilled water and placed in a plastic office folder. X-ray films and membranes were scanned and acquired using an office scanner. M indicates molecular-weight marker.

of the nitrone adducts with the added thiols during the preparation for reducing gels. To investigate this, ELISA experiments, which do not require heating steps (Fig. 17.7.3B), were performed. Apparently, 2-ME changes the DMPO-Hb radical–derived nitrone adducts to an immuno-spin trapping silent species, and in this process, the thiol group of 2-ME affects the nitrone moiety of the adduct, the epitope recognized by the anti-DMPO antiserum. 2-ME did not affect the yield of DMPO-Mb or SOD1-radical derived nitrone adducts. Based on these results, the authors do not recommend the use of 2-ME as a reducing agent for reducing gels, especially when the system under study is unknown. The authors have also found that DTT can replace 2-ME without causing this effect (Fig. 17.7.3B).

Figure 17.7.4 shows typical immunoblot results obtained when metHb or oxyHb is incubated with H_2O_2 and DMPO; the blot is less sensitive than ELISA. The choice of enhanced

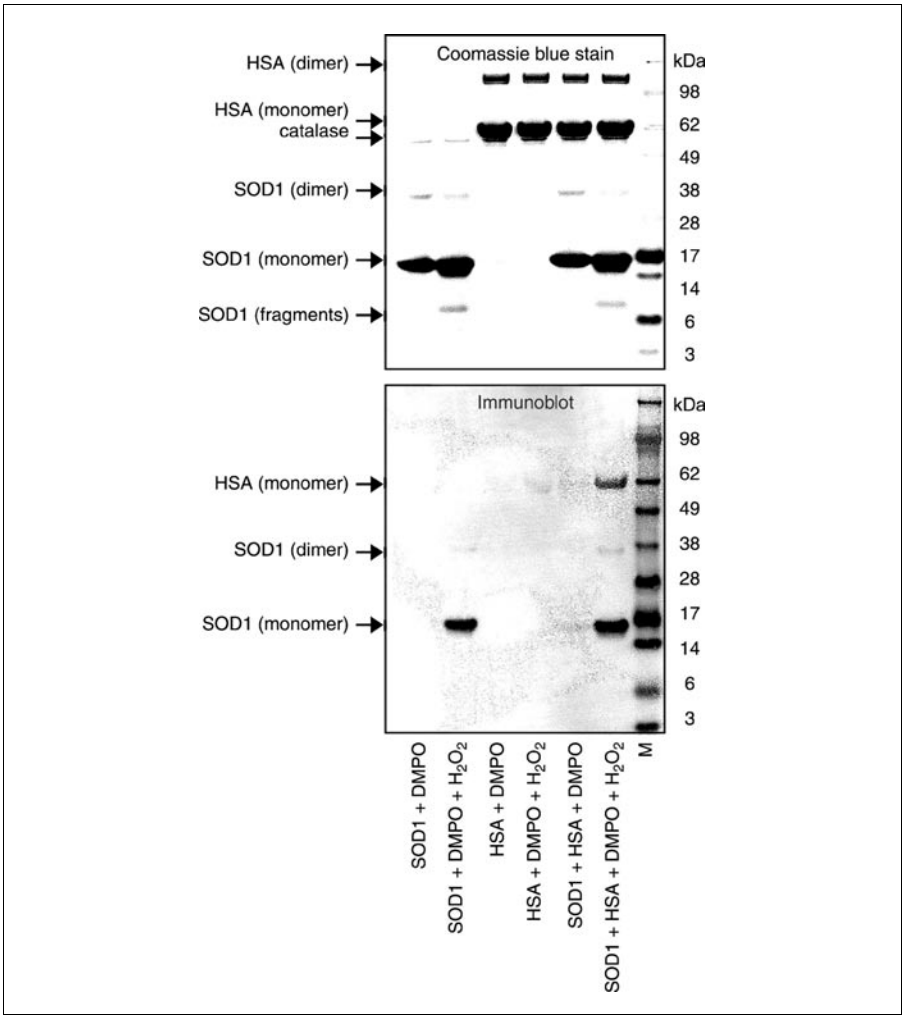

Figure 17.7.5 Simultaneous detection of two protein-centered radicals in the same system. Reaction mixtures contained 15 μM SOD1, 7.5 μM human serum albumin (HSA, $\varepsilon_{280\ nm} = 35{,}700\ M^{-1}\ cm^{-1}$), 100 mM DMPO and/or 1 mM H_2O_2 (as indicated in the figure) in 100 mM Chelex-treated (bi)carbonate buffer, pH 7.4, containing 1 mM DTPA. Reactions were incubated for 2 hr at 37°C and stopped by adding 10 IU catalase. Then 30 μl of the reaction mixtures were mixed with 10 μl sample buffer and 4 μl of 10× reducing agent. After heating 5 min at 70°C, the mixture was run on two 4% to 12% SDS-PAGE gels; one gel was stained with Coomassie blue (upper gel) and the other was blotted to a nitrocellulose membrane. Nitrone adducts were detected by immunoblotting (lower gel) as described in Basic Protocol 2. M indicates molecular-weight marker.

chemiluminescence (ECL) or colorimetric development (NBT/BCIP reagent, Pierce) depends on the sensitivity and amount of adducts to be detected and on the availability of the reagents and equipment. These results show that immuno-spin trapping is sufficiently flexible to fit academic, biomedical, or research laboratory needs in detecting protein-centered radicals.

Previously, the authors reported that DMPO-bovine Cu, Zn superoxide dismutase (SOD1) radical-derived nitrone adducts are induced by H_2O_2 only when (bi)carbonate, i.e., CO_2, HCO_3^-, or CO_3^{-2}, is present in the reaction medium (Ramirez et al., 2005). Under conditions described in that report, the generation of DMPO trappable radical sites in SOD1 was most probably due to oxidation promoted by the carbonate radical anion. When human serum albumin (HSA) is included in the SOD1/H_2O_2/DTPA/(bi)carbonate system, both SOD1- and HSA-centered radicals are produced and they can be simultaneously detected as DMPO-protein radical derived nitrone adducts by immunoblot analysis (Fig. 17.7.5). By comparison of the Coomassie blue stain (Fig. 17.7.5, upper gel) with the corresponding immunoblot (Fig. 17.7.5, lower gel), it is evident that only SOD1 monomer and dimer are detected as DMPO-protein radical derived nitrone adducts, even when fragments of SOD1 were also observed in the gel (compare lanes 2 and 6 in the upper and lower panels, Fig. 17.7.5). The origin of each one of these radicals is difficult, and sometimes impossible, to determine by direct ESR or ESR-spin trapping, due to the overlapping of ESR spectra of protein.

The application of ESR to detect protein radicals in vivo has been pursued for many years. The stability of the DMPO-protein radical–derived nitrone adducts made it possible to analyze them in red blood cells (RBC) of rats exposed to *tert*-buthyl hydroperoxide (Fig. 17.7.6). As little as 15 min after the administration of *tert*-butyl hydroperoxide and DMPO, the authors detected protein-centered radicals in RBC whose signal increased with time, demonstrating that the production of protein-centered radicals is related to the toxicokinetics of *tert*-butyl hydroperoxide. In toxicological studies, the amount and accessibility of the sample is very important. The authors used

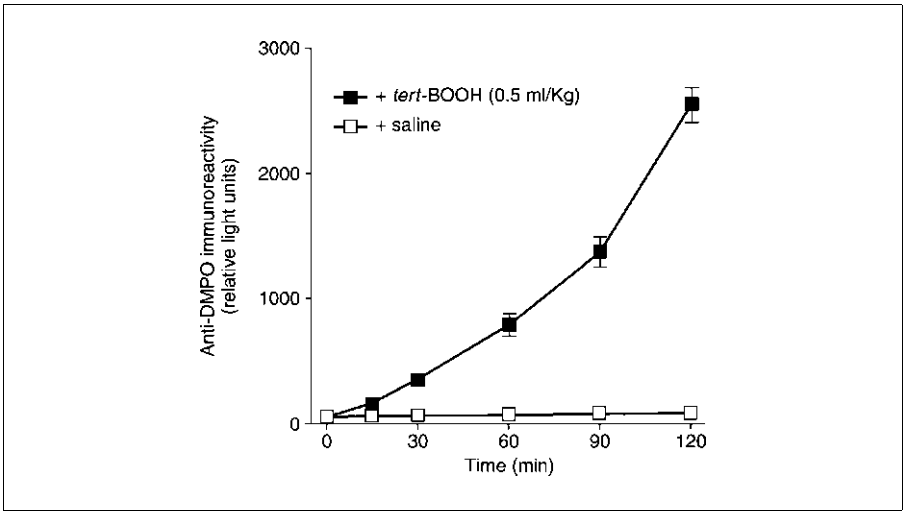

Figure 17.7.6 Detection of protein radical–derived nitrone adducts in blood of rats exposed to *tert*-buthyl hydroperoxide (*tert*-BOOH). Male Sprague Dawley rats (150 to 200 g) received 50 mg Nembutal/kg body weight (i.p.) and 50 μl blood was obtained by orbital bleeding. Then rats were injected with 1 g/kg DMPO (i.p.) and 0.5 ml/kg *tert*-BOOH or saline (8.5 g/liter NaCl) by intragastric intubation. Blood (10 to 50 μl) was obtained 15 min after the administration of *tert*-BOOH, from the orbital plexus, and red blood cells (RBC) were washed three times by centrifugation (5 min at 400 × *g*, each wash) and diluted to 10^8 cells/ml with 100 mM Chelex-treated sodium phosphate buffer, pH 7.4. Washed RBCs were broken by three freeze-thaw cycles and 15 μl (~1 μg proteins) was used to detect protein-centered radicals by ELISA as described in Basic Protocol 1. Animal studies mentioned in this protocol were performed according to an approved Animal Study Proposal, National Institute of Environmental Health Sciences.

10 to 50 μl of blood in these experiments, and this was adequate to run the sample in triplicate. In theory, any compound that can generate oxygen-active species in vivo, such as H_2O_2 or lipid peroxides, can induce protein-centered radicals that can be detected by immuno-spin trapping using very small amounts of sample.

Time Considerations

Depending on the equipment available (e.g., multichannel pipets, automated microtiter plate washer and reader), an ELISA experiment can take ~4 hr. Under the conditions described in this protocol, the authors did not find any difference between blocking overnight at 4°C and incubating for 40 to 90 min at 37°C with agitation. When an overnight experiment is required, it is important to let the plate and wash buffer stand at room temperature for at least 30 min to avoid gel formation, especially when gelatin is used as the blocking agent. Immunoblot analysis of DMPO-protein radical–derived nitrone adducts usually takes 5 to 7 hr including sample preparation if precast gels are available.

CHAPTER 18
Immunotoxicology

INTRODUCTION

As evolutionary principles would predict, the development of multicellular organisms with specialized cells has lead to highly complex, but efficient, compartmentalization (separate organ systems) for select processes. This expanded developmental organization has allowed specialized activities to increase, as is most evident with the nervous system. However, along with increased structural adaptation of an organ for a particular function, which improves upon an organism's adjustment to its environment, comes inter-organ dependency. The immune system also has been expanded in its specialization to assist with this interdependency. Immune cells and their factors (e.g., antibodies and cytokines) are critical for the homeostasis of each organ and maintenance of health.

The immune system has evolved to protect each organ against attack by pathogens and to accelerate the clearance of toxins and aberrant self cells, including those cells and cellular products altered by toxicants, drugs, carcinogenic transformations, and senescence. In performing the clearance of altered-self or non-self constituents, the immune system is unique, because somatic changes are constantly and consistently evolving to expand cellular clones to better recognize antigens. Furthermore, the antigen-specific cells (lymphocytes: B and T cells) and the innate, non-antigen-specific leukocytes (neutrophils, monocytes/macrophages, and NK cells) are continuously trafficking in search of altered-self and non-self antigens (immunosurveillance). Some immune cells also are relatively sessile cells in different organs: for example, the monocytic lineage includes the Langerhans cells of the skin, the Kupffer cells of the liver, the microglial cells of the brain, the mesangial cells of the kidney, and the osteoclasts of bones. Each of these cell types assist with normal organ functions as well as local defensive actions when necessary.

The importance of the immune system is obvious when an individual is born without a particular immune component. Lack of T cells because of a deficit in thymus development (the primary immune organ of T cells), as with DiGeorge Syndrome, causes loss of cell-mediated immunity, which manifests as the inability to eliminate numerous opportunistic infections, such as *Candida*, *Listeria*, and *Mycobacteria* infections. Lack of B cells because of a deficit in bone marrow development (the primary immune organ of B cells), as with Bruton's X-linked hypogammaglobulinemia, causes loss of humoral or antibody-mediated immunity, which manifests as the inability to clear exogenous pathogens, such as staphylococcal and streptococcal infections. Loss of both B and T cells (severe combined immunodeficiency disease, SCID) is a rapidly fatal disease unless major interventions are employed. Since the 1980's, the HIV epidemic has created public awareness of the consequences of HIV-mediated depletion of $CD4^+$ helper T cells (cells needed to promote both cell-mediated and humoral immunity), which can lead to acquired immunodeficiency syndrome (AIDS).

It is now apparent that environmental agents depleting or altering the function of just one type of immune cell can induce major illness. Although usually more subtle than HIV in their mechanisms of immunomodulation, many environmental agents can modify immune functions. Since the immune system is composed of multiple cell types, which localize

Contributed by David A. Lawrence
Current Protocols in Toxicology (2005) 18.0.1-18.0.3

in multiple organs and traffic throughout the organism, it is often arduous to delineate the cell type or cellular function being modulated, especially for clinical investigations when the only specimen usually available is blood. A further complication is age, in that early in life the immune system has not fully developed and late in life the immune system is intrinsically declining in function. Thus, the two most vulnerable times for the immunotoxic effects of environmental agents are during the neonatal and elderly stages. Additionally, immunomodulators are not restricted to pathogens and chemicals; physical and psychological stressors alone or combined with each other and/or chemical stressors can elicit changes of immune functions.

Unfortunately, immune responses, which develop to foreign antigens, can subsequently lead to pathologies, such as allergies/asthma. Additionally, immune responses can develop to self-antigens, giving rise to autoimmune responses with major immunopathologies and possibly fatal outcomes. Besides chemical, physical, and/or psychological stressors causing immunosuppression, they also may heighten immune reactivities, which could generate an overly zealous immune response that causes pathology, or induce a loss of tolerance to self. Cell-mediated and antibody-mediated immunities to self constituents are differentially involved in autoimmune diseases. Thus, both immunosuppression and immunoenhancement can lead to various diseases. This emphasizes the need to assess potential immunotoxicological outcomes for an imbalance in either direction. The units in this chapter describe in vitro and in vivo immunological assays to qualitatively and quantitatively determine various immune system changes that could accompany exposure to environmental agents or drugs.

UNIT 18.1 provides a commentary on the various types of immunotoxicological analyses necessary to fully understand the importance of immune components and immunoregulation in maintenance of a healthy state. As alluded to earlier, the immune system is a defense network sending its cellular components to multiple sites including the skin. *UNIT 18.2* describes the local lymph node assay. This is an assay to assess allergic contact dermatitis, which is a delayed-type hypersensitivity involving antigen-specific activation of T lymphocytes. Whereas the local lymph node assay evaluates allergic reactions originating in the skin, allergic hyperimmune reactions in the lungs can lead to airway hyperresponsiveness, which is referred to as asthma. *UNIT 18.3* provides an overview of the initiators of asthma, the resultant pathology, and the methods to evaluate sentization and elicitation of the asthmatic response. Respiratory distress occurs with asthma as well as with respiratory infections or septicemia. In experimental models, immune infiltrates into lung tissue can be evaluated to determine the extent of the pathology and the involved mechanisms. However, good estimates of ongoing reactions also can be achieved with investigation of the immune cells and their products in bronchoalveolar lavages. Although these lavages are invasive and can be dangerous under some circumstances, they are an efficient means to assess immune reactivities in animals as well as humans. *UNIT 18.4* describes how these lavages can be obtained and the methodologies utilized to assist in the determination of the associated lung injury.

The preceding units described more systemic approaches to evaluation of the immune system. *UNIT 18.5* delves into the molecular mechanisms by which immune cells are regulated for the proliferative and maturational changes signaled through their surface antigen-specific receptors and accessory molecules. The means to quantify the activators of transcription by enzyme-linked immunoadsorbent assays (ELISAs) are described. Although gel-shift assays have long been the standard for analysis of transcription factors, the ELISA method described outlines substantially more efficient process for screening of multiple specimens.

UNIT 18.6 provides the methodology to measure the cytolytic activity of natural killer (NK) cells and $CD8^+$ T cells. Although these cell types kill by similar mechanisms, they

represent the innate and adaptive arms of the immune system, respectively. The NK cells, often referred to as large granular lymphocytes, are not antigen-specific; whereas, $CD8^+$ T cells are activated through their antigen-specific receptor (TCR) by specific peptide presented by major histocompatability complex (MHC) class I molecules. Toxicant interference with either of these cytolytic lymphoid subsets can substantially lessen host defenses.

UNITS 18.7 & 18.8 provide protocols that are integral to most immunotoxicological investigations as well as evaluation of any antigenic or structural changes of non-immune cells and factors. *UNIT 18.7* deals with protocols that rely on antibody antigen interactions for quantification of either. The enzyme-linked immunoabsorbant assay (ELISA) has become a very standard method for multiple disciplines. For toxicological studies, however, it must be remembered that the assay relies on maintenance of the specificity of the antibody and conservation of the epitope of the antigen recognized by this specificity. A toxicant could potentially interfere with either compromising the quantitative nature of the assay. This possible complication exists for all assays that rely on complementary binding of proteins. The ELISPOT assay takes the ELISA to the level of the cells producing the antibody or antigen allowing quantification of the number of cells producing such factors. *UNIT 18.7* additionally presents a new methodology with substantial promise for future endeavors; grating-coupled surface plasmon resonance imaging (GCSPRI) takes the ELISA and transforms it into a rapid screening method. With GCSPRI, hundreds of antibodies or antigens can be simultaneously quantified with a minimum of specimen. *UNIT 18.8* describes the basics of flow cytometry procedures. Flow cytometry has become an important tool for biomedical and clinical studies. This unit provides critical methodologies that must be considered when using this method. Inaccurate results can be obtained if inappropriate gating or fluorescence compensation are not properly adjusted. Although the method can be useful for both quantification of the number of cells expressing a particular combination of markers and the quantification of these markers per cell, it must be realized that the instrument must be quality controlled for linearity and adjusted for optimal CV assessment of cell populations. This unit summarizes the important aspects that need to be considered when using flow cytometry for toxicological parameters.

UNIT 18.9 embarks on methodologies capable of assessing whether a toxicant can alter the development of an antigen-specific naive T cell and/or modify the activity of a select subclass of T cell. The approach to assay antigen-specific naive T cell utilizes transgenic T cells genetically engineered to express the α and β chains of an antigen-specific T cell receptor (TCR). Thus, most of the T cells in these transgenic mice will have many $CD4^+$ T cells or $CD8^+$ T cells dependent on whether the TCR is specific for antigenic peptide in association with major histocompatibility complex (MHC) class II or class I molecules, respectively. However, to ensure that the T cells are naive, the researcher must isolate resting, non-memory T cells ($CD62L^{hi}/CD44^{lo}/CD45RB^{hi}$ T cells). Alternatively, one can be assured of having naive T cells if the TCR transgenes are bred to Rag-deficient mice (mice with no antigen-specific lymphocytes except the TCR-transgene expressing T cells). In either case the mice need to be kept in specified pathogen free (SPF) conditions to maintain their health and lessen odds of activation by cross-reactive antigens. For analysis of differentiated T cells with specific effector functions, cloned T cells are utilized. Numerous Th1, Th2, Tc1 and Tc2 clones now exist, and can be obtained from various researchers. *UNIT 18.9* describes some of these clones and their use for toxicological assessments.

David A. Lawrence

Associating Changes in the Immune System with Clinical Diseases for Interpretation in Risk Assessment

While it is well established that immunosuppression (see Terminology) can lead to an increased incidence and/or severity of infectious and neoplastic diseases, interpreting immunosuppression data from experimental immunotoxicology studies, or even epidemiological studies, for use in quantitative risk assessment is problematic. This is mostly due to a paucity of information on the health consequence of minimal-to-moderate immunosuppression, as might be expected to occur from inadvertent exposure to immunotoxic agents in humans. It is important that a scientifically sound framework be established that allows for the accurate quantitative interpretation of such data for use in the risk assessment process. In immunotoxicology, this may require, for example, development of a model to equate moderate changes in leukocyte counts, CD4 cell numbers, and/or immunoglobulin levels, tests which can be readily performed in human populations, to potential changes in the incidence or severity of infectious diseases, as well as establishing the social and economic impact of the incidence change. Although experimental animal models usually provide an opportunity to establish more reliable exposure estimates and conduct more informative immune tests than those that can be conducted in humans, extrapolating these findings across species is always of concern.

The development of a framework to perform such extrapolations is currently being addressed by the authors' workgroup. As an integral process to this undertaking, a review of studies that address the qualitative and quantitative relationships between immune parameters and disease is contained herein. Initially, the most likely clinical consequences that may occur as a result of chronic mild-to-moderate immunosuppression are described, as well as nonimmune factors that may modify these disease outcomes. Clinical and experimental animal studies that have examined immunosuppression disease relationships are reviewed and quantitative relationships, when available, are delineated to help address gaps in human health risk assessment. To address the potential social and economic consequences that could result from immunotoxicity, a brief description of the general impact of infectious disease is provided on these parameters. The most comprehensive data bases that address immunodeficiency disease relationships, specifically primary (genetic) immunodeficiency and AIDS, are not discussed, as these represent extreme examples of immunosuppression and neither the specific clinical diseases that result nor the eventual outcomes have much in common to that which occurs in individuals with chronic mild-to-moderate immunosuppression.

TERMINOLOGY

Before continuing, it is useful to provide clarification of certain terminology. Immunosuppression, immunodeficiency, and immunocompromised are nonquantitative terms that reflect a reduced capacity of the immune system to respond to antigens, and the terms are often used interchangeably in immunotoxicology. For the purpose of risk assessment, *immunosuppression* can be defined as a loss in the ability of the immune system to respond to a challenge from a level considered normal, regardless of whether clinical disease ensues. *Immunodeficiency* often represents an alteration in the immune system that can potentially lead to clinical disease, whether primary (i.e., genetic etiology) or secondary (epigenetic) in nature. The term, *immunocompromised*, like immunosuppression, indicates a deficient immune response, independent of whether or not it is maladaptive. Immunotoxicity encompasses each of these terms, but it specifies that the effect on the immune system originates from xenobiotic exposure.

DISEASES ASSOCIATED WITH IMMUNOSUPPRESSION

As immunotoxicology testing is increasingly included in toxicological evaluations (House, 2003), there is added impetus to better associate detected changes with these tests to potential clinical outcomes. Although infectious disease is the most obvious, the consequences of maladaptive immunity can

Current Protocols in Toxicology (2004) 18.1.1-18.1.20

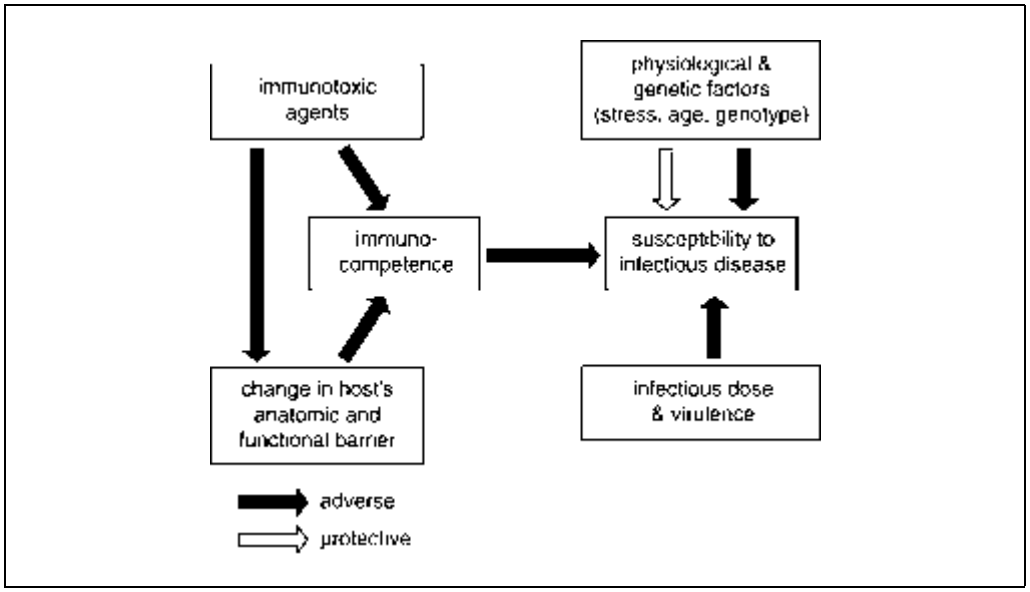

Figure 18.1.1 Changes in the onset, course, and outcome of infectious disease. Schematic shows factors which influence infectious disease susceptibility.

affect the etiology, progression, and/or severity of a much broader range of disorders, including certain cancers and autoimmune disease. Establishing the quantitative relationship between altered immune responses and frequency or severity of disease in human populations is challenging, as many factors may contribute (Morris and Potter, 1997). This is summarized schematically in Figure 18.1.1, where the appearance, progression, and outcome of infectious disease is viewed as an interrelationship between the virulence of the organism, infectious dose (number of organisms required to produce illness), integrity of the host's anatomical and functional barriers, and overall immunocompetence of the individual. The latter is affected by genetics as well as age, gender, use of certain medications, drug/alcohol use, smoking history, stress, and nutritional status. These factors probably account for most of the variability reported in mean immune values, which can exceed two standard deviations. Another challenge when establishing quantitative associations between immune function and disease is to account for the functional overlap (i.e., redundancy) that exists between the various immune responses and disease. As multiple effector mechanisms are evoked in response to a disease, redundancy is often misinterpreted as reserve; however, as with other organ-systems, such as the liver or central nervous system, the existence of an immune reserve in the general population, where disease can occur in uncompromised individuals, is unlikely. In contrast, immune redundancy, as discussed by Halloran (1996), is scientifically supported and can be empirically examined. The effect of redundancy on the interpretation of immunotoxicology studies was recently addressed by Keil et al. (2001) using factor analysis and multiple/logistic regression to quantitatively evaluate the contributions of different immune system parameters in host resistance.

Infectious Diseases

While both infectious and neoplastic diseases are associated with secondary immunodeficiency, infectious diseases are often the focus of epidemiological studies as neoplastic diseases usually have such a long latency period. The particular microorganism responsible for an infection may assist in identifying the qualitative and quantitative nature of the immunodeficiency. For example, extracellular pathogens such as *Streptococcus pneumoniae* and *Haemophilus influenza*, multiply only outside phagocytic cells and, thus, produce disease only when they can resist phagocytosis. Facultative intracellular pathogens, (e.g., *Mycobacterium tuberculosis*), are generally phagocytized but resist intracellular killing. Thus, infections with extracellular or facultative intracellular organisms are more frequent in individuals with impaired phagocytic mechanisms, (e.g., neutropenia), or when humoral immune deficiencies are present. Obligate intracellular pathogens, which include all viruses, cannot multiply unless they are within a host cell and are more commonly observed in individuals with defects in cellular immunity.

Microbial agents associated with immunodeficiency disorders can also be classified into common, opportunistic, or latent pathogens. Common pathogens occur in the general population at frequencies associated with their infectious nature (e.g., virulence, ease of transmission), as represented by viruses that cause influenza infection and severe acute respiratory syndrome (SARS). The respiratory system is the most vulnerable target for common pathogens, as it is directly exposed to the external environment and has a large surface area: four times the combined total surface area of the gastrointestinal tract and skin (Gardner, 2001). Upper-respiratory infections occur in all age groups but produce the most severe effects in the very young and very old due to their lesser immunocompetency. Although influenza is responsible for more morbidity and mortality than any other infectious agent in recorded history (Patriarca, 1994), the low individual rates of infections in the general population (only one or two episodes in an individual per year), combined with underreporting, make it difficult to detect changes in infection rates in most epidemiological studies.

While infections with common pathogens occur routinely in the healthy population, opportunistic infections are typically seen in individuals with severe immunosuppression, such as AIDS patients. Examples of microorganisms that can produce opportunistic infections are certain protozoans, including *Toxoplasma gondii*, which cause cerebral infections and intractable diarrhea, *Candida albicans*, *Mycobacterium avium* complex (MAC), and *Pneumocystis carinii*, a fungus causing severe lung diseases in AIDS patients (Morris and Potter, 1997). These organisms are commonly encountered in food, water, dust, or soil, but they cause disease in the general population at very low incidences.

Certain pathogenic microorganisms are responsible for latent infections. In the case of members of the herpes virus family, including cytomegalovirus (CMV), herpes simplex virus (HSV), and Epstein-Barr virus (EBV), the virus remains in the tissue in a latent form following primary infection for the duration of the host's life. In healthy individuals, the immune system maintains viral latency, with cellular immunity playing a major role. When the cellular immune response is compromised, viral replication can ensue and potentially cause severe complications or death. Preceding viral activation, a vigorous immune response to viral-specific antigens occurs in response to replication. As will be discussed later, changes in virus-specific immune response or activation of latent viruses has been observed in individuals with secondary immunodeficiency disorders where mild-to-moderate immunosuppression may exist.

Virally Induced Tumors

Immunodeficiency is also associated with an increased incidence of certain virally induced tumors, such as non-Hodgkin's lymphomas (NHLs) and tumors of the skin (Penn, 2000). In contrast to cancers of internal organs, in particular those in the lung and liver, which are often induced by chemical carcinogens, virus-induced cancers are more immunogenic and, thus, more likely influenced by immunological factors. Suppression of cell-mediated immunity has been associated with higher incidences of skin cancers, leukemias, and lymphoproliferative disorders in transplant patients, whereas Kaposi's sarcoma and EBV-associated B cell lymphomas are associated with severe immunosuppression as seen in patients with AIDS. Natural killer (NK) cells are more likely to play a role in resisting the progression and metastatic spread of tumors once they develop, rather than preventing initiation (Herberman, 2001). Unexpectedly, studies of individuals with NK cell deficiency states, most of which are associated with single gene mutations, have helped identify a role for NK cells in defense against human infectious disease. A resounding theme of NK cell deficiencies is susceptibility to herpes viruses, suggesting that unexplained severe herpes viral infection should raise the possibility of an NK cell deficit (Orange, 2002).

CONSIDERATIONS IN THE USE OF EPIDEMIOLOGICAL DATA IN IMMUNOTOXICOLOGY RISK ASSESSMENT

There are many advantages of using human data over experimental animal studies in quantitative risk assessment, especially as it avoids the difficulties in interspecies extrapolation and provides data on lower doses that are of interest to public health policy makers (Hertz-Picciotto, 1995). Human studies offer realistic exposure scenarios, including multiple routes of exposure, and include a much more diverse range of genetic backgrounds than experimental models, providing the potential to explore differences in susceptibility by genotype. The limitations and challenges of human studies, however, are considerable.

Here, a brief overview of issues surrounding the design and interpretation of human studies as it pertains to the assessment of risk due to immunotoxic exposures is provided.

Clinical Studies

The design of human studies can range from controlled clinical trials to large, population-based, observational studies. Clinical studies offer advantages in that exposure parameters of interest can often be controlled (e.g., chamber studies of inhaled toxicants, challenge studies of adenovirus infection), and outcomes can be prospectively monitored. There are also disadvantages, as ethical considerations provide little opportunity for exposure with toxic chemicals. Furthermore, studies with extensive biological monitoring and functional immune tests can be expensive, and exposures as well as outcomes of interest may be difficult to study in the available time frame as study participants are not typically available for long-term exposures or extended follow-up. For the purpose of obtaining data for immunotoxicological risk assessment, clinical studies are particularly useful as they can provide data on the frequency of infections or the level of immune response to vaccines. Variations on this type of study design might include follow-up of patient populations administered immunosuppressive therapy (i.e., transplant patients), that, as described below, may also have many of the characteristics of observational studies.

Epidemiological Studies
